5. It is an expensive system, relying on a highly trained and educated body of researchers becoming very familiar with local conditions, problems and farmers. The central role of the multi-disciplinary team, along with the emphasis on the site-specificity of knowledge, means that any institution using this approach must make a relatively large investment in the local farming systems team and cannot spread the effect of that investment across a very large geographic area. Not surprisingly, like T&V, most places using the farming systems model also have been the recipients of funding from the principal donor advocating the model.

The basic argument for the origination of the farming system model would seem pertinent, and the approach has been tried in a number of locations with mixed results. Like the Land-Grant model, which it resembles in many other aspects, the farming systems model depends on mutual respect among peers and between agricultural professionals and farmers. In societies where there are strong biases against effective communication between individuals of differing social, economic or cultural status, the all-important communication between researcher and farmer is likely to fail. Again, the success of this system may well depend on the social and cultural context in which it exists, and its distinct lack of success in some parts of the world may reflect cultural and social realities rather than simply the ineffectiveness of the system itself in solving farmers' problems.

Interestingly, the World Bank funded both T&V and Farming Systems projects in Africa. T&V came first as an extension effort and was followed by farming systems as a research effort (Malawi, Tanzania, Ethiopia). World Bank saw these two models as complementary. Yet, African successes at solving real problems in a cost effective manner are hard to find.

Training-Driven Research: Indonesian Integrated Pest Management

This model is relatively new and has not been implemented in many places. Basically, it has been developed as part of an Asia-wide integrated pest management effort funded originally by the Australian government and is now managed by the Global Integrated Pest Management Group within FAO in Rome, Italy. It offers exciting possibilities to overcome many of the flaws inherent in the other three models.

Training-driven research is based on two fundamental premises (i) do not conduct research unless it is needed and (ii) use training as the tool to identify what research is needed. This model is like T&V in that it trains personnel who, in turn, train others and farmers. It is like farming systems in that it focuses only on "relevant" research, and it is like the Land-Grant model in that it combines training, extension and, when needed, research.

Farmers and those who assist and advise them need to be trained. Thus, experts establish a rigorous, field-based training program for the farmer support system, then for the farmers. Beginning with field preparation, each and every step in the agricultural production annual cycle is demonstrated to the trainees, both in the field and on site. Experience of the trainers, literature and formal knowledge possessed by the trainers are incorporated into the training course. As long as the information exists to proceed in relevant fashion through all the steps of production (from field preparation, to fertilization, to pest management, to harvesting, to marketing), there is no need for research (Fig. 13).

If, at any step, the trainer recognizes that the information to train appropriately does not exist, there is a call for "research." This may take the form, however, of a demonstration rather than a full-blown, randomized experiment. In any case, the product of this research is not a journal article, but rather feedback provided directly to the training program. This is an iterative process resulting, sooner or later, in an ability to appropriately train farmers and their assistants without conducting research until a new, unknown situation arises.

Teaching and Training Entomology: Institutional Models, Figure 13 In-field training for rice farmers and support staff at a farmer field school, Indonesia.

This model differs markedly from the Land-Grant model where funded research is the top priority. Further, the first priority of Land-Grant research is not training, but publication and the volume of such publications produced is germane to continued employment in the Land-Grant system. Training-driven research also offers a paradigm to regiment discipline expertise. Often, Land-Grant multidisciplinary teams attacking some aspect of agriculture will find, once the problem is truly understood, they have the wrong expertise on the team (e.g., hiring a bacteriologist when a virologist was needed). Training-driven research avoids this issue by first identifying the particular need, then seeking the appropriate expert.

Training-driven research, to date, has not been attempted in enough places to have many proponents or critics. One criticism to date focuses on TDR's inability to demonstrate any significant research accomplished after identification of the problem in training. Indonesian rice has been the principal target to date. As it expands and is attempted, similar to the first three models, inherent strengths and weakness will be identified.

Farmer Participatory Research: CGIAR Network

Concerns over the lack of appropriate technology transfer have given rise to a more recent institutional paradigm. Farmer participatory research (FPR) has its origins within the CGIAR system and, from all appearances, has had its greatest impact to date in Asia. The conceptual foundation for FPR is a belated appreciation of mainstream agricultural scientists for the importance of indigenous knowledge to agricultural systems management, especially with resource-poor, marginal farmers.

Operationally, FPR begins with four fundamental steps (i) community-based dialogue with individuals or small groups used to identify local changes in agriculture over a generation or two; (ii) community-based analysis used to identify high-priority problems that need resolution; (iii) community-based inventory of local methods attempted to solve the key agricultural problems; and (iv) community-based assessment of how well methods tried in (iii) have performed. The purpose of FPR is to initially learn how farmers think and assess agricultural productivity and damage. Only then can new technology be injected in a socially and culturally relevant fashion.

A recent FPR project in Viet Nam illustrates how the approach functions. Vietnamese farmers were invited to test the heuristic, "We do not need to spray insecticides in the first 30 days after transplanting [rice]." Volunteer rice farmers were invited to participate, and each reported results based on individual assessment of perceived damage. Analytical variables used to determine success or failure of the project included farmers' beliefs, intentions, spray frequencies, timing and targets, yields, inputs and other management practices (Fig. 14).

Teaching and Training Entomology: Institutional Models, Figure 14 **Viet Nam farmer participatory training session on evaluation of insecticides during first 30 days after sowing. Photo provided by Dr. Kong Luen Heong, International Rice Research Institute, Los Baños, Philippines.**

Such experiments, if managed properly, usually are inexpensive and easy to conduct, and they facilitate farmer learning by pragmatically "testing" a new idea. The process provides researchers the opportunity to learn how farmers think and perceive success or failure. The FPR approach can be quite expensive if attempted over large areas. The presence of well-educated scientists will affect farmers differentially, and care must be taken to minimize this influence by including farmers at all levels of planning and decision-making. Reductionist scientists often view FRP as scientifically "weak," however, those using this approach must remember that the idea is to evaluate farmer responses and learn how they perceive success and failure. The idea is not to conduct well-controlled, reductionist experiments. Adoption rates for new varieties of plants and improved technology are well-documented in the literature, however, much less is known about the adoption or adaptation of information into farmer decision-making.

Fundamental to FPR is a concerted effort to train local agriculturists to proceed through the above four steps so that, after a few iterations, local farmers and their support network work independently of outside influence. Unlike reductionist science, FPR begins by assuming that indigenous peoples have usable solutions to many agricultural problems or they would not have survived. The effort is to extract those solutions up front and, by doing so, convince local farmers that they will not be treated simply as passive recipients of modern, science-based information. Rather, they will be partners in the experimentation and delivery phases of agricultural development. There is growing evidence that the most effective extension programs in Land-Grant models also operate this way. Unfortunately, this is not yet the norm.

FPR is a unique approach and quite different from station-based research and traditional extension-delivery systems. It is, in many ways, the antithesis of the Land-Grant model. Unlike farming systems, FPR does not have to "adapt" station-based research because the blend of indigenous knowledge and modern science is inherent in FPR. Unlike the T&V approach, there is no hierarchy involved and no loss of information between tiers. FPR most closely resembles the training-driven research model, but has been tried in more places to date than TDR. There are on-going efforts in Asia, Africa and Latin America that use FPR as the paradigm. In Ecuador, small groups of farmers form committees and decide on a theme they want to research and then conduct that research under the guidance of an extension specialist. Colombia, under the auspices of CIAT, has adopted the same approach. There is increasing awareness that talking with farmers is an improvement over talking at farmers.

Unlike the Land-Grant, T&V and farming systems models, FPR is a new approach. In essence, it has been developed out of the perception that the other models have failed to resolve real problems with marginal farmers. The concept of formalized farmer field schools appears unique to TDR and FPR, although, Land-Grant extension experts would argue their "turn row conversations" with farmers serve precisely the same purpose. As TDR and FPR gain maturity, the global agricultural community can begin to assess their real impact and their relative value as compared to the other three institutional paradigms.

In agricultural societies of relative wealth where individuals, not social groups, make decisions, and where egalitarian norms prevail, systems resembling, at least in part, the Land-Grant system have prevailed. Land holdings and economies conducive to high-yielding agriculture seem to be requirements for the success of Land-Grant style entomological programs, probably because of the emphasis on the ability of individual farmers to make critical decisions about how they will manage their resources. The other four models have both been conceptualized and implemented with farmer groups who have virtually none of these characteristics. The latter groups consist of farmers that are relatively poor, often make group or community decisions, typically have poor access to credit and are labor intensive. These models appear to be more successful in places where cultural norms play a stronger role in determining acceptance of new practices than in places where decisions about technological innovation are less subject to social and political control.

By far, the Land-Grant system is the model that adheres most rigorously to reductionist experimentation. Large numbers of farmers under the Land-Grant, T&V, and farming systems approaches are today still treated as passive recipients of information, not as active participants in the identification and generation of new information. The farming systems approach does ask farmers what they think is important as a way to initiate the model. Training-driven research and Farmer Participatory Research truly involve the farmer and the associated support system as active participants in the process. Both these latter paradigms make use of indigenous knowledge systems and thus strive to have as end products agricultural programs that are blends of traditional approaches and modern science.

All five models (Table 5) have inherent strengths and weaknesses, but only three have been attempted to date on a fairly broad scale.

Teaching and Training Entomology: Institutional Models, Table 5 Characteristics of five institutional models of agricultural (including entomology) research, training and extension

Characteristic	Land-Grant	T&V	Farming systems	Training driven research	Farmer participatory research
Major focus on research	Yes	No	Yes	No	Yes (with an altered definition of research)
Major focus on publication	Yes				
Major focus on extension	Yes	Yes	No	Yes	No
Focus on use of indigenous knowledge	No	No	No	Yes	Yes
Major focus on farmer training	No	Yes	No	Yes	Yes
Targets users with relatively good resources	Yes	No	No	No	No
Targets marginal users	No	Yes	Yes	Yes	Yes
Regiments technical expertise	No	No	No	Yes	Yes
Puts farmers in active role	No	No	No	Yes	Yes
Combines research, training and extension	Yes	No	No	Some	Inherently
Sufficiently tested outside area(s) of origin	No	No	No	No	No
Area(s) targeted to date	USA	Asia; some Africa; some Latin America	Latin America; some Africa	Asia	Asia; some Latin America; some Africa

Clearly, the questions asked about insects, the methods chosen for investigation, the methods used in training and the consequences of entomological programs can vary markedly from one model to the next. Recognition of which model predominates in any effort is fundamental to success, and global entomologists need to address, perhaps in a side-by-side comparative fashion, just how transportable information developed under one model is to farmers living under another. This could be one of the reasons that "technology cannot be simply exported." International donor organizations clearly need to be attentive to matching the institutional model being promoted with appropriate cultural, social and economic norms.

An Example

How might the use of an exotic biological control agent in a particular crop be implemented under each of the five models? For argument, the crop is soybean and, among its insect pests, is one that pesticides have failed to control. It is the key pest and it limits yield annually. The idea is to try a biological control approach.

Under the Land-Grant Model

Entomologists with biological control expertise, either individually or in small groups, would survey the literature for what is known about biological control of the target pest. Two avenues would be explored initially: the potential use of indigenous natural enemies and the importation of exotic ones. As the indigenous complex was not maintaining the pest's population density below acceptable levels, the choice might be made to search for exotic natural enemies. The USDA/APHIS protocol would be utilized for permits, and travel likely would be to China, the indigenous home of the soybean plant. If the pest has been subjected to biocontrol previously through the efforts of others and the results were published, travel to China might not be necessary.

Collections of potential natural enemies would likely result in the importation of each and every one found to inflict mortality on the pest in China. In quarantine, each potential natural enemy would be checked for hyperparasites, and then reared to sufficient densities to test any deleterious effects a release might have. Later, progeny of the imports would be released and evaluated for effectiveness. Results would be published in the refereed journal literature. At this point, extension agents and farmers would best get access to the information if they had been working in teams of individuals from the various agencies involved. Otherwise, those responsible for implementation would need to be keenly aware of the refereed journal literature.

Practical use of the new imported natural enemy(ies) might demand a mass rearing facility. Thus, further development could occur if, and only if, someone procured the resources for that facility and dedicated it to the rearing and release of natural enemies in soybean. If inoculative releases worked, the problem would be less costly. A key point here is the fragile relationship between research and extension. Researchers perceive that they get "rewarded" for publishing the results, not implementing them. Extension specialists have to be alert to know the new technology has been developed, especially if they have not been included as part of the overall team. Viewed as too simplistic a solution by some, one way around this dilemma is to have scientists who have formal, evaluated appointments in both research and extension.

Under the T&V Model

Once someone else did the research, experts who understood biological control could bring the imported biocontrol agents to a regional training session where extension specialists were being trained. Those extension agents could be shown how to identify the natural enemies, what they did to the pests and how to tell if the biological control worked. They also could be taught how to establish a cottage rearing operation. This process would continue down the training hierarchy, provided there were enough natural enemies to go around and provided the extension specialists had enough formal education to grasp some basic entomology and the concept of biological control. A lot of useful information likely would get lost between training tiers, leaving the ultimate farmer user wondering what all the fuss was about.

Under the Farming Systems Model

The entire issue would likely never even come up unless there was an entomologist or other biological scientist on the rapid rural appraisal team who was aware of the biological control agents that might be tested on local farms. Given the presence of the expertise, biocontrol agents could be imported, released on the farm and evaluated, with the farmers observing. If the biological control was effective, farmers would of course want to adopt it and the entire farming systems effort would have to become more akin to a T&V effort to train the farmers about the conservation of natural enemies and perhaps a cottage rearing and release operation.

Under the Training-Driven Research Model

Like farming systems, this model would demand that trainers be up to date on the latest research literature and recent progress to even know there was a new biological control agent that might be used locally. If so, use of the agent in field training exercises would be quick and would not have to pass through as many tiers of training as with the T&V model. The same problem outlined above exists in this model, too. It does little good to educate farmers about a new technique and entice them to adopt it if nobody teaches them how to implement it in a self-sufficient fashion.

Under the Farmer Participatory Research Model

If the CGIAR or other staff working with local farmers were able to identify the indigenous knowledge including experiences with natural enemies, there likely would be receptivity to the importation and use of an exotic biocontrol agent. In fact, such indigenous knowledge might even identify a better candidate for use than the one potentially coming from China. If there was no evidence that indigenous knowledge systems reflected previous exposure to natural enemies, training in the concepts and uses of natural enemies would, in essence, have to occur. Techniques to sustain the biocontrol effort, if accepted in local culture, would become part of the training.

Some General Conclusions

Institutional models for the research–extension–training activities would appear to best serve and reflect the societies in which they originate. The Land-Grant model likely could never develop in a strong hierarchical society. Much of the success of T&V in Asia and Israel comes from the fact that the organization of T&V "fits" those societies. The farming systems approach or Land-Grant approach do not work well in places where people are simply afraid of, or are unused to, expressing their opinions (e.g., Haiti and Cameroon).

There does appear to be a single model potentially usable in the wide array of situations that exist in today's world: farmer participatory research. All farmers and farming communities, save large industry systems, have an indigenous culture. This is especially true for resource poor farmers anywhere in the world. They have survived to date with, to one extent or another, a blend of traditional approaches and modern science. FPR and, to almost as great an extent, TDR offer what appear to be extremely high probabilities for solutions to agricultural problems that are acceptable to farmers almost by definition, that include farmers in the process and that avoid the inherent loss of information quality that occurs in the transfer of information.

There is debate over the extent to which the Land-Grant system involves farmers as active participants. No doubt, the better extension systems do just that, however, the extent to which farmer involvement permeates the breadth of Land-Grant efforts has not, to our knowledge, been gauged. FPR has been harder to implement in relatively wealthy nations like the USA where farmers see their tax revenues as providing agricultural services and resources they can tap "free of charge" without having to participate themselves.

Very few people outside the USA really understand the role of the extension specialists in the Land-Grant Model. To make this model work as designed, this is a key position, yet, some Land-Grant universities only recently have begun to employ individuals with formal, evaluated appointments in BOTH extension and research. Others utilize the inter-agency committee approach, and still others do not address the problem in any overt fashion. Joint appointments are still the exception, not the rule. The whole idea of state specialists grew up informally in the Land-Grant model as a need, but has over time become detached from formal research. Europeans do not employ extension advisory groups at all.

Three of the aforementioned systems have a rather disappointing track record on environmental issues. The reason is that all three fail to really focus on the farmer and long-term sustainability. It is hard to think of the off-site impacts of items like synthetic, organic pesticides if the farm is not viewed as part of a larger ecological and cultural system. Farming Systems appears to have the worst track record of the group on environmental and pest issues, with T&V a close second. The Land-Grant model is a classic example of how the system can derail on environmental issues (e.g., total commitment to pesticides for almost 25 years). FPR and TDR try overtly to avoid this problem by beginning their paradigm with farmer knowledge. Many modern Land-Grant extension personnel argue that current extension programs involve farmers in active decision-making more now than at any time in history.

Relationships among research, extension and training, independent of institutional models, demand choices be made on various levels. Some cultural, social, and economic systems clearly are more amenable to one choice versus another:

- Public versus private
- Government versus non-government
- Top-down (bureaucratic) versus bottom-up participatory)
- Profit versus nonprofit
- Free versus cost-recovery
- General versus targeted sector
- Multipurpose versus single purpose
- Technology-driven versus need-oriented

The role of publicly funded research and extension is changing. In the U.S., large-scale farmers depend less and less upon information generated and delivered through Land-Grant models. Part of the reason is that more and more of total agricultural productivity comes from corporate, rather than individual farmer, sources. Corporations have their own staff. The agricultural chemical companies provide all sorts of information and technical advice, but are single-minded in approach and profit motivated. Even in developing nations, where farming systems, T&V, FPR and TDR have predominated, they have been sponsored mostly by international donors and have regressed once funding ceased. So, just what is the role for public sponsored research-extension-training? There is a role if such programs will re-define their clientele base from richer corporate-industrial programs to poorer, smaller farming enterprises and beginning producers. With this new clientele definition must come a commitment to long-term sustainability of both the farmer and the farm.

Teaching Entomology: A Review of Techniques

CARL S. BARFIELD
University of Florida, Gainesville, FL, USA

Both positive and negative interactions with insects have long been a part of the human experience. However, people have not always had an opportunity to study insects in any formal, systematic fashion. Insects as biological organisms and various institutions where they can be studied are both part of the discussion on teaching entomology.

With the Neolithic Revolution (ca. 8,000 BCE), humans began the process of sedentary agriculture and civil development. Social scientists have provided us with at least anecdotal information on some of the roles played by insects in the human quest for survival and expansion. Early in human existence, insects vectored diseases, competed for food, consumed structures and were general irritants. They also were subjects of curiosity and sources of food and food products like honey.

Insects are the single largest and most diverse group of living organisms on Earth, and humans begin noticing and interacting with them almost from birth. Insects are among the first living organisms that children notice, and today's elementary education includes a host of activities that center on insects – butterfly gardens, games, music and use of the Internet being but a few examples. Students can choose to study entomology formally as part of their college education. A bit of historical context on the university as an institution where entomology is taught is relevant.

Entomology and Higher Education

Virtually none of the biological sciences existed as logical, written disciplines until Aristotle, and not until the ancient Greeks did the study of insects become characterized by the delight in observational opportunity insects provided. The 11th Book of the Roman Pliny's Historia Naturalis (AD 77) was the most comprehensive treatise on insects to date; however, it contained almost no original observations. Pliny's time and writings marked the beginning of a body of knowledge that would allow university degree programs to arise in the ninteenth century.

Higher education in Europe, from antiquity until the end of the middle ages, was maintained in the monastic and cathedral schools, enriched by a huge influx of knowledge from the Islamic world. These institutions eventually developed into universities as products of cross-cultural influence. Modern universities thus treasure a multi-cultural faculty and student body and a plethora of teaching styles. Those early European institutions were places where ideas spread, and where local and national authority was engaged. Entomology was not an area of formal study in these early institutions. Insects were engaged as plentiful examples of the biological world and, fairly often, as "pests." Indeed, the first real concerns about insects as a group were more in the context of "sources of products" (e.g., honey) and "competitors" (e.g., agricultural pests) than just for the need to understand their biology and history. The Catholic Church would often put "bad" insects on trial and hire them defense attorneys, ultimately "banishing" them from select provinces. These practices occurred fairly frequently from the middle ages right up to the start of the nineteenth century. Both the Bible and the Torah refer frequently to insects, paying special attention to the parables that can be extracted from insect life and to whether or not select insects are kosher. Entomology was important because most everyone had personal experiences with insects, not because it was a recognized area of study.

The study of entomology was nested within the general biological sciences in Europe and America throughout the seventeenth and most of the eighteenth centuries. Things began to change toward the start of the American Civil War. In 1862, President Abraham Lincoln established the United States Department of Agriculture and set in motion what would ultimately be three key Federal Acts to institutionalize the research and teaching (Morrill Land Grant Act and Hatch Act) and extension (Smith-Lever Act) functions by which all Land-Grant Universities are recognized today. While entomology is taught at many higher education institutions, the vast majority of American entomology majors are housed within colleges of agriculture and life sciences at Land-Grant institutions. Part of the reason for this situation is that, to many in the general public, insects are viewed as pests and colleges of agriculture were developed, at least in part, to help solve the public's pest problems.

After WWII, departments of entomology grew at almost every Land-Grant institution. Today, many of these institutions offer undergraduate degrees in entomology, and most offer graduate degrees. An undergraduate major in entomology, depending on the institution, will take 18–30 h of entomology courses offered in sequence. Graduate entomology degrees take 30–90 additional hours, the majority of which are insect-related. Graduate degrees usually include a research experience.

Teaching Entomology at the University Level

The present treatise will focus very little on the content of entomology courses; rather, the focus will be aimed at the style and methods through which any given content may be delivered. Clearly, different styles are applicable to different audiences, and the professor of any single course must understand the background and motivation of his/her audience before the most appropriate style can be selected. Interestingly, this is not how it usually works. Most often, any professor has his/her long-adopted style, and it is left to the clientele (students) to make the adjustments. There are possible consequences of this long-adopted practice, as illustrated in Table 6.

These various professor roles translate in myriad ways to an individual style used in the professor-student classroom experience. The entire point is that there is not a single best way to teach. The capabilities of both professor and students are basic ingredients in the choice of teaching style. An assessment of the students' optimum learning style early in the term is ideal if the professor has both the desire and the capability to shift teaching styles to align with learning styles. Here are a few possibilities (Table 7).

The Socratic, Discussion Approach

This approach to teaching entomology is used most often in small classes and can be applicable to either entomology students or general students simply curious about insects. It is commonly used in undergraduate honors classes at large universities, and small colleges and universities often use this approach throughout their curriculum. Students who take these classes typically are interested, motivated, and engaging. They are willing to read and discuss a plethora of historical, social and current issues related to insects and then perhaps, via a series of essays, analyze and critique what they have read. In this context, entomology becomes merely the biological medium in which to have students develop their interpersonal, analytical, critical thinking, oral presentation, and English grammar skills. Such students may become enticed to explore entomology as a major and an ultimate career, but most often these students, if they are interested in the biological sciences at all, are focused on medicine or veterinary medicine.

Success in this approach demands specific criteria on the part of both students and professor. The professor must be knowledgeable of a wide array of entomological issues and literature. Even more important, he/she must be charismatic, engaging and able to entice bright students to develop curiosity about entomology. The professor must be able to write and speak well, as these students will discern quickly between what is said and what is done in critique of written and oral presentation performances. The students must be engaging and willing to participate in class discussions. The Socratic Approach is, in many ways, the antithesis of more traditional presentation of copious facts about insect morphology, physiology, behavior and control. The idea is to entice students to explore, on their own, issues presented incompletely in discussion periods, thus developing skills that will serve them well during their university tenure. This approach will simply not work if either the students or the professor are not engaging or if the class resorts to a host of information-laden

Teaching Entomology: A Review of Techniques, Table 6 **Five models for the presence of an instructor in the classroom (summarized from Grasha 1966)**

	Expert	Formal authority	Personal model	Facilitator	Delegator
Professor role	Source of knowledge; status as expert; gets students prepared	Status symbol; reinforces correct, acceptable and standard methods; establishes learning goals	Role model; teaches students to emulate him as model	Emphasizes personal student–professor interactions; guides learning; creates independent students; supports and encourages	Focuses on student independence; serves as a resource
Advantages	Copious information; development of skills	Clear expectations; identification of acceptable approaches	Emphasis on direct observation and following the role model	Personal flexibility; focus on students' needs and goals; open-mindedness	Students become independent learners
Disadvantages	Volume of information; students may be intimidated; lack of focus on underlying processes that led to information	Rigidity in approach to students	Feeling of inadequacy if students feel they cannot live up to model	Time-consuming; often lacks positive reinforcement	Student anxiety; student may be misperceived as ready for independent work

Teaching Entomology: A Review of Techniques, Table 7 Comparison of five entomology teaching styles

	Socratic	Lecture/lab	Land lab	FFS	Internship
Experientially based	No	No	Yes	Yes	Yes
Focus on insect facts	No	Yes	Yes (limited)	Yes (limited)	Yes (limited)
Focus on student analytical skills	Yes	No	Yes	Yes	Yes
Demands large resources	No	No	Yes	Yes	No
Teacher focused	No	Yes	No	No	No
Student focused	Yes	No	Yes	Yes	Yes
Ideally requires supplemental funding	No	No	Yes	Yes	Yes

slides, films, blackboard text or, more frequently now, Power Point or Internet presentations.

Topics typical of this style of teaching may include many that do not appear, on the surface, to have anything to do with entomology. However, discovering their links to entomology is part of the desired outcome. For example:

1. Pliny's Historia naturalis
2. The Idea of "Food Insurance"
3. Social attitudes on pesticides versus pharmaceuticals
4. What was The Green Revolution?
5. In your supermarket, what foods are indigenous to the contiguous 48 states?
6. Medieval higher education?
7. Colonial American living?
8. What is social Darwinism?
9. Who is Norman Borlaug and what did he do?
10. What is the role of empiricism in science?

For example, in a classroom of 20 or so students, the professor initiates a discussion about the diet of Colonial Americans. Initially, the professor seeks to understand what the students already know about this subject. He discovers this by asking them and expecting them to engage in dialogue with him and with each other. The conversation expands to include the crops grown and the problems the colonists had with food production. Analogies are drawn periodically to modern agriculture and its problems. As some of the problems were insect related, the dialogue eventually permits the students to discover the linkages between Colonial American diet and the study of insects, as well as the various means of controlling those insects under social and technological conditions existing in colonial times. The result is a group of students who are better able to place insects and entomology into appropriate historical context and then draw inferences to the importance of entomology today.

This teaching style assuredly contributes to the student's knowledge of biological science and thus meets both professorial and student objectives in this context. There is a decent chance this approach will entice such students to become interested in entomology as a major and a career – something the vast majority of them have never before considered. Many will not even know it is possible to major in entomology.

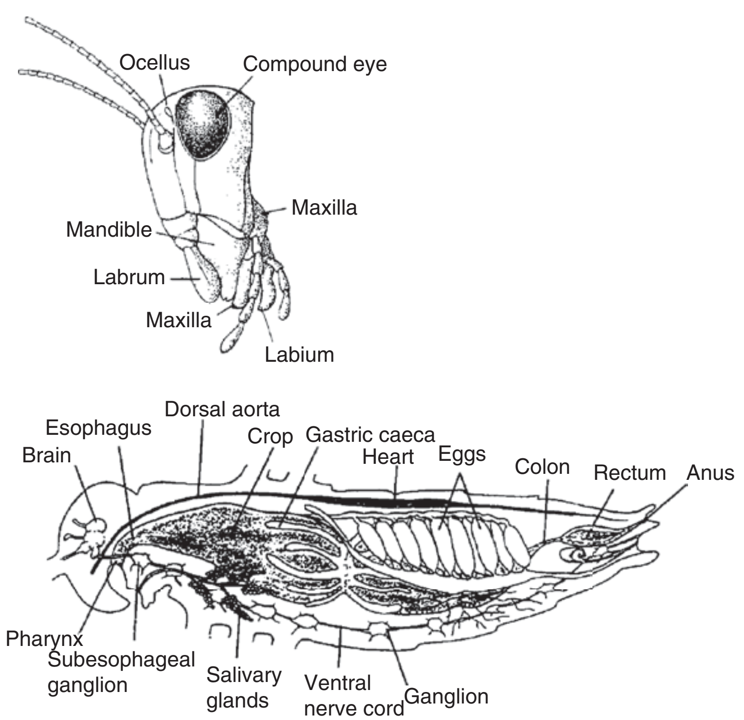
The Lecture/Lab Approach

By far, the most common way entomology is taught in modern universities is as a 3- or 4-credit hour course. This involves a series of lectures (2–3 per week) and 1–2 laboratory sessions per week. Lectures are used to present facts about entomology, and the lab is experientially based and involves dissection and study of the various physical and physiological features of insects. Interestingly, what actually occurs during the lecture period can follow any of the teaching styles presented in this paper; however, by far the most common is using the professor as the expert whose role it is to pass entomological facts and knowledge on to the students. The labs, if scheduled as typically desired, mirror the lecture periods and provide visual, hands-on experience for the topics discussed that week during lecture.

Lecture approaches vary from professor to professor, but there is concern under this model to ensure sufficient information is imparted to justify the student moving on to the next course in the sequence. General undergraduates who simply want biological science credits do take these type courses just because they want to learn about organisms they have experienced daily. It is the entomology majors, however, who professors feel the need to get ready for continued study of entomology. Lectures are replete with facts, drawings, information; labs follow suit. Figure 15 illustrate typical information presented under this style.

The emphasis is often on learning facts about insects. Professors pursue these facts in various ways. Some choose a systematic approach that focuses on the principal orders and a comparison of their morphologies, physiologies, behaviors and control. Others use a type of comparative biology approach that may compare insect adaptations with those of other animals (Fig. 16). While various entomological issues may be discussed, students spend time hearing the expert impart expertise, then committing that expertise to memory. Labs will have students dissecting, searching for, and identifying these morphological structures, and a test may include a lab practical where students must identify parts labeled. This is precisely the approach used in Colleges of Medicine.

Entomology lecture/lab courses do not have to unfold in any pre-determined fashion, and many professors use creativity in what they impart as entomological knowledge. The point here,



Teaching Entomology: A Review of Techniques, Figure 15 Elements of insect morphology and anatomy.

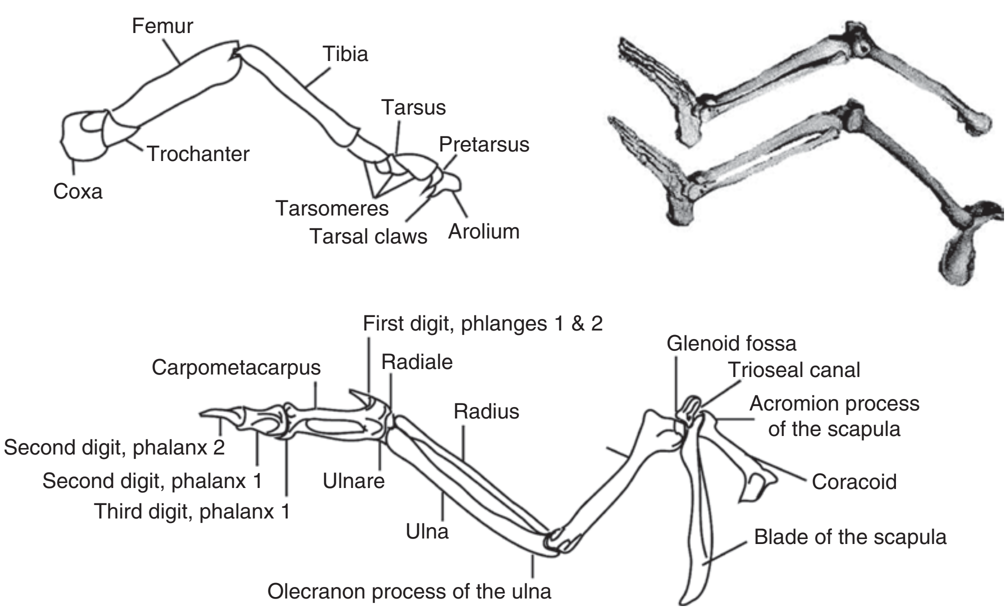
however, is that introductory entomology courses are typically taught for entomology majors or at least biological science majors, not for non-science students, despite the fact that diverse students often enroll. Under this approach, more emphasis is placed on facts about insects than on issues associated with insects. This is not a criticism, but rather an observation.

Introductory entomology textbooks offer a range of approaches to teaching the subject. Most will begin with chapters that discuss the general importance of insects to science and to humans. From there, the authors' approaches vary greatly. Likely, the most common approach is to begin immediately with external and internal anatomy and physiology. Sensory systems, reproduction, development, life history, and systematics follow. Then, insects as part of special habitats (e.g., aquatic and terrestrial systems) are presented, followed by subjects like insect societies, insects and plants, predation, parasitism, medically important insects, insect pest management and collection/preservation methods. Several texts will place collection and preservation methods, plus insect systematics, immediately following introductory chapters. In any case, most existing entomology texts will cover the above subjects, independent of which order of presentation is chosen.

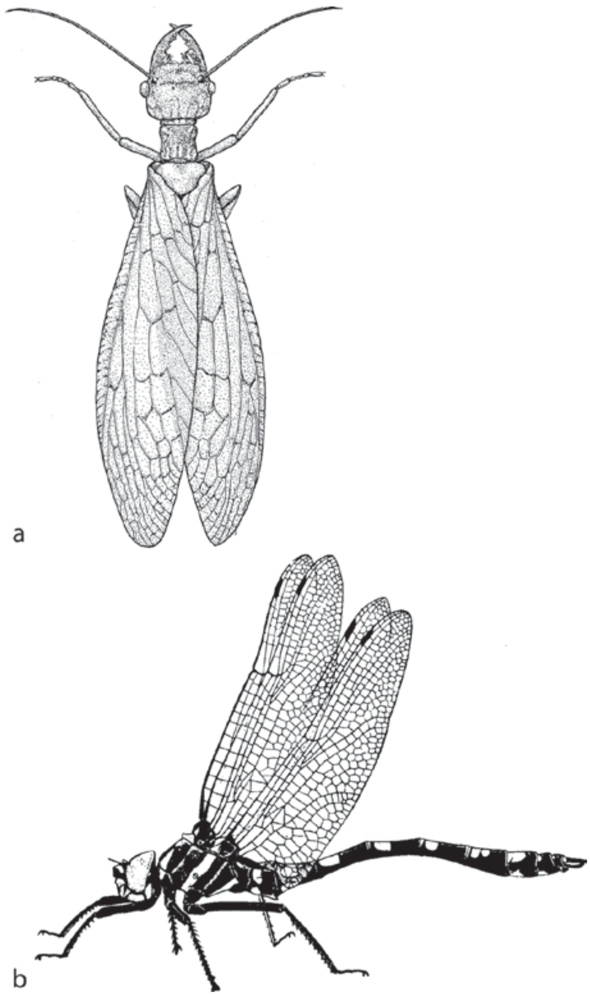
The teaching approach used is tied more to the bent and capability of the individual professor than to the subject matter. One teaching strategy is more of a comparative biology approach that might compare, for example, the insect leg and locomotion to analogous structures and functions in mammals, birds, reptiles, etc. This approach is effective in placing insects and their adaptations in perspective among all animals and is depicted in Fig. 16.

Another strategic approach is to compare insects among the various orders and explore metamorphosis, wing type, locomotion, habitat, life history, etc., as a means to compare-and-contrast the different orders of insects. This approach is illustrated in Fig. 17.

There is no shortage of information (journals, books, Internet sources) from which to supplement the basic text to expand student knowledge



Teaching Entomology: A Review of Techniques, Figure 16 Comparative biology approach to teaching insect leg morphology and its analogous structure and function in other animals. Human leg unlabeled; an exercise might be for students to locate analogous structures on human anatomy.



Teaching Entomology: A Review of Techniques, Figure 17 Neopterous (a) versus Paleopterous (b) wing types characteristic of different orders of insects.

of insects both as biological organisms and as social entities interacting with humans. Indeed, social scientists (especially anthropologists) often use insects to illustrate daily life, problems and indigenous approaches indicative of specific cultures. Some instructors of basic entomology will include sections on indigenous cultures and the role insects played therein.

Increasingly, entomology departments are offering courses to non-science majors. This is both as a way to educate undergraduates to the possibility of entomology as a major and as a mechanism to capitalize on the general student's previous experience with insects and their required enrollment in a specific number of science courses. Perusal of university catalogs usually will reveal courses such as: The Insects, Bugs and People, Pesticides and Pills, Ecology and Human Intervention, Insects and Society, The Insect World and You. These type courses typically are taught in one of two diverse formats. First, they frequently appear as honors courses taught to small-sized classes consisting of very intelligent students. In this context, the aforementioned Socratic style is most prevalent. Such students are often searching for creative majors, as their academic credentials permit them to select most any major they desire. The second prevalent delivery format is a lecture, replete with detailed syllabus and copious illustrations, to a large class. This delivery style is the aforementioned lecture/lab, but without the lab portion in most cases. Most every academic unit, including entomology, in a large university now offers such courses for non-majors. Strategically, these courses expose searching students to possibilities of a major they had not theretofore considered. Further, these courses allow students more flexibility in fulfilling general education requirements.

Internships

Most professional disciplines in the biological sciences require extensive internship experiences prior to certification. One cannot imagine a licensed Medical Doctor or Veterinarian without such experiences before they are sanctioned to ply their trade. The basic biological sciences in general, and entomology as one example therein, do not typically make such requirements. However, those parts of entomology related to agricultural plant protection often do require internships as part of graduation requirements. While wonderful in their intent and educational possibilities, internships are not without their potential problems.

An internship typically occurs toward the end of an undergraduate degree program. The idea is to match a student's need for hands on experience with a public or private sector business. The student would typically leave the university and locate at the business site for 1–2 semesters. Under the supervision of the business contact, the student would work daily in several of the tasks in which the business is involved. This might include plot preparation, fumigation, sampling, pest control, assessment of pest damage, interaction with the public, identification of insect pests, bookkeeping, and seminars. The entire experience would be aimed at permitting the student to translate academic knowledge obtained to marketplace demands. The university professor in charge of internships would make periodic visits to assess the student's progress and to witness first-hand the range of activities in which the student was involved. The student would register for a university course and pay associated tuition, and he/she may or may not receive salary compensation for the work.

Matching undergraduates with appropriate public or private internship opportunities often means asking them to relocate or commute for 1–2 semesters during their undergraduate studies. Many students are reticent to encumber the additional travel and per diem costs. Parents express similar concerns. If an internship is a requisite for graduation, care must be taken to ensure the intern's experience does not resort to a more trivial exercise based on student economics rather than on learning needs. Care also must be taken to ensure the business contact understands the needs of the student intern and is not simply looking for a short-term source of cheap labor. Medical and Veterinary interns accept the requisite; however, they are older, graduate students, away from parental influence and knowledgeable that the economic pay-offs of certification are potentially great. Often, none of these issues are the same for undergraduates. The more successful undergraduate intern programs provide financial support, if justified, to offset additional costs to students.

Field-Based Courses

This section refers to courses taught totally in the field, not to courses where sporadic field trips are part of a lecture/lab style. If field-based courses are targeting agricultural entomology, they require facilities: land, equipment, etc. There is debate over the cost needs for such facilities. Some feel adequate field-based courses are limited only by the creative imagination of professors teaching them. Others feel adequate land, equipment and staff are crucial to the success of such courses. As universities often do not consider such teaching resources high-priorities, these courses often piggyback onto research efforts, using plots developed for some professor's research. This can work, but often encounters problems as the timing associated with teaching conflicts with the timing of needed research activities.

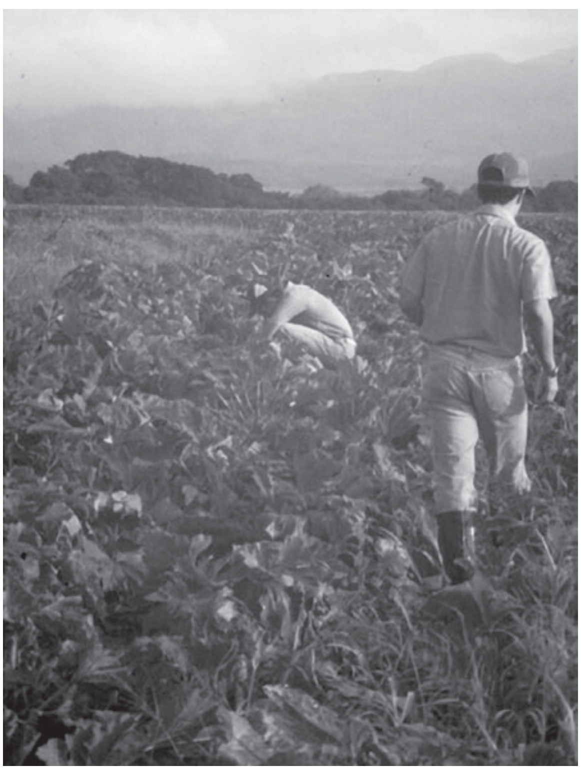
Many universities have natural areas that can, within certain guidelines, be used to teach various aspects of entomology. In any case, the fundamental idea in a field-based course is to provide students with experiential learning. Under ideal conditions, such a course would be offered on facilities set aside exclusively for teaching and would be under the control of teachers so that the timing of activities could occur in an orderly fashion consistent with educational paradigms.

Also known as the Land-Laboratory Approach, this style is somewhat analogous to a teaching hospital where doctors and nurses get experiential learning under real situations – all supervised by professorial experts. Where else is it possible to give developing professionals the opportunity to gain practical experience in a supervised learning environment? Many educators feel such practical experience should be a mandatory part of science education.

Joliet Junior College in Joliet, Illinois, exemplifies the intent and structure of the Land-Laboratory concept. As stated in their advertisements, they exist to "serve as a teaching tool for instructors to use hands-on learning as a means to reinforce classroom instruction." The Land-Laboratory exists as

101 acres of land donated for the exclusive purpose of teaching. The Pennsylvania State University has a similar facility dedicated to land analysis. In most cases, Land-Laboratories exist because the land and perhaps the infrastructure needed to make it operational were donated. Rarely do universities encumber the costs of a Land-Laboratory from their operational budgets.

The Escuela Agrícola Panamericana (Pan American School of Agriculture, EAP) in Honduras, Central America, provides an example of both experiential learning and the Land-Laboratory style (Fig. 18). Students attend from throughout the Caribbean Basin and beyond and spend 0.5 day in class and 0.5 day in the field in a wide array of agricultural experiential learning activities including land preparation, planting, harvesting, processing, marketing, plant protection, outreach and with both plant and animal systems. Entomology plays a prominent role in the experiences of the "Zamoranos."



Teaching Entomology: A Review of Techniques, Figure 18 **Zamorano students in land-laboratory exercise, Pan American School of Agriculture, Honduras, Central America.**

Teaching at the International Rice Research Institute (Philippines) exemplifies the same approach and has been in place much longer than the EAP. The general trend is for international research institutes that also teach to place a higher premium on Land-Laboratory approaches than do U.S. universities. This is true likely because they have the land and labor to make this approach work and because they understand that hands-on experience for their student clientele is of maximum importance.

Extra-University Models

The international arena offers a variety of teaching approaches aimed directly at farmers and professionals who provide technical support to farmers. In this context, the stakes (possible food self-sufficiency) are much higher than the pursuit of an undergraduate college degree. These programs offer both challenge and opportunity to university-based degree programs in entomology.

The Farmer Field School Approach

The principal sponsor and promoter of this approach is the United Nations Food and Agriculture Organization, Rome, Italy. Principally, the Global Integrated Pest Management Group within the UN/FAO developed this model based on experiences in Rice Integrated Pest Management programs in Indonesia. This approach serves as a model that universities might want to emulate in those aspects of entomological education that demand experiential learning.

The FFS was established to provide training to farmers and their support network (researchers and extension specialists) on the problems and opportunities associated with specific crops (Fig. 19). The idea is to follow crop development

Teaching Entomology: A Review of Techniques, Figure 19 **Farmer field school training in corn-based agriculture, Honduras.**

from land preparation to marketing of the harvest, teaching at every step the techniques demanded, the pests encountered, the sampling needed, the pest management approaches needed, etc. Those same trained people obtain the multiplier effect by training others. The idea is to teach, in a hands-on fashion, the details for any specific crop. As the crops change, so do the issues and thus additional training may be needed. In 2002, FAO is assisting Korea in the establishment of a junior college level curriculum of study based exactly on the FFS concepts. Students would hold night sessions on the more general aspects of, say, entomology. Unlike the lecture/lab approach typical of American Universities, the FFS approach begins with the field and then moves to general classroom experience (Fig. 20).

The FFS approach served as the basis for development of The Farmer Centered Agricultural Resources Management (FARM) Program that, until funding declined, consisted of the member countries of China, India, Indonesia, Nepal, Philippines, Sri Lanka, Thailand and Viet Nam. The entire FARM program was supported by the UNDP and implemented by FAO. In 2002, there were 19 sites in eight nations covering some 10,000 Asian households (Figs. 21 and 22). FARM, and its parent idea, the FFS, was one of the most rapidly expanding teaching resources in the world.

Teaching Entomology: A Review of Techniques, Figure 20 **Farmer field school classroom training, Indonesia.**

It offered practical hands-on training that could be supplemented with more traditional academic education in a wide array of subjects, including entomology. Sadly, politics overtook needs and funding was cut to the point the program vanished in its original form.

The purpose of the FFS is not pursuit of academic degrees. Training is focused on the specificities of individual crops or cropping systems and is increasingly supplemented with "after hours" academic work on subjects like entomology. Students are adults, not undergraduates in pursuit of degree requirements. Results of this educational style are improved chances of food self-sufficiency, not a B.S. degree and employment. However, in the few places where the fundamental

Teaching Entomology: A Review of Techniques, Figure 21 Farmer field school plot facilities for rice-based agriculture, Indonesia.

Teaching Entomology: A Review of Techniques, Figure 22 In-field training on rice insects, Indonesia.

concepts of the FFS or its close relative, the Land-Laboratory, have been directly combined with academic programs, the results have been astonishing. These are the rare situations that make agricultural and entomological education the most analogous to professional school education in the USA.

Cross Style Comparisons

Three things limit what style is used to teach entomology (i) imagination, (ii) budget, and (iii) either professor or student capability. The most appropriate criterion for a comparison among styles is whether or not students achieved course objectives. The reality is that various styles have different intents and expected outcomes. The problem occurs when a style of teaching is used that has a low probability of generating the desired outcomes.

Use of the lecture/lab approach where the lecture is used to present copious facts about insects which are to be memorized and repeated on a multiple choice exam may not be the most appropriate for a group of students who have selected beginning entomology for its general education function and who are simply curious about insects. Not providing the future field practitioner of agricultural entomology a field-based experience will not achieve desired outcomes in the most efficient manner.

If the professor desires students to become independent thinkers, capable of analysis and presentation, playing the role of "expert" who imparts facts about insects that are to be learned and demonstrated on an exam is probably not the most ideal approach. Tailoring teaching style to a particular student audience is hard, not easy. It takes effort and does not occur automatically. Just like any other aspect of the human experience, some professors can do it and others cannot. This is not a criticism, but a fact. Ideal learning experiences tend to occur in entomology or any other subject when care is taken to match the style of teaching to the needs and learning styles of students in that class that term. Adoption of a single teaching style to be used throughout one's tenure is, quite literally, a "hit and miss" proposition where desirable and less desirable outcomes will occur among semesters.

The key to any professor adjusting to dynamic learning styles of students is an ability to gauge quickly their response to a variety of styles. Literally, what works well one term and gets students involved and responsive is not automatically what will work best next term, given a new group of students. Many, if not most, university professors of basic entomology courses offered to entomology or science majors, do not attempt to adjust to perceived student learning styles. Such adjustments are much more common in entomology courses offered to non-science majors.

Teak Moths (Lepidoptera: Hyblaeidae)

JOHN HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Teak moths, family Hyblaeidae, are a small tropical family of 18 species, mostly Indo-Australian and in the genus *Hyblaea* (one pantropical species is also established in southern Florida). The family is in the superfamily Pyraloidea in the section Tineina, subsection Tineina, of the division Ditrysia (sometimes placed in its own superfamily, Hyblaeoidea). Adults medium size (25–49 mm wingspan), with head relatively smooth-scaled; haustellum naked; labial palpi porrect and prominent; maxillary palpi 3- to 4-segmented. Maculation mostly shades of brown, with colorful spotted hindwings. Bodies are usually robust. Adults are diurnal or perhaps crepuscular. Larvae are leaf rollers. Host plants are in Bignoniaceae and Verbenaceae. One economic species: the teak leafroller. Due to their robust form, these moths were often associated with Noctuidae in the past (Fig. 23).

Technical Grade

A chemically pure preparation. This is often used to describe research-grade pesticides as opposed to commercial formulations.

► Insecticides

Tegmen (pl., Tegmina)

The thickened front wing of Orthoptera and related insects.

► Wings of Insects

Tegula

A small flap or lobe at the anterior edge of the forewing of some insects. It is also known as the patagium.

Telegeusidae

A family of beetles (order Coleoptera). They commonly are known as long-lipped beetles.

► Beetles

Telephone-Pole Beetles

Members of the family Micromalthidae (order Coleoptera).

► Beetles

Teloganellidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Teloganodidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Telomere

Telomeres are the physical ends of eukaryotic chromosomes. They protect the ends of chromosomes and confer stability. Telomeres consist of DNA repeats and the non-histone proteins that bind specifically to those sequences.

Telopodite

The portion of the limb beyond the base; the shaft.

Telmophages

Arthropods that feed at blood vessels, and specifically from pools of blood created by lacerating vessels (contrast with solenophages).

Telson

The terminal portion of the abdomen bearing the anus. In insects the telson is usually found only in the embryonic stage. It is not normally recognized as a body segment in insects, but it is in some other invertebrates.

Template

A macromolecular mold for synthesis of another macromolecule. Duplication of the template takes two steps; a single strand of DNA serves as the template for a complementary strand of DNA or mRNA.

Tenaculum

In Collembola, a small structure on the third abdominal segment that serves as a clasp for the furcula (Fig. 24).

► Abdomen of Hexapods

Tenebrionidae

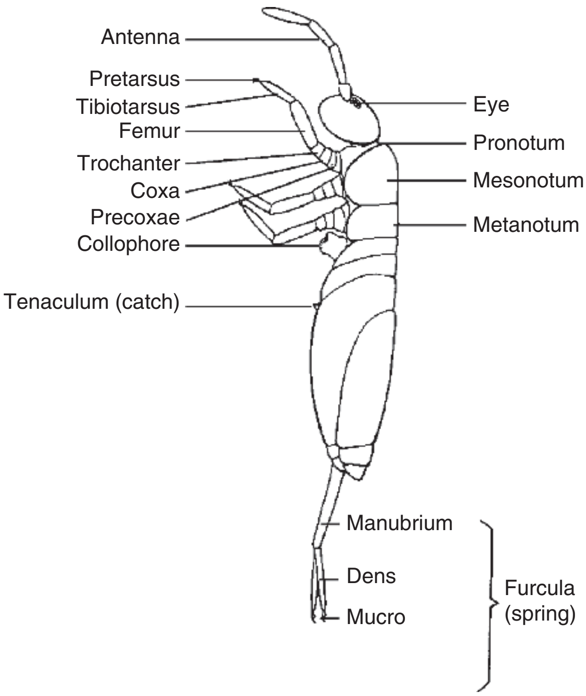
A family of beetles (order Coleoptera). They commonly are known as darkling beetles.

► Beetles

► Darkling Beetles

Teneral

The condition of an insect after molting but before the new cuticle has hardened.



Tenaculum, Figure 24 Lateral view of a springtail (Collembola).

Tent Caterpillars

Some members of the family Lasiocampidae (order Lepidoptera).

► Lappet Moths
► Butterflies and Moths

Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae)

TERRENCE D. FITZGERALD
State University of New York at Cortland, Cortland, NY, USA

Tent caterpillars occur in the family Lasiocampidae and are related to silk moths in the families Bombycidae and Saturniidae. Tent caterpillars are placed in the genus *Malacosoma* established by Hübner in 1820. The name *Malacosoma* derives from the Latin for *malakos* (soft) and *soma* (body). In the earlier literature, tent caterpillars were referred to the genus *Clisiocampa* which was erected by Curtis in 1828, unaware that Hübner had already named the group.

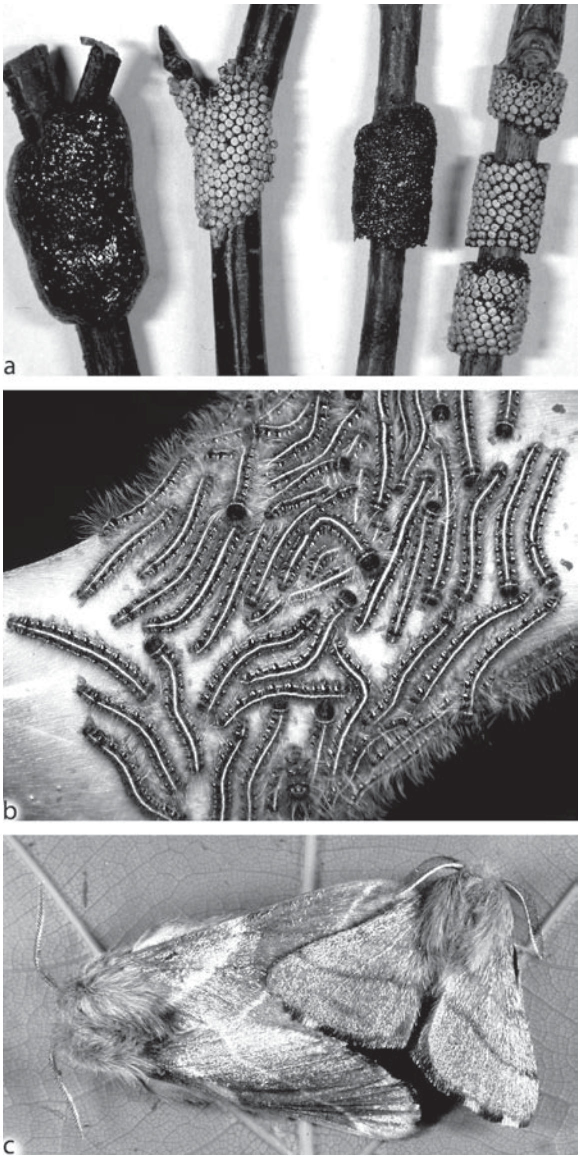
Species of *Malacosoma* occur throughout the Holarctic region. Although the taxonomy of the group is far from settled, currently there are 26 valid species. Six of these occur in North America and the rest in Eurasia. A number of these species are also further divided into subspecies. The best-known of the tent caterpillars are the North American species, particularly the eastern tent caterpillar, *M americanum* (Fig. 25), the western tent caterpillar, *M. californicum* and the forest tent caterpillar, *M. disstria* (Fig. 26). Of the Eurasian species, *M. neustrium* is the best known and has the broadest geographical range.

Life Cycle and Behavioral Ecology

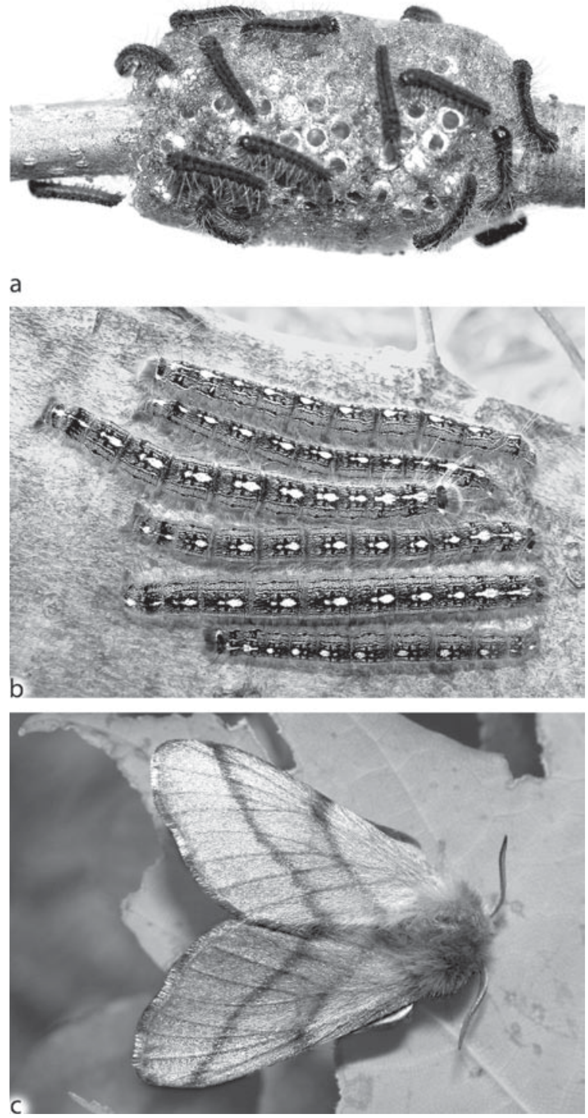
Little detailed information is available for many of the species of *Malacosoma*, but the evidence we have suggests that their life history features are similar to those of the eastern tent caterpillar, the most studied of the group. The seasonal history and behavioral ecology of this species is described here.

The eastern tent caterpillar obtains all the energy required for its adult life while still a larva and reproductively mature moths emerge from their cocoons in late spring. Females secrete sex pheromones to attract males. Mating typically takes place soon after eclosion and the female may oviposit the evening of the same day she emerges.

The moth produces a single egg mass, typically containing 150–250 eggs, though larger egg masses are not uncommon. The egg mass is attached to a branch of the host plant and is covered with a foamy substance termed spumaline. The material serves to protect the eggs from desiccation and may also prevent parasitoids from reaching the larvae inside the eggs. Embryogenesis proceeds rapidly and fully formed larvae can be found within the shells of their eggs several weeks following oviposition. The sequestered caterpillars undergo an obligatory



Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae), Figure 25 Eastern tent caterpillar, *Malacosoma americanum*: (a) egg masses of the eastern tent caterpillar with and without spumaline (left) and of the forest tent caterpillar (right) (b) mature larvae, (c) adults. (Photos by Terrence Fitzgerald.)



Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae), Figure 26 Forest tent caterpillar, *Malacosoma disstria*: (a) larvae hatching on egg mass, (b) mature larvae, (c) adult. (Photos by Terrence Fitzgerald.)

diapause which is broken only after exposure to cold temperatures over the winter. Eclosion of the caterpillars in the spring is closely synchronized with the flushing of leaves of the host tree but if eclosion occurs before leaves have flushed the young larvae may obtain food by mining buds. Development occurs rapidly and most species finish the active larval stage of their life cycle in 6–8 weeks. The last of the six larval instars spins a cocoon in a protected place and the moth emerges about 2 weeks later.

All tent caterpillars are social species that live in sibling groups. Although they are commonly viewed as pests because of their habit of defoliating forest and ornamental trees, they are among the most social of all caterpillars and exhibit many noteworthy behaviors. Their life histories are highlighted by four collective behaviors: shelter building, thermal regulation, cooperative foraging, and predator defense.

For those species that make large, permanent tents such as the eastern tent caterpillar, the tent site is selected by the first instar caterpillar, typically in a part of the tree that receives the early morning sun. In the eastern tent caterpillar, the parent moth may facilitate this process by selecting an oviposition site on the south side of a tree. The tent is expanded daily to accommodate the growing colony, allowing the caterpillars to rest, molt, and thermoregulate in synchrony. Silk is added to the structure during episodes of spinning which precede bouts of foraging. The colony expands their tent until they enter the last stadia of their lives as caterpillars; the last instar retains its silk to construct its cocoon.

The tent is multi-functional. It serves primarily as a secure mat, providing the caterpillars with purchase during their extended periods of rest. The tent also serves as a staging area from which colonies launch intermittent forays in search of food. It may also serve as a communication center where successful foragers alert their hungry tent mates to food discoveries as detailed below. The extent to which the tent protects the caterpillars from predators and parasitoids is unclear. When the caterpillars rest within the tent they may be secure from certain predators and parasitoids that cannot enter the structure. However, the caterpillars often rest on the outside where they are more vulnerable but not defenseless. Caterpillars assembled on the surface of the tent respond to predators with a defensive body-flicking display. The display may serve to alert tent mates to danger.

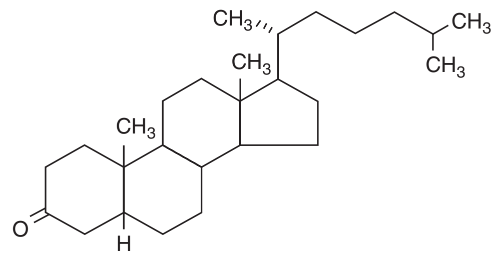
Tent caterpillars are active during the time of the year when the days are typical cool and the tent serves the important function of facilitating thermoregulation. Although eastern tent caterpillars are capable of locomotion at temperatures as low as 3–5°C, they cannot process food at temperatures much below 15°C. The caterpillars can achieve temperatures in excess of ambient only by basking in the sun, and on cool and cloudy days they grow little if at all. The caterpillars have dark bodies and are effective behavioral thermal regulators but the tent enables the caterpillars to elevate their body temperatures far above ambient. They aggregate on the surface of the tent or within the structure. When basking on the surface, the caterpillars arrange themselves in a tight cluster, minimizing heat loss due to wind currents. The tents act like greenhouses, trapping the heat of the morning sun. Because of its layered structure, the tent is thermally heterogeneous and the caterpillars can adjust their temperature by moving from layer to layer. One study showed that a cluster of models simulating an aggregation of caterpillars basking in the sun on the tent surface achieved temperatures as great as 44°C in excess of ambient temperature. Indeed, the tent may become so hot by midday that the caterpillars overheat and take evasive action to avoid the sun. They do this by moving to the shaded side of the tent and by hanging suspended in the air, attached to the tent only by the posterior ends of their bodies. This minimizes the amount of heat that is conducted to their bodies from the hot tent surface and maximizes the cooling effect of convective air currents.

Eastern tent caterpillars secrete a chemical trail marker as they move over the branches of the host tree. The marker is secreted from the ventral surface of the tip of the abdomen and caterpillars actively mark trails by lowering and dragging the tips of their abdomens against the substrate. Although eastern tent caterpillars also lay silk strands as they move over branches, silk does not elicit trail following; the elicitation of trail following is dependent on the trail pheromone.

The eastern tent caterpillar utilizes a bilevel trail system consisting of exploratory and recruitment components. Hungry foragers in search of food mark *exploratory* trails with a pheromone as they move over the bark surface. The caterpillars show great reluctance to move over surfaces not already marked with the exploratory trail pheromone, advancing slowly in close proximity to others. Exploratory trails enable foraging columns to stay together without necessitating direct physical contact among the caterpillars. Larvae that locate food and feed to repletion lay down *recruitment* trails as they follow their exploratory trails back to the tent. Recruitment trails are more effective in eliciting trail following than exploratory trails; they function to lead hungry tent mates to food finds in a manner similar to the recruitment trails of ants and termites. It is presently not known whether the difference between exploratory and recruitment trails is qualitative or quantitative, but recent studies of the related genus *Eriogaster* suggest that the difference may be quantitative.

The foraging system of the forest tent caterpillar differs from that of the eastern tent caterpillar in that the larvae range widely in search of food and do not establish a nest or other permanent resting site. The caterpillars travel between feeding sites en masse, laying down an exploratory trail marker as they proceed. After feeding, the caterpillars move to a temporary resting site or bivouac. Trails marked by the caterpillars immediately after feeding are more stimulating than exploratory trails and serve to recruit fed colony mates to the new bivouac where they rest en masse.

Studies undertaken to identify the trail pheromone of the eastern tent caterpillar showed that the chemical 5β-cholestane-3,24-dione, isolated from the tips of the abdomens of eastern tent caterpillars, elicited trail following when applied to paper cards at rates as low as 10^{-10} g/mm trail. Bioassays, however, showed that while the chemical was competitive with the exploratory trails of the caterpillar, it was not competitive with authentic recruitment trails. A number of compounds with similar structure were subsequently obtained and bioassayed for activity. Of these, the steroid 5β-cholestane-3-one (Fig. 27) proved more effective in eliciting trail following than



Tent Caterpillars, *Malacosoma* spp. (Lepidoptera: Lasiocampidae), Figure 27 5β-cholestane-3-one, a chemical that elicits trail following in caterpillars.

5β-cholestane-3,24-dione and was shown to be fully competitive with the authentic recruitment trails of the caterpillar.

Tent caterpillar larvae are highly sensitive to the amount of pheromone present in trails and carefully compare trails at branch junctures by sweeping their maxillary chemoreceptors from trail to trail. Caterpillars choose stronger over weaker trails and newer over older trails when foraging allowing them to move efficiently between feeding and resting sites.

Economic Importance and Caterpillar Outbreaks

Gregarious caterpillars are among the most economically important of forest and shade tree insects. Studies indicate that about 70% of the lepidopterous pests of trees capable of achieving outbreak proportions deposit eggs in batches and over half of these form social larval aggregates. The ability of social species of caterpillars to reach outbreak numbers has been attributed to enhanced predator defense, collective thermoregulation, and foraging efficiency. Although all species of North American tent caterpillars may be capable of achieving outbreak numbers, the most significant are the forest tent caterpillar, the eastern tent caterpillar, the western tent caterpillar (*M. californicum*), and the southwestern tent caterpillar (*M. incurvum*). *Malacosoma disstria* is the best-known of these species, causing considerable damage during its periodic outbreaks. Surveys conducted by the U.S. Department of Agriculture showed that between 1953 and 1983, the forest tent caterpillar achieved outbreak status on 70 occasions. The Eurasian species *M. neustrium* is an economically important defoliator of oak and other forest and shade trees.

It is commonly reported that outbreaks of tent caterpillars occur at ten-year intervals but the historical record shows that the actual interval between successive outbreaks varies widely. The most complete records of forest tent caterpillar outbreaks are from Ontario, Canada. From 1867 to 1987, province-wide outbreaks occurred at intervals of 9–16 years. Caterpillars remained in outbreak numbers for 1–8 years (average = 3 years). In Manitoba and Saskatchewan, outbreaks occurred at 6–16 year intervals from 1923 to 1957 but some areas in these provinces experienced only one outbreak in the 34-year period.

Density dependent mortality factors that bring population explosions of the tent caterpillar to a close are fungal, viral, and to a lesser extent bacterial diseases, starvation, and predators and parasitoids. The primary density independent factors are elements of the weather. Cool and cloudy springs can be lethal for tent caterpillars. As noted above, studies of the eastern tent caterpillar show that when a tent caterpillar's body temperature drops below about 15°C, the insect cannot digest food. Although air temperature in the spring is often less than this threshold temperature, caterpillars bask in the sun to raise their core temperatures. However, basking is not possible if there is dense cloud cover, and a prolonged episode of cool, cloudy weather can lead to the death of the caterpillars due to starvation. A combination of density dependent and density independent mortality factors may interact to bring a population explosion to a close. Thus, disease may sweep through a population of forest tent caterpillars, precipitated by the cool and wet weather that favors the pathogen *Furia*.

In addition to its importance as a defoliator, the eastern tent caterpillar has been implicated in the death of horses. During the spring of 2001 and 2002 horse breeders in central Kentucky experienced an unprecedented loss of foals, a phenomenon now known as Mare Reproductive Loss Syndrome or MRLS. In 2001 alone, more than 3,000 mares aborted, causing an estimated loss of over $330 million. At the time of the abortions there was an outbreak of tent caterpillars, and studies showed that pregnant mares fed the caterpillars aborted their foals. The exact cause of MRLS is not known but one possibility is that irritation of the mare's gut by setal fragments facilitates the invasion of bacteria which infect the placenta and induce abortion. Apparent instances of MRLS have also been reported from other areas experiencing outbreaks of tent caterpillars including New York, New Jersey, Florida, and Washington State.

Tenthredinidae

A family of sawflies (order Hymenoptera, suborder Symphyta). They commonly are known as common sawflies.

► Wasps, Ants, Bees, and Sawflies

Tentorium

The internal invaginations of the exoskeleton occurring in the head tergite.

► Head of Hexapods

Tephritidae

A family of flies (order Diptera). They commonly are known as fruit flies (but not to be confused with small fruit flies, Drosophilidae)

► Flies

Teratembiidae

A family of web-spinners (order Embiidina).

► Web-Spinners

Teratomyzidae

A family of flies (order Diptera).

► Flies

Tergum

The dorsal section of a body segment. Also called tergite. They sometimes are named after their body segment (e.g., mesotergum is the tergum of the mesothoracic segment) (Fig. 28).

Termen

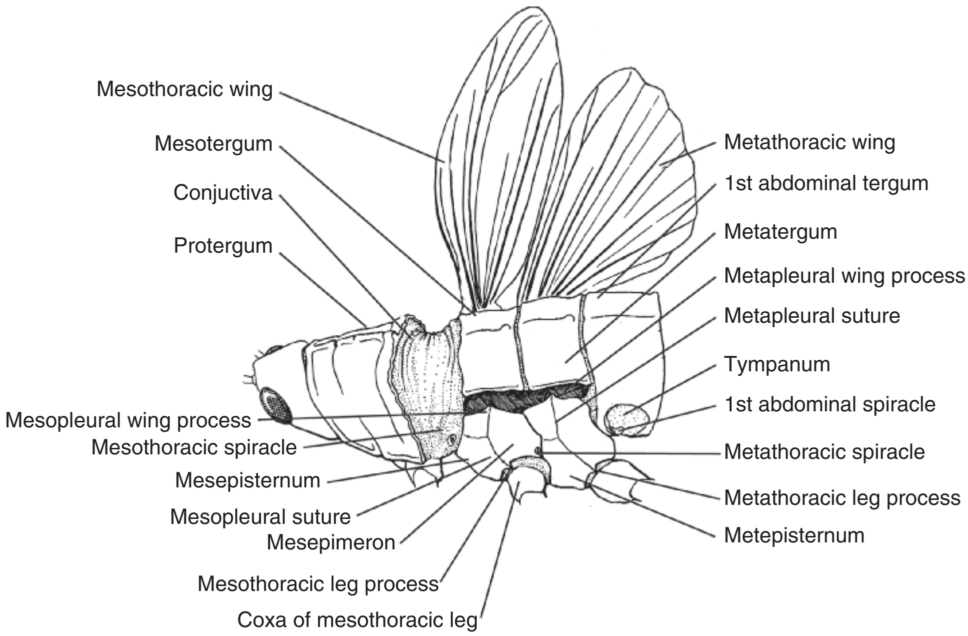
In Lepidoptera, the edge of the wing in the distal (lateral) area.

Terminal Arborization

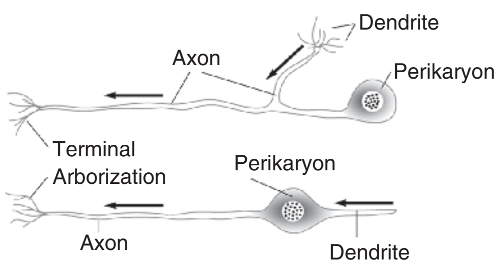
An extensive branching of the dendrites at the end of a nerve cell (Fig. 29).

Terminal Filament

Long, slender projections from the last abdominal segment.



Tergum, Figure 28 **Head and thorax of a grasshopper (Orthoptera).**



Terminal Arborization, Figure 29 **Diagrams of insect nerve cells showing direction of nervous impulse (adapted from Chapman 1998, The insects: structure and function).**

Termitaphididae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Termitarium

A termite nest, or the artificial net used to house termites in a laboratory.

Termites (Isoptera)

RUDOLF H. SCHEFFRAHN
University of Florida, Ft. Lauderdale, FL, USA

Termites are small to medium-sized orthopteroid insects that are cryptic in habit. All species live in eusocial colonies and feed primarily on cellulose. Although referred to in older literature as "white ants," termites are unrelated to ants. The name of the order is derived from the Greek words "iso" (equal) and "ptero" (wing) that describe the similar length and shape of both the fore and hind wings of the reproductive alates. Mature colonies are composed of task-specific castes that typically include one or more pairs of reproductives, about 0–25% soldiers, and a majority of immature or sterile workers. During part of the year, colonies may also contain some maturing or fully winged reproductives (alates, imagos) destined to leave their colony in brief, but often intense, dispersal flights. The order Isoptera is divided into seven families. The family Rhinotermitidae is divided into seven small and closely allied subfamilies and the Termitidae into four large

Termites (Isoptera), Table 8

Order: Isoptera, the termites	No. genera	No. species

Subfamily: Termitinae	91	771
Family: Termopsidae, Primitive Dampwood or Rottenwood Termites	5	21
Total	286	2,870

and diverse subfamilies (Table 8). By historical convention, all but 2% of termite genera end in the suffix "*termes*," the Latin word for termite.

Phylogeny and Fossils

Termites are closely related to cockroaches and mantids. Based on molecular and morphological characters, the Mastotermitidae are the most primitive termite family, followed by the Termopsidae, Hodotermitidae, Kalotermitidae, Serritermitidae, Rhinotermitidae, and finally the "higher" termites of the family Termitidae. The earliest fossil records of termites are from the Cretaceous period (144–65 million years before present, YBP) and include the families Mastotermitidae, Hodotermitidae, and Termopsidae. Cretaceous fossils consist of wings or imago bodies in sedimentary deposits or amber. Excellent soldier and alate fossils have been found for the Mastotermitidae, Kalotermitidae, Rhinotermitidae, and Nasutitermitinae in Dominican amber from the Oligocene to early Miocene (20–30 million YBP). Over one hundred extinct termite species have been identified worldwide except from Africa.

Description of Important Taxa

The family Mastotermitidae consists of a single primitive species, *Mastotermes darwiniensis*, a large subterranean nester that attacks sound wood in northern Australia. The alates of *M. darwiniensis* have some roach-like characters and queens lay eggs in batches that resemble cockroach ootheca. The Termopsidae are large to very large primitive wood-nesting termites found in damp logs in temperate forests of both hemispheres. The Hodotermitidae are an Old World family consisting of large termites that nest in the soil and openly forage in grasslands and savannas for herbaceous growth. Unlike other termites, the eyes of Hodotermitidae workers are rather well developed. The Kalotermitidae include wood-dwelling species found throughout the tropics and subtropics. Although some species require wood with moderate to high moisture content, other kalotermitids thrive in low moisture conditions and are called drywood termites. Drywood termites produce characteristic six-sided fecal pellets that are stored in galleries and periodically ejected from the wood through surface holes. One drywood species in particular, *Cryptotermes brevis*, is a worldwide pest known only from structural lumber and furniture.

The family Rhinotermitidae is worldwide in distribution and contains primarily wood-feeding subterranean nesters and includes some of the most important pest genera attacking buildings: *Coptotermes* (Coptotermitinae), *Heterotermes*, and *Reticulitermes* (Heterotermitinae). A few *Coptotermes* are known to build mounds in Australia. The Prorhinotermitinae (*Prorhinotermes*) typically locate their nests inside and under damp logs near oceanic coastlines. The Psammotermitinae constitute one genus (*Psammotermes*) of subterranean termites that occurs in arid lands of Africa and the Middle East. Some genera of the Rhinotermitinae, such as the neotropical *Rhinotermes* and the paleotropical *Schedorhinotermes* have dimorphic soldiers, one with large mandibles and the other with an extended labrum, that bear little or no resemblance to one another. The monogeneric subfamilies Stylotermitinae and Termitogetoninae are limited to central and Southeast Asia, respectively. The Serritermitidae are an obscure family known only from a few collections of two species in Brazil.

By far the largest termite family is the Termitidae inclusive of all evolutionarily advanced or "higher termites." The soldierless subfamily Apicotermitinae includes grass feeders and humivores. Most apicotermitine species live in diffuse underground gallery systems but some African genera, such as *Apicotermes*, build elaborate geometrically proportioned nests. The Macrotermitinae are an Old World subfamily of large mound-building termites. These medium to very large termites eat fungus grown on special combs in their nest. Many species provision the fungus with herbaceous vegetation that is gathered by workers from forests, grasslands, and agroecosystems. The massive 8 m high chimney mounds of *Macrotermes* have classically defined the landscape of the African savanna. The Macrotermitinae, which also include the diverse genera *Microtermes* and *Odontotermes*, range east to the Philippines. The Nasutitermitinae are a tropicopolitan subfamily of arboreal, mound, and subterranean nesting termites that are characterized by long-snouted soldiers. The snout, or nasus, is the armature from which a volatile and sticky secretion is exuded as a defensive mechanism. Some Nasutitermitinae, primarily in the genus *Nasutitermes*, feed on wood and can be serious pests of structures, while others are humivores. In some Neotropical genera, e.g., *Armitermes*, the soldiers have both a nasus and long sickle-shaped mandibles. The subfamily Termitinae is the most diverse of all the termitid subfamilies. Included is the genus *Cubitermes* of sub-Saharan Africa which is characterized by mushroom-shaped mounds. The pantropical *Termes* and related genera have soldiers with snapping mandibles and arboreal or rotten log nests. The *Amitermes* and related genera like *Microcerotermes* occur in the tropics and subtropics worldwide where they feed on wood, grasses, and cellulosic debris. *Amitermes* is subterranean nester in the Nearctic Region while species from northern Australia build large epigeal mounds. *Microcerotermes* tend to be arboreal or subterranean in nesting habit.

Diversity and Distribution

Almost 2,900 termite species in 286 genera have been described and it is likely that more than 4,000 species may ultimately be recorded. Termites are found in all zoogeographic regions of the world and many oceanic islands between latitudes of about 50°N (southern British Columbia) and 45°S (southern Chile and South Island, New Zealand) (Table 9, Figs. 30 and 31). The greatest diversity, measured by numbers of genera and species, occurs in the tropical non-arid regions of Africa, Asia, and the Americas. Some regions show remarkable speciation by single genera such as the *Cryptotermes* from the circum-Caribbean with 25 species, the *Amitermes* of Australia with 61 species, the *Nasutitermes* of the Neotropics with 72 species, and the *Odontotermes* of tropical Asia with nearly 100 species. Certain genera, such as *Reticulitermes* (Rhinotermitidae) and all those of the Termopsidae are characteristic elements of more temperate climates. In turn, *Heterotermes* and *Neotermes*, respectively, occupy similar niches in the tropics. Numerous genera are found in all tropical regions of the world. These include the *Neotermes*, *Glyptotermes*, *Kalotermes*, *Procryptotermes*, *Cryptotermes* (Kalotermitidae), *Coptotermes*, *Heterotermes*, and *Prorhinotermes* (Rhinotermitidae), and *Anoplotermes*, *Microcerotermes*, *Amitermes*, *Termes*, and *Nasutitermes* (Termitidae).

International trade has facilitated the spread of "weedy" species from native habitats across natural barriers to non-native locations worldwide. Human transport, especially by boat, has facilitated the spread and establishment of about a dozen major pest species. Among them are the drywood termites (Kalotermitidae) *Cr. brevis* (West Indian drywood termite), *Cr. havilandi*, *Cr. dudleyi*, *Cr. domesticus*, *Cr. cynocephalus*, and *Incisitermes minor* (Western drywood termite). Invasive species among the lower subterranean termites include *Coptotermes formosanus* (Formosan subterranean

termite), *Co. gestroi*, and *Reticulitermes flavipes* (Eastern subterranean termite). Among the Termitidae, only one species, *Nasutitermes costalis*, has become established in a non-native habitat.

Morphology

All termite castes are soft-bodied. Only the soldier head-capsules, the heads and bodies of some imagos, and the mandibles of all castes have moderate to heavy sclerotization. Termite workers and imagos have chewing mouthparts, filiform or moniliform antennae, and a shield-like pronotum behind the head. Soldier mandibles are highly developed to atrophied and variable in shape depending on the defenses employed. Important morphological characters used to classify termites include wing venation and mandible dentition in imagos, head capsule and mandible shape in soldiers, and gut configuration and mandible dentition in workers. Alates have compound eyes and ocelli while eyes of other castes are reduced to spots or are completely absent. The tarsi of most termites are not well suited for climbing smooth surfaces. Worker and soldier bodies are usually light colored but some have darker pigmentation. Alate bodies and wings range in color from pale yellow to black. Soldier head capsules range in color from light yellowish to orange, reddish-brown, or black. Among the smallest of termite soldiers is *Atlantitermes snyderi* (Nasutitermitinae) from Trinidad and Guyana with a total length of 2.5 mm while one of the largest is *Zootermopsis laticeps* (Termopsidae) from Arizona and Mexico at 22 mm long. The largest termite alates are the African *Macrotermes* measuring up to 45 mm in length with wings while the smallest is *Serritermes serrifer* (Serritermitidae) at 6 mm with wings. Alates of some *Incisitermes* and *Glyptotermes* (Kalotermitidae) and Apicotermitinae are less than 7 mm long with wings (Figs. 32 and 33).

Life Cycle and Behavior

The inception of a termite colony occurs when a male and female alate pair after a dispersal flight. Flights are typically associated with weather conditions superimposed over annual cycles. Rainfall is a prerequisite for flights by many subterranean species. The beginning of a rainy season coincides with flights by many species. After separation from their wings along specialized suture lines, the reproductive pair runs in tandem until a suitable nesting site is encountered and selected. Once in the protected site, e.g., a crevice in a branch, a tree hole, or underneath a log or stone, the new king and queen build a small nuptial chamber in which the first eggs are deposited and hatch into larvae. The first batch of developing workers and first soldier are cared for by the reproductives. The workers, usually blind and composed of both sexes, in turn begin to forage and feed the royal pair, soldiers, and younger sibling larvae. Feeding is accomplished by trophallaxis in which food is passed mouth-to-mouth from workers to their dependent nestmates. As foraging and food resources increase, the size and reproductive output of the queen grow accordingly. The abdomens of mature queens in the Rhinotermitidae and Termitidae, filled with egg-swollen ovaries, reach a state of near immobility

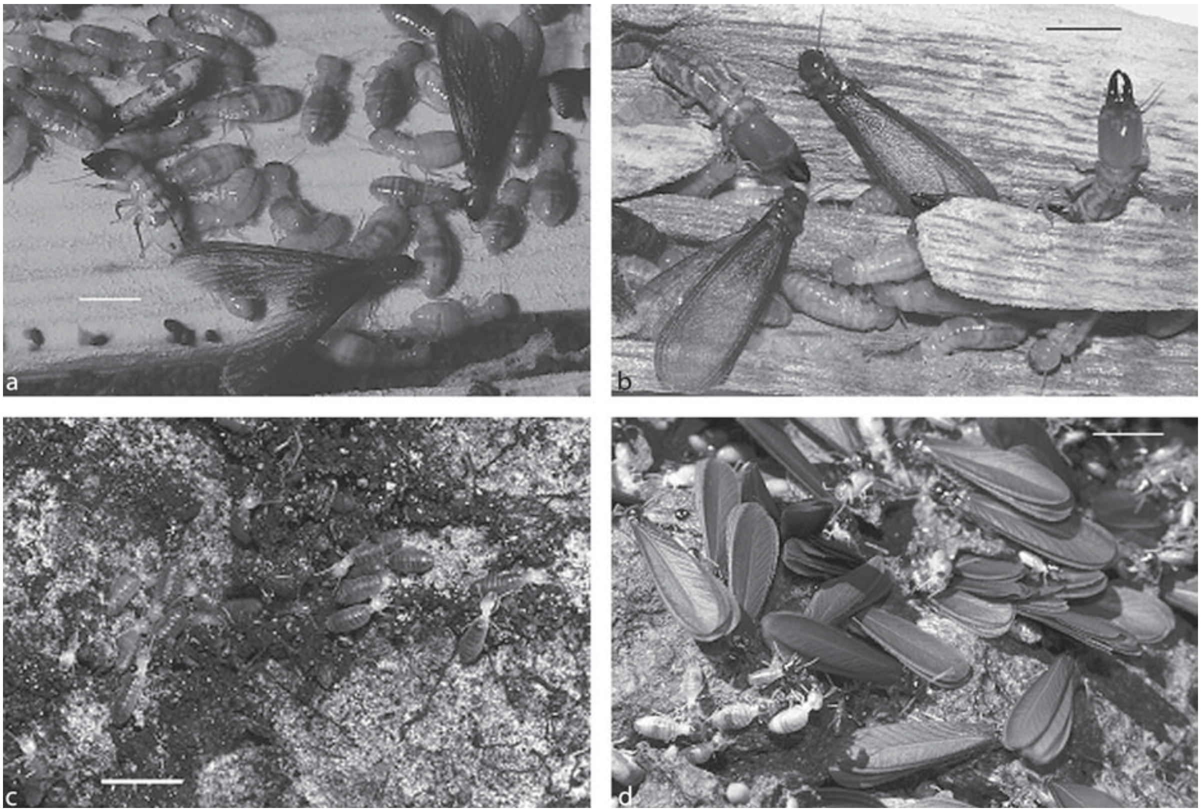
called physogastry. In the Kalotermitidae, castes develop along a single line with both soldiers and alates molting from the immature worker (pseudergate) line. In the higher termites, each caste differentiates along separate developmental pathways after hatching with the workers becoming sterile adults. Unlike social Hymenoptera, the king is retained and periodically fertilizes the queen. After a number of years when a large crop of workers and soldiers are present, the colony matures to produce its first batch of alates, completing the reproductive cycle. Colonies will produce alates for many years after maturation. Termites have some complex symbiotic relationships with a community gut-inhabiting microorganisms. Various bacteria (prokaryotes) and protists (eukaryotes) are important for cellulose digestion, nitrogen fixation, and metabolism. Protists are absent from the Termitidae. Termites also produce their own cellulytic enzymes. Proctodeal feeding, the transfer of gut contents via anus to mouth, facilitates the exchange of gut biota to freshly molted nestmates (Fig. 34).

Defense Mechanisms and Natural Enemies

Termites are an ideal food source for other animals. They are relatively slow moving, soft-bodied, and rich in fat and protein. Termites passively



Termites (Isoptera), Figure 34 **Termite colonies. (a)** ***Zootermopsis angusticollis*** **(Termopsidae), California. (b)** ***Neotermes castaneus*** **(Kalotermitidae), Florida. avoid casual predation because of their cryptic habits of living in nests, feeding mostly under cover, and foraging in narrow galleries constructed in soil or wood. Most termite species, however, have a highly specialized soldier force to defend the colony from specialized invaders, especially ants. Soldiers of the Kalotermitidae, Termopsidae, and Hodotermitidae rely solely on mechanical defenses including powerful crushing mandibles. Some kalotermitid genera, e.g., *Cryptotermes* and *Calcaritermes*, have soldiers with plug-shaped or phragmotic heads used to seal off nest galleries in wood from ants. Termites in other families use various combinations of biting, piercing, or slashing mandibles and repellent, sticky, and/or toxic chemical secretions which they exude, brush, or squirt onto ants. In most species of Nasutitermitinae, soldier mandibles are altogether lacking and instead, the soldiers use their conical nasi to squirt repellent secretions over several body lengths.

Many animals, especially birds, bats, rodents, reptiles, and amphibians opportunistically gorge themselves on termite alates during dispersal flights. Some large mammals, such as the aardvark and aardwolf of Africa, pangolins of the paleotropics, anteaters of the neotropics, the echidna of Australia, and the sloth bear of Asia are specialized predators of termites and use claws and long tongues to excavate and feed inside hard nest structures. Humans, especially in Africa, trap and eat *Macrotermes* alates during seasonal dispersal flights from their mounds.

Some arthropods have evolved an association with termites that includes living in termite nests. Those arthropods that have an obligate relationship with the termite colony are called termitophiles. Usually the termitophiles rely on termites for both food and shelter. The great majority of termitophiles are beetles. Some staphylinid beetles even resemble their hosts. Other termitophile taxa include isopods, millipedes, phorid flies, and silverfish.

Ecology

Termite nests consist of a network of galleries that interconnect all colony members and foraging sites. Nest types include single-piece wood nests, (Termopsidae, Kalotermitidae), diffuse subterranean nests (Mastotermitidae, Rhinotermitidae, Termitidae), hollow tree, log, and stump nests connected to other food resources via subterranean galleries (Rhinotermitidae, Termitidae), on-soil (epigeal) mounds (Hodotermitidae, Rhinotermitidae, Termitidae), and arboreal nests (Termitidae). Arboreal nests are constructed of feces while epigeal nests are composed mostly of soil (Fig. 35). Foraging is the means by which termite colonies locate and exploit new food resources. If such resources are abundant, secondary nest structures may be constructed nearby. Usually workers, but in some cases soldiers, follow specific search patterns to locate food. If food is encountered, the foragers will recruit additional nestmates to exploit the food source for the colony. When on exposed surfaces, foraging trails are usually protected from predators by tube or sheet-like enclosures made of feces or soil. Recruitment to food locations is enforced and oriented by chemical trails released from the sternal gland located on the ventral surface of the abdomen. Large immovable food sources may be covered with a protective fecal or soil sheeting. Smaller food items such as leaves and grasses are either covered with soil sheeting or

(f) Foraging tubes of *Microcerotermes arboreus* (Termitinae), Trinidad.**

are subdivided and carried back to the nest for consumption, storage, or fungal gardens. Foraging territories for single termite colonies may extend 100 m or more from the nest. Water, either in food or substrata, can have a profound influence on foraging. Most termites forage in the direction of moisture gradients and prefer moist foods and nesting sites. In savannas and arid lands, surface objects caste heat shadows that are often investigated by termites foraging near the soil surface.

Although cryptic for the most part, the absolute numbers of termites in most tropical and semitropical forests, deserts, and savannas ranges from several hundred to thousands of individual termites per square meter. Colony populations of termites vary from several hundred (Kalotermitidae) to several million (Rhinotermitidae, Termitidae) individuals.

The biomass of termites often rivals that of terrestrial vertebrates and ranges from less than 1 g/m^3 to over 10 g/m^3. Food consumption by termites can be greater than that of large ungulates. Termite foods include dry, moist, wet wood, bark, live wood, leaf litter, soil (humus), live and dried grasses and herbs, and leaves, lichens, fungi, and algae. Termites are also significant, albeit, relatively minor sources of global atmospheric methane and carbon dioxide. Termites, along with earthworms, create large turnover and aeration of organic and mineral content in soil and thus benefit plant growth and nutrient cycling.

Termites as Pests

About 10% of the termite species worldwide attack structural lumber, wood products of a broad array including paper, and agricultural and forage crops. About 1–2% of all species are major pests and account for the bulk of the untold billions of dollars in damage caused by termites around the world each year. The vast majority of termites is a cryptic and essential component of the environment but has very little direct impact on humans. Termite control in developed countries relies on chemical applications in the form of specialized residual soil termiticides, wood preservatives, baits, dusts, and fumigants often applied by professional pest control operators. People in developing countries may treat termite infestations with unsafe or unproven methods or simply replace damaged and infested wood.

Collecting

Because termites are delicate and can desiccate rapidly, they should be preserved in alcohol (85% ethanol is best) while still alive. A hatchet, trowel, and aspirator are essential collecting tools. Obvious places to collect termites include nests, foraging tubes, and dead limbs and logs. Subterranean species also congregate under boulders, stones, and other surface debris. Herbivore dung, under which some subterranean termites forage, is another surface feature to collect from. Small dried twigs on trees, tree holes, leaf litter, and disturbed areas such as road, trail sides, or even garbage dumps are good collecting places. A few species even infest branches, stems, and roots of live trees and shrubs. Termite alates that fly at dusk or at night are attracted to lights where they can be collected by aspirator or net. Because identification relies heavily on characters of soldiers or imagos, one should take multiple samples of each caste present. When alates are not found, one might be lucky to find a queen, king, or both. Nestmates from one colony should be combined as a single sample to confirm their relationship.

Termites (Isoptera) in South America

REGINALDO CONSTANTINO
Universidade de Brasília, Brasília, Brazil

Termites are abundant in most parts of South America, especially in tropical lowland forests, savannas and grasslands. In many places, termitaria comprise a conspicuous element of the landscape. Early European naturalists who traveled in South America often mentioned termite damage or termite constructions in their writings. The South American fauna contains representatives of the termite families Kalotermitidae, Rhinotermitidae, Serritermidae, Termitidae, and Termopsidae (Figs. 36 and 37). This fauna comprises 76 genera (54% endemic) and 422 known species (90% endemic). Family Serritermitidae, which includes two genera and three species, is restricted to South America. Table 10 summarizes the number of genera and species recorded in each country. The termite faunas of Brazil, Argentina, Guyana, Chile and Trinidad are relatively better studied, while the faunas of Colombia, Ecuador, Paraguay and Suriname remain very poorly known. The knowledge in the remaining countries is intermediate.

Taxonomy

Family Kalotermitidae

This family is represented in South America by 67 species and 11 genera. Genera *Eucryptotermes* and *Tauritermes* are endemic and genus *Comatermes* occurs only in South America and Panama. The most diverse genera of Kalotermitidae in this region are *Neotermes* (16 species), *Cryptotermes* (11 native species) and *Glyptotermes* (10 species). Four species of *Cryptotermes* have been introduced from other regions as urban pests: *C. brevis*, *C. domesticus*, *C. dudleyi* and *C. havilandi*. However, only *C. brevis* is widespread and there is a single unconfirmed record of *C. domesticus* from Trinidad. In general, this family has been little studied in South America, and there are still many undescribed species.

Family Rhinotermitidae

There are 21 species of rhinotermitids reported from South America, belonging to six genera: *Acorhinotermes*, *Coptotermes*, *Dolichorhinotermes*, *Heterotermes*, *Reticulitermes* and *Rhinotermes*. *Acorhinotermes* is endemic, with only one species, and *Dolichorhinotermes* is mostly endemic, with five species in South America and one in Panama. *Heterotermes* is the most important genus, with six species. *Heterotermes tenuis* is the most common species and an important agricultural pest. Despite the low diversity, this is a very important family including several major pests. Two species of Rhinotermitidae were introduced into South America and became major urban pests: *Coptotermes gestroi* in Brazil and *Reticulitermes flavipes* in Chile and Uruguay.

Family Serritermitidae

This family is endemic to South America and includes two genera and three species. *Serritermes serrifer* is endemic to the Cerrado and lives in nests built by *Cornitermes* spp., where it feeds on the dark organic matter of the nest walls. The genus *Glossotermes* includes two species, *G. oculatus* from Guyana, and *G. sulcatus* from Brazilian Amazonia. *Glossotermes* feeds on decayed wood.

Family Termitidae

This the largest family and comprises 76% of the South American species. The so-called nasute

Termites (Isoptera) in South America, Figure 37 (a) Soldiers of South American nasute termites (Termitidae: Nasutitermitinae). (1–2) *Angularitermes clypeatus*; (3) *Caetetermes taquarussu*; (4) *Coatitermes clevelandi*; (5–7) *Velocitermes heteropterus*, major, intermediate and minor soldiers. (b) Soldiers of South American Termitinae (Termitidae) (1) *Cavitermes tuberosus*; (2) *Genuotermes spinifer*; (3) *Orthognathotermes humilis*; (4) *Dihoplotermes inusitatus*, major soldier; (5) *D. inusitatus*, minor soldier (6) *Neocapritermes pumilis*; (7) *Crepititermes verruculosus*; (8) *Planicapritermes planiceps*; (9) *Onkotermes brevicorniger*; (10) *Cylindrotermes parvignathus* (drawings previously published in Zootaxa and used with permission).

termites (subfamily Nasutitermitinae) are the dominant group, with more than 50% of the species. Genus *Nasutitermes* alone includes 65 South American species. Most species of this genus are wood-feeders and live in arboreal carton nests, but some are subterranean or mound builders. The other 35 genera of Nasutitermitinae occur in South America, 22 of them endemic. Among them, *Syntermes* is the most diverse, with 23 species, including some of the largest known termites. They are mostly subterranean and feed on leaf or grass litter. Another important genus is *Cornitermes*, with 14 species, most of them mound-builders. Some species of *Cornitermes*, such as *C. cumulans*, occur in high densities and dominate the landscape of some grasslands. Other common and diverse genera of Nasutitermitinae are *Armitermes*, *Embiratermes*, *Labiotermes* and *Velocitermes*. Subfamily Termitinae is the second in diversity, with 16 genera (10 endemic) and 72 species in South America. The most important genus is *Neocapritermes*, with 16 species. Other common genera are *Termes*, *Microcerotermes*, *Spinitermes*, and *Orthognathotermes*. Very few South American Termitinae are strict wood-feeders and many are soil-feeders. A few

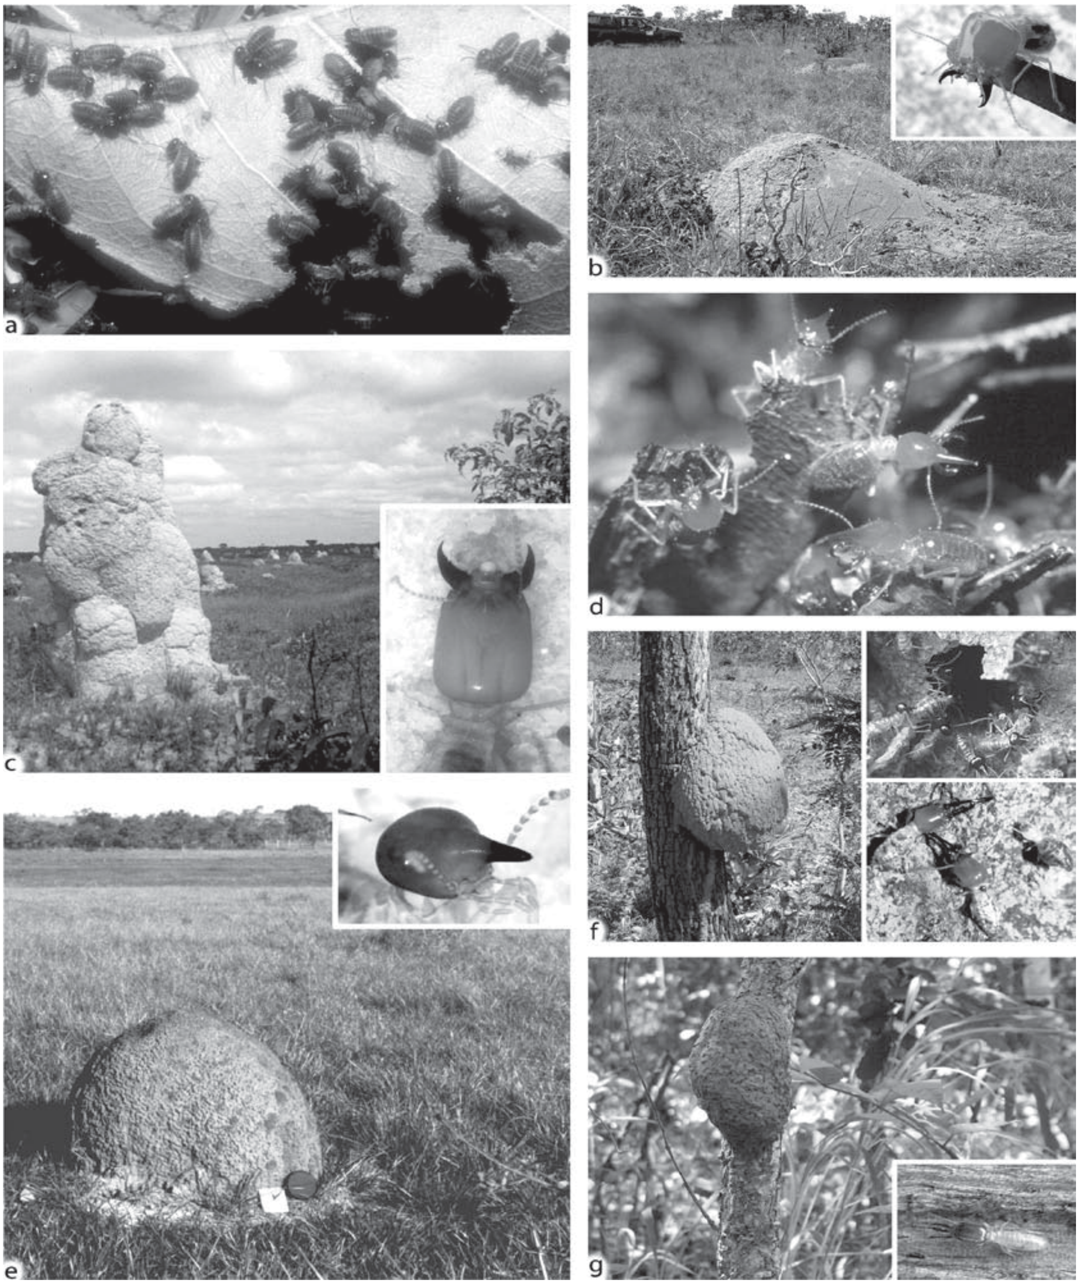
species have been reported damaging living plants, but in general they are of little economic importance. Subfamily Apicotermitinae is also important and diverse, but has been very little studied. All New World species of this subfamily are soldierless and most are subterranean, soil-feeders, and live in diffuse nests in the soil. They are difficult to collect and identify and have been neglected by termitologists. The South American species are classified in five genera: *Anoplotermes*, *Aparatermes*, *Grigiotermes*, *Ruptitermes* and *Tetimatermes*. *Anoplotermes* is the most common and diverse, with more than 25 South American species, and also occurs in North and Central America. The other four genera are endemic to South America and have a few species each. *Ruptitermes* feed on leaf litter. These termites are important in the soil fauna, but are not pests (Fig. 37 and 38).

Family Termopsidae

Porotermes quadricollis is the only representative of this family in South America. It occurs only in the Valdivian forests of Chile and Argentina, living in humid places. *Porotermes quadricollis* may damage structural wood, but it is not an important pest.

Vegetation Zones of South America and Their Termite Fauna

South America can be divided into distinct vegetation zones or biomes, each with a more or less typical termite fauna (Fig. 39). These zones are not homogeneous and the limits between them are not precise. There are no termites at higher elevation in the Andean region.



Termites (Isoptera) in South America, Figure 38 **(a) Workers of *Ruptitermes reconditus* (Termitidae: Apicotermitinae) feeding on leaf-litter. (b) Nest of *Syntermes wheeleri* (Termitidae: Nasutitermitinae) in a pasture. *Top right*: soldier. (c) Nests of *Cornitermes cumulans* (Termitidae: Nasutitermitinae) in a grassland in the Cerrado region. *Bottom right*: soldier. (d) *Armitermes teevani* (Termitidae: Nasutitermitinae) in the Amazon forest. (e) Nest of *Nasutitermes* sp. (Termitidae: Nasutitermitinae) in a grassland in the Amazon region. *Top right*: soldier. (f) Arboreal nest of *Constrictotermes cyphergaster* (Termitidae: Nasutitermitinae). *Top right*: *C. cyphergaster*. *Bottom right*: *Inquilinitermes fur* (Termitinae), an obligatory inquiline termite which feeds on the organic matter of the nest wall. (g) Nest of *Microcerotermes* sp. (Termitidae: Nasutitermitinae) in a dry forest ("cerradão"). *Bottom right*: soldier.**

The largest and most diverse zone is Amazonia, with nearly 6 million km^2, mostly covered by tropical rain forest. About 250 termite species have been recorded in Amazonia. Termite biomass in Amazon forests has been estimated as about 2 g/m^2, which corresponds to nearly 20% of the total animal biomass. As many as 60–70 species can be found in a single hectare of upland Amazon forest. The genus *Nasutitermes* is dominant, and their arboreal nests are conspicuous in the forest. Mound builders are also common, but most mounds are relatively small. Many termite genera are endemic to the Amazon region, including *Glossotermes*, *Anhangatermes*, *Caetetermes*, *Coendutermes*, *Macuxitermes*, *Rotunditermes*, *Triangularitermes*, *Cornicapritermes*, and *Planicapritermes*.

The second largest zone is the Cerrado, a kind of savanna vegetation which covers almost 2 million km^2. Termites are extremely abundant in the Cerrado and their mounds comprise a conspicuous element of the landscape, reaching densities between 300 and 750 nests/ha. There are about 150 species recorded in this region, almost half of them endemic. Litter-feeding termites are abundant in the Cerrado, and forage on the surface at night in large numbers. Mound-building *Cornitermes* can reach impressive densities in some places and are considered keystone species.

The Atlantic forest originally covered 1.2 million km^2, but has mostly been destroyed and only about 8% remains. There are approximately 70 termite species recorded from the Atlantic forest. The dominant termites are arboreal nesting *Nasutitermes* spp. Dry-wood termites (Kalotermitidae) are also abundant. Mounds are much less common in this region than in Amazonia and the Cerrado. The termite fauna is more diverse in the northern part, which shares many species with the Amazon forests.

The termite fauna of the Caatinga vegetation, a xerophytic open forest or savanna of northeastern Brazil, is poorly known. There are little more than 20 species recorded for the entire region, but some recent surveys indicate the presence of many undescribed species. Mounds and arboreal nests are rare, just a few per hectare. The most common genera are *Heterotermes*, *Nasutitermes*, *Constrictotermes* and *Amitermes*.

The Chaco region is a large extension of xerophytic open forest of Bolivia, Paraguay and northern Argentina. Its termite fauna is still little known, but it seems to be similar to that of the Cerrado. There are only about 20 termite species recorded in this region, but it is likely that the total number is considerably higher, probably including undescribed taxa.

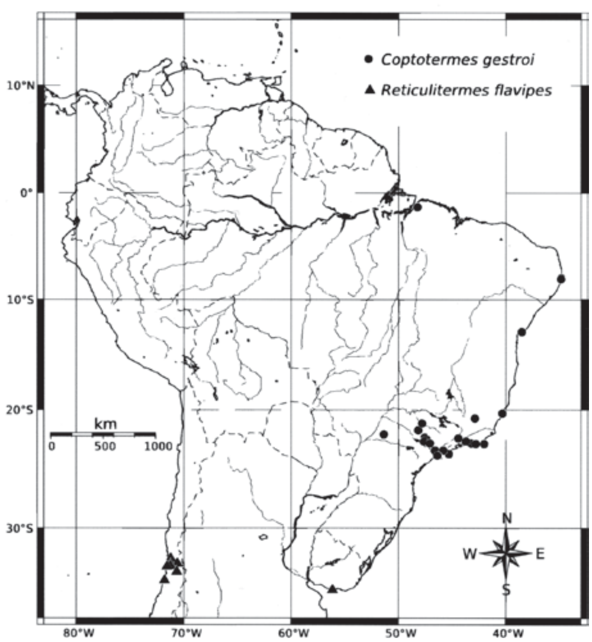
The Pampa region of Argentina, Uruguay and southern Brazil is mostly covered by open grassland, which is often used as pasture. There are about 32 species recorded for this region, but many seem to be restricted to patches of forest. Most of these species are also present in the Atlantic forest, Chaco or Cerrado. Typical species of the Pampa grassland are *Cortaritermes fulviceps* (=*Nasutitermes fulviceps*), *Procornitermes striatus* and *Termes saltans*.

The Llanos of Venezuela and Colombia is a tropical grassland situated in the Orinoco basin. Its termite fauna is poorly known, but it seems to be composed mainly of mound-building *Nasutitermes* and *Velocitermes*, which may reach high densities and feed on grass litter.

The Caribbean zone of Colombia and Venezuela includes tropical forest and xerophitic vegetation. Its termite fauna shares many species with Central America and the Antilles. The forests are dominated by arboreal nesting *Nasutitermes*, especially *N. corniger*, *N. ephratae* and *N. acajutlae*. *Amitermes foreli*, *Heterotermes convexinotatus*, *Microcerotermes* sp., and *Obtusitermes* sp. are also common.

The North Pacific region, which includes part of Colombia and Ecuador, is mostly covered by tropical forests connected to Central America. Its termite fauna is little known, but it is also dominated by *Nasutitermes* spp. and includes at least one endemic species, *Cornitermes acignathus*.

Patagonia is the southernmost portion of South America, including part of Argentina and Chile. The vegetation of this region is mostly



Termites (Isoptera) in South America, Figure 39
Main vegetation zones of South America (*above*), and current distribution of two introduced termite species (Rhinotermitidae) in South America (*below*).

grassland. The only termite that occurs in the lowland of Patagonia is *Onkotermes brevicorniger*, with a southern limit near 43°S.

The Valdivian forest zone is located in Chile and a small part of Argentina. The dominant vegetation is temperate rain forest. There are only two termite species native to this region, both also endemic: *Porotermes quadricollis* and *Neotermes chilensis*.

Termites as Urban and Structural Pests in South America

Many termite species live in urban spaces in South America. More than 20 species have been reported in some cities. However, few of them can be considered pests and most live in green spaces such as gardens and urban parks. The most important pest species have been introduced from other regions: *Cryptotermes brevis*, *Cryptotermes dudleyi*, *Cryptotermes havilandi*, *Coptotermes gestroi*, and *Reticulitermes flavipes*. *Crytotermes brevis* is an ubiquitous house termite present in most cities except in cold places. The southernmost record for this species is Montevideo (34°51′S). *Cryptotermes dudley* and *C. havilandi* have been reported in a few cities in Brazil and Trinidad. *Coptotermes gestroi* (previously also referred to as *Coptotermes havilandi*, a synonym), is a very destructive species native of Southeast Asia, which was introduced in Brazil in the 1920s. It was first recorded in Rio de Janeiro in 1923, and today it is present in many large and important cities. *Reticulitermes flavipes*, which is native of North America, was introduced into Uruguay (Montevideo) in the 1960s and into Chile in the 1980s, where it became an important urban pest. Before the introduction of *Reticulitermes*, these regions were relatively free of termite problems. Among native species, the most important urban pests are *Nasutitermes* spp. and *Heterotermes* spp., which occur in most cities north of 30°S. *Nasutitermes corniger* is a wood-feeder, arboreal nesting termite, which occurs from Mexico to northern Argentina and is a major pest in many cities. *Nasutitermes macrocephalus* is also present in many cities and has a similar biology. *Heterotermes* ssp. are subterranean wood-feeders which are widespread and may damage wood. There are six species in South America, the most common of which is *H. tenuis*.

Termites as Agricultural Pests in South America

Several cultivated plants are significantly damaged by termites in South America, especially sugarcane, upland rice, and eucalyptus. Other plants affected include maize, cotton, peanuts, soybean, coffee, cassava, fruit trees and vegetables. Termites may cause injury to plants by feeding on roots, leaves, stems, and woody tissue. The most important pests belong to genera *Heterotermes*, *Nasutitermes*, *Cornitermes*, *Procornitermes*, and *Syntermes*. Besides injuring living plants, some termites also build large mounds, which may be a problem for the use of machinery and reduce the useful soil surface. Some species of mound-building *Cornitermes* are present at high densities in pastures, but their effect is controversial. Farmers dislike their presence but they do not seem to cause real loss of production. These are all native species and, unlike the urban pests, they are associated with their natural biomes. Therefore, a plant species may be damaged by different termite species in different regions. The following conditions favor termite damage in agriculture: (i) use of exotic crops, which are not resistant nor tolerant to termites; (ii) no-tillage systems, because subterranean termite colonies develop better in undisturbed soil; (iii) non-irrigated crops or crops that are under stress, because vigorous crops are more tolerant to termites.

Termitidae

A family of termites (order Isoptera).

► Termites (Isoptera)

Termitology

The scientific study of termites.

► Termites (Isoptera)

Termitophile

An organism that spends at least part of its life cycle with termites.

Termopsidae

A family of termites (order Isoptera). They also are called primitive dampwood termites or rotten-wood termites.

► Termites

Territorial Pheromone

Pheromones that serve as markers, delineating territory used by an insect and causing others of the same species to avoid that space.

► Pheromones

Tertiary Period

A geologic period extending from about 65 to 2 million years ago. The beginning of the Cenozoic era.

► Geological Time

Tessaratomidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Test

The covering of scale insects (Hemiptera: various families). The test is a glandular secretion consisting of wax, polyphenols and proteins. It provides protection for the nymph and adult that secrete it, and then for the eggs which the female deposits within it.

Testicular Follicles

Tubules in the testes that form sperm.

► Testis

► Reproduction

Testis (pl., Testes)

An assemblage of testicular follicles, each of which produces sperm (spermatozoa). Each testis empties into a tube called the vas deferens, the seminal vesicles, and then into the ejaculatory duct. The seminal vesicles may be simply an extension of the vas deferens, or may be expanded for sperm storage. Associated with the ejaculatory duct is the accessory gland, which produces secretions that aid in sperm transfer. Most noteworthy of the secretions is the spermatophore, a sac containing sperm (Fig. 40).

► Reproduction

Tethinid Flies

Members of the family Tethinidae (order Diptera).

► Flies

Tethinidae

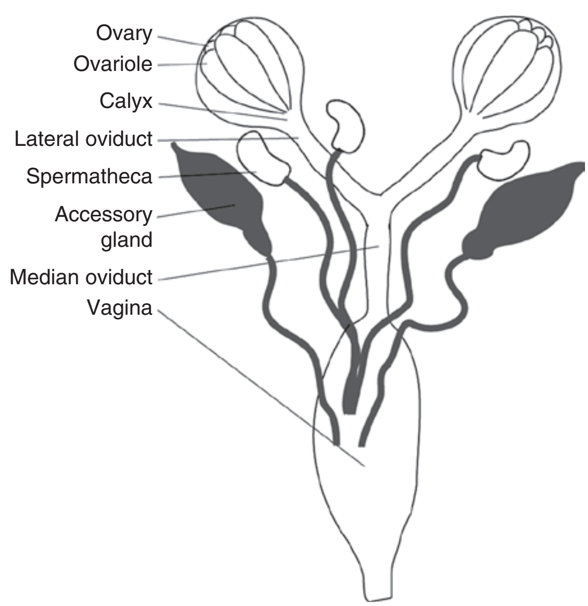
A family of flies (order Diptera). They commonly are known as tethinid flies.

► Flies

Tetracampidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees, and Sawflies



Testis (pl., Testes), Figure 40 **Diagram of a male reproductive system as found in *Tenebrio* (Coleoptera) (adapted from Chapman 1998, The insects: structure and function).**

Tetratomidae

A family of beetles (order Coleoptera). They commonly are known as polypore fungus beetles.

► Beetles

Tetrigidae

A family of grasshoppers (order Orthoptera). They commonly are known as pygmy grasshoppers or grouse locusts.

► Grasshoppers, Katydids and Crickets

Tettigarctidae

A family of bugs (order Hemiptera, suborder Cicadomorpha).

► Bugs

Tettigometridae

A family of bugs (order Hemiptera, suborder Fulgoromorpha). All members of the suborder are referred to as planthoppers

► Bugs

Tettigoniidae

A family of katydids (order Orthoptera). They commonly are known as longhorned grasshoppers.

► Grasshoppers, Katydids and Crickets

Texas Beetles

Members of the family Brachypsectridae (order Coleoptera).

►Beetles

Texas Cattle Fever

This ailment is caused by a tick-transmitted protozoan.

► Piroplasmosis

Texas Citrus Mite, *Eutetranychus banksi* McGregor (Acari: Tetranychidae)

These mites are citrus pests in North America.

Thanatosis

This behavior is also called death-feigning, a response to disturbance displayed by some insects that may help them escape predation. For example, when disturbed, beetles may release their hold on a plant, retract their legs, and drop to the ground. Likewise, chrysidid wasps may roll into a ball and drop. Thanatosis may be displayed in addition to or instead of other defensive reactions such as stridulation, dodging, flight or reflex bleeding. For example, *Crioceris asparagi* (Coleoptera: Chrysomelidae) displays severe thanatosis, dropping at even minor disturbance, whereas its sibling species *C. duodecimpunctata* displays only mild thanatosis but readily stridulates.

Thaumaleidae

A family of flies (order Diptera). They commonly are known as solitary midges.

► Flies

Thaumastellidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Thaumastocoridae

A family of bugs (order Hemiptera). They sometimes are called royal palm bugs.

► Bugs

Theileria

An important genus of protozoans causing disease in animals, and transmitted by ticks.

► Piroplasmosis

Theileriosis

Several related diseases caused by infection with *Theileria* protozoans, and transmitted by ticks.

► Piroplasmosis

Thelytokous Parthenogenesis

A type of parthenogenesis wherein females produce only diploid females from unfertilized eggs.

Theochodaeid Scarab Beetles

Members of the family Ochodaeidae (order Coleoptera).

► Beetles

Therevidae

A family of flies (order Diptera). They commonly are known as stiletto flies.

► Flies

Thermoregulation in Insects

ALLEN SANBORN
Barry University, Miami Shores, FL, USA

Temperature is a physical component of the environment that affects animals from the subcellular to the population level. Because cells are units of chemical reactions and chemical reactions are temperature dependent, animal activity is determined by temperature. Temperature has been shown to be an important influence on all aspects of insect life. Numerous studies have shown that temperature influences cellular activity by changing the efficiency of enzymes, changes the physiological responses of tissues such as nerves and muscles, alters the rate of development, determines when species emerge, limits the biogeography of species, and determines when a species can be active. There are two strategies for any animal to deal with temperature: they can be a thermoconformer or a thermoregulator.

A thermoconformer is an animal that permits its body temperature to fluctuate with, and is about equal to, environmental temperature. For many insects, being a thermoconformer is determined by the size or activity patterns of a species. For example, a very small insect will exchange heat with the environment so rapidly that its body temperature will always approximate ambient temperature, or a nocturnal insect with a low metabolism may not be able to elevate body temperature above ambient conditions. The major problem with being a thermoconformer is that enzymes must be able to work over a greater temperature range than the enzymes of a thermoregulator. This means that the enzymes are less efficient at any particular temperature in the thermoconformer. The benefit to being a thermoconformer is that an animal spends no time or metabolic energy attempting to regulate body temperature.

A thermoregulator is an animal that maintains body temperature within a limited range regardless of changes in ambient temperature. A thermoregulator has the benefit of keeping its enzymes and physiological systems within the temperature range where they operate most efficiently. The cost to a thermoregulator is the use of time or metabolic energy needed to maintain their body temperature within a specific temperature range. Thermoregulators can be classified as either ectotherms or endotherms based on the source of the energy used in the regulation of body temperature (the terms poikilotherm or cold-blooded and homeotherm or warm-blooded are no longer used due to ambiguities).

An ectotherm is an animal that uses energy from the environment to regulate body temperature. These animals generally are heliotherms, using the radiant energy of the sun to regulate body temperature, but there are also thigmotherms, animals that use the energy of the substrate to regulate body temperature. Ectothermy is a metabolically inexpensive form of thermoregulation. The major metabolic expense is the cost of transporting the animal from sun to shade. The problem with ectothermy is the animal is still dependent on the environment for a heat source and thus activity. This problem was solved by the evolution of endothermy.

An endotherm is an animal that produces metabolic heat specifically for thermoregulation. Endotherms have been identified in a wide variety of insects orders. The source of heat in endothermic insects is the flight musculature. Endothermic insects will increase heat generation through muscular activity to elevate body temperature to the range necessary for activity. The heating can occur without flight or wing movements but shivering can be observed in many night flying moths or bees at flowers on cool days prior to take-off. The body temperatures of endothermic insects have been recorded more than 35°C above ambient temperature. The use of metabolic energy for thermoregulation frees the endotherm from possible environmental constraints on activity.

Behavior

Thermoregulation can occur through behavioral and/or physiological mechanisms. The first option used by any organism to thermoregulate is behavior. Behavioral mechanisms are metabolically inexpensive and produce immediate results. Very simple forms of behavioral thermoregulation are changing body orientations and shuttling between the sun and shade. Changing body orientation to the sun is a common behavior that alters the heat exchange of an insect. When an insect has a low body temperature, it will sit in an exposed position to gain radiant heat from the sun. Often they will orient their body axis perpendicular to the sun to maximize radiant heating. Conversely, when an insect has an elevated body temperature, it will seek a shaded location to decrease the radiant gain and lose heat to the environment. Also, insects will orient their body parallel to the sun's rays when they have an elevated body temperature, which minimizes the exposed surface area and radiant heat uptake. One benefit an insect has in thermoregulating is its small size. The high surface to volume ratio means that heat exchanges quickly with the environment and it can take advantage of small microclimates within the habitat.

Microhabitat selection is another important behavioral mechanism of thermoregulation. For example, a desert insect can change the ambient temperature to which it is exposed by more than 30°C simply by selecting a particular microhabitat within the environment. Insects will also employ vertical migration as a means to optimize the ambient conditions in which they are found. Desert animals will move away from the ground as ground temperature (and the boundary layer above the earth) becomes warmer. Similarly, if it is cool and windy, insects will move toward the ground in an effort to find a warmer microclimate. Stilting is a similar behavior seen in some beetles and grasshoppers. When their body temperature is low, the insects will press their body against the ground to increase the rate of heat uptake by conduction and keep their body in the warm boundary layer next to the ground. When their body temperature becomes elevated, they will extend their legs, lifting their body as high as possible above the ground. These types of behavioral mechanisms are used by endotherms as well as ectotherms.

Physiology

Physiological mechanisms of thermoregulation can occur through endothermy, evaporative cooling, or thermal adaptation. Endothermic insects generally use the heat generated by the flight musculature to raise body temperature. The flight musculature is a good source of heat because it makes up a significant portion of body mass and it is a highly aerobic tissue. Electrical recordings from the muscles of moths and bees show that the moths shiver (simultaneously activating wing elevator and depressor muscles) to elevate heat production. As the body temperature of the insect increases, the activity of the wing elevator and wing depressor muscles become more out of phase and flight is then initiated. Overheating is prevented by varying the rate of heat production, through circulatory adaptations that increase heat loss, or through the cessation of activity. The functional significance of endothermy has been described for many insect species and represents the diversity of insect behavior. Endothermy permits such diverse behaviors as flight, foraging, acoustic activity, dung ball rolling, maintenance and defense of territories, the use of habitats unavailable to ectothermic species, predator avoidance, defense, brood incubation, and hive temperature regulation.

Evaporative cooling represents a significant avenue of potential heat loss for animals. The problem with using evaporative cooling is that there must be a water source for the animal to replace water used for cooling. The small size of insects means they have a relatively small water reservoir in their bodies, but several evaporative cooling mechanisms have evolved in insects. Evaporative cooling by extruding a bubble from the mouth has been described in moths and bees. A bubble of saliva is extended, heat is lost as water evaporates, the bubble is withdrawn back into the mouth to pick up more heat, and the process is repeated until the animal is sufficiently cool. This system is very good at cooling the head but is limited in its ability to cool the entire body. Locusts evaporatively cool through an abdominal pumping mechanism while some caterpillars will spread rectal fluid on their ventral surface to cool through evaporation.

Another group of insects in which evaporative cooling has been studied extensively is cicadas. Cicadas can avoid the potential water balance problems because they feed on xylem fluid. Thus, the desert cicadas that evaporatively cool have access to a water source that other animals cannot use. As a result, desert species like *Diceroprocta apache* (Davis) and *Okanagodes gracilis* Davis can continue their activity while other animals in the environment have sought shelter from the extreme desert heat. In addition, these animals can survive water loss of over 40% of their total body mass. Water is evaporated through pores in the cuticle of the thorax and abdomen of cicadas. The evaporative response of cicadas appears to be energy dependent, as toxins can eliminate the response and the response can change dramatically by altering ambient temperature. Evaporative cooling responses are not universal in insects and appear to be restricted to desert species or species whose metabolism may cause dangerous increases in body temperature.

A final physiological mechanism of thermoregulation is thermal adaptation. Insects will adapt their enzymes to work best under particular thermal conditions. The enzymes will show optimal activity temperatures that are related to their environment. In addition, the membrane composition of insects will change dependent upon where the insect lives and even with the daily fluctuations in ambient temperature. These changes in membrane composition are necessary to maintain the fluidity of the membrane and, thus, the integrity of the cell.

Finally, there have been several morphological adaptations that assist insects in thermoregulating. Light coloration in hot environments or dark coloration in cool environments changes the rate of heating and the maximum temperature that can be attained by an insect which increases the time a species can be active in their particular environment. In fact, some dragonflies undergo a temperature dependent color change to alter the amount of radiation uptake. Animals from warmer climates may also reflect more infrared radiation. There are desert beetles that have highly convex elytra forming a large subelytral space that acts to decrease heat transfer to the body while the animal is active in the sun. Some desert tenebrionid beetles have legs that are much longer than their forest relatives. These long legs elevate the animal above the boundary layer and significantly increase the time of activity for the species. Many endothermic and ectothermic species that live in cool habitats are covered with pile. The pile acts as insulation to help conserve heat within the body.

Thermotaxis

Taxis response with respect to temperature.

Thick-Headed Flies

Members of the family Conopidae (order Diptera).

► Flies

Third Generation Insecticide

Organic insecticides derived from knowledge of insect's hormones. By mimicking hormones, the insecticides provide great selectivity, and are less disruptive to nontarget organisms.

Thomas, Cyrus

Cyrus Thomas was born at Kingsport, Tennessee, USA, on July 27, 1825. A lawyer and Lutheran minister by training, he became one of America's foremost systematists and economic entomologists. Thomas had little formal education and did not attend college; nevertheless, he learned science, mathematics, and practiced law. He sought an area of science where he could be recognized, and which could be mastered with little expense and the materials at hand; entomology met those needs. While still practicing law, he began to publish entomology papers. Thomas served with the Hayden Geological Survey of the territories of the West and Southwest from 1869 to 1874. From 1874 to 1876 he taught natural history at the University of Illinois, and was state entomologist for Illinois, publishing six annual reports. Thomas served on the United States Entomological Commission for 5 years. One of his most significant achievements was to author a comprehensive treatment of Aphididae, included in the "Third annual report of the state entomologist of Illinois on noxious and beneficial insects," published in 1879. He is also remembered for authorship of the "Synopsis of the Acrididae of North America," published in 1873. In his taxonomic work he named chiefly aphids and grasshoppers. Despite a successful career in entomology, he devoted the last 25 years of his life to archaeological and ethnological studies, and became an authority on the Cherokee, Shawnee, and Maya people. Thomas died at Washington, DC, on June 27, 1910 (Fig. 41).

Thomson, Carl Gustav

Carl Gustav Thomson was born at Skaane, Sweden, on October 13, 1824. He became a student at Lund in 1843, and attained his Ph.D. in 1850. Beginning in 1850 he worked in various capacities at the Lund Zoological Museum. Thomson tackled difficult taxonomic problems successfully. He studied principally Hemiptera, Hymenoptera, and Coleoptera, but also Diptera. A prolific author, he published nearly 9,000 pages during his lifetime, though his work on Diptera is not highly regarded. He died on September 20, 1899, in Lund, Sweden.

Thoracic Plate

In caterpillars, the shield-like dorsal covering or plate on the body segment immediately behind the head, usually dark in color. Also known as the cervical shield.

Thorax

The second or middle of the three major body regions of insects, and the section bearing wings (if present) and jointed (true) legs.

► Thorax of Hexapods

Thorax of Hexapods

SEVERIANO F. GAYUBO
Universidad de Salamanca, Salamanca, Spain

The arthropods, and particularly the insects, present a basic model of body organization constructed on a metameric base, about which is produced the process of tagmosis. This process consists of the grouping of a variable number of segments to form a suprasegmentary unit called the tagma.

Tagmosis is probably produced to establish a more operative model in the development of certain functions important to the life of those animals. In this case, in the hexapods, the thoracic tagmata have come about by the grouping of three segments, called the prothorax, mesothorax and metathorax, which have developed principally for locomotion.

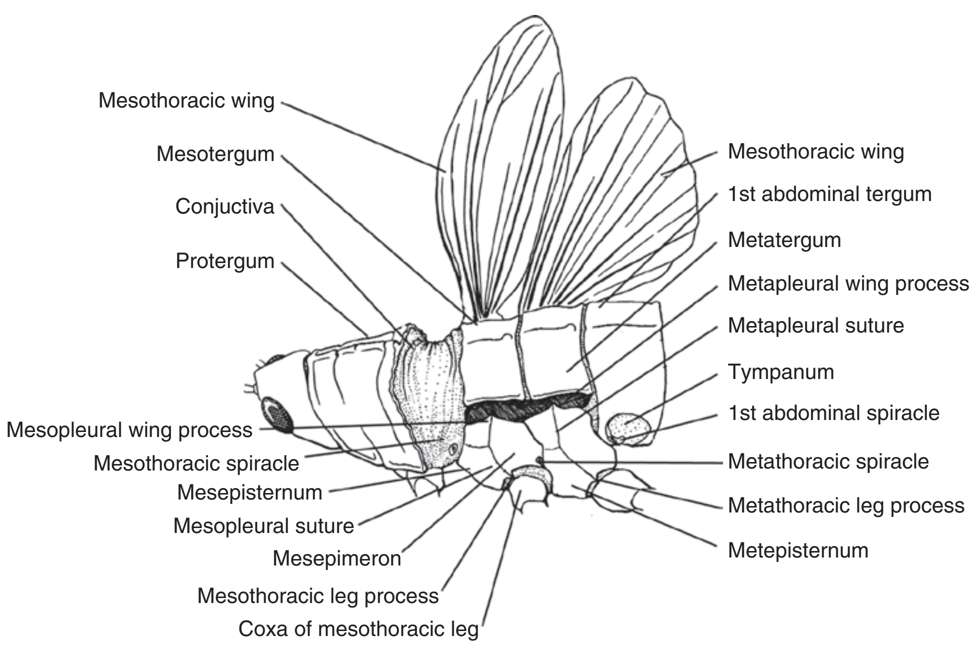
The formation of the thorax by three segments was pointed out in the nineteenth century by Adouin and later recognized by the majority of authorities, except by some like Verhoeff, who at the beginning of the twentieth century considered that the intersegmentary regions were authentic segments, whereby five segments would form the thorax. This theory was rapidly rejected, as it was demonstrated through comparative studies of morphology and embryology that the hexapod thorax consists of only three segments.

Except in the apodous larvae of certain orders, each thoracic segment carries a pair of legs, and in addition the winged forms present a pair of wings on the mesothorax and on the metathorax, with both segments constituting a functional "subtagma" called the pterothorax. The presence of legs and wings on the thorax demonstrates that it is a tagma specialized for locomotory function, developed and controlled by muscles and ganglia situated in the thorax itself. It is probable that this locomotory function originated the differentiation of the thoracic tagma from the other two that form the body of the hexapods: the head and the abdomen (Figs. 42–47). The fact that the thorax is found basically formed in the most primitive hexapod groups and that it appears perfectly individualized in the first stages of ontogenetic development makes one think that the differentiation of this tagma ought to have occurred in early periods of insect evolution. As much from the structural as functional point of view, the hexapod thorax is the most specialized and centralized tagma if we compare it with analogous tagmata of other arthropods.

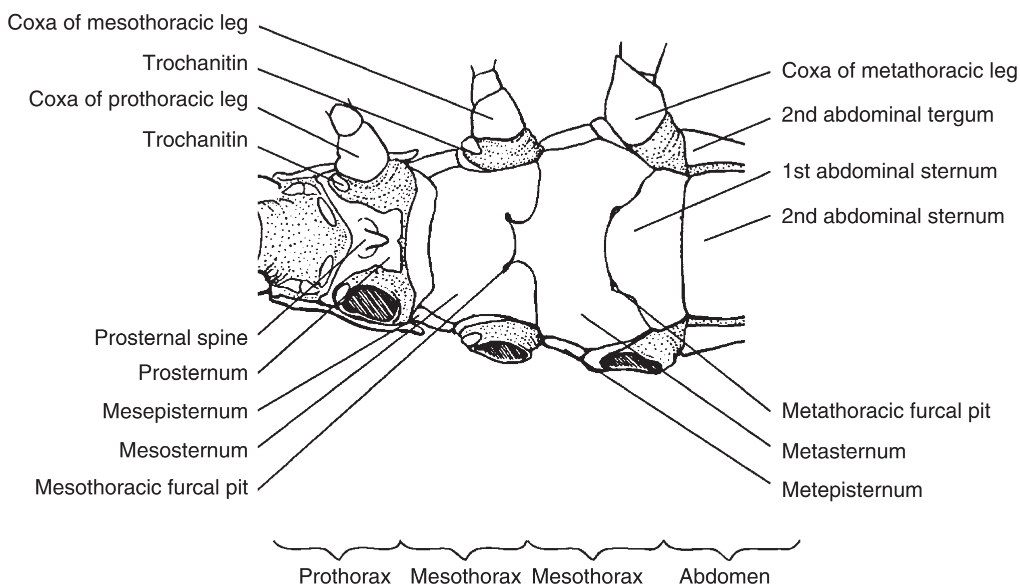
Before beginning a description of the thorax itself, it is necessary to emphasize the existence of an anterior region of the body called the neck or cervical region (Fig. 42), which is of mixed origin: labial and prothoracic. The morphological, embryological, musculature and neurological data demonstrate that the neck results from the fusion of the dorsal and ventral parts of the labial and prothoracic segments, respectively. The cervical sclerites can be found in the dorsal position (dorsal cervical or dorso-cervical sclerites), lateral (lateral cervical or latero-cervical sclerites) and ventral (ventral cervical or ventro-cervical sclerites) (Figs. 42 and 43). The lateral cervical sclerites can originate from the anterior part of the propleura [some Thysanura (Zygentoma) and the majority of holometabolous insects] or from the presternal region (hemimetabolous insects and Coleoptera). The dorsal cervical sclerites are considered structures of secondary formation and are united anteriorly to the dorsal posterior margin of the occiput. The same occurs with the ventral ones.

Modern studies of the hexapod thorax began with the decade of the 1940s, particularly such authors such as Snodgrass, Weber, Barlet, Carpentier, Francois, La Greca, and Matsuda. As in each arthropod segment, each hexapod segment presents a dorsal region called the notum or tergum, another ventral region named the sternum, and between the two, a zone that constitutes the pleuron.

The tergal region presents variations in the number of sclerites and sutures, whose interpretation in Pterygota should be analyzed with a previous



Thorax of Hexapods, Figure 42 **Lateral view of a grasshopper head and thorax (Orthoptera: Romaleidae).**



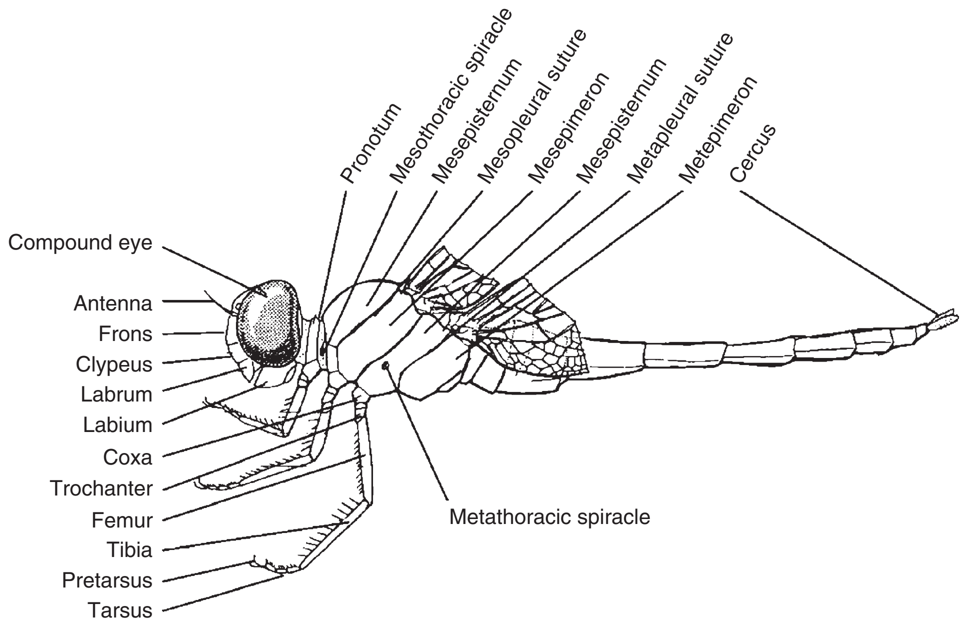
Thorax of Hexapods, Figure 43 **Ventral view of a grasshopper thorax (Orthoptera: Romaleidae).**

understanding of what occurs in the Apterygota. The Protura display a more elaborate tergum whose homologization with the rest of the hexapods is difficult. In Diplura, Archaeognatha and primitive Thysanura, an anterior zone exists, which, according to Matsuda, is named the pseudoprescutum. It is separated from the rest of the tergum by a pseudoprescutoscutal suture that produces toward the interior a suture named the pseudophragma. The study of *Nicoletia* is interesting in that it explains the passage of a primitive tergum to another evolved in the Pterygota by the loss of the pseudophragma, which would have no functional significance on developing a phragma with the incorporation of an acrotergite; the pseudoprescutoscutal suture would be transformed into the prescutoscutal suture and the pseudoprescutum into the prescutum. In the case of *Lepisma*, a narrow antenotum (delimited by an antecosta), a prescutum and a scutum (separated by a prescutoscutal suture) and a postnotum united laterally to the pleuron are differentiated; these sclerites are already homologous to those of the Pterygota.

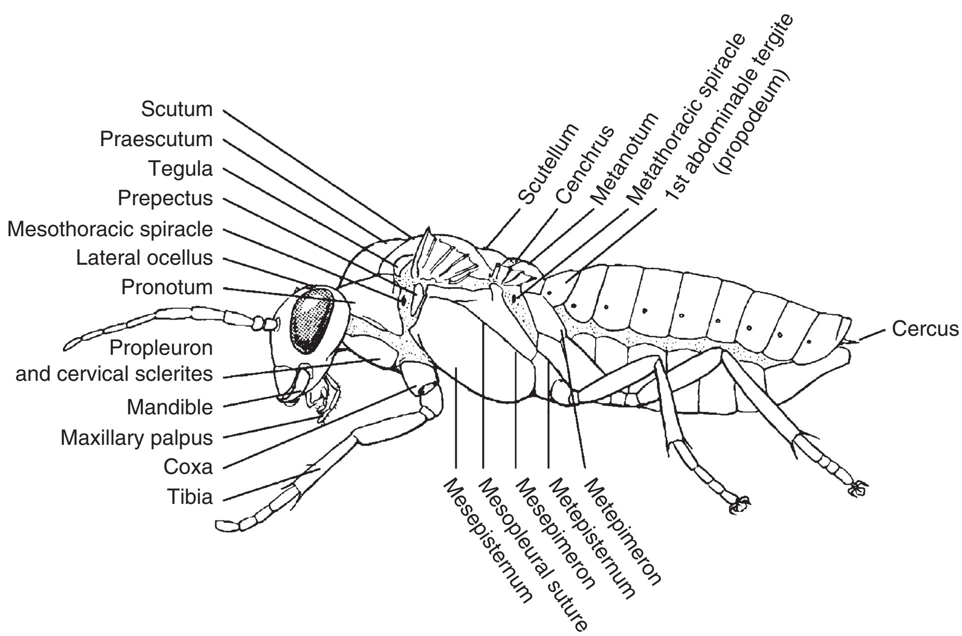
The tergal region of the pterothorax of Pterygota (meso and metathorax of winged insects), presents sclerites delimited by two types of sutures: some homologous to those of the Apterygota and other, new ones that appear by the wings. The wings, in addition, produce modifications in the zone of insertion that fundamentally affect the lateral margins of the tergum (Fig. 44).

Among the sutures homologous to those of the Apterygota are the antecosta, which delimited anteriorly a zone that corresponds to the acrotergite and gives rise to a phragma toward the interior. The prescutoscutal suture is situated behind the antecosta, delimiting a sclerite named the prescutum, whose lateral zones form the prealar arms.

Among the sutures not homologous to those of the "Apterygota" stands out the scutoscutellar suture, which has a sinuous form and reaches the axillary ligament. This suture separates two sclerites, an anterior (scutum) from another posterior (scutellum). The proper parapsidal lines and the lateral parapsidal lines are differentiated as intrascutal formations; both arising from the prescutoscutal suture, the first in a more or less median position and the second lateral. Two marginal lines exist within the scutum, one that delimits the anterolateral angle of the scutum, forming the suralare, a sclerite that includes the anterior and antemedian notal wing processes. The other marginal

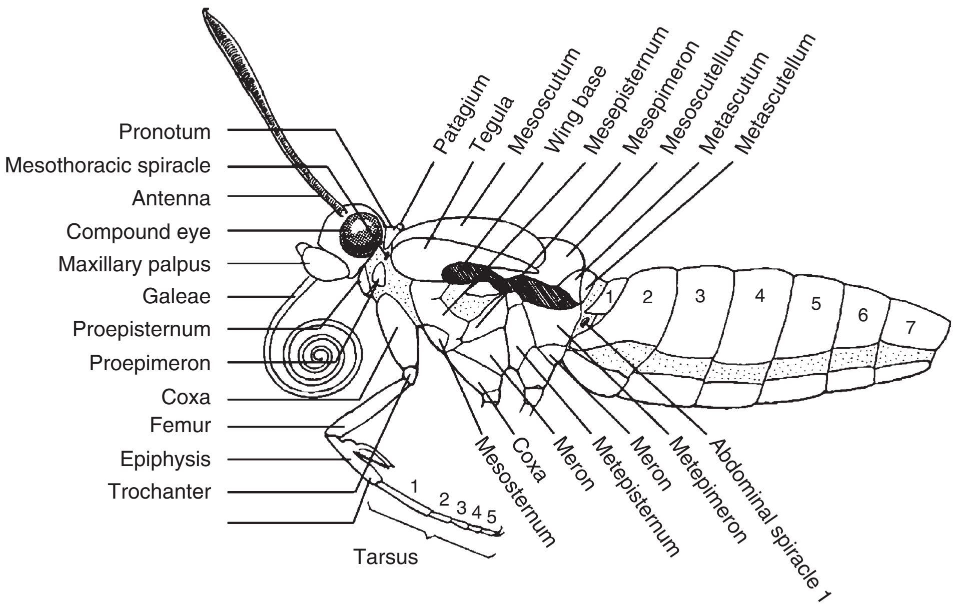


Thorax of Hexapods, Figure 44 **Lateral view of a dragonfly (Odonata: Libellulidae).**

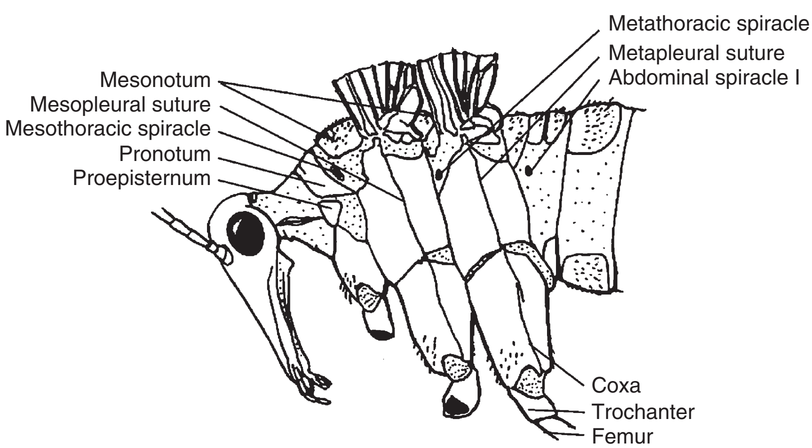


Thorax of Hexapods, Figure 45 **Lateral view of a sawfly (Hymenoptera: Tenthredinidae).**

suture delimits the posterolateral angle of the scutum, which includes the posterior notal wing process. In primitive forms of certain orders a tergal fissure is differentiated, which transversally unites the sides of the scutum at the level of the anterior or antemedian notal wing process. The recurrent scutoscutellar suture originates from or near the center of the posterior margin of the scutellum, diverging toward the anterior part. The last sclerite is the postnotum.



Thorax of Hexapods, Figure 46 **Lateral view of a moth (Lepidoptera: Sphingidae).**



Thorax of Hexapods, Figure 47 **Lateral view of a scorpion fly (Mecoptera: Panorpidae).**

The presence of the wings brings with it a series of modifications in the lateral margins of the tergum, differentiating a series of processes, some of which have been mentioned previously. Thus, the most anterior process is called the prealar arm or branch, which in the majority of orders is a prolongation of the prescutum, although in others like the Hymenoptera it does not exist. Posteriorly, five points of articulation with the wings are differentiated, which are called notal wing processes. From the anterior part to the posterior, they are the anterior and antemedian (already mentioned), median, postmedian, and posterior (also mentioned). In the case where the five processes are evident, the first four are joined with the first axillary sclerite and the last with the third axillary sclerite.

The notal region of the thorax can present different modifications. Among the most customary and conspicuous is the prolongation of the mesothoracic scutellum, which in certain cases projects toward the back, on top of the metanotum (for example, Hemiptera: Scutelleridae), and in other cases adapts to its conformation.

The sternum, as already mentioned, corresponds to the ventral zone. In generalized Diplura, Archaeognatha and some Thysanura, five parts or apotomes are distinguished, which from the anterior to the posterior part are: the presternum, the basisternum, the furcasternum, the spinasternum and the poststernum. In principle, the question is posed of whether the poststernum, instead of representing the final portion of the sternum, constitutes the more anterior of the following sternum that would have been incorporated. In any case, the different apotomes of the sternum of Aptergygota have a relatively well-defined position, with the poststernum being a posterior segmentary structure, although it does not appear in Ptergygota.

The association of the mentioned sclerites to the sternum, and the reductions that occur during evolution toward advanced hexapod groups, are justified through the study of endosternal formations. In the Apterygota, a non-cuticular endoskeletal complex is distinguished, in addition to spinasternal processes in Diplura and pleural apodemes in Archaeognatha. Cuticular formations are well defined in Ptergygota, corresponding to the furca and the spina.

As a consequence of losses, modifications and fusions of certain zones, the original division of the sternum in Pterygota has suffered changes that do not permit delimiting a clear position from its apotomes. Thus, the lack of a presterno-basisternal suture makes the differentiation of a presternum very difficult. The posternum is lost in the Pterygota, with this loss affecting the two anterior apotomes (spinasternum and furcasternum). The reduction affects, in the first place, the most posterior apotome, which is the spinasternum, being reduced in certain cases to the spine, as occurs in the mesosternum of the Orthoptera. The spine is also lost in more evolved groups like Coleoptera, Diptera and Hymenoptera, causing reductions to the furcasternum, which can reach the point of disappearing. The anterior part of the metasternum then occupies its place, shifting toward the front and situating itself close to the furcal bases. When this occurs, obliteration is produced on the ventral border between the meso and metathorax. This obliteration, which exists in different levels of development in advanced insects, appears to directly affect the formation of a functional subtagma, the pterothorax, to which reference has already been made. In this process, a tendency for the reduction of the anterior and posterior parts of the sternum can be observed, always leaving a well-developed apotome, the basisternum.

All the studies carried out on the origin of the pleuron demonstrate that this zone of the thorax, situated between the tergum (or notum) and the sternum in Archeognatha, Thysanura (Zygentoma) and Pterygota, consists of a ventral subcoxal area and another dorsal or pleural area, which have become indistinguishable because of the sclerotization. In this sense, an evolutionary sequence can be established from the pleuron of Archaeognatha to that of the pterothorax, considering the increase in sclerotization tied to the development of the wings. In primitive Pterygota like Blattodea, the sclerotization is not very pronounced, and the sclerites that surround the base of the coxa have not been obliterated, so clear homologies can be established with Archaeognatha.

If one considers the pleural formations existing in the segments of the pterothorax, there are distinguished, in the first place, a pleural suture and its corresponding internal costa. In principle, this suture ought to present a vertical path as is observed in certain orders like Neuroptera, with a tendency to present an oblique path toward the front. The most dorsal part constitutes the pleural wing process. This suture has been obliterated in some orders of advanced hemimetabolous insects like Hemiptera (Heteroptera) while conserved in secondarily apterous orders like Siphunculata, Mallophaga and Siphonaptera, and in orders like Psocoptera. Internally, it is distinguished by way of a pleural branch that is united to the furca through a tendinous structure or a muscle. This pleural suture divides the pleuron into two regions: an anterior one (episternal region or episternum) and a posterior one (epimeral region or epimeron).

Another important suture is the paracoxal, which divides the pleuron into two rings, an external anapleural ring, or anapleurite, and an internal ketapleural ring, or katapleurite. Its presence in Archaoegnatha indicates that it is a primitive suture.

Considering the two pleural sutures mentioned up to now, the pleuron remains divided into four regions: anepisternum, katepisternum, anepimeron and katepimeron. In species of certain orders like Neuroptera, Hemiptera and Hymenoptera, another suture exists, named the transepimeral, which is a continuation of the paracoxal suture in the episternal part. The anepisternum remains divided by the anapleural suture in one part dorsally (the anepisternum proper), and another part ventrally (the preepisternum). In species of some orders like Psocoptera, the anapleural suture is situated more ventrally, with another suture being differentiated in those cases named the transepimeral suture, which divides the anepisternum proper into two portions (dorsal and ventral). In primitive orders, beginning from the anepisternum a small sclerite called the basalare is differentiated, situated just in front of the pleural wing process. When the area that surrounds the basalare is membranous, it can extend posteriorly, originating a basalar incision that in some orders like Dermaptera forms the episternal suture. Behind the pleural wing process the subalar sclerite is differentiated, which in reality is a sclerite differentiated from the tergum.

Three bridges exist. The prealar bridge or prealare, which has already been mentioned in the section dedicated to the tergum. The precoxal bridge or precoxale, which is formed by the preepisternum uniting with the basisternum and, are separated by the pleurosternal suture. This suture is obvious in Apterygota and in the majority of hemimetabolous Pterygota but does not exist in certain holometabolous insects, in those in which the preepisternum and basisternum are fused. This fusion is not produced in other holometabolous insects, since the preepisternum extends forward, forming the lateral cervical sclerite. The third bridge is the postalar bridge or postalare, a structure similar to the prealare, but formed by the connection between the dorsal margin of the anepimeron and the lateral extension of the postnotum.

The trochantin is a sclerite differentiated from the katepisternum, which can present four points of articulation in Thysanura, one dorsal with the katapleuron and three ventral with the coxa. In Pterygota, only the anterior coxal-trocantinal articulation is conserved, with various modifications of the trochantin being observed. It can be isolated (prothorax of Psocoptera), partially fused to the katepisternum, conserving the anterior coxal-trocantinal articulation (eutrochantin), and it can even be undifferentiated due to the strong sclerotization of the katepisternum, as occurs in advanced orders.

In the more primitive groups, in the posterior zone of the katepisternum the sternopleurite is found, which appears to correspond, according to Matsuda (1970) to a part of the ventral zone of the katapleuron. This ventral pleurite in holometabolous insects is not appreciated, and it is possible that it has been transformed in the ventral articulation process of the coxa.

It can be concluded that the evolution of the hexapod thorax has been a continual process, between the thorax of the groups of Apterygota and that of the Pterygota, a process based on the loss and modifications of different structural elements.

Thripidae

A family of thrips (order Thysanoptera). They commonly are known as common thrips.

► Thrips

Thrips-Parasitic Nematodes

STEVEN ARTHURS
Texas A&M University College Station, TX, USA

Several species of nematodes belonging to the genus *Thripinema* (=*Howardula*) (Tylenchida: Allantonematidae) are known to naturally parasitize thrips (Thysanoptera).

Taxonomy, Host Range and Distribution

The genus *Thripinema* was erected by Siddiqi in 1986 during a taxonomic revision of the species. To date, there are five described species of *Thripinema*: *T. reniraoi*, *T. aptini*, *T. nicklewoodi*, *T. khrustalevi* and *T. fuscum*. Together these nematodes have been recovered from twelve species among eight genera of thrips: *Thrips physapus* L., *T. trehernei* Prisner, *T. physopus* L., *Aptinothrips rufus* Gmelin, *Frankliniella vaccinii* Morgan, *F. occidentalis* Pergade, *F. fusca* Hinds, *Taeniothrips vaccinophilus*, *Stenothrips graminium*, *Catinathrips vaccinophilus*, *Heliothrips* sp., *Megaluriothrips* sp. The biogeographical range of thrips parasitic nematodes is known to include the UK, Germany, USA, Canada, Russia and India. However, the extent of this distribution probably reflects where surveys have been made. Given *Thripinema* spp. hosts include introduced agricultural pest species found worldwide, thrips-parasitic nematodes are probably widely distributed.

Biology and Life Cycle

Unlike soil-dwelling nematodes of the family Rhabditidae, *Thripinema* spp. are not mutually associated with pathogenic bacteria and do not appear to kill their host. Rather, *Thripinema* spp. have evolved a parasitic lifestyle and develop through a single heterosexual generation in the live host. Although infected thrips show no obvious physical signs of the internal parasite, a consequence of infection is that embryos do not develop and adult female thrips are effectively sterile. The cause of host sterility is unknown, but nematodes may deprive the host of the protein required for oogenesis or secrete a toxin, which damages the reproductive organs. Male thrips are similarly parasitized, although the effect of infection on male fertility is unknown. During the infection stage, parasitic female nematodes penetrate a thrips host through intersegmental membranes. Following infection, the female nematode swells to a sac-like organism in which her reproductive organs become the only visible structure. Nematode eggs are laid into the host hemocoel. Upon hatching, the resulting vermiform juveniles feed on fluids within the thrips' abdominal cavity. When mature, both male and female nematode progeny penetrate into the lumen of the hosts' gut, and are continually released for the lifetime of infective thrips via the anus in the frass or via the ovipositor. Relatively little is known about the biology of *Thripinema* spp. following its emergence from the host. However, an intriguing aspect of the life cycle of the free-living stage is that they appear to attack their hosts in the above-ground parts of the plant. While all free-living nematodes require high humidity, *Thripinema* spp. appears to exploit the moist microclimate found within a leaf gall, flower perianth or developing foliage terminal. Since mature thrips nematodes exit the host via the anus or ovipositor, these free-living forms naturally accumulate in and around thrips foraging sites where defecation and oviposition are pronounced and where susceptible hosts may be found. Fertilization of parasitic female nematodes is thought to occur outside the host despite the fact that survival of this "free-living" stage may only be a few hours; thus the cycle is complete.

Thripinema spp. are not currently mass produced commercially. However, the ability of these nematodes to attack thrips in their preferred feeding sites, areas that are often impenetrable to insecticides and natural enemies, have led several investigators to speculate that thrips parasitic nematodes have potential for thrips management in agriculture.

Thrips (Thysanoptera)

CHRISTOPHER TIPPING
Delaware Valley College, Doylestown, PA, USA

The Thysanoptera, thrips, are a diverse insect order with worldwide distribution (Table 11). There are approximately 5,800 species described from nine families. The order is divided into two distinct suborders: Tubulifera and Terebrantia. These two suborders can be distinguished by the shape of the last abdominal segment of the adult stage which is short and pointed in the Terebrantia, or long and tubular in the Tubulifera. Nearly all described species are less than 5 mm in length, and can be yellow, green, black, or red colored. The name Thysanoptera, derived from the Greek words, "thysanos" meaning fringe and "ptera" meaning wings, refers to the two pairs of slender wings which have few or no veins and bear a dense fringe of long hairs (Figs. 48 and 49). These hairs allow for greater wing area and increased flight efficiency. Thrips are thought to be closely related to Hemiptera and Psocoptera.

Order: Thysanoptera
- Suborder: Tubilifera
  - Family: Phlaeothripidae
- Suborder: Terebrantia
  - Family: Aeolothripidae
  - Family: Merothripidae
  - Family: Heterothripidae
  - Family: Thripidae
  - Family: Melanthripidae
  - Family: Uzelothripidae
  - Family: Adeheterothripidae
  - Family: Fauriellidae

Thrips are holometabolous insects with complete metamorphosis. Development includes the egg, 2 larval instars, 2–3 pupal stages and the adult. The pupal stages do not feed but are capable of limited movement. Females of terebrantia have a curved ovipositor which is used to insert eggs into

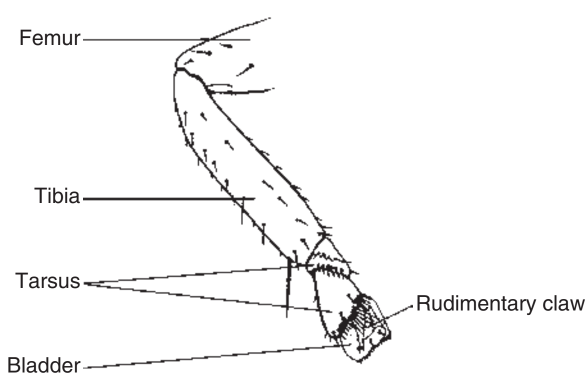
Thrips (Thysanoptera), Figure 48 Diagram of a thrips, showing fringed wings.

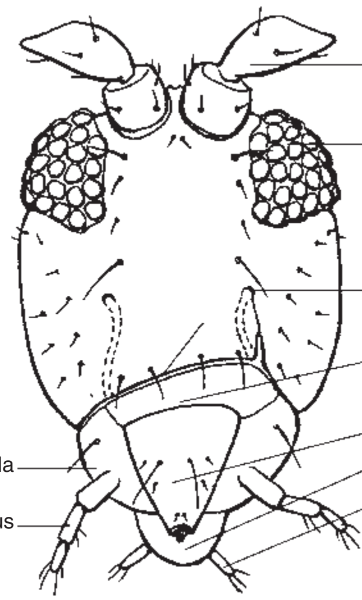


Thrips (Thysanoptera), Figure 49 Leg of a thrips; note that claws are not apparent.

plant tissue. The antenna are short with 6–10 segments. Thrips have asymmetrical sucking mouthparts, possessing only the left mandible (Fig. 50). Thrips are weak flyers and short directed flights are called thripping. Longer range dispersal is dependent on wind currents. Within the same species, populations may have individuals with reduced wings (brachypterous) or no wings (apterous) depending on environmental conditions such as density, food quality, and season.

Thrips are important members of the ecosystem as both herbivores and predators. Many species live in leaf litter or dead wood and feed nearly exclusively on fungus and will often supplement their diet with plant pollen. Other thrips species are gall formers and display primitive eusocial behavior. Predatory thrips are often beneficial species in agronomic situations and can help regulate populations of mites and other small insect pests including other thrips. Thrips are often associated with disturbed growth areas where large numbers can occur quickly on new plant growth.

The vast majority of the described species of thrips are herbivorous, with several being destructive pests of grain crops, fruits, vegetables and ornamentals. Certain species are important pests of plants grown in greenhouses. Feeding activities can result in plant deformities, scarring, loss



Thrips (Thysanoptera), Figure 50 Head of a thrips; note lack of symmetry due to absence of the right mandible.

of yield, and in some cases, transmission of plant pathogens. Plant-feeding thrips pierce and suck juices from the outer layer of cells, causing stippling, or small scars, on leaves, flowers and fruit. This feeding damage may result in stunting of the plant, premature leaf drop and aborted fruit. Flowers that have been damaged by thrips feeding may be deformed and fail to open properly. As many as 90 species of thrips are of economic importance, including nine species capable of vectoring plant viruses in the genus *Tospovirus*. These viruses are the most important disease of agronomic crops in many regions of the world today.

Thunberg, Carl Peter

Carl Thunberg was born at Joenkoepping, Province of Smaaland, Sweden, on November 11, 1743. He studied at the University of Uppsala under Linnaeus, and served as a medical doctor in South Africa for several years before returning to Sweden. While in South Africa, he also visited the Dutch colonies of the Far East, and was able to investigate the fauna of Ceylon, Java and Japan. He replaced Carl Linnaeus, Jr., at the University of Uppsala, and transformed the Royal Gardens into botanical gardens to honor Linnaeus. Though known principally as a botanist, Thunberg published numerous entomological papers, including some descriptions. A prolific publisher, he authored over 150 scientific publications. He died August 8, 1828.

Tick Paralysis

TIM LYSYK
Agriculture and Agri-Food Canada, Lethbridge, AB, Canada

Adult ticks inject considerable quantities of saliva into the hosts during feeding. In some species of ticks, proteins in the saliva can paralyze the vertebrate host. At leas t 43 species of ticks have been reported to cause paralysis, but some records are doubtful. Paralysis caused by *Dermacentor andersoni* Stiles in North America and *Ixodes holocyclus* Neumann in Australia have been studied most extensively. *Dermacentor andersoni*, the Rocky Mountain Wood Tick, causes paralysis in a variety of hosts including sheep, cattle, horses, dogs and humans. Paralysis has been reported in various wildlife species, but this is rare and may be because affected animals are not readily visible. Wood ticks can paralyze cattle at doses of 25–83 mg tick per kg host body weight, and in sheep at doses of 37–70 mg tick per kg host. Increasing numbers of ticks per host may increase the incidence of paralysis, but this has only been demonstrated for laboratory animals. Humans may be paralyzed by a single tick. There are at least 10 cases of human paralysis in children aged 3–8 years that were caused by single ticks ranging in weight from 60 to 300 mg.

Although *D. andersoni* is widely distributed in western North America, paralysis is mainly associated with tick populations in a relatively small portion of its range. Paralysis occurs in the interior of British Columbia, and extends into Idaho, Oregon and Montana. Paralysis is relatively rare in the prairie regions of its distribution. Even though paralysis is associated with a particular geographic location, the ability of individual ticks to cause paralysis varies considerably within areas that paralysis occurs. Only a small proportion of ticks may be capable of causing paralysis when placed singly on susceptible laboratory animals.

Paralysis is typically associated with unmated female ticks that have fed for at least 4–5 days on the host. Males do not cause paralysis as they do not engorge to the extent that females do, and not inject the copious amounts of saliva into the host that females do. Female ticks are most likely to cause paralysis after they have attained a minimum weight of 40 mg. Although paralysis will occur in humans of all ages, it is less common in adults compared with young children as adult humans are more likely to detect and remove feeding ticks. In cattle, yearlings are the most susceptible age class as older cattle may develop immunity, and calves can have ticks removed by maternal grooming. Paralysis typically occurs in the early spring when adult ticks are actively searching for hosts. Cattle placed on pasture in the early spring are most at risk for paralysis (Fig. 52).

Tick paralysis is a progressive condition and worsens the longer that ticks are attached. Regardless of the host, paralysis begins with loss of hind limb function (posterior ataxia), proceeding to full ataxia. The victims lose the ability to stand or sit. Cattle will become sternally recumbent, and as paralysis proceeds, will become laterally recumbent.

Tick Paralysis, Figure 52 **Cow immobilized by tick feeding.**

If ticks are not removed, death due to respiratory failure will occur. Prompt removal of ticks from paralyzed animals can result in rapid recovery, even as the ticks are being removed. The earlier ticks are removed, the more rapid is the recovery. Paralysis is most common in cattle. Several thousand cattle have been reported paralyzed, with some occurrences involving entire herds of over 100 head. Death rates vary, but may range upwards of over 20–25% of an affected herd. Several hundred cases of human paralysis have occurred in the interior of British Columbia since the early 1900s.

Tick paralysis is believed to be caused by a toxin produced in the salivary glands and released during feeding. Injection of artificially collected saliva can cause paralysis. The rapid recovery of the host following tick removal suggests that infectious agents are not directly involved. Increasing incidence of paralysis with increasing doses of ticks further suggests that a toxin is involved. To date, the nature and identity of the toxin has not been identified. The mode of action of the toxin is not well understood, but is associated with reduced nerve conduction, possibly by attacking the nerve membrane. It is thought to involve motor polyneuropathies, with only limited participation of the afferent pathways.

Paralysis caused by *Ixodes holocyclus* is similar in some respects to that caused by *D. andersoni*, and markedly different in others. *Ixodes holocyclus* is among the most virulent of paralyzing ticks, and is common in moist areas along the eastern coast of Australia. Approximately 10 females can paralyze young calves 30–40 kg in weight, and 20–25 can paralyze calves 80–160 kg. The main hosts of the tick are various species of bandicoots, but the tick will cause paralysis in dogs, cats, domestic livestock and humans. Paralysis is associated with feeding by the adult females, and these are active from June through December. Toxins are secreted by the tick after the third day of attachment, and paralysis occurs after feeding for 4–5 days. Variation in virulence has not been found as has with *D. andersoni*. Symptoms are similar to those caused by *D. andersoni*, including an ascending flaccid paralysis, however, the victim may become acutely ill, and vomiting may occur. The symptoms may worsen following removal of the tick, and symptomatic treatment or administration of a canine hyperimmune antiserum. Immunity to paralysis can develop through previous exposure, through mother's milk, or by immunization.

The toxin produced by *Ixodes holocyclus* appears to have a different mode of action compared to other tick paralysis toxins, and may act to inhibit acetylcholine release at the neuromuscular junction. Considerable research has been conducted to isolate and identify the toxin produced by *Ixodes holocyclus*. Initial work suggested the toxin was a 40–80 kDa protein, but more recent studies suggest the toxin is of a lower molecular weight and related to scorpion neurotoxins. Toxins from other tick species, such as *Rhipicephalus evertsi evertsi*, are approximately 68 kDa.

The evolutionary significance of the toxins remains unclear. Toxins may have evolved to reduce mortality caused by host grooming, may have been con-served from an ancestor that used venom to immobilize prey, or may have other functions associated with tick-host interactions and paralysis is accidental.

Ticks (Acari: Ixodida)

LEWIS B. COONS, MARJORIE ROTHSCHILD
The University of Memphis, Memphis, TN, USA

Ticks are obligatory blood-feeding ectoparasites of reptiles, birds and mammals. They belong to the subclass Acari, order Ixodida. Ticks are the largest mites, ranging in length from about 2 mm to 30 mm depending on the species and life stage. All ticks pass through an egg and three active stages, a six-legged larva also known as a "seed tick," an eight-legged nymph and an adult. Each active stage molts into the next and, with few exceptions, each requires a blood meal before molting. The complex relationship of the tick to its vertebrate host that may date back to the dinosaurs, and the need for the tick to obtain a blood meal, have been the principle driving forces for their evolution.

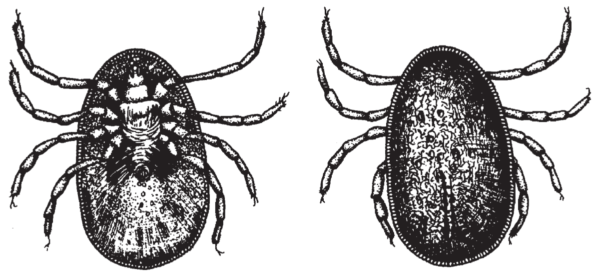
Classification of Ticks: The Order Ixodida

About 850 species of ticks are arranged in three families:

- Class: Arachnida
  - Order: Ixodida
    - Family: Argasidae
      - Subfamily: Argasinae
      - Subfamily: Ornithodorinae
      - Subfamily: Otobinae
      - Subfamily: Antricolinae
      - Subfamily: Nothoaspinae
    - Family: Nuttallielinae
    - Family: Ixodidae
      - Subfamily: Ixodinae
      - Subfamily: Rhipicephalinae
      - Subfamily: Amblyomminae
      - Subfamily: Haemaphysalinae
      - Subfamily: Hyalomminae

Argasidae

The Argasidae with some 159 species is divided into five subfamilies, each with one genus: Argasinae (*Argas* with seven subgenera and 56 species), Ornithodorinae (*Ornithodoros* with 100 species), Otobinae (*Otobius* with two species), Antricolinae (*Antricola* with about eight species), and Nothoaspinae (*Nothoaspis* with one species) (Fig. 53).



Ticks (Acari: Ixodida), Figure 53 **Adult of *Argas persicus*, the blue bug. The *left side* is a ventral view and the *right side* is a dorsal view (from Marquardt et al. 2000, used with permission of Harcourt Academic Press).**

Nuttallielidae

The Nuttallielidae has a single species *Nuttalliella namaqua* known only from females and nymphs. It is found in South Africa and Tanzania where it is believed to be a parasite on small mammals such as rodents and the rock hyrax. What little is known about this species suggests that it has many characteristics in common with both of the other two tick families.

Ixodidae

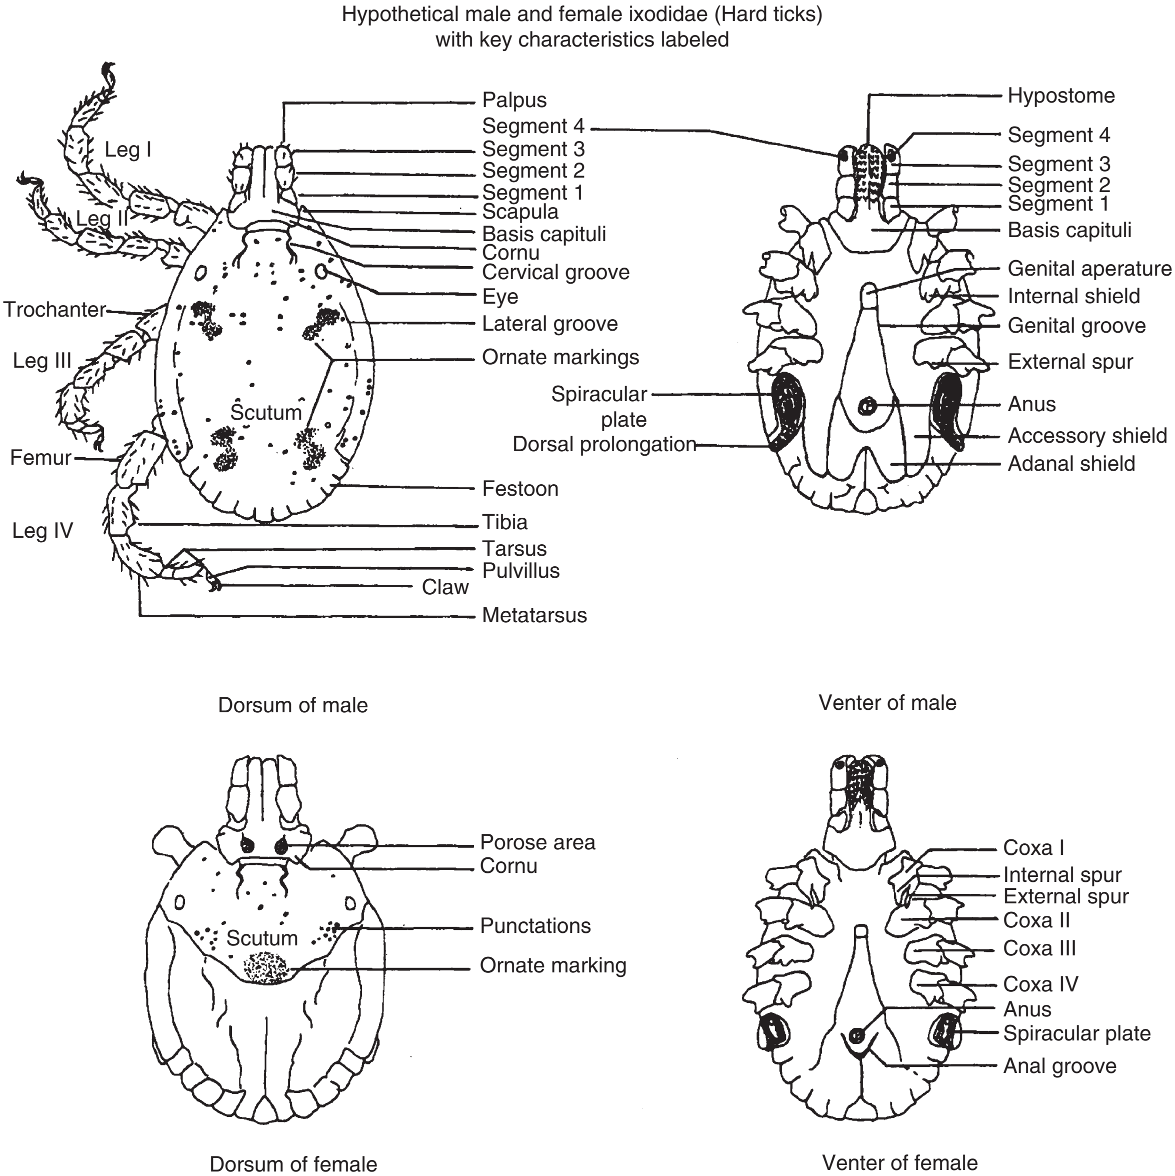
The Ixodidae, with some 650 species, is divided into five subfamilies. The subfamilies are grouped into two divisions, the Prostriatia and the Metastriata. The Prostriata has a single subfamily, the Ixodinae, with one genus, *Ixodes*, and some 245 species. The Metastriata contains four subfamilies. The largest of these, the Rhipicephalinae, has eight genera, *Dermacentor* with 30 species, *Cosmiomma* with one species, *Nosomma* with one species, *Rhipicephalus* with 70 species, *Anomalohimalaya* with three species, *Rhipicentor* with two species, *Boophilus* with five species, and *Margaropus* with five species. The other three subfamilies are smaller: Amblyomminae with two genera, *Amblyomma* with 102 species, and *Aponomma* with 24 species; Haemaphysalinae has one genus, *Haemaphysalis* with 155 species, and Hyalomminae has one genus, *Hyalomma* with 30 species.

External Morphology of Ticks

Ticks have a typical acarine body, but one that has been adapted to an ectoparasitic life. The body is divided into a movable head region, the capitulum or gnathosoma and the idiosoma, which makes up the rest of the body. There is no visible segmentation. The small dorso-ventrally flattened body of unfed ticks makes it difficult for the host to remove them (Fig. 54).

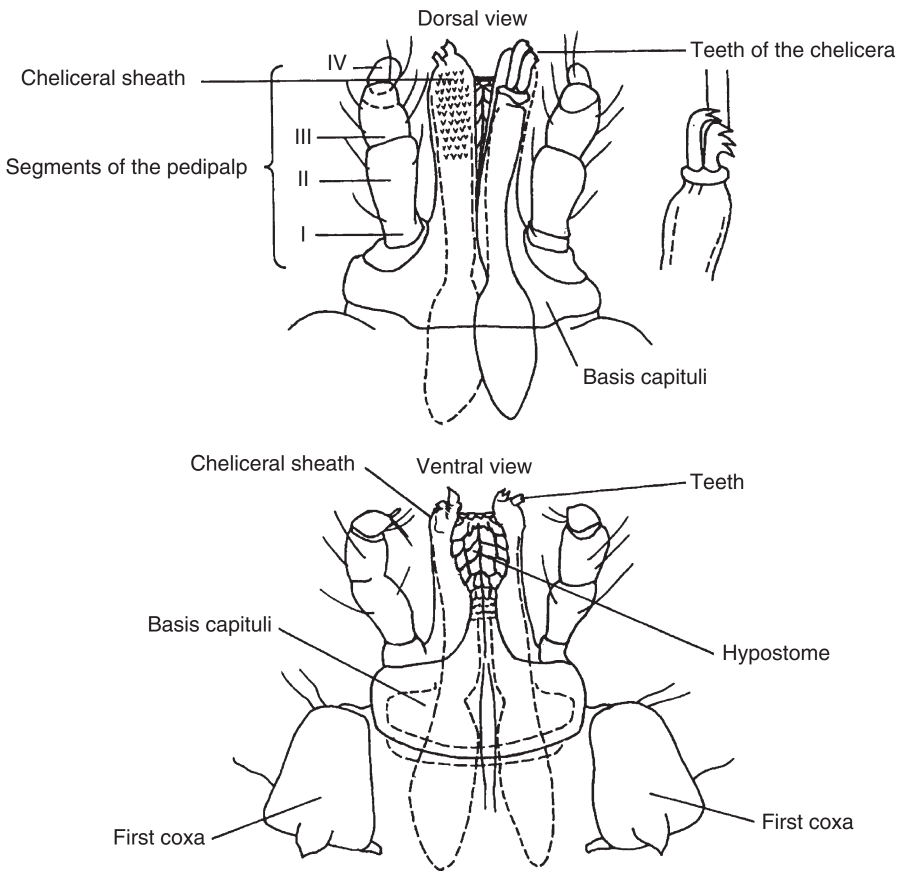
The capitulum, or gnathosoma, consists of the basis capituli, the palps, and the chelicerae, and the hypostome. The gnathosoma is anteriorly situated in the larvae of soft ticks and in all instars of hard ticks. In postlarval instars of soft ticks, it is not visible from above, being mostly hidden by the overlapping anterior part of the idiosoma. The gnathosoma is connected with the idiosoma by a cavity, the emargination in hard ticks, or the camerostome in soft ticks. The connection is via a soft articulation membrane that allows the gnathosoma to be flexed or extended (Figs. 55 and 56).

The basis capituli, an integumental ring that encircles the mouthparts, contains the shafts of the chelicerae, the salivary ducts and the pharynx. Its dorsum bears the area porosa in female hard ticks. The paired palps have four segments, and resemble legs in soft ticks, but have a more flattened shape than legs in hard ticks. In soft ticks, the terminal segment is normal in appearance but, in hard ticks, it is much shorter and can be retracted or protruded. The palps bear several types of setiform sensilla.



Ticks (Acari: Ixodida), Figure 54 **Diagrams illustrating the external anatomy of a hypothetical male and female ixodid tick with key characteristics labeled. Note that the chelicerae have been removed (compare to following figure) (from Marquardt et al. 2000, used with permission of Harcourt Academic Press).**

The paired two-segmented chelicerae have been modified as cutting organs that are unique among the mites. Chelicerae consist of a bulbous base, an elongated shaft, and the cutting digits, or articles. In many species, a cheliceral hood covers the articles. The cutting edges of the internal and external articles are laterally oriented. The internal article is moved from side to side by the tendons attached to the powerful muscle masses in the bulbous cheliceral bases. The external article moves with it. This movement is used by the tick to tear into the hosts skin prior to embedding its mouthparts. Sensory structures occur on the external and internal articles.



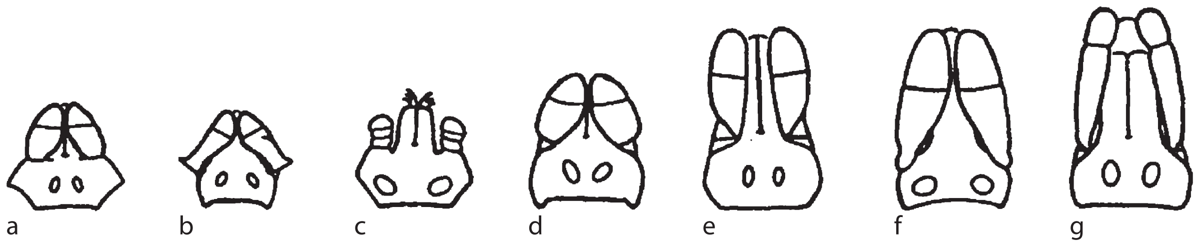
Ticks (Acari: Ixodida), Figure 55 **Capitulum and mouthparts of a tick (from Marquardt et al. 2000, used with permission of Harcourt Academic Press).**

The hyopostome, located on the ventral gnathosoma, is a dorso-ventrally flattened protrusion with recurved teeth on its ventral side, and a preoral canal on its dorsal side. The preoral canal leads to the mouth and the muscular pharynx. The action of the pharynx sucks up blood through the preoral canal. The preoral canal and the space between the dorsal surface of the hypostome and the ventral surfaces of the chelicerae are the common channels for blood intake and saliva outflow. In hard ticks, the intake of blood alternates with saliva flow with some pauses between the two events. At the junction of the preoral canal with the pharyngeal valve, a short and pointed flap-like labrum exists.

The mouthparts of hard ticks vary in length. Those species with longer mouthparts are referred to as longirostrate, and those with smaller mouthparts as brevirostrate.

The idiosoma is divided into the podosoma which bears the walking legs and, in adults, the genital opening, and the opisthosoma that lies posterior to legs IV and bears the spiracular plate and the anal opening. Some hard ticks have patterns in the cuticle, usually in the scutum or the dorum of the basis capituli, which are referred to as markings or ornamentations.

The idiosoma of soft ticks is tough and leathery and, with the exception of some larval forms, has no sclerotized plates or shields. Eyes, when present, are found laterally above the fourth pair of legs in soft ticks and, in hard ticks, on the lateral surface of the scutum. The cuticle of all Argasidae, but *Argas*, have tiny ridges (mammillae) and



Ticks (Acari: Ixodida), Figure 56 **Capituli of the genera of hard ticks, family Ixodidae. (a) *Rhipicephalus*; (b) *Haemaphysalis*; (c) *Boophilus*; (d) *Dermacentor*; (e) *Ixodes*; (f) *Hyalomma*; (g) *Amblyomma* (from Marquardt et al. 2000, used with permission of Harcourt Academic Press).**

depressions (discs) to which muscles attach. Some hard ticks have grooves, or festoons, along portions of the ventral posterior body margin.

The idiosoma of hard ticks bears several sclerotized plates or shields. In female hard ticks, an anterior shield, the scutum, occurs on the dorsum. The alloscutum covers the remainder of the idiosoma. The alloscutum is not sclerotized and is folded in unfed ticks. This allows the alloscutum to greatly enlarge during feeding to accommodate the large blood meal. Male hard ticks take small blood meals, the alloscutum is lacking, and the scutum covers the whole dorsum. Various shields such as the accessory shield and adanal shield occur only in male hard ticks. Sexual dimorphism is well developed in hard ticks. Soft ticks are so-called because they lack the scutum. There is little visible external difference between males and females in soft ticks, except the shape of the genital opening.

The podosoma contains the walking legs. Each leg is divided into six segments or podomeres, from proximal to distal: the coxa, trochanter, femur, tibia, metatarsus and tarsus. Muscles, hydrostatic pressure from hemolymph and bending stresses are used to produce movement. Muscles and tendons run between the joints. Joints between the body and the legs, between the podomeres, and between the tarsus and the apotele allow movement of the legs. The direction of movement is determined by the type of articulation, the extent of the flexible arthrodial membranes, and the insertion points of the muscles and the position of the tendons. The tarsus of each leg has an apotele, or pretarsus, which includes the claws and, in hard ticks, only the pulvillus. The pulvillus is a flap-like structure with a central lumen containing lipid compounds that are secreted onto the surface and may act as an adhesive that allows the tick to walk on almost any surface and to move vertically.

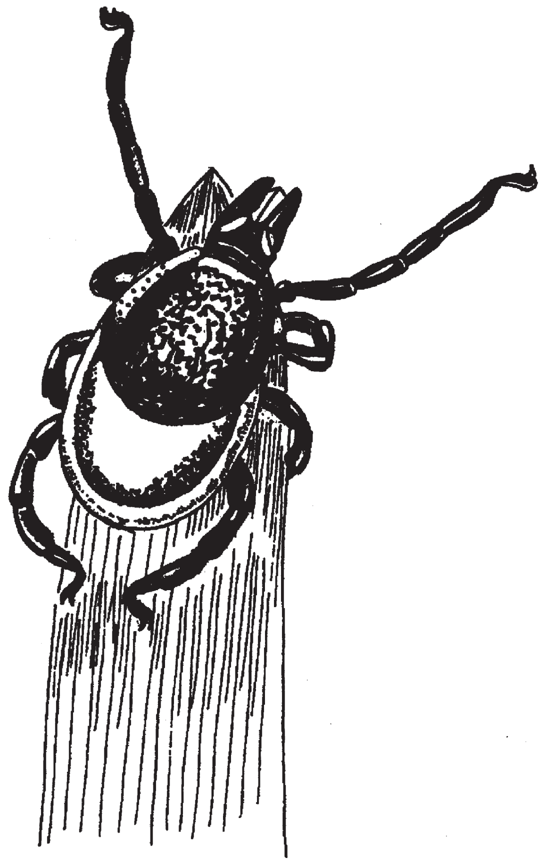
The opisthosoma contains the opening of the respiratory tract and the anus. Adult and nymphal ticks respire through tracheae, most larvae and all eggs respire through their integument. However, the larvae of some species of *Argas* and *Ornithodoros* have a simple tracheal system that opens through minute apertures between coxae I and II. Tracheae in other ticks open to the outside through a complex structure, the stigmata (or spiracle). This is associated with a sclerotized elevated region of the cuticle, the spiracular plate. A pair of spiracular plates occur near coxae IV in all adult and nymphal ticks. The spiracles of soft and hard ticks are similar, although the spiracular plate is often less conspicuous in the Argasidae. The exchange of gases occur through pores that perforate the spiracular plate and lead to a labyrinth of chambers that in turn lead to the trachea. Spiracular pores help prevent dust and other debris from entering the trachea. Pillars of cuticle (pedicles) run from the floor to the top of these chambers. A valve-like structure, the atrial valve, occurs beneath the spiracular plate. High carbon dioxide concentrations stimulate the atrial valve to open.

The tick respiratory system is designed, in part, to conserve water. Ticks that live in arid habitats have the most efficient spiracles to reduce water loss. The pores and the elaborate labyrinth system beneath the sieve plate function to reduce water transpiration during respiration. When stigmata remain open, loss of water increases, which explains why a discontinuous ventilation cycle exists in hard ticks. A discontinuous ventilation cycle coupled with a low metabolic rate is probably the reason unfed adults can survive long periods of starvation and desiccation off the host. Engorged hard ticks ventilate continuously with little spiracular control.

Host Seeking and Tick Feeding

Most ticks are ambushers, seeking their hosts in a passive manner. The exceptions are some species of *Hyalomma*, which are active hunters that will crawl several meters toward a host after perceiving their odors and movements. Ticks have evolved specialized structures to sense the presence of a host. The most important of these is Haller's organ, a specialized area of the dorsal surface of the first pair of legs found on all ticks. Haller's organ, along with other setae, can sense CO_2, ammonia found in sweat and urine, hydrogen sulfide found in the breath, belches or flatulence, nearby movement, and a rapid rise in temperature. When seeking a host ticks extend their first pair of legs and assume a questing position (Fig. 57). Ticks process sensory information through their central nervous system, or synganglion, which is described in the section on mites. Host seeking behavior is rhythmic in some ticks. *Rhipicephalus appendiculatus*, which mostly infests cattle, has a bimodal diurnal periodicity, that is, a peak of host seeking that occurs twice during each day. The peaks shift depending on the time of year.

Once on the host, a tick selects a feeding site then embeds its mouthparts into the skin. First, the tick uses its legs to elevate the body to a sharp angle, then it cuts the skin with its chelicerae and inserts the hypostome and chelicerae into the wound using a rocking motion of the body.

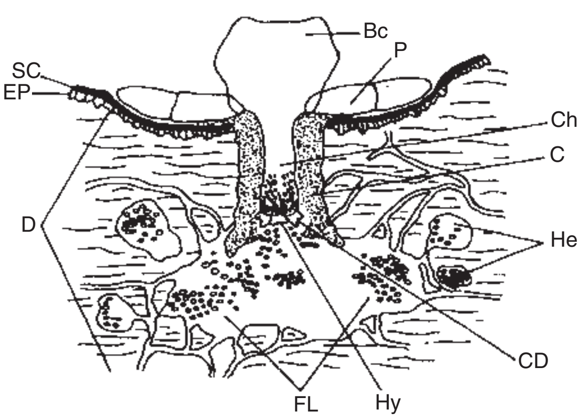


Ticks (Acari: Ixodida), Figure 57 **Female *Ixodes persulcatus* in questing posture, waving its first pair of legs (from Marquardt et al. 2000, used with permission of Harcourt Academic Press).**

The palps are splayed out on the surface of the hosts skin. Ticks are pool feeders, that is, they feed on blood that flows into a wound site in the case of soft ticks, or a feeding lesion in the case of hard ticks. Soft ticks create wounds by using their chelicerae to tear into small blood vessels and capillaries. Soft ticks are rapid feeders compared to hard ticks, finishing their blood meal in 20–60 min depending on the species. Exceptions to this rapid feeding are the larvae of many species of *Argas* and *Ornithodoros*, which require several days to complete a blood meal.

After insertion of the hypostome, all hard ticks, with the exception of some species of *Ixodes*, secrete a substance from their salivary glands that hardens into a cone-like structure. This "cement" cone covers the mouthparts but not the palps. This cone has multiple functions. It cements the tick onto the host. It creates a feeding tube that make the mouthparts more effective at taking up blood. It limits contact with the host to a small opening at the apex of the cone. Hard ticks do not create a wound at the feeding site similar to that of soft ticks. Instead, a specialized feeding lesion develops beneath the cement cone. This lesion does not develop without the host's initial inflammatory reaction. Both the bite wound of soft ticks, and the feeding lesion of hard ticks are maintained by saliva from the tick's salivary glands (Fig. 58).

The paired salivary glands of ticks are complex, multifunctional organs that are very important in off-host physiology as well as feeding. Salivary glands consist of grape-like acini connected to a system of salivary ducts. The ducts lead to a preoral cavity, the salivarium, which is isolated by a trap door mechanism. When the salivarium is opened, saliva flows into the host; when it is closed, blood is sucked into the digestive system by the



Ticks (Acari: Ixodida), Figure 58 Diagram of the feeding lesion that develops beneath the attached female ixodid. The lesion is filled with blood and inflammatory infiltrates. action of the muscular pharynx. Both soft and hard ticks alternate blood sucking with saliva production. Acini contain specialized cells that produce the many bioactive compounds found in the saliva. One type of acini produces a salt that takes up atmospheric water when secreted on the mouthparts of nonfeeding ticks. This is used to replenish the water lost during the off host part of the tick life cycle. The salivary glands of hard ticks undergo a great developmental change during feeding to become organs of osmoregulation that return excess water and ions from the bloodmeal back into the host via the saliva. Tick salivary glands are innervated with a catecholaminergic-like synapse.

Tick saliva compounds have anti-hemostatic, anti-inflammatory and immunosuppressant properties. These compounds help the tick to obtain an adequate bloodmeal and avoid rejection by the host.

Antihemostatic compounds in tick saliva inhibit platelet adhesion, activation and aggregation, blood coagulation, and vasoconstriction. Some compounds promote vasodilation. The importance of preventing platelet activation at the tick feeding site is apparent by the number of compounds that *Ornithodoros moubata* has evolved to prevent platelet activation that include at least five different compounds. Moubatin, a 17 kDa polypeptide, Tick Adhesion Inhibitor, a 15 kDa polypeptide, and disagregin, a 6 kDA peptide, prevent exposed collagen on damaged blood vessel walls from activating platelets. Disagregin also prevents the formation of fibrinogen and ADP. Apyrase, an enzyme that hydrolyzes adenosine diphosphate (ADP) is also present in the saliva of *Ornithodoros moubata*. ADP can activate platelets and is released from injured cells and activated platelets. Apyrase is found in the saliva of a wide variety of ticks in addition to *O. moubata*. An exception is *Amblyomma americanum*, which has no apyrase. In this tick, inhibition of platelet aggregation is carried out by high concentrations of prostaglandins (PGE_2 PGD_2). *Ixodes scapularis* saliva also contains high levels of prostaglandins (PGI_2, PGE_2).

The prostaglandins are the most powerful known inhibitor of platelet aggregation known and can actually cause desegregation of aggregated platelets. Prostaglandins, PGI_2, PGE_2 and PG_2, are also potent vasodilators that can help increase blood flow during feeding.

Blood coagulation is initiated by either the extrinsic system or the intrinsic system. The extrinsic system is initiated by exposure of blood to subendothelial components such as collagen, which then activates tissue factor. The intrinsic system is initiated by the release of tissue thromboplastin from injured cells. Each system leads to a common reaction that involves factor Xa (the Stuart factor), catalyzing prothrombin to thrombin. Thrombin catalyzes the conversion of soluble fibrinogen to an insoluble fibrin mesh that forms a blood clot. Most tick anticoagulants inhibit either the serine protease factor Xa, or thrombin. An exception to this is a compound from *Dermacentor andersoni* saliva that inhibits the serine protease VIIa, and a compound from *Dermacentor variabilis* salivary glands that inhibits tissue factor.

The vertebrate host's inflammatory and immune systems are closely linked and many anti-inflammatory compounds of tick saliva also inhibit or suppress the host's immune system. Compounds in tick saliva can inhibit both the innate and the acquired immune response of the vertebrate host. Innate immune responses include those mounted by the host immediately without the requirement of previous contact with the foreign invader. These include the process of inflammation and a series of soluble proteins (complement) that can destroy or damage foreign objects. Other components of the innate response are natural killer cells and the interferons. Studies have shown that some factors in tick saliva can inhibit complement, suppress the activity of natural killer cells and also suppress the anti-viral action of some interferons. This includes the production of nitric oxide by host macrophages, which is used to destroy foreign objects. The acquired immune response is highly specific and requires prior exposure to the foreign object which must be antigenic. Acquired immunity can be divided into humoral immunity carried out by antibodies, which are bloodborne proteins of the Immunogloblin superfamily manufactured by B lymphocytes or B cells, and cell-mediated immunity, which is carried out by T lymphocytes or T cells. Compounds in tick saliva suppress antibody production and responses of host T lymphocytes. The cement cone, which is known to be antigenic, binds host immune response factor IgG. This may act as a molecular mask to prevent recognition of the cement cone as a foreign object by the host's acquired immune response. A novel family of immunoglobulin-binding proteins (IGBPs) may also play an important role in evading the host's acquired immune response. IGBPs have been found in all ixodid species studied to date, and have been isolated from both saliva and hemolymph. IGBPs secreted by males co-feeding with their mates have been shown to enhance the female's ability to complete her blood meal and lay a larger clutch of eggs.

After formation of the feeding lesion early in feeding, hard ticks suppress the host's inflammatory response. The high levels of prostaglandins in tick saliva inhibit neutrophil function and suppress the release of inflammatory mediators from mast cells. Bradykinin, an inflammatory mediator of vertebrates that potentiates pain, is deactivated by the saliva of *Ixodes scapularis*. Histamine binding compounds and host immunoglobulin binding compounds have been identified in tick saliva. Histamine is an important mediator of the inflammatory response, and immunoglobulins mediate the host's immune response.

Tick drop-off from the host after feeding is not uniform with respect to day/night cycles. Completion of feeding at certain times has evolved to ensure that ticks drop off into habitats that are the most advantageous for their reproduction and for the availability of hosts for the next life stage. Photoperiod is the most common external factor that affects drop-off timing. Individual ticks of the same species feeding on the same host may finish at different times.

Physiology of Ticks

Digestive System

Ticks have a typical acarine digestive system consisting of a foregut, midgut and hindgut. The foregut is divided into a mouth, a muscular pharynx that is designed to suck up blood, and an esophagus. The midgut is divided into a ventriculus, or stomach, and several ceaca. Digestion takes place in the midgut, which is the largest division of the digestive system. A peritrophic membrane occurs in several species of ticks. A short hindgut leads from the midgut to the anal opening. Digestion starts when the bloodmeal is taken up by the midgut cells using receptor-mediated endocytosis into coated vesicles. These are sorted into endosomes that fuse with lysosomes. The bloodmeal is digested in the lysosomal system in a process termed heterophagy. The end products are residual bodies that accumulate in the cell as digestion proceeds. The products of digestion are released into the hemolymph. A pulsating organ, the heart, is located dorsally and helps circulate the hemolymph throughout the body cavity. Soft ticks digest only a portion of the bloodmeal as needed. This probably contributes to their ability to live for relatively long periods without an additional bloodmeal. Hard ticks digest the entire bloodmeal, but do so in stages. The first stage occurs before rapid engorgement. Cells in the epithelial lining of the midgut fill up with residual bodies during the digestive process and are sloughed off into the midgut lumen. They are replaced by new cells that repeat the digestive process, slough off and are replaced. The second stage of digestion occurs during rapid engorgement. To enter rapid engorgement, a female must be inseminated. During rapid engorgement, midgut cells become greatly distended and are filled with endosomes containing the bloodmeal. At this time, digestion is minimal. Following completion of the bloodmeal, the female drops off the host and the third stage of digestion occurs. During this time, all the bloodmeal is utilized and the midgut cells fill up with residual bodies. Cells do not slough off during second or third stage of digestion.

Osmoregulatory and Excretory Organs

Osmoregulatory organs are used to eliminate the excess water and ions of the blood meal. In hard ticks, salivary glands develop into osmoregulatory organs and return water and ions to the host as saliva. In soft ticks, coxal glands are the osmoregulatory organs and eliminate excess water and ions to the outside through the coxal fluid, which appears as a colorless drop between the base of legs I and II during, or shortly after, feeding. Coxal glands are absent in hard ticks. In hard and soft ticks, paired Malpighian tubes accumulate guanine, the end product of nitrogenous metabolism. Malpighian tubes empty into the lower digestive tract near the junction of the midgut and hindgut. Guanine is then expelled through the anus as a white paste-like substance along with the undigested portion of the bloodmeal, which appears as small red pellets.

Water Loss

Unfed ticks must prevent desiccation to survive. This is accomplished by physical barriers and physiological and behavioral adaptations. The most important physical barriers are the impermeable cuticle and a discontinuous respiratory cycle in which the spiracle remains closed except during gas exchange. Physiological adaptations include the excretion of guanine which is a dry waste product, and dry fecal material. An important behavioral adaptation is that ticks move down close to the ground into microenvironments with increased humidity following questing. Here, the tick can actively reabsorb water from the environment using a salt solution secreted onto its mouthparts by the salivary glands.

Reproduction

Male ticks inseminate their mates by transferring packets of sperm in a structure termed a spermatophore. Parthenogenesis is rare, but occurs in both hard and soft ticks and involves thelytoky where females produce only females. In female ticks, a large amount of the blood meal is converted to the female-specific glycolipoheme protein vitellogenin, which is secreted into the hemolymph and taken up by the eggs to become vitellin. Vitellin is the yolk of the tick egg and is the main energy source of the developing embryo.

Soft and hard ticks wax their eggs using Gene's organ which is located in the anterior body cavity. The Gene's organ turns inside out during oviposition. Unwaxed eggs dehydrate and do not develop. In female hard ticks, secretions from the porous area on the dorsal surface of the basis capituli are also added to the eggs during waxing.

Semiochemicals

Semiochemicals are informational chemicals. Two types of semiochemicals have been identified in ticks. Pheromones regulate beneficial functions between the same species, and allomones repel predators. Four different types of pheromones occur in ticks: assembly pheromones, aggregation-attachment pheromones, sex pheromones and a primer pheromone.

Assembly pheromones are common in many species of soft and hard ticks and induce clustering of ticks. These pheromones are interspecific and effect all life stages. Perception of assembly pheromones cause free living ticks to cluster. Guanine, the major excretory product of nitrogenous metabolism in ticks, acts by contact as a non-specific assembly pheromone in the species of *Argas*, *Ornithodoros*, *Amblyomma*, and *Rhipicephalus*.

Aggregation-attachment pheromones induce attachment of ticks to areas where males are feeding. They are produced by males of *Amblyomma* and affect the behavior of adults and, in some cases, nymphs. Females of *A. maculatum*, *A. hebraeum*, *A. variegatum*, and *A. marmoreum* will not embed in hosts unless feeding males are present.

Sex pheromones elicit behavior patterns that lead to copulation. A pheromone in the coxal fluid of female *Ornithodoros*, which is most active a few days following feeding, elicits courtship behavior in sexually active males. In all hard ticks except *Ixodes*, there is a complex, but similar, courtship behavior. Three different types of sex pheromones are involved. A volatile attractant sex pheromone, 2,6-dichlorophenol, is produced by the foveal glands in most of these species. These glands are located on the dorsal alloscutum just posterior to the scutum in all metastriate ticks. After contact with the female, males must identify a second pheromone, the mounting sex pheromone, or they will abandon the female. A third sex pheromone, the genital sex pheromone, must be recognized by males of some species before a spermatophore is formed and copulation completed.

A primer pheromone, in this case the fecundity reducing pheromone, has been identified in *Argas arboreus*, where its effect is most noticeable when ticks are crowded. The large wax glands of *Dermacent variabilis* and *Amblyomma americanum* secrete an allomone that repels predators.

Life Cycles and Habitats of Ticks

Many aspects of the life cycles and habitats of soft and hard ticks differ. Differences also occur between two divisions of hard ticks, the Prostriata and Metastriata.

Postembryonic Development

The Argasidae have multiple nymphal stages with different species having different numbers of nymphal molts. Following a final blood meal, the last instar nymph molts into the adult stage. The Ixodidae have a single nymphal stage.

Feeding

Depending on the species, soft ticks feed on the host once to many times in a given life stage.

Feeding is much shorter for soft ticks (15 min to several hours) than for hard ticks, although some larvae require several days to complete feeding. Soft ticks ingest a relatively small amount of blood compared to hard ticks. In a few species of soft ticks, the larval stage molts to a nymph without feeding. Hard ticks take a much larger blood meal (up to or greater than 100 times their unfed body weight in some species) than soft ticks, and feed for a long time (9–13 days depending on the species). Hard ticks feed only once in a given life stage. Larvae complete feeding in the shortest time, adult females in the longest time. Females pass through a feeding stage known as rapid engorgement, while the males do not. It is during this feeding stage, which occurs 24–48 h prior to the completion of feeding that most of the blood meal is taken up. Depending on the species, each ixodid tick can consume up to 15 ml of blood during feeding. This is made possible by the tick returning excess water and ions from the blood meal to the host through its saliva. Compared to females, males produce only about one-twentieth the amount of saliva.

Mating and Reproductive Cycles

Ticks either mate on, or off, the host. Almost all soft ticks mate off the host. Two exceptions are *Argas (Microargas) transversus*, and *Otobius megnini*. The former is a small tick that spends its entire life on the Galapagos giant tortoise, and is the only known tick to oviposit on its host. The latter tick is the spinose ear tick, an economically important species. A blood meal is not necessary to initiate gametogenesis in species of Prostriata. They can mate before feeding, and can mate on, or off, the host depending on the species. In many of the nidicolous (nest or burrow dwelling) species of *Ixodes*, males cannot feed and do not occur on hosts. Instead, they seek out females and usually mate off the host. This life cycle may have evolved in nidicolous, or nest dwelling species, to ensure that females can survive long periods without feeding and still oviposit. An exception occurs in the subgenus *Ixodiopsis* where, despite a nidicolous life, males feed. All species of Metastriata mate on the host.

Soft and hard ticks have different reproductive cycles. Soft ticks go through multiple egg laying (gonotrophic) cycles. Females lay a clutch of eggs during each cycle. Each clutch of eggs is usually progressively smaller. Autogeny, the ability to lay eggs without a bloodmeal, is obligatory in genera where females have nonfunctional mouthparts, i.e., *Otobius*, *Antricola*, and possibly *Nothoaspis*; and facultative in *Argas persicus*, and several species of *Ornithodoros*, including *O. lahorensis*. Female hard ticks go through one gonotrophic cycle, lay a single clutch of eggs, then die.

Hosts

Ticks either have multiple hosts, or have a one-, two-, or three-host life cycle. Almost all soft ticks have multiple hosts although the hosts may be the same species. Two exceptions are *Argas transversus*, and *Otobius megnini*.

All species of ixodids have either a one, a two- or a three-host life cycle. In a one-host life cycle, ticks infest the host as larvae then remain on the same host as nymphs and adults. Adults mate following a blood meal. Mated females drop off the host and lay eggs in a protected niche such as a crack in the ground, or under vegetation litter. About 12 species of metastriate ticks have a one-host life cycle. In a two-host life cycle, the larvae infest a host then remain on the host to feed as nymphs after molting. Following completion of feeding, the replete nymph drops off to molt into an adult. The adult then infests a second host to feed and mate, after which the female drops off to oviposit. Only a dozen or so species of metastriate ticks have a two-host life cycle. Two examples are *Hyalomma anatolicum excavatum* and *Rhipicephalus evertsi*. By far the majority of metastriate ticks have a three-host life cycle where each life stage infests a host. Usually, each host is a different species and each is larger than the previous host. Molting from one stage to another occurs off the host, and mating occurs on the penultimate host then the replete female drops off to oviposit.

In their preference of hosts, ticks are categorized as either host-specific or opportunistic. Host-specific ticks are less common, and are considered specialists. An example is the cattle tick *B. microplus*. These ticks respond dramatically to the odors of cattle, but not to human odors. Opportunist ticks are generalists and have a wide range of hosts. Two examples are *Ixodes scapularis*, whose hosts include a number of species of birds and mammals, and *Amblyomma americanum*, whose host list includes reptiles, birds and mammals.

Many species of ticks have repeated feeding success on their natural hosts, but not on unnatural laboratory hosts. Repeated infestations of *Dermacentor variabilis* on their natural hosts, such as deer mice, results in successful feeding, but when larvae and nymphs are fed on guinea-pigs, feeding success is reduced. Successful molting to the next stage by ticks that have completed feeding is also reduced.

Habitats

Ticks can be divided into nidicolous and non-nidicolous. Nidicolous ticks either live in, or in close association with, the host's dwelling. That is, the host's nest, burrow, cave or shelter. Non-nidicolous ticks live throughout the host's range. Almost all species of Argasidae and many Prostriata are nidicolous. Most Metastriata are non-nidicolous. The behavior of nidicolous ticks is adapted to specialized niches. Such behavior can include (i) the ability to survive for years in the absence of a host, (ii) negative phototropism, an avoidance of light, (iii) thigmotropism, a positive reaction to contact with a solid object, so these ticks prefer small cracks or crevices in their environments that contact both surfaces of their body, (iv) a narrow tolerance of temperature and humidity, often the optima is that of the host's residence.

Non-nidicolous ticks live throughout the host's range, but most are not distributed in a uniform fashion throughout this range. Some are found in several different habitats of their host's range, while others have a single preferred type of habitat, for example a deciduous forest, where most of their population is found. Important factors that determine this non-uniform type of distribution are climate, vegetation, availability of hosts, presence or absence of diapause, and the ability of the tick species to withstand adverse environmental conditions. No single ecological factor can account for this non-uniform type of distribution.

The presence of diapause enables many tick species to synchronize their populations with the presence of hosts or with favorable climatic conditions. Diapause is a state of low metabolic activity in an arthropod that is mediated by neurohomone(s). Two types exist in ticks, behavioral diapause, or developmental diapause. Ticks in behavioral diapause will not feed when offered hosts and often fail to quest for hosts. Behavioral diapause is the most common type. Developmental diapause involves delayed completion of development in an egg, or fed immature. Developmental diapause is often an important regulator of the developmental cycle in nidicolous ticks that use migratory birds or bats for hosts. Usually this diapause occurs as delayed oviposition, which ensures that expansion of the tick population is related to the presence of the host. Great numbers of nidicolous ticks can occur in a given nest or burrow. Bird nests can contain up to 20,000 ticks per square foot, and warthog burrows have contained 250,000 ticks per burrow. In some cases, seabirds have abandoned their nests and fledglings due to the presence of large numbers of ticks. Diapause has not been reported in nidicolous ticks that have non-migratory hosts. Diapause is widespread in non-nidicolous ticks. In *Ixodes rincinus*, developmental diapause exists in the egg and all active stages, which results in separate spring and fall feeding populations. Delayed oviposition (developmental diapause) occurs in *Dermacentor marginatus*. Behavioral diapause occurs in *Dermacentor albipictus*, *Dermacentor andersoni* and *Dermacentor variabilis* to name a few species.

Dispersion

Ticks move slowly over short distances and must rely on their hosts for dispersal. Most widespread tick species have hosts that, in turn, are widely dispersed, or are migratory. An example is the brown or red dog tick, *Rhipicephalus sanguineus*, which is found throughout the world. Many ticks have at least one life stage that infests migratory birds that can carry them between continents. Using hosts as mechanisms of dispersal has resulted in the spread of tick transmitted diseases through large distances, and has made many of the diseases transmitted by ticks multifocal.

Ticks of Medical and Veterinary Importance

Three genera of soft ticks, *Argas*, *Ornithodoros* and *Otobius* have species that are medical or veterinary pests. The other genera, *Antricola* and *Nothoaspis*, are parasites on bats.

The genus *Argas* is divided into seven subgenera, two of which, *Argas* and *Persicargas* infest birds. The other subgenera are parasites on bats and small mammals. Almost all species in the genus *Argas* are nocturnal and occur in arid habitats with long dry seasons. *Argas (Persicargas) persicus*, the fowl tick or blue bug, is the most widespread soft tick on poultry. Larvae of this tick feed on the host for 2–10 days depending on the situation. Fed larvae drop off and molt in 4–16 days. Nymphs seek hosts and complete feeding within 30 min. There are three nymphal stages. Adults complete feeding within 45 min. Females feed before laying each clutch of eggs, and this cycle may occur daily. Several hundred eggs are laid in the early clutches, and only a couple of dozen in the later ones. *Argas (Persicargas) persicus* originated in the Palearctic region but, following domestic poultry, this tick has spread throughout the world with the possible exception of the Neotropical region. In addition to domestic poultry, it is found on wild birds. The fowl tick transmits two diseases to poultry, fowl spirochetosis and a rickettsial disease caused by *Aegyptianella pullorum*. Three other closely related ticks, *Argas (Persicargas) walkerae*, *Argas (Persicargas) persicus*, and *Argas (Persicargas) arboreus*, are also parasites on birds. In the southern U.S.A., *Argas persicus*, *Argas sanchezi*, and *Argas radiatus* are parasites on poultry, but are not problems in large commercial poultry houses.

Three species of *Ornithodoros*, *Ornithodoros moubata*, *Ornithodoros savignyi*, and *Ornithodoros lahorensis*, are important parasites of man and domestic animals. The African tampan, or eyeless tampan, *Ornithodoros moubata*, is a complex of at least four species. *Ornithodoros moubata* sensu strictu (in the narrow sense) occurs throughout semi arid, or arid Africa from Kenya southward to South Africa. The life cycle is relatively short, about 4 months from egg to adult. The larvae are nonfeeding and molt directly into a nymph. There are three or more nymphal stages. Females deposit several hundred eggs per batch. More than seven clutches are laid, which can total over 2,500 eggs. Large infestations of this tick can kill pigs. The tick can become a parasite of humans that live in huts or in dwellings with cracks. *Ornithodoros moubata* is the vector of *Borrelia duttoni*, which causes endemic relapsing fever. Other species in this complex include *Ornithodoros moubata porcinus*, found in Africa, *Ornithodoros tholozani* and *Ornithodoros erraticus*, found in the Middle East. *Ornithodoros moubata porcinus*, the African warthog tick, and *Ornithodoros erraticus*, transmit the causative agent of African swine fever. The eyed tampan, *Ornithodoros savignyi*, occurs in the arid regions of Africa, the Middle East, India and Sri Lanka where it is a parasite on domestic stock and humans. It does not transmit disease, but heavy infestations can cause severe damage. *Ornithodoros* *lahorensis* is a parasite of domestic stock throughout its range in Asia and the southern republics of the former Soviet Union. *Ornithodoros hermsi*, *Ornithodoros turicata* and *Ornithodoros parkeri*, feed on humans along with other hosts, and can vector *Borrelia* species that cause relapsing fever.

The spinose ear tick, *Otobius megnini*, is a parasite on cattle, horses and companion animals. It occurs mostly in stables and in other animal shelters. The spinose ear tick has spread from America to southern Africa and India, and has been reported from humans in the later region. The larvae have a capitulum that is over one-third its body length. Larvae invade the ear and feed for 5–10 days then molt to a nymph. Nymphs reattach within the ear. The integument of the nymph has numerous spines from which the tick gets its common name. The second stage nymph drops off the host and seeks small, hidden areas such as cracks where they molt to a fiddle-shaped adult. The adult does not feed. Its hypostome is small and has no teeth. Mated females lay up to 1,500 eggs in cracks in the walls of the shelters at a height suitable for transfer to a large host. Larval spinose ear ticks die within 4 months, but adults can live up to 2 years without hosts.

In the Ixodidae, the genus *Ixodes* has the largest number of species. All are three-host ticks without eyes and festoons. The capitulum is much longer in the female than in the male. The most important species group is the *Ixodes ricinus-persulcatus* complex which has a wide distribution from North America south into Mexico, and in Europe south to the Sahara, and in Asia south to the Himalayas. This complex is important in vectoring pathogenic viruses of man, the *Borrelia* that causes Lyme disease, and the protozoa that cause piroplasmosis. Important species of this group are the blacklegged tick, or American deer tick, *Ixodes scapularis* (=*dammini*), found in North America, the European sheep tick, or European castor bean tick, *Ixodes ricinus*, and the tiaga tick, *Ixodes persulcatus*. *Ixodes scapularis* occurs in North America. *Ixodes ricinus* is found along the western parts of the British Isles, and Norway southward to Iran and Turkey, Bulgaria, Italy and the Pyrenes. *Ixodes persulcatus* has a wide distribution from Japan westward into Germany. All three are vectors of the causative agent of Lyme disease. *Ixodes persulcatus* is also the main vector of the virus that causes Russian spring-summer encephalitis. This tick is more tolerant of temperatures and is more cold hardy than *Ixodes ricinus*. Two other species, the Karoo paralysis tick *Ixodes rubicundus* in southern Africa, and *Ixodes holocyclus* in Australia, cause paralysis in mammals. Lyme disease is transmitted by *Ixodes rincinus* in Europe, *Ixodes scapularis* in the Eastern U.S. and *Ixodes pacificus* in the Pacific coast states and intermountain west of the U.S. *Ixodes pacificus* is a major cause of tick paralysis.

The European sheep tick, *Ixodes ricinus,* is a three-host tick with a 2- to 6-year life cycle depending on location. Immatures attack birds, but sheep can be the hosts for all three life stages. This tick has separate spring and fall feeding populations. The larvae, seek a host in the spring or fall, feed for 3–6 days, then drop off and molt. After molting, the larvae ascend grass and twigs to assume a questing position but, here, they tend to lose body water causing them to descend to a microclimate on or near the ground where water is at or near saturation. They rehydrate in this microclimate. The nymphs seek a host the next spring or fall, engorge for 3–5 days, then drop off the host and molt. The adults seek a host the next spring or fall. Females take from 5 to 14 days to complete feeding. Fertilized females lay from 500 to 2,000 eggs that hatch by late spring or late fall, but the larvae usually do not feed until the following spring or fall.

Ixodes scapularis is found from Maine south to Florida and west into central Texas and possibly Mexico, and from Maine west into Minnesota and Iowa. It is a small three-host tick that attacks a wide variety of birds and mammals including man. Larvae and nymphs attack small rodents especially the white footed mouse *Peromyscus leucopus*. Adults occur on larger animals with the white-tailed deer *Odocoileus virginianus* being the most common. A large population of deer is an important factor in the presence of large populations of *Ixodes scapularis*. Changes in agriculture and patterns of human use in the eastern U.S. have resulted in humans coming more into contact with areas supporting populations of *Ixodes scapularis*. The tick population in these areas has increased dramatically due to the increase in the deer population. This tick is an important vector of the causative agent of Lyme disease, human babesiosis and human granulocytic ehrlichiosis. The Western black legged tick, *Ixodes pacificus*, is found on the pacific coast states and British Columbia. It is closely related to *Ixodes scapularis*. Immatures of *Ixodes pacificus* feed on small rodents and lizards, the adults feed on deer, horses and man. Throughout its range, this tick occurs in regions of higher mositure. *Ixodes pacificus* transmits the causative agent of Lyme disease and equine granulocytic ehrlichiosis.

Species of *Dermacentor* are mostly large, ornate, brevirostrate ticks with eyes and festoons. This genus is most common in the New World. *Dermacentor marginatus* transmits Siberian tick typhus and *Dermacentor reticulatus* infests livestock. Both occur throughout Europe and Asia. *Dermacentor albipictus*, the winter tick, occurs from the west coast to the east coast of Canada and far north to almost 60°N latitude. This one-host tick does not feed during the summer. Heavy infestations on large horned animals such as moose can result in death. The Pacific Coast tick, *Dermacentor occidentalis*, is found from Oregon to California where it transmits anaplasmosis. This species also causes paralysis in livestock and deer.

The American dog-tick, *D. variabilis,* occurs in the central and eastern United States (U.S.) northward into southern Canada and Nova Scotia. The American dog tick vectors the *Rickettsia* bacteria that causes Rocky Mountain spotted fever, the bacterium that causes tularemia and anaplasmosis. *D. variabilis* is an important pest of domestic animals and man throughout its range. It can cause canine paralysis. In the southern U.S., a life cycle can be completed in 3 months under favorable conditions. However, in the northern regions of its distribution, a life cycle can take 2 years. *D. variabilis* has expanded its range in recent years. It is found in the mid-western U.S. and Pacific states where local populations have been established, mostly along river valleys. Northward expansion is probably limited by cold temperature because the tick has not established breeding populations beyond the mean winter (December–February) 0°C isotherm. Westward expansion is probably limited by the lack of rainfall and deciduous forests or brushy habitats. The American dog-tick prefers field-forest ecotones. *D. variabilis* is a three-host tick. Replete females drop from the host and, within 4–10 days, lay a clutch of 4,000–6,500 eggs preferably in cracks and crevices on the ground. In the summer, the eggs begin to hatch in about 35 days depending on the temperature. The larvae feed mostly on wild mice and voles for 3–12 days then drop off and molt to nymphs. The nymphs also prefer wild mice and voles as hosts. They feed for 3–11 days then drop off to molt on the ground and emerge as adults. The adults prefer dogs and other larger mammals including man. The females engorge in 6–13 days. Mating takes place on the host. Unfed adults may live for more than 2 years.

The Rocky Mountain wood tick, *D. andersoni*, occurs in the western U.S. and British Columbia. It is a three-host tick with a similar life cycle to that of *D. variabilis*. The adults prefer large mammals, the nymphs smaller mammals and the larvae feed mostly on wild mice. *D. andersoni* transmits the causative agents of Rocky Mountain spotted fever, Colorado tick fever and anaplasmosis. The tick causes paralysis in mammals.

The genus *Anocentor* has a single species, the Neotropical ear tick of horses, *A. nitens*, found in the southern U.S. westward to Texas and southward to Brazil. This one-host tick has no ornamentation and the eyes are obsolescent. Some workers place this tick in the genus *Dermacentor*.

Nosomma has a single species, *N. monstrosum*, which has a wide range of hosts including cattle, buffalo, humans, boar, bear, horses and dogs, with the larvae infesting rodents. This three-host tick occurs in India and Southeast Asia.

Species of *Rhipicephalus* are brevirostrate, small, mostly inornate ticks. This genus is found in the Old World, mainly in Africa south of the Sahara and southern Arabia. One species, the brown or red dog tick *R. sanguineus*, is now cosmopolitan with a greater geographical distribution than any other species of tick. *R. sanguineus* has a wide host range preferring dogs and other carnivores, some large herbivores, lagamorphs, rodents, bats, reptiles, and some primates including humans. This tick is a warm-climate species that probably originated in Africa. Its ability to colonize shelters in cold climates has significantly contributed to its distribution. The brown dog tick vectors *Babesia canis* and *Rickettsia conorii*. The latter pathogen causes boutonneuse fever. In some areas of Mexico, this tick transmits *Rickettsia rickettsii* that causes Rocky Mountain spotted fever.

Other important species of *Rhipicephalus* on domestic animals are the brown ear tick *R. appendiculatus*, *R. evertsi* and *R. simus*. *R. appendiculatus* is a three-host tick that occurs in the eastern and southern parts of Africa south of the equator. This tick is found on goats and sheep but is mostly a parasite of cattle. Its distribution reflects an interaction between climate, vegetation and hosts. It is thought that the presence of cattle is necessary for the tick to become established. Temperatures around 4°C will kill all stages of engorged *R. appendiculatus*. A dry climate prevents eggs from hatching through desiccation. Under ideal conditions, a life cycle in this tick can be completed in 3–4 months. The number of cycles per year depend on the local conditions. In southern Africa, there is one generation per year, but in Tanzania, two generations per year can occur under optimal conditions. *R. appendiculatus* vectors *Theileria parva* which causes east coast fever in cattle, the Nanovirus that causes Nairobi sheep disease, and *Babesia bigemina* that causes babesiosis in cattle.

The two-host African red tick, *R. evertsi*, infests domestic cattle, goats, sheep and wild ungulates. The eggs of this tick hatch on the ground and the larvae seek a host animal where they attach to the inner surface of the ear. After feeding to repletion, larvae detach and molt into nymphs that attach in the same area of the ear and feed to repletion then drop off the host to molt on the ground. The adults seek a second host, attaching mostly in the perianal region under the base of the tail or less commonly on the teats, the base of the legs, or the scrotum. Here they mate and females feed to repletion then drop off to lay eggs on the ground.

All five species of *Boophilus* are brevostriate, one-host ticks and all are parasites on large hoofed mammals, especially cattle. No festoons, or eyes are present. Three species are important vectors of babesiosis to cattle: *B. microplus*, the cattle tick, is found in the Neotropical, Afrotropical and Australian regions; *B. decoloratus* occurs in tropical Africa; and *B. annulatus* is found in North America. The life cycle of *B. microplus* is completed in about 5 weeks under favorable conditions and can require up to several months under less favorable conditions. Females lay a single clutch of 2,000–3,000 eggs that hatch in about 2 weeks at 70% humidity. Larvae quest on the tips of grass and twigs but do not move down to rehydrate in a microenivronment. Larvae feed for about 4 days on the host then molt into a nymph after a quiescent period of about 2 days. The nymphs may move about the host before attaching. They feed for about a week and then molt into an adult. This molt is also preceded by a short quiescent period. The adults mate on the host. The females take about 3 weeks to feed to repletion, then drop off to lay eggs. The oviposition period lasts some 10 days and is preceded by a short preoviposition period of several days. *B. microplus* must have a high rainfall, and cannot be found in dry areas with a low humidity. This tick is widespread throughout the warmer climates of the world. In the tropics, *B. microplus* are found on cattle throughout the year. In subtropical regions, it has a seasonal cycle. A commercial vaccine has been developed against "concealed antigens" of the tick midgut. This vaccine has reduced tick fertility by as much as 70% in some cases. Booster shots are necessary.

Some species of *Margaropus*, infest giraffes in the Sudan and East Africa, but *M. winthemi*, the winter horse tick, is a parasite on horses in southern Africa. *Margaropus* are one-host ticks that are considered relic boophilids.

Amblyomma are mostly large, highly ornamented, longirostrate ticks with eyes and festoons. Most species occur in the tropics. All have a three-host life cycle. Their long mouthparts are especially damaging to cattle hides. Species from the southern U.S. are the only members of this genus from the temperate region, although some nymphs occur on migratory birds from Africa northward through Europe and Asia. The African brown ear tick, *A. appendiculatus*, and the tropical bont tick, *A. variegatum*, transmit *Cowdria ruminantium*, the causative agent of heartwater fever in cattle. *A. nuttali* has the distinction of producing the largest clutch of eggs ever recorded from a single tick, over 22,000.

The lone star tick, *Amblyomma americanum*, is found across the southeastern U.S. from central Texas to the Atlantic coast and north to New York. It prefers a forested habitat. The questing activity of this tick is most active from sundown to the late evening hours when its principle host, white-tail deer, forage. Large numbers of ticks occur in, or near, the bedding of hosts. Active stages have no host preference. Immatures are found on birds and all sizes of mammals, but adults occur mostly on medium to large mammals. All stages of this tick attack man. *Amblyomma americanum* is well adapted to forest communities. Two factors that must be present to support large populations of *Amblyomma americanum* are suitable hosts, and a moist microenvironment to protect the ticks from desiccation. An area with a forest canopy and lots of vegetative ground cover is ideal habitat for *Amblyomma americanum*. Male ticks are found on deer all year. Engorgement of the females may be a photoperiod response as there is a small drop-off period that begins in May, and is over in late August. The larvae first occur on deer in late June and continue until mid-November. The nymphal activity, which occurs from March to October, is the longest of any stage. The lone star tick is a vector of Rocky Mountain spotted fever and Q fever.

The Cayenne tick, *Amblyomma cajennense*, is also found in the southwestern U.S. south through Mexico and Central and South America and the West Indies. It commonly attacks man and many other animals. It transmits Rocky Mountain spotted fever from Mexico south to Brazil. The Gulf Coast tick, *A. maculatum*, is a parasite on deer and cattle. The deer population has dramatically increased, and this has resulted in an increase in the population of *A. maculatum*.

Some or all species of *Hyalomma* are longirostrate, medium-sized ticks with eyes that may or may not have festoons and scutal ornamentations. This genus most likely originated in the dry deserts of Kazakhstan and Iran in the Palaearctic. Some or all species of *Hyalomma* are hardy ticks. Several economically important species exist. The *H. marginatum* complex and *H. anatolicum anatolicum* are major vectors of the arbovirus that causes Crimean-Congo haemorrhagic fever. The *H. marginatum* complex extends from India and Indochina westward throughout southern and southeastern Europe into the Near East and North Africa. Populations are scattered throughout the drier areas of Africa south of the Sahara from the Red Sea to the Atlantic Ocean. Hosts of immature ticks in this complex include wild birds, small mammals, hedgehogs and hares. The adults attack any domestic animal especially cattle, horses and camels. Migrating birds are important in spreading these ticks. A typical *H. marginatum* life cycle is completed in 116 days at 18–19°C. All stages of this tick complete feeding in about 6 days. The females lay from 4,300 to 15,500 eggs in a single clutch. Unfed adults can live for over a year.

Species of *Haemaphysalis* are small, inornate, brevirostrate ticks. The genus is most common in the tropics where it probably originated. *H. punctata* in the Australian region, and *H. longicornis* in the Oriental region, are important parasites of cattle. The latter tick is also found on red deer in New Zealand. *H. leachi*, the yellow dog tick of Africa, is a common parasite of dogs and carnivores throughout the tropics and subtropics of Asia and Africa. It transmits the protozoan pathogen of malignant jaundice in dogs. In the Oriental region, *H. spinigera* transmits the arbovirus that causes Kyasanur Forest Disease. Two species of *Haemaphysalis* occur in North America. The rabbit tick, *H. leporispalustris*, occurs in the New World from Alaska south to Argentina. It has a large host list that includes horses, cats, dogs and birds. It rarely attacks man, but is responsible for the transmission of Rocky Mountain spotted fever and tularemia among wild animals. The bird tick *H. chordelis*, is common on upland game birds in North America and is an important parasite of turkeys. *H. mageshimaensis* is found in Japan, and is rare in that it has both bisexual and parthenogenetic reproduction.

Economic Importance of Ticks

Ticks are of great economic importance. Many disorders are caused directly by the interaction of the host to the tick. These can occur locally at the tick bite area, but some are systemic such as toxic reactions, or toxicoses and host paralysis produced by tick toxins. Ticks have a high vector potential and transmit more varieties of serious diseases to vertebrates than any other blood feeding arthropod. They are second behind mosquitoes in transmitting diseases to humans, and first in veterinary importance. Some species of ticks have a toxin in their saliva that can cause death through paralysis. Another of the many afflictions imposed on their host has to do with blood loss through heavy tick burdens. Large mammals can harbor enormous numbers of ticks. A moose can have more than 50,000 ticks feeding on it at any given time, as can a small giraffe. The record is probably a single caribou found with more than 400,000 ticks. Heavy tick infestations also occur in livestock and companion animals where loss of blood can result in the development of anemia, or in extreme cases, death.

Several superficial local disorders such as dermatosis, inflammation, itching, swelling and ulceration can occur at the tick feeding site. In some individuals, tick feeding can produce a hypersensitivity reaction that can be local, or in severe cases, systemic, and can even result in anaphylactic shock. These reactions usually occur early in the course of tick feeding. The feeding site can become a means of secondary infections from pathogens not transmitted by the tick. The infestation of the auditory canal by ticks, otocariasis, can cause serious secondary infections. Proper removal of ticks is important to minimize secondary infections because skin ulceration and lesions can result from improper or partial removal of tick mouth parts.

Tick toxins introduced into the host through the saliva cause paralysis or death in domestic animals, some wildlife, and humans. Tick paralysis manifests itself as a motor paralysis that spreads from the lower limbs to the upper limbs and head region within hours. Paralysis rescinds following removal of the tick, or ticks, except in the case of *Ixodes holocyclus*, which is discussed below. Paralysis is most likely to occur when a tick embeds on the neck, especially near the base of the skull. Many different ticks can cause paralysis, but five species are notorious. These are *Dermacentor andersoni* and *Dermacentor variabilis* in North America; *Ixodes rubicundus*, *Rhipicephalus evertsi evertsi* and *Argas walkerae* in South Africa; and the Australian paralysis, or scrub tick, *I. holocyclus* in Australia. The toxin of the latter tick, known as holocyclotoxin, has been isolated, characterized and an antitoxin developed. The scrub tick is the most virulent paralysis tick in the world. Most cases of paralysis are caused by females because larvae and nymphs have much less toxin, and the adult males feed only by inserting their mouthparts into females. Removal of *I. holocyclus* does not rescind the paralysis, which must be treated by an antitoxin given intravenously.

The high vector potential of ticks is a direct result of the following characteristics: (i) Ticks are persistent blood feeders that stay attached to the host for long periods allowing ample time for the transfer of pathogens. Hard ticks feed for 5–14 days depending on the species. (ii) Ticks have great longevity that enhances the chances of acquiring and transmitting pathogens. (iii) Ticks have a high reproductive potential. Hard ticks lay a single clutch of eggs that can number over 20,000 depending on the species. (iv) Ticks have few natural enemies due to heavy body sclerotization. (v) Pathogens in ticks can persist through transovarial transmission to the next generation, and from one life stage to another through transstadial transmission. (vi) Ticks transmit pathogens through several routes. Most are transmitted through the saliva, but some *Borrelia* are transmitted through the coxal fluid. Stercoral transmission occurs through the feces and requires pathogens that can survive in the dry excrement of ticks, so this route is uncommon. However, *Coxiella burnetti* and *Rickettsia conori* are transmitted in this fashion. (vii) Some pathogens are transmitted directly from an infected tick to a non-infected tick while both are feeding on the same host. This phenomena is termed co-feeding and may be an important means of maintaining tick-borne pathogens. Anti-hemostatic, anti-inflammatory and immnuosuppresant actions of tick saliva facilitate blood-feeding and may indirectly enhance pathogen transmission. This is termed saliva-activated transmission (SAT). In some diseases, such as tick-borne encephalitis, uninfected ticks can acquire the pathogen when co-feeding with infected ticks on hosts that do not exhibit a viremia, or systematic infection. This phenomenon is known as non-viremic transmission and may be due to SAT. Bacterial pathogens may be acquired by continuing to feed at a localized site where previously infected ticks have fed.

Tick transmitted pathogens include arboviruses (arthropod-borne viruses), rickettsiae, other bacteria, and protozoans. Most tick-borne diseases are zoonoses, that is they occur in wild and or domestic animals that act as a natural reservoir of infection. Man is only an incidental host in many of these diseases. Some zoonotic diseases are transmitted within their natural reservoirs by a species of tick that does not attack man. A different tick species then transmits the disease to man. If the zoonoses includes a large wild animal reservoir with multiple vector species of ticks it becomes difficult to control.

Tick-borne arboviruses are members of three families, the Flaviviridae, the Bunyaviridae and the Reoviridae. The Flaviviridae includes the genus *Flavivirus* whose virons are spherical, about 40–50 nm in diameter with a lipoprotein envelope, and a genome that consists of a single molecule of single-stranded RNA. The Bunyaviridae includes the genus *Nairovirus* in which all species are transmitted by ticks. The *Nairovirus* are spherical in shape, 80–100 nm in diameter, with a lipid envelope that has glycoprotein projections. Their genome consists of three molecules of single-stranded RNA. The Reoviridae contain the genus *Orbivirus* which causes Colorado tick fever. This virus is icosahedral in shape, 60–80 nm in diameter, with an outer protein coat and a genome of 12 pieces of RNA. All tick-borne arboviruses replicate in intermediate vertebrate hosts as well as in the tick. The major arboviral diseases transmitted by ticks include Tick-Borne Encephalitis, Louping Ill, Omsk Hemorrhagic Fever, Kyasanur Forest Disease, Powassan Encephalitis, Crimean-Congo Hemorrhagic Fever, Nairobi Sheep Disease, Colorado Tick Fever and African Swine Fever. Other lesser known tick-borne arboviral diseases occur in birds, especially seabirds. Treatment for human arbovirus diseases is often relegated to supportive measures. Hospitalization can help especially if a high fever or other symptoms can be treated.

Tick-Borne Encephalitis (TBE) is caused by a *Flavivirus* and can affect humans, sheep, monkeys, mice and hamsters. It is transmitted by species of *Ixodes*. In Europe and Northern Asia, it is transmitted mostly by *Ixodes ricinus*, and in areas of the Far East by *I. persulcatus*. TBE can also be transmitted through fresh milk or cheese from infected goats or sheep. TBE is most common during spring and summer. The disease is maintained in nature by infections of small mammals such as rodents. Agricultural and forest workers are most at risk of infection, but urban residents that spend time in the forests and countryside are also at risk.

Two subtypes of TBE are recognized, Russian Spring-Summer encephalitis (RSSE), which is found in Siberia, the southern republics of the former Soviet Union and in north-eastern China; and Central European Encephalitis (CEE), which occurs in Russia west of the Ural mountains and Europe. RSEE is more serious than CEE. RSSE is a life-threatening disease with a mortality rate of from 8% to 54%. However, an effective vaccine exists. RSSE is characterized by high fever, headache, nausea followed by the symptoms of developing encephalitis, which include paralysis especially in the upper body regions. Paralysis may persist in some patients that have recovered. The milder European form is biphasic with a brief remission after 4–6 days of illness followed by renewed fever. Brain dysfunction and meningeal irritation are common. Mortality in the milder CEE subtype is from 1% to 5%.

Louping Ill (LI) is caused by a *Flavivirus* and is found in Great Britain where it has been known for centuries among sheepherders in Scotland and Ireland. LI infects a variety of mammals including man, and some birds, especially upland game birds. The virus is transmitted by *I. ricinus*. Transstadial, but not transovarian, transmission occurs. The disease is so named because it causes an erratic "louping" gait in sheep. The mortality in sheep is severe, often as high as 60%, and has been known to reach 100%. LI causes a severe, fatal encephalitis that often results in permanent neurologic damage in animals that recover. In humans, LI also produces an encephalitis that can be severe and even result in death. Those at risk include farmers, veterinarians, and animal husbandry workers. A vaccine for sheep exists, but sick animals are destroyed. Lambs are protected by a maternal antibody that disappears after weaning.

Omsk Hemorrhagic Fever (OHF) is caused by a *Flavivirus* and affects humans, rats, mice, muskrats and wild rodents. OHF occurs in Siberia and is transmitted by *D. reticulatus* and *I. apronophorus*. Immature *D. reticulatus* ticks bite mostly water voles, which are found in a forest-steppe habitat. The cyclic nature of the vole population can produce a huge population of ticks, many of whom are infected with the virus. Adult *D. reticulatus* ticks infect several different large mammals and humans. The tick is the reservoir, which is maintained by transovarial transmission. *I. apronophorus* does not transmit the virus to humans, but is thought to help maintain the virus in nature by feeding on many different small mammals especially voles and muskrats. Muskrats have a high incidence of infection (up to 30% of the population). Transmission of OHF to humans can occur through handling infected muskrat carcasses, or by drinking infected water contaminated by muskrats or voles. Muskrats are amplifying hosts for the disease. Hunters of muskrats are at severe risk. The disease occurs during the spring and summer seasons. OHF is characterized by hemorrhagic symptoms. Mortality is less than 5%. No vaccine is available, but some cross-protection occurs with the Tick-Borne Encephalitis vaccine.

Kyasanur Forest Disease (KFD), caused by a *Flavivirus* affects humans and monkeys. KFD occurs in the Kyasanur State Forest and a surrounding area in India where it is transmitted by *H. spinigera*. Increased human activity in the forest has increased the opportunity of this tick to attack humans. The pathogen is maintained within a given tick by the transstadial route, but is not transmitted transovarially. KFD has a sudden onset after a short incubation period (2–7 days). Symptoms include coughing, diarrhea, vomiting, a severe fever for up to 12 days and muscle pain. Mortality is 8–10%. Monkeys are very susceptible to KFD. They are viremic for days, during which time they have many ticks feeding on them. In this fashion, monkeys act as an amplifying host for the disease. Human cases of this disease are increasing. Individuals working in the forest are especially at risk, however, an effective vaccine exists.

Powassan Encephalitis (PE) is caused by a *Flavivirus*. It occurs in Canada, Russia and northeastern parts of the U.S. where it has been isolated from a variety of vertebrates and causes a sickness in humans, horses, and foxes. PE is transmitted by several species of *Ixodes*, *Dermacentor* and *Haemaphysalis*. *I. cookei* is an important vector of PE in North America. No vaccine for PE exists.

Crimean-Congo Hemorrhagic Fever (CCHF) is caused by a *Nairovirus* that is transmitted by a wide range of tick species. It was first described in ad 1100. CCHF is widely distributed throughout Europe, Asia and Africa, and is most common in arid or semiarid regions of these areas. CCHF is transmitted mostly by ticks of the genus *Hyalomma*, or by contact with blood or tissues from human patients or infected livestock. Person to person spread can occur through respiratory secretions and excreta, which can cause serious outbreaks of the disease in hospitals. In Eurasia, *Hyalomma marginatum marginatum* and *D. marginatus* are the principal vectors. The clinical disease has been found only in humans, but the virus occurs in a wide variety of mammals. CCHF is found in isolated enzootic foci throughout its range. An enzootic disease occurs in a population of animals at all times. Ground-feeding birds are important in maintaining the disease and migratory birds are important in its spread. Incubation of CCHF takes from 3 to 7 days. The disease has a sudden onset with fever, chills, photophobia and severe headache. Muscle pain occurs mostly in the legs and back. The hemorrhagic state of the disease involves bleeding from the mucous membranes and the appearance of a round red spot, which is due to intradermal hemorrhage. Mortality is from 10% to 50%. Ticks are the reservoirs of CCHF. The rate of infection in ticks is amplified by feeding on infected mammalian hosts, and by transstadial and transovarial transmission. A vaccine exists in Russia and parts of Eastern Europe. Controlling this disease is very difficult due to its widespread distribution and the large number of different tick species involved.

Nairobi Sheep Disease (NSD), also known as Ganjam virus disease, is caused by a *Nairovirus*. NSD is found in sheep, goats, and wild ruminants in East Africa. The principle tick vector is *R. appendiculatus*. There is no evidence for a wildlife reservoir. Onset of the disease is sudden with a dramatic rise in temperature as high as 41°C. A nasal discharge and diarrhea is common, along with abdominal pain. Mortality is high. Humans exposed to the virus develop an antibody, but no symptoms, with the exception of one case. Treatment of NSD involves destroying sick animals. In areas of enzootic NSD, sheep are protected by a maternal antibody. Epizootics, diseases that spread rapidly through an animal population, are related to large increases in the vector populations and require the use of acaricides.

Colorado Tick Fever (CTF) is caused by an *Orbivirus*, and is found in the Western U.S. where it infects humans and many other mammals. The principle vector to humans is *Dermacentor andersoni*. Transovarian transmission does not occur. The disease is enzootic in wild rodents. Wherever the principle vector occurs with infected reservoirs of wild rodents and humans, local outbreaks will occur. CTF has a short incubation period in humans of 1–4 days. A biphasic fever occurs in about 50% of the cases. Symptoms include chills, nausea, sore throat and retroorbital pain. Sometimes meningitis occurs, and leukopenia is common. However, mortality is low, less than 0.2%. The peak incidence of CTF occurs from April to July. Treatment is supportive and no vaccine exists. Prevention of tick infestation in focal areas of the disease is the best method of control.

African Swine Fever (ASF) occurs in Europe, Africa, South America and the Caribbean. This icosahedral-shaped virus is about 200 nm in diameter with a lipoprotein coat and a single molecule of double-stranded DNA. It is the only known DNA virus to be transmitted by an arthropod. Originally, it was placed in the family Iridoviridae, but is now unassigned to any family. Wild swine, including warthogs, harbor the virus. Domestic pigs are at risk with the mortality being as high as 100% in herds. Several species of *Ornithodoros* have been shown to be vector-competent in the laboratory, but the only natural vectors are

O. erraticus and *O. m. porcinus*. Transstadial, transovarial and sexual transmission of ASF has been shown to exist in *O. moubata*. Many of the vector-competent species exist outside the known distribution of ASF suggesting that the disease has a good possibility of spreading. ASF is characterized by sporadic epizootics. Ticks are not the only way of spreading the disease, direct contact with animals is also a factor. Three forms of the disease are known in domestic pigs – acute ASF, subacute ASF and chronic ASF. Acute ASF causes a high fever (up to 41°C) about 3 days following infection. Then the fever subsides and the animal dies. In the subacute form of ASF, the fever follows an irregular course for 3–4 weeks, then the sick pigs either die, or recover and become carriers of the virus. In chronic ASF, the main symptoms are stunted growth and emaciation. In chronic ASF, sick pigs often remain carriers and can live for a long time. They eventually die from a secondary illness.

The *Rickettsia* are bacteria that are obligate, intracellular parasites of vertebrates. Unlike viruses, they have both DNA, RNA and bacterial cell walls. During evolution, the *Rickettsia* have lost several enzymes and cell components necessary to live outside the cell. Some 15 genera of *Rickettsia* are recognized, seven of which are transmitted by ticks: *Rickettsia*, *Coxiella*, *Ehrlichia*, *Cowdria*, *Anaplasma*, *Aegyptianella*, and *Haemobartonella*.

Rickettsia are divided into three groups, each containing serologically related species. Two groups, the Spotted Fever Group (SFG), and the Typhus Group (TG) are transmitted by ticks. The third group, the Scrub Typhus Group, is transmitted by a mite. The only species of TG transmitted by ticks is *R. canada*, which was first isolated from rabbit ticks in Ontario. *R. canada* has not yet been shown to cause a human disease despite a single case of possible human infection where the patient presented with Rocky Mountain Fever-like symptoms. The SFG is made up of the following species: *R. rickettsii*, *R. montana*, *R. belii*, *R. rhipicephali*, *R. parkeri*, *R. conorii*, *R. australis*, *R. sibirica*, *R. slovaca*, *R. helvetica*, and *R. akari*. In general, species of the SFG cause severe diseases characterized by headache, chills and fever. These rickettsiae grow mainly in the cytoplasm of the host's cells, but can also grow in the nucleus. Infected host cells are seldom killed by SFG rickettsiae. They have an optimal growth temperature of 32–34°C. They do not cause hemolysis. The associated rash in humans is the result of damage to capillaries that causes blood to leak out. SFG rickettsia can cause collapse of the cardiovascular system.

Several SFG rickettsiae are not associated with human disease. *Rickettsia parkeri* occurs in *A. maculatum* and *Amblyomma americanum*, from Texas through Mississippi and Georgia. The principle hosts are domestic animals. *Rickettsia montana* is found in *D. andersoni* and *D. variabilis* in at least 13 states in the U.S. and is maintained naturally by small mammals. *Rickettsia rhipicephali* is found in *R. sanguineus*, *D. andersoni*, *D. variabilis*, and *D. occidentalis* in the southeastern U.S., and is maintained by small mammals. It is not pathogenic in dogs. *Rickettsia belii* is found in *D. andersoni*, *D. variabilis*, *D. occidentalis*, *D. albipictus*, *H. leporispalustris*, *A. cooleyi*, and *O. concanensis* in eight states in the U.S. Again, it is maintained in nature by small mammals.

A species of tick can harbor more than one serotype of *Rickettsia*. However, experimental evidence shows that a serotype present in a given tick interferes with the establishment of another serotype of *Rickettsia*. This phenomena is termed rickettsial interference. Ticks are considered the reservoir of infection in rickettsial diseases. This is due to the fact that infected animals remain rickettsemic for just several days and horizontal transmission of rickettsiae from an infected animal to a feeding tick is not as efficient as transstadial and transovarial transmission. Venereal transmission of rickettsiae in ticks during mating does not occur.

Treatment of rickettesial diseases is greatly dependent on the proper early diagnosis of the disease. Several effective antibiotics exist including tetracyclines, doxycyclines, chloramphenical, chloromycetin and cotrimexazol.

The most severe disease caused by SFG rickettsiae is Rocky Mountain Spotted fever (RMSF) caused by *R. rickettsii*. This disease is covered in a separate entry. The other human diseases caused by SFG rickettsiae are discussed below.

Boutonneuse Fever (BF) (=Mediterranean spotted fever, Fievre Boutonneuse, Marseilles fever, Kenya tick typhus, South African tick bite fever, Indian tick typhus) is caused by *Rickettsia conorii*, which is closely related to *R. rickettsii*. BF is widely distributed in Southern Europe, Africa, Western and Central Asia and India. It can be transmitted by many species of hard ticks. The principle vector in the Mediterranean is *R. sanguineus*, while in southern Africa, *R. evertsi*, *A. hebraeum*, *H. leachi* and *R. sanguineus* transmit the disease. In India, *I. ricinus*, *H. leachi* and *R. sanguineus* are vectors. BF is maintained in nature by a wide variety of smaller mammals. It is principally a seasonal disease. Endemic areas exist in Israel and throughout Africa. The disease is characterized by chills, fever, lymphadenitis, headaches and joint and muscle aches following a 5- to 7-day incubation period. Fever can reach 40°C. A distinctive ulcer, known as a tache noire, is covered with a black crust and appears at the site of the tick bite. Untreated cases recover, but some virulent strains can result in death. The pathology is similar to RMSF, but milder. Vaccines are not available. Control of ticks on dogs is the most effective method of preventing the disease.

North Asian Tick Typhus (NATT), is caused by *Rickettsia siberia*, and is transmitted by species of *Dermacentor*, *Hyalomma* and *Haemaphysalis*. The most common are *D. marginatus*, *D. silvarum*, *D. reticulatus*, *D. nuttalli*, *Hy. asiaticum*, *Hy. japonicum*, *H. punctata* and *H. concina*. NATT occurs from Siberia to Mongolia, and from Central Asia to Eastern Europe. Natural foci of this diseases exist in populations of small mammals. Ticks can harbor *R. siberia* for long periods of time. The pathogen is moved through the tick's life cycle by transstadial and transovarial transmission. In the former Soviet Union, NATT most commonly occurs in farm workers. It occurs from spring to fall. After an incubation period that lasts about a week, the disease manifests as chills and a fever that becomes intermittent after about a week. A small lesion may develop at the tick bite. A rash appears on the extremities and spreads to the trunk.

Queensland Tick Typhus (QTT) is caused by *Rickettsia australis* and transmitted by *I. holocyclus*, and possibly other species of this genus. The disease occurs in Queensland, Australia, mostly in a savanna habitat with intermittent rain forest. A large population of rodents and marsupials is necessary to support the tick population. QTT is a mild disease. The incubation period varies from a few days to over a week. QTT manifests as a general malaise, headache and a mild fever pattern that is often remittent. The tick bite site shows an eschar, a lesion similar to that of the tache noire seen in Boutenneuse fever. Nearby lymph nodes are enlarged and painful. A variable rash appears.

Q-Fever (QF), also known as nine mile fever or the Balkan grippe, is caused by the rickettsiae *Coxiella burnetii*, and is transmitted by many species of hard and soft ticks. The disease was first recognized in Australia in 1936, where the Q in Q-fever came from the word "Query." The disease is world wide in distribution, except in Antarctica. The pathogen is found in small mammals, reptiles, birds and domestic animals. *Rickettsia* are shed in the feces of infected animals. Unlike other members of the *Rickettsia*, *C. burnetii* can survive long period outside the host cells. It is believed to be able to survive up to 6 years in tick feces. This hardiness may be due to the presence of a spore-like cell in its life cycle. *Coxiella burnetii* is only secondarily transmitted by ticks. Most commonly, it is transmitted through airborne transmission, consumption of infected milk, handling of contaminated wool or hides, infected animal feces, animal bedding and contaminated clothing. The most susceptible people are agriculture and laboratory workers where sheep and goats are used for scientific experiments. The pathogen can enter the body through abrasions in the skin, inhalation in the lungs, mucous membranes, the gastrointestinal tract and possibly placental transfer. The disease has an incubation period of about 20 days. It starts with a sudden fever of 38–40°C which may last for up to 2 weeks and can have a biphasic pattern. Headache, diarrhea, sore throat, sweats and chills also occur. A rash is usually absent, but when it occurs, is found on the trunk and shoulders. Pneumonia can occur in some areas with acute Q-fever. Mortality rates usually are less than 1%, and a vaccine exists.

Ehrlichia are obligate, intracellular parasites of white blood cells, especially monocytes. They cause ehrlichiosis, a serious and sometimes fatal blood disease in animals and humans. Canine ehrlichiosis, caused by *Ehrlichia canis*, and transmitted by *R. sanguineus*, is found world wide. Following an incubation period of about 2 weeks, the infected dog has a fever that can reach 40.5°C, edema, anorexia, conjunctivitis and pancytopenia. Dogs lose weight. In most breeds, the disease has a mild form, but in German shepherds, it may produce a severe hemorrhagic condition known as tropical canine pancytopenia. Ehrlichiosis can persist in dogs for years without clinical symptoms. *E. ewingii* causes canine granulocytic ehrlichiosis, a similar but less severe disease. *E. (=Cytoecetes) phagocytophila*, is transmitted to cattle and to sheep by *I. ricinus*. The disease, known as tickborne fever, manifests itself in weight loss, reduced milk production and sometimes abortion. It occurs in Ireland, Great Britain and is widely distributed in Europe. This disease can make young animals, especially lambs, susceptible to other more serious diseases. *E. chaffeensis* causes human ehrlichiosis. The pathogen is believed to be transmitted by *Amblyomma americanum* and *D. variabilis*, but the vector has not been proven. The disease in man is similar to RMSF. However, in human ehrlichiosis, a rash occurs in less than a 33% of patients, and a rash on the palms and feet occurs in less than 5% of patients, which differs from the rash found in RMSF. *E. equi*, which is transmitted by *I. pacificus*, causes equine granulocytic ehrlichiosis in horses and a wide variety of other mammals in California. Several *Ehrlichia* have unknown vectors, but all are assumed to be transmitted by ticks. Examples are *E. risticii*, which causes equine monocytic ehrlichiosis (=Potomac horse fever); *E. bovis*, from cattle; *E. platys*, which infects canine blood platelets; and *E. senetsu*, which causes ehrlichiosis in humans in Japan.

Two important livestock diseases are heartwater, which is caused by *Cowdria ruminantium*, and anaplasmosis, which is caused by three species of *Anaplasma*. Two other species of rickettsiae are transmitted by ticks. *Aegyptianella pullorumn* is transmitted by species of *Argas*, especially *A. persicus*, and causes a disease of fowl that can be severe in young chickens. *Haemobartonella canis*, transmitted by *R. sanguineus*, is found in the red blood cells of dogs, but is not associated with any pathology. *H. canis* is widely distributed throughout the world. It is transmitted by *R. sanguineus*.

Ticks transmit pathogens from four genera of bacteria other than *Rickettsia*. These are *Borrelia*, *Francisella*, *Klebsiella* and *Staphylococcus*. *Borrelia* are helically coiled, Gram-negative, motile spirochetes that cause Lyme disease, several types of relapsing fever, epizootic bovine abortion, bovine borreliosis and fowl (avian) spirochetosis. *Borrelia* are similar to the spirochetes that cause syphilis and Leptospirosis. Lyme disease is covered in a separate entry.

Several species of *Borrelia* cause tick borne relapsing fever, a disease known since ancient times. Each of these species of *Borrelia* is transmitted by a given species of soft tick. Some species of *Borrelia* are transmitted in the coxal fluid of their vectors, but other vector species do not produce coxal fluid until they leave the host and, therefore, transmission must follow a different route. Some vectors, such as *O. hermsi* and *O. turicata*, transmit the spirochetes in their saliva. In Africa south of the Sahara, *B. duttoni* is transmitted by *Ornithodoros moubata*. In Spain, Portugal and northern Africa exclusive of Egypt, *B. hispanica* is transmitted by *O. erraticus* and causes Hispano-African relapsing fever. In Morocco and Libya, *B. crocidurae* is transmitted by *O. erraticus*, and causes North African relapsing fever. *O. erraticus* also transmits *B. merionesi* in Egypt and Senegal, *B. microti* in Kenya and Turkey, and *B. dipodilli* in Iran. All cause relapsing fever. *B. persica* is transmitted by *O. tholozani*, from China through India and Iran to areas of the former USSR into Egypt. It causes Asiatic-African relapsing fever. *B. caucasica* is transmitted by *O. verrucosus* from the Caucasus to Iraq, and causes Caucasian relapsing fever. *B. latyschewii* is transmitted by *O. tartakovskyi* in Iran and central Asia, and causes relapsing fever. American tickborne relapsing fever is caused by at least six different species of *Borrelia*: *B. hermsii* is transmitted by *O. hermsi* in the Western U.S.; *B. turicatae* is transmitted by *O. turicata* in the southwestern U.S.; *B. parkeri* is transmitted by *O. parkeri* in the western U.S.; *B. mazzotti* is transmitted by *O. talaje* in the southern U.S.; and *B. venezuelensis* is transmitted by *O. rudis* in Central and South America. Relapsing fevers are zoonoses that involve the circulation of the *Borrelia* between reservoir hosts and vector species of *Ornithodoros*. With one exception, the primary reservoir hosts of all species of *Borrelia* that cause tick borne relapsing fevers are species of rodents, chipmunks and squirrels. The exception is *B. duttoni*, which has humans as its primary reservoir host. This form of relapsing fever is endemic in Kenya and other East African countries because the vector *O. moubata* has adapted to human dwellings, especially the huts made of mud or straw. Studies on the DNA of the relapsing fever *Borrelia* suggest that all species are closely related.

All tick-borne relapsing fevers have similar clinical features and pathology. Relapsing fever spirochetes migrate rapidly from the bite site into the hosts circulatory system. An incubation period lasts from 2 to 18 days. Symptoms appear abruptly and include headache, fatigue, chills and fever that can be as high as 41°C. Subsequent periods of fever are relapses. The first attack lasts about 3 days, followed by another after 7 days, and one or more attacks after that. The virulence of the disease abates with secondary relapses, which tend to be shorter and milder. Relapses are probably due to the pathogen's change in its antigenicity thus evading the host's immune system. Relapsing fevers are treated with antibiotics. Because all *Ornithodoros* that transmit relapsing fever *Borrelia* are nidicolous, humans are incidental hosts and are not involved in the zoonotic cycle. Relapsing fevers are enzootic and occur in humans as scattered local outbreaks.

Epizootic bovine abortion is caused by *B. coriacease*, and is transmitted by *O. coriaceus*. It is a serious problem in the western U.S. *Bovine borreliosis*, caused by *B. theleri*, is transmitted by the *Boophilis* species and *R. evertsi*. Fowl or avian spirochetosis is caused by *B. anserine*, and is transmitted by *A. persicus*, *A. reflexus*, and *A. miniatus*. All are species of the *Argas* subgenus *Persicargas*. The disease is pathogenic for most domestic fowl, but less so for guinea fowl and pigeons. It occurs world wide mostly as an endemic disease.

Francisella tularensis causes tularemia, which has a worldwide distribution. The most common mammals with the disease are cottontail rabbits, muskrats and rodents. Many species of ticks can transmit the disease. The pathogen undergoes transovarial transmission in ticks. In the U.S., the disease is most commonly associated with rabbit hunting. Transmission can occur in three ways: through the skin, through inhalation of the pathogen and through contaminated water or meat. Each method of transmission produces a distinct form of the disease. Entry of the pathogen through the skin from the bite of a tick results in the ulceroglandular form of tularemia. Following a 2-day incubation period, the patient has a fever of up to 41°C, accompanied by chills and shaking. The fever plus enlarged lymph nodes (buboes) and severe headache can last up to a month in untreated patients. A vaccine exists, but must be administered every 3 years and is not always protective. Streptomycin is effective. *Klebsiella paralytica*, transmitted by *D. albipictus*, causes moose disease in North America. The disease is of limited importance. *Staphylococcus aureus*, transmitted by *I. ricinus*, causes tick pyaemia in sheep in Britain. This disease is not widespread or very pathogenic, and ticks may not be necessary for its transmission.

The protozoan class Piroplasmea contains the genera *Babesia* and *Theileria*. All of whose species are transmitted by ticks. These are parasites of vertebrate blood cells and cause piroplasmosis such as human babesiosis and east coast fever in cattle.

Control of Ticks

The high reproductive rate, host variability, wide dispersion, secretive habits and longevity of many ticks make control difficult. Strategies for tick control involve the reduction of transmitted diseases and the reduction of numbers of ticks on animals to an acceptable economic level. Surveillance of ticks in a given area, which involves determining the species, their population density and any pathogens present, is an important part of any control strategy. Control measures have included one or more of the following: use of pesticides, vaccination of susceptible animals, environmental management, and protection of individual humans. The latter, coupled with education about the species of tick present and its life cycle, is probably the most effective measure to prevent transmission of tick-borne diseases to humans. Biological control, which has proven valuable in controlling many insect pests, has so far not been of much use in controlling ticks. Some parasitic wasps have been released in an attempt to control *D. variabilis* in the northeastern U.S., but this has not proven effective. Oxpeckers are natural agents of biological control and, in Africa, consume large numbers of ticks from ungulates. Likewise, fire ants will eat ticks. How these natural enemies can be used by man to control ticks is unclear.

Pesticides

Pesticides (=acaricides) are applied by spraying a given area, or more commonly, by dipping or spraying individual domestic animals. Other methods of application use a systemic acaricide, or involve controlled delivery systems such as collars impregnated with a slow releasing acaricide. The use of acaricide impregnated cotton fibers that are taken by wild mice to their nests has been successful in reducing populations of *Ixodes scapularis*; or the use of baited stations that dispense the acaricide to the animal when it takes food from the device has been successful in controlling tick populations on domestic livestock in some regions and on deer in the southwestern U.S. The development of resistance to acaricides in recent years and their adverse environmental effects have prompted the use of other means such as vaccines and environmental management to control ticks. Other strategies use pheromones or CO_2 to attract ticks to stations containing pesticides.

Vaccines

Several commercial vaccines against ticks now exist. These all take advantage of the fact that host IgG in the midgut of the tick is immunologically competent, and is transported through the midgut as such into the hemolymph of the tick. The most effective vaccines use concealed antigens. These are antigens from the tick that the host has never been exposed to before being vaccinated. Concealed antigens usually require booster shots of the vaccine.

Environmental Management

Ticks need a suitable habitat and suitable hosts for an abundant population to develop. Habitat modification involves controlled burning, use of herbicides, mowing to destroy vegetation, and plastering to seal cracks and crevices in human dwellings. The latter is an effective control on some species of nidicolous ticks such as *Ornithodoros moubata*. Indigenous herdsman in Africa have used controlled burning for centuries to limit ticks that attack cattle. In some cases, removal of vegetative litter and opening up the ground to intense sunlight by altering the forest canopy has been effective. Reducing or denying hosts is most effective when the target area is isolated and has little possibility of their reintroduction. If a wildlife host exists, control of ticks in an area is very difficult, although fencing has been used with some success to exclude large wildlife hosts such as the Cervidae. It is possible to keep domestic animals out of tick infested areas by rotating pastures.

Protecting Humans

Protecting humans against ticks involves prevention of infestation, and proper removal of attached ticks. Within the urban environment, measures to prevent infestation include strategies to kill and repel ticks inside the home and on companion animals. In the home, foggers and sprays for the house and yard are important. Topical repellants and sprays, anti-tick collars and shampoos are effective means of killing and repelling ticks on dogs and other companion animals. Measures that prevent infestation outside the urban environment involve avoidance of heavily infested areas, especially during high tick activity. If this is not possible, then tucking trousers into exposed socks using some sticky tape and the use of repellents to clothes and or exposed skin (follow the directions on the label). Complete inspection of one's person immediately after leaving the area is essential. Ticks prefer the area around the waist, the axillary region, the genital and perianal region, the neck and the head. It is important to know how to remove ticks because improper removal can result in secondary infections and, in some cases, the transmission of pathogens from the tick to the person removing the tick. Attached ticks should be removed by placing tweezers between the tick and the skin of the host and pulling slowly and gently up until the tick is removed. Once removed, the tick should be examined to make certain that the mouthparts are not still in the host. Once removed, the tick should be saved. Preserve the tick in a container with 70% ethanol or rubbing alcohol. Preserved in this manner, a physician or scientist can identify the tick, and also determine if it is capable of transmitting a disease. Following removal, the bite area should be cleaned, an antiseptic applied and the area covered with a small dressing.

Ticks as Vectors of Pathogens

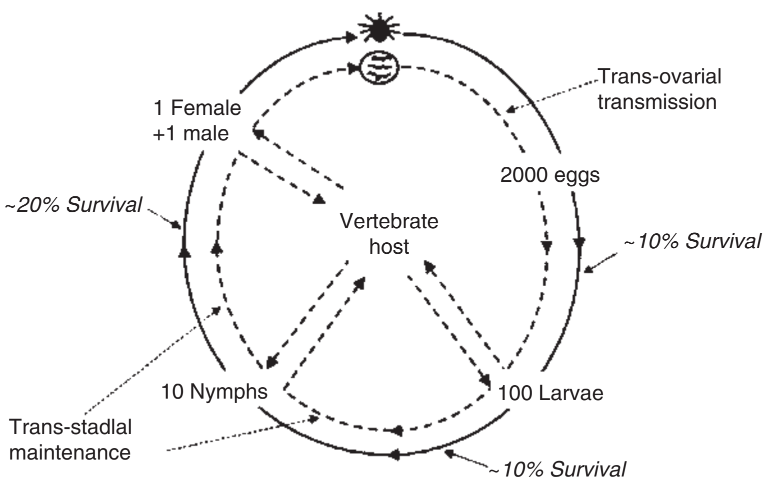
SARAH RANDOLPH
University of Oxford, Oxford, United Kingdom

Worldwide, ticks transmit an exceptional number and diversity of micro-parasites (viruses, bacteria, rickettsia, protozoan parasites, even filarial worms) that cause disease in humans and their livestock. In temperate regions, ticks surpass insects in importance as vectors, and a number of "new" tick-borne pathogens recently have been recognized as causing human disease in the northern hemisphere. These include the spirochete bacteria (*Borrelia burgdorferi* s.l.) that cause Lyme disease and the rickettsia *Erhlichia* spp. In reality, however, the burden of these infections pales into insignificance beside the medical and veterinary impact of ticks in the tropics. Added to the ticks' role as vectors, the direct damage they do as parasites is a major brake on livestock productivity. Together, this imposes huge economic burdens where they can least be afforded.

Like most true vectors, ticks are blood feeders, for which they are superbly designed; they cut through the host's skin with a pair of toothed chelicerae and suck up body fluids from the sub-dermal lesion through a hypostome. Yet as vectors, ticks appear to rather poorly designed, lacking the high mobility and frequent feeding habits characteristic of most insect vectors. Ticks have no wings, nor do they jump. Nidiculous (nest-dwelling) Argasid (soft) ticks live in semi-permanent, or seasonally repeated, close association with their hosts. Most Ixodid (hard) ticks are not nidiculous; typically they climb to some vantage point on the vegetation from where they contact a passing host, a procedure that exposes them to considerable moisture stress. Intermittently, they must return to the ground where they can absorb water from the moist air, but this is energetically expensive.

Ticks minimize the costs of achieving contact with their host by taking very few, very large meals. This is taken to extreme by Ixodid ticks, which feed once per life stage, as larvae, nymphs and adults, and reproduce once after the adult meal. Most ticks drop to the ground after each meal, where they develop to the next stage. Some species take both the larval and nymphal meals from the same host, and *Boophilus* ticks, worldwide vectors of cattle babesias, take all three meals from the same individual host before dropping back to the ground. Each meal is enormous; even after concentrating the blood by returning 30–70% of the imbibed fluid to the host via salivary secretions, on average immature tick stages increase their body weight by about one order of magnitude, and adult females by two orders of magnitude. To accommodate such a large volume of blood, ticks secrete new endocuticle during a long phase of very slow blood intake, before engorging rapidly toward the end of the meal that typically takes from about 4 (immature stages) to 14 (adult females) days to complete. This prolonged feeding itself incurs a cost as hosts mount strong hemostatic and immunological defenses; in response, tick saliva contains an impressive cocktail of pharmacologically active components. At the same time, the large volume of saliva can transport large numbers of infective parasites, whose infectivity is enhanced by their entering the host at an immuno-modulated site (Fig. 59).

To exploit as a vector an hematophage that feeds only once per life stage, a parasite must survive trans-stadially. It is acquired from an infected host by a tick of one stage, maintained through the tick's development and moulting processes, and transmitted to a new host by the following tick stage.



Ticks as Vectors of Pathogens, Figure 59 ***Ixodes ricinus*** **life cycle with typical reproduction and mortality rates and pathogen transmission cycle.**

The parasite's transmission cycles are thus determined by the tick's stage-specific host relationships (larvae that acquire infections from one host species may later feed as nymphs on hosts of a different species) and rates of development, survival and reproduction. An infection in one host acquired by many feeding larvae may be retained and transmitted to several new hosts by individuals of one or both of the succeeding stages, nymphs and adults. This achieves horizontal amplification between vertebrate hosts, but as only about 10% of ticks survive from one stage to the next, this route is more limited than it may at first appear. On the other hand, those parasites that are passed trans-ovarially, from females via the eggs to larvae of the next generation, can exploit the tick's impressive fecundity (several thousand eggs) to achieve considerable potential for vertical amplification of prevalence in addition to any horizontal amplification. Even though trans-ovarial transmission is usually inefficient, with less than 20% of an infected tick's larval progeny being infected, nevertheless the abundance of larvae (typically 100 times more numerous than adult ticks and 10 times more than nymphs) can make this route quantitatively significant.

Due to these biological peculiarities of ticks, the quantitative framework (i.e., model) for estimating the transmission potential of tick-borne pathogens differs from that for insect-borne pathogens. The tick's feeding pattern makes the concept of an individual's daily biting rate inappropriate, but, most importantly, it introduces a long delay between acquisition and transmission of an infection. The off-host inter-stadial period, comprising both post-engorgement development and questing for the next host, is functionally equivalent to a very long extrinsic incubation period as the tick is not infective until it is ready to feed again. This period is specific to the vector rather than to the transmitted parasite, and may last from one month to more than a year depending on the tick stage, the temperature-dependent rate of development and whether diapause occurs.

Ticks are renowned for their longevity. Engorged ticks must survive the long, temperature-dependent inter-stadial development periods, and unfed ticks must survive the long period while they quest for hosts, which may not always be available just when and where the tick needs them. Unlike insect vectors, however, a tick's vectorial capacity does not increase proportionally with a prolonged life-span. This is because however long an individual tick survives, it does not feed on and infect more than one host per life stage. Although tick longevity (which may exceed that of smaller host species such as rodents) ensures an enduring reservoir of infection, it slows the pace of transmission, because long survival as any one life stage increases the delay between acquisition and transmission of infection.

An important limiting factor on the transmission potential of any parasite is the period of host infectivity, determined by rates of host mortality and recovery from infection. If the transmitted parasites are highly virulent, high daily mortality rates of infected hosts may significantly reduce transmission potential. If a host dies prematurely, the feeding ticks will not complete their blood meals. The risk of killing their hosts is avoided by those tick-borne viruses that limit their infection to a non-lethal, non-systemic form (i.e., limited to certain parts of the host's body) that is, nevertheless, highly transmissible to ticks over short periods of time. The quantitative impact of this transmission route arises from the large numbers of infectible ticks that co-feed with an infected tick at sites of localized infection. This is a natural feature of tick-host interactions, as prolonged meals taken on certain preferred parts of the host's body result in very large aggregations of ticks feeding close together on some host individuals. The immuno-modulatory effects of saliva secreted by so many co-feeding ticks further facilitate this transmission route. Although first recognized for tick-borne viruses, this route has now been identified for *B. burgdorferi* s.l., and shown to be sufficient to allow sheep to support natural cycles of Lyme borreliosis in the absence of other, systemically infected hosts.

Whereas insect vectors are viewed as the bridge between reservoir vertebrate hosts, the identity of reservoir host and bridge is reversed for the many parasites that survive in their long-lived tick vectors rather than in vertebrates. A multitude of specific parasite-vector-host interactions have clearly evolved to allow many micro-parasites to exploit the transmission potential offered by ticks, even though ticks are not endowed with the features we normally associate with insect vectors.

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae)

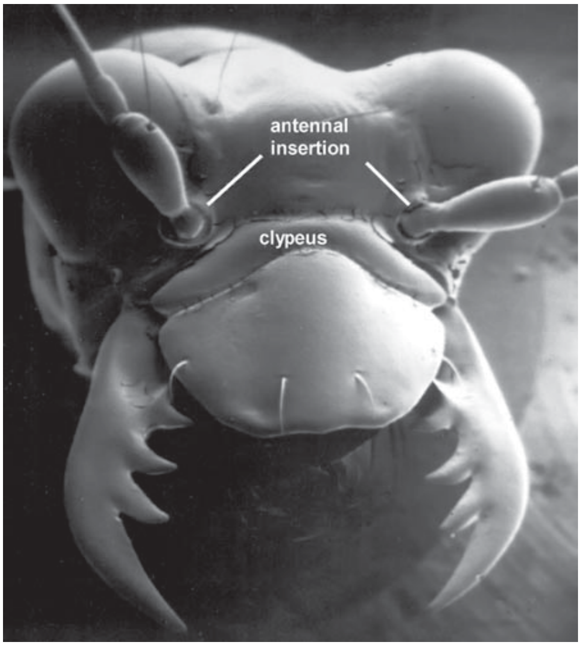
PAUL M. CHOATE
University of Florida, Gainesville, FL, USA

Tiger beetles are very active, predaceous beetles. Often brilliantly colored, they derive their common name from the fierce appearance of their large mandibles and protruding eyes. Their popularity among scientists and the general public stems from their relatively large size, accessibility for observation and study, available literature for many parts of the world, and a reasonably stable classification system. An entire journal, CICINDELA, is devoted to this group of beetles. Many web sites are devoted to various aspects of these insects, and many colorful photographs have been posted for internet viewing. Conservationists are using species of tiger beetles as bio-indicators, and more than a few species are now included on endangered species lists.

Taxonomy

Most modern taxonomists believe that tiger beetles should be considered a subfamily of the beetle family Carabidae (ground beetles). Historically they have been considered a family (Cicindelidae) separate from other ground beetles, due largely to their easily recognizable features and appeal with collectors. Many workers have now accepted the close relationship of this group to the ground beetle subfamily Carabinae. This is in agreement with many larval and adult structural characters. Throughout the history of the classification of the group, this close association has been maintained. It is more a matter of personal opinion whether this group should or shouldn't be recognized as a separate family. As there are no set rules for the determination of family rank, their status remains a matter of opinion pending further cladistic analyses (Fig. 60).

Tiger beetles are usually placed in the family Cicindelidae Latreille, 1804, or as a subfamily of the ground beetles, as Cicindelinae. Historically,



Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 60 **Head of *Cicindela* illustrating characters used to separate tiger beetles from other ground beetles.**

the following families were also proposed to incorporate new taxa (currently considered tribes): Collyridae Hope, 1838; Ctenostomidae Castelnau, 1835; Mantichoridae Castelnau, 1835; and Megacephalidae Castelnau, 1835.

Tiger beetle suprageneric classification is reasonably stable (tribes). Generic classification is very unstable, however, due primarily to the 1954 splitting of *Cicindela* into many genera, based solely on male genitalia characteristics. Thus, many genera are not readily identifiable. Species definition within each genus is oftentimes also problematic. There are a great many subspecies and color variants, most of which are named. Their status and synonymy is confusing. Much work must be done before all species can be properly understood. However, in spite of the complexity of their classification, many species groups and regional faunas have been sufficiently studied so that now it is possible to place names on most forms (Fig. 61). As for generic identification, there is no modern identification key that incorporates all of the currently accepted genera. There is presently only Willis' 1969 translation of Horn's outdated key to the world genera of tiger beetles, which does not reflect modern supraspecific classification.

In 2002, K. Werner published the only complete world checklist of tiger beetles. His classification scheme is reproduced here. Tiger beetles are divided into two subfamilies, Collyrinae and Cicindelinae. Subfamily Collyrinae is divided into two tribes, Ctenostomini with two genera and Collyrini with six genera. The subfamily Cicindelinae is divided into three tribes, Manticorini (two genera, African only), Megacephalini (nine genera), and Cicindelini with many ill-defined genera resulting from the splitting of *Cicindela*. The approximate geographical distribution for many genera is given here. Genera are listed in phylogenetic order (related genera close together) according to J. Wiesner's 1992 checklist, along with their approximate world distribution.

(*genus treated as a subgenus of *Cicindela* by many authors)

Description

Most species have conspicuous eyes, long legs, and frequently display brilliant colors, a characteristic shape, rapid locomotion, and nervous behavior. The body is elongate or round, with a large head and prominent eyes. Their size ranges from 6 mm to over 70 mm (*Manticora latipennis* – South Africa) in length (Fig. 62). Their color often includes iridescent markings, though some genera are uniformly brown or black (*Omus*, *Amblycheila*, *Mantica*, *Manticora*). Body hair is usually sparse, though sometimes with long, stout setae, especially on legs and mouthparts.

The head is variously shaped, prominent, but not elongate. The antennae are filiform, long and slender, with eleven segments (Fig. 63). The mandibles are stout, toothed, sometimes very large and prominent, much larger than the head, and other mouthparts also are large (Fig. 64). The eyes vary from very small to very large and prominent.

The pronotum is variously shaped, but is narrower than the elytra, usually cylindrical, and without lateral margins or (rarely) with lateral margins. The legs are long and slender, and

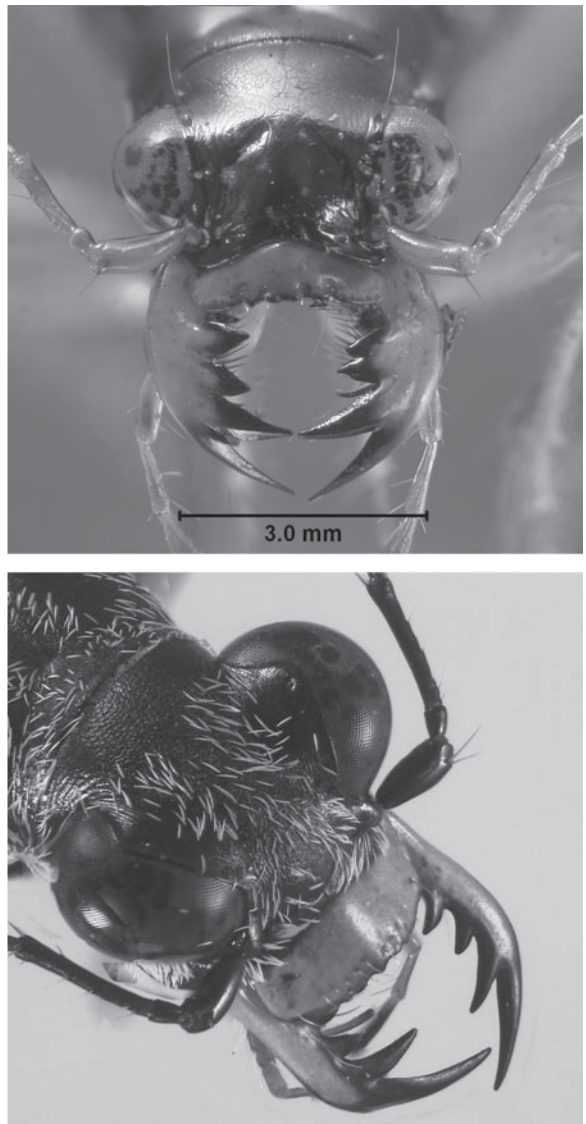
Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 63 **Head of male *Manticora latipennis*.**



Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 64 **Face of adult tiger beetles showing prominent toothed mandibles: (*above*) *Megacephala carolina*; (*below*) *Cicindela marginata*.**

well suited for running. The tarsal segment formula is 5–5–5. Tiger beetles display typical carabid-type wings; the elytra cover the abdomen, and sometimes are connate, rounded behind, and sometimes possess lateral margins. The wings may be present or absent.

The abdomen of tiger beetles is sometimes narrow, with elytra covering the sides, with four to six visible ventral sternites. Male genitalia are highly modified, carabid-like tri-lobed parameres with a separate *pars basalis* (unlike that found in other ground beetles) entirely separate from the base of the penis and forming a lateral connection between the parameres at a mid-point. Larvae are distinguished by two or three pairs of hooks present on the tergum (top) of the fifth abdominal segment (Fig. 65).

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 65 **Tiger beetle larva.**

Members of Cicindelinae are separated from other Carabidae by a combination of the following characters: clypeus laterally extending beyond antennal insertion, both spurs of protibiae apical, and larvae with dorsal hooks on fifth abdominal tergite (dorsal plate). Consistent treatment of the families of beetles requires that these beetles be placed within the rest of the ground beetles.

Species Numbers and Distribution

There are approximately 2,100 described species found in all regions of the world except Hawaii, Antarctica, Maldives Islands off the southern tip of India, and Tasmania (Table 12). They occur at elevations from −60 m to over 4,000 m. The Indian subcontinent is home to the largest number of species of tiger beetles.

Fossil Records

There are very few tiger beetle fossil records. Some published records are suspect; their identity may not be correct, and there is even evidence that more than one record may be a fraud. The oldest known tiger beetle fossil (*Oxycheilopsis cretacicus* Cassola and Werner) was described in 2003 from the Santana Formation of Nova Olinda, Brazil, Mesozoic formation, dating from the Lower Cretaceous, ca. 120 million years ago. Other fossil records include Oligocene Baltic Amber, Quaternary from USSR and Trinidad, Pleistocene (California, Minnesota, and Washington, USA) United Kingdom (Europe), and Ontario, Canada.

Reproduction

Males visually locate potential mates. It is not uncommon to see males attempt to mount other males, as well as other species trying to mate. Frequent encounters between conspecific

males result in brief wrestling/aggressive behavior. Once a male is successful at mating, he will frequently be seen riding on the back of a female after mating has occurred. This is called mate guarding, and this behavior is believed to be used to prevent other males from mating the same female. There also are morphological differences between species that act as interspecific barriers. A mandible coupling sulcus occurs in many species. A combination of male mandible shape and thoracic sulcus on females is believed to be a selection mechanism to prevent interspecific breeding. The mandible of conspecific males fits into the sulcus on the female. Males of other species have mandibles that are not fitted for female sulci (Fig. 66).

Karyology

Karyotypes are known for fewer than 100 species of tiger beetles, which are among the organisms with two to four multiple X sex chromosomes. These multiple X chromosomes are unique among insects because they do not form chiasmata, crossover points which allow recombination during meiosis. Another characteristic of male chromosomes is that they do not align in parallel during meiosis, but rather form a conspicuous sex particle, chromosomes linked at their ends, forming a circle.

Development

Tiger beetles undergo complete metamorphosis, passing through the egg, larval, and pupal stages before emerging as adults. Eggs are laid singly by females. Hatching occurs from 9 to 38 days after oviposition. Larvae undergo three instars. The newly hatched larva forms a vertical burrow in which it will remain through pupation. Larvae for most known species live in vertical tunnels, holding themselves with the aid of dorsal hooks on the fifth abdominal segment. If suitable prey comes within range of a tunnel entrance, the larva seizes it and drops down into the burrow to feed. The abdominal hooks also serve to anchor the larva in its tunnel if a prey is too large to subdue. Larvae of the Ctenostomatini (*Neocollyris* and *Ctenostoma*) are unusual in that they develop in rotting logs and branches or standing vegetation rather than in burrows in the ground.

Larvae of many species have been described. A list and key to all known tiger beetle larvae was published by Putchkov and Arndt. The entire life cycle from egg to adult may take as long as 4 years. Food availability seems to be a major factor in the rate of larval development. Many species appear to be able to endure long periods of fasting, entering into a quiescent stage which may last for months. Adults normally live from 8 to 10 weeks, but some may live for several years (*Manticora*).

Survival from Heat and Flooding

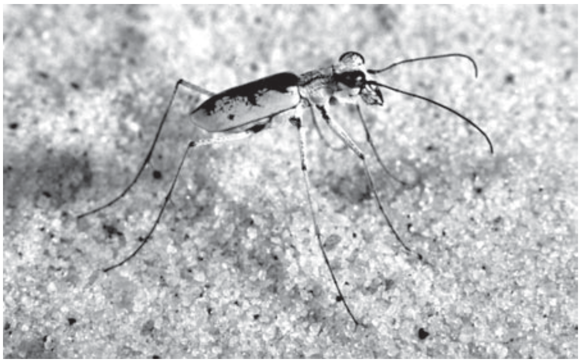
Many species inhabit extremely hot regions, where air temperatures during the day may easily exceed 37°C. Those species that are active during hot times of the day may exhibit a behavior known as "stilting," where the individual stands with legs fully extended, keeping the insect as far away as possible from the hot soil (Fig. 67). They may also seek out shaded structures, or hide under debris, or hide in leaf litter. Larvae of riparian species are able to survive long periods of anoxia (lack of oxygen) during seasonal flooding of their sandbar and bank habitats (Fig. 68). Larval burrows may contain sufficient oxygen to allow their inhabitants to survive weeks under flood waters. The salt marsh-inhabiting species *Cicindela togata* is reported to have larvae that can survive 5 days of burrow immersion in salt water.

Activity

Tiger beetles often run very rapidly over the ground, frequenting sandy banks of streams, along roadways and paths and other such sunny places. Many species are rapid flyers. In spite of their often brilliant metallic colors they are often difficult to see because of their quick movements. Unlike most beetles, a net is often necessary to collect these insects. Some desert-inhabiting species can be collected in abundance by hand. Pitfall trapping has also proven a successful technique for some species. Many species are more easily collected at night with such attractors as UV black-light or mercury vapor lights. The use of lights to collect many of the more elusive species has led to the demise of some populations due to overzealous collecting. Several species are on the verge of extinction, with over-collecting appearing to be as responsible as habitat destruction.

The genera *Manticha* and *Manticora* inhabit deserts and steppes of southern Africa. A few species of *Cicindela* live in termite nests. The tropical tribes Ctenostomini and Collyrini are arboreal, searching out their prey among the branches of trees and bushes.

Adults of *Megacephala*, *Amblycheila*, and *Omus* are crepuscular/nocturnal and are most effectively collected with pitfall traps. Some species



Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 67 ***Cicindela hirtilabris*** **displaying "stilting" behavior.**

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 68 ***Cicindela blanda*****, a river sandbar species from the southeastern USA.**

of *Megacephala* have been reported to be attracted to electric lights, but are usually found beneath stones, hiding in crevices in the earth, or under almost any debris. *Megacephala affinis* was reported to prey on dung beetles in Panama. *Megacephala fulgida* was reported to appear at sound traps being used to attract *Scapteriscus* mole crickets. Individuals of *Amblycheila* have been reported to become active soon after sunset. Adult *Omus* have been reported to be predators on millipedes.

Species of *Cicindela* are both diurnal and nocturnal. Many species prefer dry sunny areas, but others are known to prefer semi-aquatic sites. Some species, while active both during daytime and night, appear to accomplish most of their mating at night. Many species are strong flyers, but some have fused elytra and are incapable of flight. Others appear reluctant to fly even though flight wings are present.

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 69 **Clay bank at Thomasville, Georgia, USA, with holes marking entrances to larval burrows.**

Predators and Parasites

Larvae have only a few methods of escaping predation and parasitism. They will either drop to the bottom of their burrow when danger approaches, or they may even leave the burrow and run to another location. Since they are restricted to the one vertical burrow during their development, parasites are able to locate and attack larvae with a fair amount of success. Members of the hymenopteran family Tiphiidae (*Methoca*, *Karlissa*, and *Pterombus*) hunt for larvae, sting them, then deposit an egg on the paralyzed larva. The burrow is then closed by the wasp. The parasite larva develops, killing the tiger beetle larva. A fly family (Bombyliidae) also is a parasite of tiger beetle larvae. These flies flip eggs near or into the larval burrow. Eggs fall to the bottom of the burrow, hatch, and the new larva attaches to the tiger beetle larva, remaining attached until the larva pupates (Fig. 69).

Adult tiger beetles will defend against such predators as bats, mites, lizards, other tiger beetles, flies (Asilidae), birds, dragonflies, and, of course, collectors (Fig. 70). Defensive strategies

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 70 **Natural enemies of tiger beetles: (*above*) robber fly (Asilidae) predator; (*below*) bee fly (Bombylidae) parasitoid.**

include running, hiding (camouflage and cryptic coloration), flying (quick short flight or long sustained flight), dropping from the canopy (arboreal species), displaying a warning coloration such as bright orange abdomen, and chemical defenses. Many (but not all) species of tiger beetles produce the chemical benzaldehyde, a chemical known to be an effective predator deterrent.

Sound Production

Some species of tiger beetles have been found to produce sounds through stridulation. The mechanisms behind sound production are being investigated, and only a few species have been analyzed. Sound production may be useful in predator avoidance, or it may be part of intraspecific communication. Two different types of sound production have been found in tiger beetles. One method is the scraping of a *pars stridens* found on the dorsal side of costal and subcostal veins upon a plectrum on the ventral apical area of the elytra. Others have rings on the elytra which are rubbed by either the hind tibia (*Manticora*) or hind femur (*Oxycheila* and *Cheiloxya*).

Sound Detection

Tiger beetles are capable of detecting sound. It is believed that some species have evolved a hearing organ (tympanum) to detect the hunting sounds of bats. Not all species of tiger beetles have tympana. When present the tympanum has been found to be located on the dorsal-lateral side of the first abdominal segment. It is believed that some species use night dispersal flights to avoid daytime predators such as robber flies, dragonflies, and birds. This exposed them to predatory bats. Detection of the ultrasound cries of bats results in the tiger beetle dropping out of the air to the ground.

Defensive Behavior

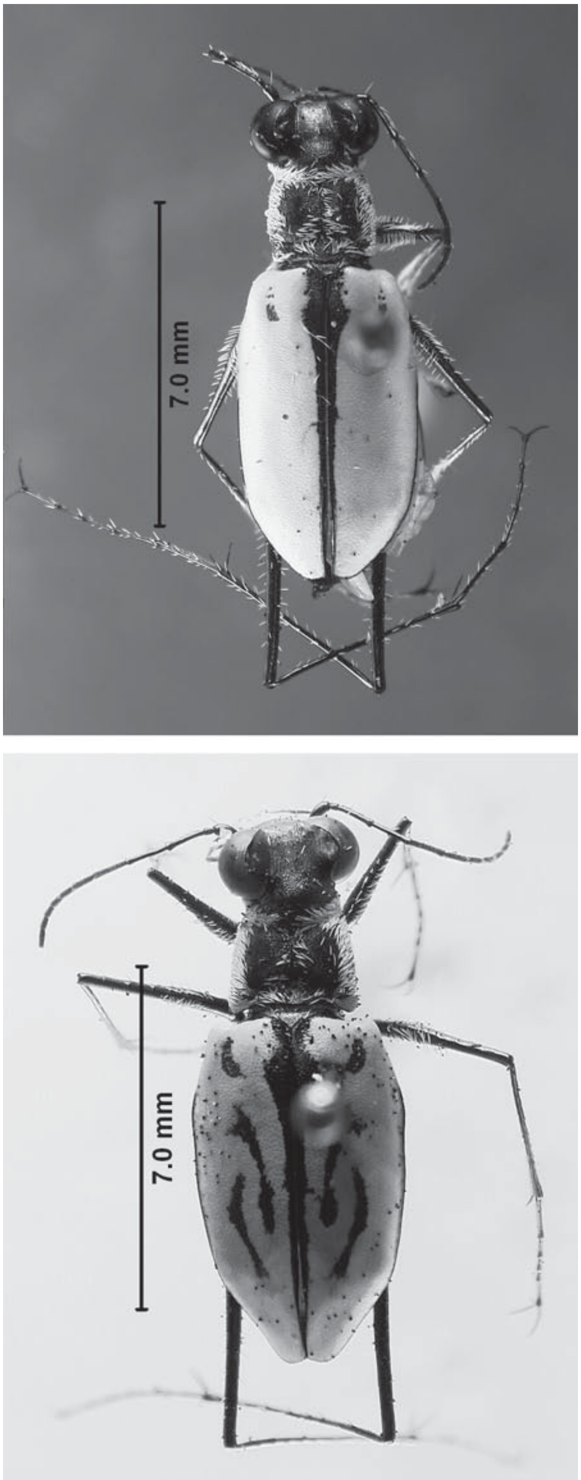
Benzaldehyde and cyanide have been identified as defensive secretions in *M. virginica*. Other species are reported to have similar defensive secretions, but of 89 species investigated, only 39 produced these compounds. Other defensive behavior includes crypsis, aposematism, evasive running, evasive flight, deception, roosting aggregations, and release of noxious chemicals from pygidial glands. While the principal predators of tiger beetles are believed to be birds, lizards, spiders, robber flies, and bats, birds are believed to be the major force behind selection for defensive coloration.

Phenotypic Variation

Intrapopulation color and extent of maculation is common among tiger beetles. This variation has resulted in many named subspecies. The taxonomic validity of many of these names has not been resolved, and many of these most likely represent variation of little taxonomic value (Fig. 71).

Sexual Dimorphism

Many species exhibit sexual dimorphism in extent of maculation, degree of hairiness of the head, number of labrum teeth, overall color, protarsal pads, shape of the elytral apex, overall body shape and size (Fig. 72). Females tend to be larger and wider, while males are often smaller and narrower. Males have many more erect setae between their eyes, and the first four segments of their protarsi have dilated pads that are used to hold onto females during mating. In species that have dimorphic coloring to their labrum, males usually have a white or pale labrum, while females may have a totally black or dark labrum. This may aid in mate recognition, and reduce the number of male/male encounters (Fig. 73).



Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 71 **Male *Manticora latipennis*, 70 mm long, from South Africa. Members of this genus contain the largest species of tiger beetles.**

Tiger Beetles in Folklore and Religion

Though there are relatively few references to tiger beetles in religious literature, the African genus *Manticora* is one that has been a part of local legends and folklore. A recent revision of *Manticora* described the folklore concerning the derivation of the name *Manticora*, and the beliefs surrounding the insects by native populations. The name *Manticora* was derived from the mythological beast, the Manticore. The Manticore was a beast that had the head of a lion, the body of a serpent, and the tail of a scorpion. The genus *Manticora* was proposed for these beetles in 1792 by Johann Fabricius. This name was taken from the Persian for a man-eating monster. This may have been the result of reports of these beetles feeding on cadavers of warriors killed in native conflicts, or from sighting of these beetles occasionally emerging from skulls, presumably used as hiding places to avoid the midday heat. According to native legend in southern Africa, manticoras cannot die, and are believed to be personification of the Grim Reaper. They are thought to bring nothing but ruin and destruction to native tribes. They are so feared that it is believed that if a manticora points its mandibles in the direction of a person, that person will die within 3 days. The natives try to sneak up behind any manticora and crush it with their feet before it can point its mandibles in their direction. If a person is so unfortunate as to see a manticora, that person must undergo a lengthy religious purge ceremony to be saved from this demon.

Tiger Beetles on Stamps

A few countries have used images of tiger beetles on their stamps. Examples of these are shown here, with insect species name and country where used (Fig. 74):

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 72 ***Cicindela hirticollis*** **(*left*, male; *right*, female) showing increased maculation in female and narrower body shape of male.**

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 73 **Female *Cicindela unicolor*. Note the elongate middle tooth and unicolorous black color of the labrum.**

- Vietnam – *Cicindela aunulenta*, *Cicindela tennipes*, *Cicindela japonica*
- Senegal – *Cicindela lunulata*
- Ethiopia – *Cicindela petiti*
- North Korea – *Cicindela chinensis*
- Albania – *Cicindela hybrida*
- Portuguese Guinea – *Cicindela brunet*
- East Germany – *Cicindela campestris*
- Madagascar – *Cicindela andriana*
- Republic of Equatorial Guinea – *Cicindela purpurea*
- Democratic Republic of Congo – *Cicindela regalis*
- Niger – *Cicindela cicindela*
- Vietnam – *Collyris collyris*
- Republic of South Africa – *Cicindela regalis*
- Japan – *Cicindela japonica*

Conservation

The attractive appearance of many tiger beetles has been one of the reasons that collectors have sought out specimens, sometimes to the detriment of populations from over-zealous collecting.

Tiger Beetles (Coleoptera: Carabidae: Collyrinae and Cicindelinae), Figure 74 **Examples of stamps displaying tiger beetles: (*top row, left* to *right* – *Cicindela japonica*, *Cicindela aunulenta*, *Cicindela petiti*, *Cicindela cicindela*; *bottom row, left* to *right* – *Cicindela regalis*, *Cicindela purpurea*, *Cicindela andriana*).**

The biology of many species is sufficiently well known to permit estimates of their survival status. As a result, several species of North American tiger beetles have been elevated for protection under the Endangered Species Act. Among USA endangered species are *Cicindela highlandensis* Choate (central Florida), *Cicindela puritana* G.H. Horn (Maryland, Connecticut), *C. ohlone* Freitag and Kavanaugh (California), *C. dorsalis dorsalis* Say (northeastern seacoast), *Cicindela nevadica lincolniana* Casey (Nebraska), and *Cicindela limbata albissima* Rumpp (Utah). Many other species are listed as "species of concern," meaning that they are potential candidates for endangered species status in the future as their habitats disappear. The following list (by state) includes most of the U.S. species that are being monitored:

- Minnesota – (Endangered) *Cicindela fulgida fulgida* Say, *Cicindela limbata nympha* Casey; (Threatened) *Cicindela denikei* W.J. Brown, *Cicindela fulgida westbournei* Calder, *Cicindela lepida* Dejean; (Special concern) *Cicindela hirticollis rhodensis* Calder, *Cicindela macra macra* Leconte, *Cicindela patruela patruela* Dejean, *Cicindela splendida cyanocephalata* Eckhoff;
- Washington – *Cicindela columbica* Hatch;
- South Dakota – *Amblycheila cylindriformis* (Say);
- Texas – *Cicindela chlorocephala smythi* E.D. Harris; *Cicindela cazieri* Vogt, *Cicindela hornii* Schaupp, *Cicindela nevadica olmosa* Vaurie, *Cicindela nigrocoerulea subtropica* Vogt, *Cicindela obsoleta neojuvenilis* Vogt, *Cicindela politula barbarannae* Sumlin; *Cicindela politula petrophila* Sumlin;
- Nebraska – *Cicindela nevadica lincolniana* Casey;
- Vermont, New Hampshire – *Cicindela marginipennis* Dejean;
- California, Santa Cruz Co. – *Cicindela ohlone* Freitag and Kavanaugh;
- Massachusetts – *Cicindela rufiventris hentzii* Dejean, *Cicindela dorsalis dorsalis* Say, *C. marginipennis* Dejean, *C. patruela* Dejean, *C. puritana* G.H. Horn;
- Utah – *Cicindela limbata albissima* Rumpp, confined to the Coral Pink Sand Dunes formation in southern Utah;

- Ohio – *C. hirticollis* Say, *C. marginipennis* Dejean.
- While less well-studied, a few species elsewhere are also candidates for protection. Among those are the following:
- Canada, British Columbia – *Cicindela parowana* Wickham;
- Spain – *Cicindela* (*Cephalota*) *deserticoloides* (Codina), endemic to the few remaining salt steppes of southeastern Spain;
- South Africa – *Dromica* spp., all species; *Manticora* spp., all species; *Megacephala asperata* Waterhouse, *Megacephala regalis* Boheman, *Platychile pallida* (Fabricius), *Prothyma guttipennis* Boheman;
- Japan – *Lophyridia angulata* (Fabricius), *Abroscelis anchoralis* (Chevrolat), *Cicindela lewisii* Bates, and *Chaetodera laetescripta* Motschulsky.

Habitat destruction from encroachment by recreational vehicles, housing construction, damming of rivers, and forest harvesting are risk factors that may eventually lead to species extinction. Even night-lights have been investigated as potential risk factors in the life cycle of some tiger beetles because they draw adults from their habitat and interrupt their mating behavior.

Tiger Moths (Lepidoptera: Arctiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Tiger moths, family Arctiidae (including flag moths and wasp moths), total 11,155 species worldwide, primarily Neotropical (about 6,000 sp.); actual world fauna likely exceeds 14,000 species. The family is in the superfamily Noctuoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. There are five subfamilies among three groups: group Pericopinina (with Pericopinae), group Arctiinina (for Lithosiinae and Arctiinae), and group Ctenuchinina (for Ctenuchinae and Syntominae). Various specialists use other classifications. Adults small to large (8–115 mm wingspan); tympanal organs absent or vestigial in Syntominae; hindwings greatly reduced in some groups (wasp moths). Maculation extremely varied, but mostly very colorful, especially among the wasp moths (Ctenuchinae and the Old World Syntominae) which mimic wasps in many cases. Adults mostly nocturnal but many are crepuscular or diurnal (Pericopinae, Ctenuchinae, and Syntominae). Larvae are leaf feeders. Host plants are varied among numerous plant families, including mosses and lichens. A few are economic. Among the largest adults are females of *Aglaomorpha histrio*, from China, while the smallest are some of the Lithosiinae (Fig. 75).

Tillyard, Robin John

Tillyard, Robin John, Figure 76 **Robin Tillyard.**

Robin Tillyard was born January 31, 1881, at Norwich, England. He was educated at Dover College and Queen's College, University of Cambridge, and received a Sc.D. in 1920. He taught math and science in Sydney, Australia, from 1905 to 1913, and began publishing on dragonflies in 1905. He was named a lecturer in zoology at the University of Sydney in 1917, and received several honors from that University and from the Linnean Society of London. He also served as Chief of the Biological Department of Cawthron Institute in New Zealand, and Chief of the Division of Economic Entomology, CSIRO, Canberra, Australia. Tillyard published nearly 100 scientific papers, on many aspects of entomology and most orders of insects, but was especially interested in their evolution, in fossil insects, and in dragonflies. He also provided numerous contributions to "The illustrated Australian encyclopedia" (1925) and "The insects of Australia and New Zealand" (1926). Tillyard died in 1937 (Fig. 76).

Timarcha latreille (Coleoptera: Chrysomelidae, Chrysomelinae)

PIERRE JOLIVET
Paris, France

The leaf-beetle genus *Timarcha* Latreille comprises about four subgenera, 125 species and 30 subspecies, spread in eastern North America and around the Mediterranean basin. They are absent from Syria, Lebanon, Israel, and Egypt, where very probably European and African species once met, but were eradicated during the Pleistocene desertification. In Libya, it survives along the coast on the western side and in Cyrenaica, but also survives on some oases, 80 km south. *Timarcha* does not reach or survive in the central Sahara (Hoggar, 2,918 m) where some *Chrysolina* live.

Fossil *Timarcha*, before the Pleistocene, are unknown, but *Timarcha* is a very old genus, perhaps related to the Upper Jurassic Timarchopsis, a Siberian fossil. The genus *Timarcha* combines plesiomorphic characters (very primitive nervous system, primitive aedeagus and tegmen, etc.) with apomorphic ones, like the welding of the elytra in tenon and mortise and a complete aptery. How long has the beetle been apterous? Probably very early, during the Cretaceous, because it is found with Meloe (Meloidae), one of the rare beetles that is apterous at the pupal stage. Aptery and a subelytral cavity are forms of protection against heat and water loss in many tenebrionids living in desert and semidesert areas. Such structures reduce transpiration, act as a thermal buffer for heat flow and allows the beetle to store the maximum amount of water possible to compensate for the loss of liquid through reflex bleeding. Lack of flight muscles and shortening and widening of metasternum are a direct consequence of aptery. *Pimelia* spp. (Tenebrionidae), also totally apterous, often mimic the *Timarcha* spp. and there seems to be a certain concordance in northern Africa between the local *Timarcha* and *Pimelia* species. It could be more Müllerian mimicry than Batesian, however, because Pimelia regurgitates liquid when disturbed.

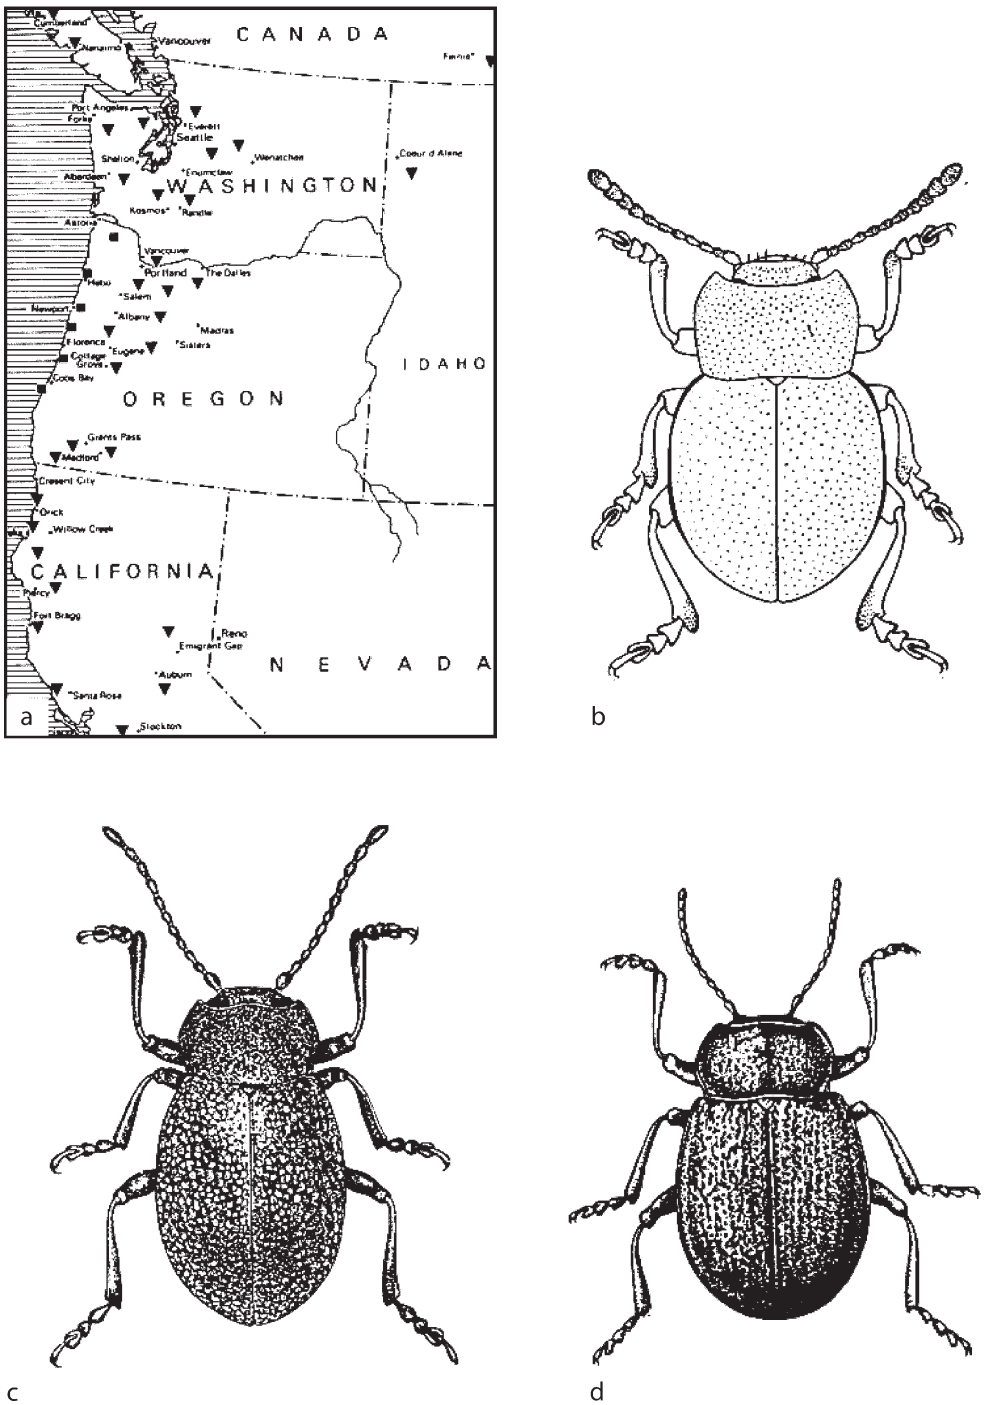
The archaic characteristics of the adult, and morphological structures of the larvae, probably warrant for *Timarcha* a subfamily of its own, the Timarchinae, situated between primitive ones (Aulacoscelinae, Sagrinae) and more evolved ones (Chrysomelinae). That status has already been proposed by various authors, but many others remain hesitant and prefer the status of tribe (Timarchini) at the beginning of the Chrysomelinae. Timarchini would be a monogeneric tribe with four subgenera. All other genera formerly included among the Timarchini are now listed among the Entomoscelina, a subtribe. No other Chrysomelinae has a ring piece around the aedeagus, divided at its base, with a ciliated cap-piece on the top. Several rare chrysomeline genera show a ring piece (tegmen) devoid of any cap piece on the top. Normally Chrysomelinae genera and species have a V or Y-shaped tegmen, a more evolved form of aedeagus. Farrell's molecular analysis of the Chrysomelinae unfortunately missed *Timarcha*, a key genus.

The genus *Timarcha* probably originated in the steppes of Central Asia, from where it has been eliminated by the Pleistocene glaciations. It adapted through a complicated system of egg or adult diapause to Middle Europe and North America, including middle-sized mountains. It still does not occupy areas that were glaciated in the Pleistocene in the U.S. and Canada (except Vancouver island) and in Europe (below Scotland, the Baltic States and Denmark). Species of *Timarcha* can survive moderate cold, but in Normandy, for instance, one species (*T. goettingensis* (Linné)) becomes active in February when the sun shines. Most of the species are diurnal, but some can be crepuscular or entirely nocturnal. *Timarcha punctella* Marseul in Tunisia and Libya, and *T. laevigata* (L.) in Morocco, are active during the day when other species in the North African mountains are mostly crepuscular. Through the Middle European mountains, adults of the subgenus *Metallotimarcha* Motschulsky (*T. metallica* Laicharting, *T. hummeli* Faldeman, etc.) seem to be mostly crepuscular or nocturnal in activity. In the United States and southern Canada, adults of the subgenus *Americanotimarcha* Jolivet are entirely nocturnal. During the summer, they climb over *Rubus* plants at around 9 p.m. and start to go down around 5 a.m. to hide under the trash, fallen leaves, and near the roots of brambles. They do the same on strawberry plants. European and African *Timarcha* show abundant reflex bleeding (haemorrhage) around the mouth and between femur and tibia. American species, being nocturnal and in this way being protected from most of the predators, show a very discrete bleeding. Not only does *Timarcha* blood taste bitter, but it is toxic in its contents (anthraquinones). Also, the purely nocturnal species of *Timarcha* (the American species, and also some of the *Metallotimarcha*) do not have the elytra fused. Probably, problems of water loss are not acute during the night.

Timarcha species fed originally on *Plantago* species (*P. albicans* L., *P. maritima* L., etc.) and this choice is maintained with most of the African and southern European species (no data are known on Asian *Timarcha*). This host selection behavior is absent among north European and North American species. However, the dual choice (Rubiaceae/Plantaginaceae) is still shown along the French Atlantic coast with *Timarcha maritima* Perris which feeds alternatively on *Galium arenarium* Lois and *Plantago maritima* L. Many Iberian or Moroccan species have adapted to the same diet, Rubiaceae/Plantaginaceae, related taxonomically and chemically, but they eventually switch to other related plant families: *Veronica* (Scrophulariaceae), *Scabiosa* (Dipsacaceae) or not related: *Launaea* (Asteraceae), *Carrichtera*, *Iberis*, *Alyssum* (Brassicaceae). Southern species (Sicily, Spain, Morocco) display such adaptations, but generally Rubiaceae (*Galium*, *Rubia*, *Crucianella*, *Asperula*, *Sherardia*) along with various species of *Plantago* form part of the diet. There are also reports of *Timarcha metallica* feeding on *Vaccinium* spp. (Ericaceae) and other Ericaceae. The difference in food plants between Old and New World stocks of *Timarcha*, and the big difference in chromosome formula between the two groups, indicate a long isolation, probably since the separation of the northern land masses of the Atlantic in the early Eocene period. American *Timarcha* feed on Ericaceae and Rosaceae.

Timarcha is a K-strategist and lays few big eggs protected by a primitive ootheca mostly made of buccal secretions. Aptery and suppression of flight muscles likely allows the female to increase its egg production. Aptery is a serious handicap in case of fragmentation of the habitat. Once *Timarcha* is eliminated from a habitat, repopulation is unlikely.

Timarcha is distributed in middle and southern Europe, northern Africa and western North America, and new species are described from time to time in Turkey, Italy and Corsica. However, *Timarcha* has completely disappeared from central Asia, and its ephemeral and possible existence in Teneriffe, Japan and elsewhere (Iceland) seems to be due to accidental introduction with forage not followed by survival. *Timarcha* has survived in some big islands (Corsica, Sardinia, Sicily, Mallorca, Minorca) and small ones (Channel Islands, Chausey archipelago, Aegades, small islands off the coast of eastern Spain, etc.), but has disappeared or has never existed in the eastern Mediterranean islands, including Cyprus and Crete. Malta remains *Timarcha* free, but probably lost the beetle due to intense urbanization since the Greek and Roman times. It was connected with Sicily during the Cenozoic. Stranger is the lack of *Timarcha* in three small Balearic islands, perhaps due to geological history. *Timarcha* has disappeared completely from the eastern and central USA (Fig. 77), probably during



Timarcha latreille (Coleoptera: Chrysomelidae, Chrysomelinae), Figure 77 ***Timarcha*: (a) Distribution of the genus *Timarcha* in the USA and Canada. Localities in Montana are not visible on the map; (b) *Timarcha (Metallotimarcha) metallica* Laicharting from Belgium; (c) *Timarcha (Americanotimarcha) intricata* Haldeman, Oregon, USA; (d) *Timarcha (Americanotimarcha) cerdo* Stål, Oregon, USA.**

the Pleistocene, though host plants are present in the Apalachian Mountains and elsewhere. It is also difficult to understand why the *Timarcha* did not cross the Sahara when it was vegetated, and did not colonize the Hoggar and the East African mountains as *Chrysolina* did. In some ways, the original distribution of *Timarcha* could have been similar to that of *Pimelia* and Pimeliinae in the West before the desertification of the Middle East, with a wider distribution toward Mauritania and the western Sahara, plus Egypt, Sudan, eastern Mediterranean and western Asia.

Being protected by their toxic fluid (by regurgitation) and prebuccal and tibio-femoral reflex bleeding (by anthraquinones) and eventually also by a nocturnal life, *Timarcha* spp. have few parasites and parasitoids (Ichneumonidae and Braconidae), mites under the subelytral cavity (Canestriniidae) and microbial commensals: gregarines. Practically no predators (birds, lizards) feed on them. When resting during the cold season in the Mediterranean, adults of *Timarcha* often gather together under tufts of plants, showing a tendency to gregarism.

American and European species of *Timarcha* differ in number of chromosomes, the American species having a much greater number. The basic formula in Europe is: $2n = 12$ and in America: $2n = 44$.

The black body color of *Timarcha* and the red blood extruded abundantly likely have an aposematic effect because of the contrast with the green background of the food plant. However, aposematism is of no use for nocturnal species.

The size of *Timarcha* adults varies from 5–8 mm (*T. cerdo*) to 18–23 mm (*T. tangeriana* Bechyne). Generally a size of 10–12 mm (*T. goettingensis* (L.)) is common.

Conclusions

The genus *Timarcha* remains rather enigmatic. In certain areas it seems to be evolving very quickly. Isolated valleys and mountains, acting as islands, like the Pyrenees in France and Spain, and the Atlas in Morocco, seem to be the focus of strong variation. Along the Moroccan coast and in the Pyrenees, small morphological differences, probably linked with interbreeding, sometimes show small variations in food habits. In the Pyrenees, each river, each valley seems to have a small variation.

Separation of the genus between America and the Old World has always puzzled entomologists. Very few other cases are similar among the arthropods. Transpacific migration remains a possibility, but the genus is absent in the Far East.

Extinction is caused by urbanization, fragmentation of the habitat, use of insecticides and herbicides, general pollution and many other reasons. The survival of many species is actually in jeopardy in Europe and in the USA. Probably several species will soon be extinct, and many more are endangered.

Tineid Moths

Members of the family Tineidae (order Lepidoptera).

► Fungus Moths

► Butterflies and Moths

Tineidae

A family of moths (order Lepidoptera). They commonly are known as tineid moths, fungus moths, or clothes moths.

▶ Fungus Moths
▶ Butterflies and Moths

Tineodidae

A family of moths (order Lepidoptera) also known as false plume moths.

▶ False Plume Moths
▶ Butterflies and Moths

Tingidae

A family of bugs (order Hemiptera). They sometimes are called lace bugs.

▶ Lacebugs
▶ Bugs

Tiphiidae

A family of wasps (order Hymenoptera).

▶ Wasps, Ants, Bees, and Sawflies (Hymenoptera)
▶ Tiphiid Wasps (Hymenoptera: Tiphiidae)

Tiphiid Wasps (Hymenoptera: Tiphiidae)

MICHAEL E. ROGERS, DANIEL A. POTTER
University of Kentucky, Lexington, KY, USA

The family Tiphiidae belongs to the informal group (series) Aculeata, which includes all stinging wasps, of the order Hymenoptera (ants, wasps and bees). The Tiphiidae were previously placed in the superfamily Scolioidea and later Tiphioidea. The current classification of the Hymenoptera which recognizes only three aculeate superfamilies, Chrysidoidea, Apoidea and Vespoidea, places the Tiphiidae in the superfamily Vespoidea.

Order: Hymenoptera
Suborder: Apocrita
Informal Group: Aculeata
Superfamily: Vespoidea
Family: Tiphiidae

Most members of the Tiphiidae are believed to be parasitoids of the edaphic (soil inhabiting) larval stage of certain beetles (Coleoptera). Primarily a tropical family, the Tiphiidae are represented worldwide by seven subfamilies containing about 1,500 species. These subfamilies are the Anthoboscinae (six genera), Diamminae (one genus), Thynninae (50 genera), Tiphiinae (nine genera), Brachycistidinae (13 genera), Myzininae (12 genera) and Methochinae (two genera). The Thynninae is the largest subfamily of the Tiphiidae, present mainly in the Neotropical regions and Australia. The five subfamilies represented in North America include the Tiphiinae, Myzininae, Methochinae, Anthoboscinae and Brachycistidinae. Of these subfamilies, the Tiphiinae is the largest containing about 140 species in North America. The most common group of Tiphiinae are the members of the genus *Tiphia*, represented by about 100 North American species.

External Morphology

The adult Tiphiidae range from 5 to 30 mm in length. The wasps are typically black but may have red, yellow or white markings. The antennae are 12-segmented in females and 13-segmented in males. The pronotum and mesonotum are separated by a suture and not fused. The middle and hind legs are often heavily spined. Sexual dimorphism ranges from slight to pronounced and in some species, the wings of the female are reduced or absent. Males often have a modification of the eighth sternite (or hypopygidium) forming an upward curved spine that may be mistaken for a sting. Two morphological features which help to distinguish the Tiphiidae from other families are a mesosternum with two posterior lobes and the separation of abdominal segments by well-defined constrictions.

Life History and Habits

The Tiphiidae are all solitary wasps and develop as ectoparasitoids on their soil-dwelling hosts. Most tiphiids are parasitoids of larval Scarabaeidae, commonly referred to as white grubs. The Thynninae, Tiphiinae and Myzininae contain species that, for the most part, are parasitoids of white grubs. The exception is the Myzininae, in which a few of the species parasitize larval Tenebrionidae, Cicindellidae or Cerambycidae (all Coleoptera). The biology of the Anthoboscinae and Brachycistidinae has not been studied but it is believed that members of these two subfamilies are also parasitoids of scarabaeid larvae. The Diamminae, an Australian group, parasitizes mole crickets (Orthoptera: Gryllotalpidae) and the Methochinae parasitize the larvae of tiger-beetles (Coleoptera: Cicindellidae).

Adult Tiphiidae feed primarily either on honeydew produced by other insects, or on the nectar of flowering plants. Female wasps may also feed by biting a paralyzed host during an oviposition event and then imbibing the hemolymph exuding from the wound. Females lay about 50 eggs over their 3- to 4-week lifespan, but in a few species may lay as many as 100 eggs. As in most members of Hymenoptera, fertilized eggs become females and males are produced with unfertilized eggs. Females control the sex of their offspring, with male eggs placed on smaller hosts and female eggs placed on larger hosts (Fig. 78).

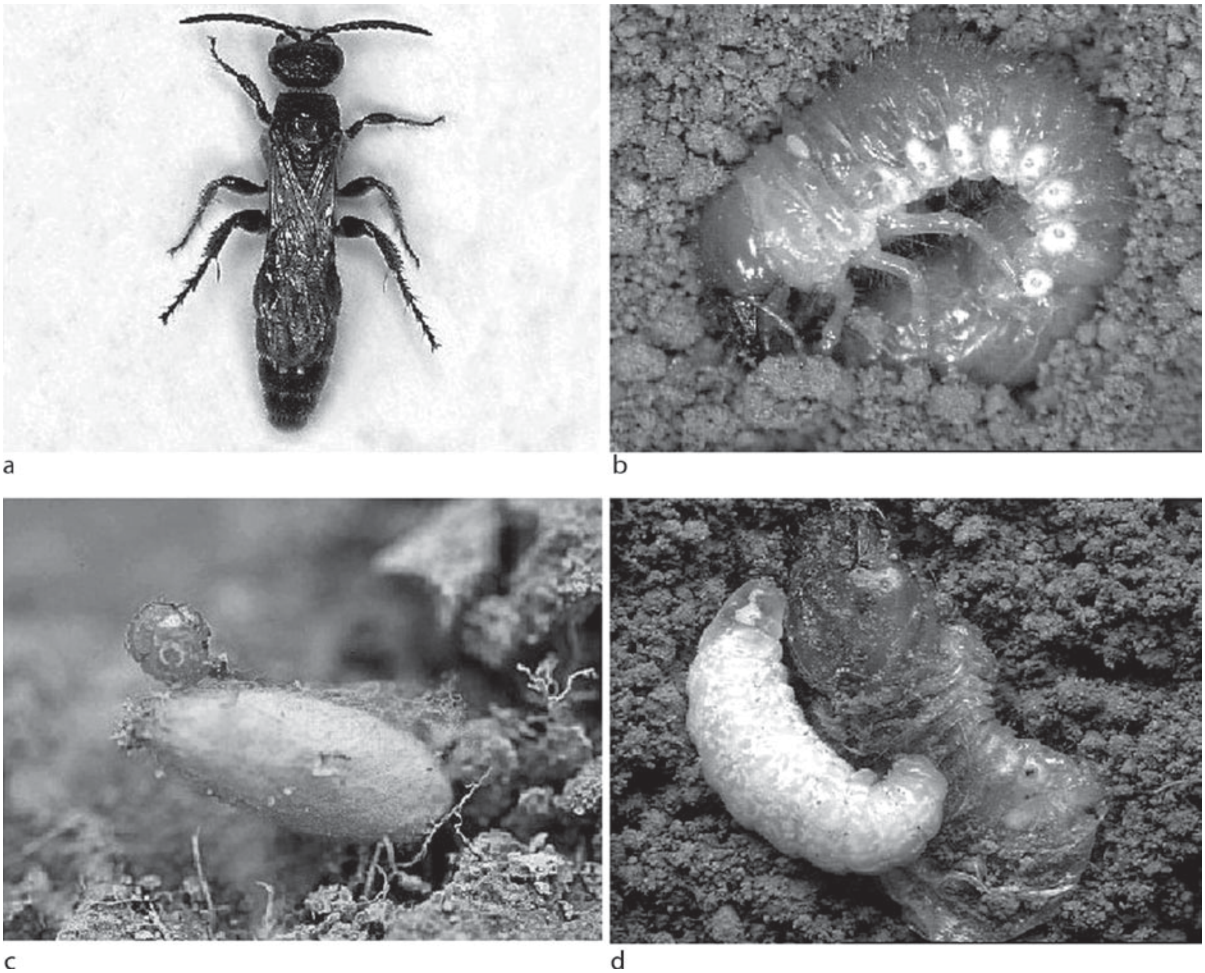
The best-studied group of Tiphiidae is the genus *Tiphia*. *Tiphia* are mostly host specific, i.e., each wasp species parasitizes larvae of only one species of grub. In cases where more than one grub species is parasitized, all host grub species are usually of the same genus. The emergence of adult wasps is synchronized with the presence of the third instar of grubs with a 1-year life cycle or the second instar of grubs with a 2- or 3-year life cycle. After mating, the female burrows into the soil and uses kairomones from grub frass (feces) and body odor trails to locate a host. Once a host is found, the wasp stings the grub ventrally between the first and second thoracic segments causing temporary paralysis. An egg is then laid on the host. The position of the egg on the host differs among the species of *Tiphia*. The larval *Tiphia* hatches from the egg in 3–7 days. Upon hatching, the wasp larva pierces its host's cuticle with its mouthparts and feeds on its body fluids. After a period of about 21 days, the fifth instar *Tiphia* devours the remaining non-sclerotized body parts of its host and then spins a silken cocoon. In temperate regions, *Tiphia* have one generation per year and will overwinter in the cocoon. Tropical species of *Tiphia* have multiple generations each year.

Predators and Parasites

The impact that natural enemies have on tiphiid populations is not known. Bombyliid flies (Diptera) and rhipiphorid beetles (Coleoptera) are common parasites reared from the cocoons of various Tiphiidae. Sphecid and mutillid wasps (Hymenoptera) and nematodes are less commonly observed as natural enemies of tiphiids.

Importance in Biological Control

During the 1920s and 1930s, 14 species of *Tiphia* were introduced into the U.S. from Japan and China to control the spread of the Japanese beetle, *Popillia japonica* (Coleoptera: Scarabaeidae). Only two of them, *Tiphia popilliavora* and *T. vernalis*, became established. Only *T. vernalis* is known to still be established throughout much of the range of the Japanese beetle. Currently, efforts are under way to move *Tiphia vernalis* to areas of the U.S. where the Japanese beetle has recently spread but *Tiphia vernalis* is not yet established. Of the native Tiphiidae, *Tiphia pygidialis* and *T. relativa* are common parasitoids of masked chafer,



Tiphiid Wasps (Hymenoptera: Tiphiidae), Figure 78 **Tiphiid wasps: (a) Adult female *Tiphia pygidialis*, subfamily Tiphiinae, 12 mm long, North America. (b) Masked chafer, *Cyclocephala* sp. with egg of *T. pygidialis*. (c) Fifth instar *T. pygidialis* devouring *Cyclocephala* sp. host. (d) *Cocoon* of *T. pygidialis*.**

Cyclocephala spp., grubs and *T. berbereti*, *T. intermedia*, *T. tegulina*, *T. transversa* and *T. vulgaris* parasitize June beetle, *Phyllophaga* spp., grubs.

Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

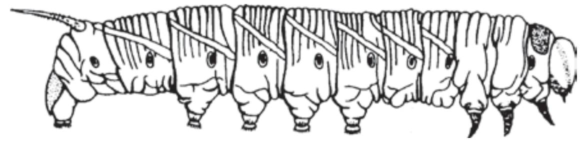
These species occur in North, Central and South America, and the Caribbean Islands. The tobacco and tomato hornworms are very similar in appearance, biology, and distribution, and are commonly confused. However, the tobacco hornworm is more common in warmer climates, such as the Gulf Coast States of the USA, whereas the tomato hornworm is more common in cooler regions such as the northern USA and Canada.

Life History

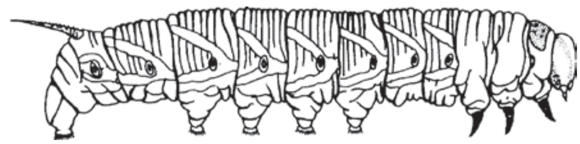
The number of annual generations ranges from one in cool locations such as Canada to perhaps four in warmer locations such as Florida, USA. The proportion of insects that enter diapause increases from about 5% in June to 95% in mid August, as day length decreases. In northern Florida, the insects are active from April to November, but they are abundant only for the first two generations because many pupae enter diapause. In North Carolina they occur from mid May to October, and evidence of a third generation is weak. Throughout their range, hornworms overwinter in the pupal stage, and in the northernmost portions of their range may not overwinter successfully, occurring only after dispersal northward during the summer. The life cycle can be completed in 30–50 days, but often is considerably protracted.

The eggs are spherical to oval in shape, and measure 1.25–1.50 mm in diameter. Eggs are smooth and vary in color from light green or yellow when they are early in development, to white at maturity. Eggs are deposited principally on the lower surface of foliage, but also on the upper surface. Mean fecundity is about 250–350 eggs, with seasonal fluctuations and maximum egg production at mid-season. However, with adequate adult nutrition, fecundity of nearly 1,400 eggs per female could be attained. Duration of the egg stage is 2–8 days, but averages 5 days.

The larva is cylindrical in form and bears five pairs of prolegs in addition to three pairs of thoracic legs. The most striking feature of the larva is a thick pointed structure or "horn" located dorsally on the terminal abdominal segment. The horn is as long as the body in newly hatched larvae, but becomes relatively smaller as the larva matures. Young larvae are yellowish white but during the second instar become green with white lines laterally. The tobacco hornworm develops seven straight oblique whitish lines laterally. The white lines are edged with black on the upper borders, and the horn is usually red in color. The tomato hornworm is superficially similar, but instead of the seven oblique lateral bands it bears eight whitish or yellowish "V"-shaped marks laterally, and pointing anteriorly. The V-shaped marks are not edged in black (Figs. 79 and 80). Also, in tomato hornworm the horn tends to be black in color. The body of both species is usually light green in color, but occasionally dark brown or blackish forms occur; the larvae blend in very well with the foliage on which they feed. There normally are five instars, but occasionally six are observed. The mean head capsule width is 0.8, 1.2, 2.0, 3.0, and 5.0 mm for instars 1–5, respectively. Corresponding mean larval body lengths are 6.7, 11.2, 23.4, 49.0, and 81.3 mm, respectively. Larval development time averages about 20 days, but ranges from 13 to 44 days depending on temperature. Mean development time for larvae reared under insectary conditions in northern Florida is 3.4, 2.9, 3.0, 3.9, and 6.6 days for instars 1–5, respectively.



Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 79 Tomato hornworm larva.

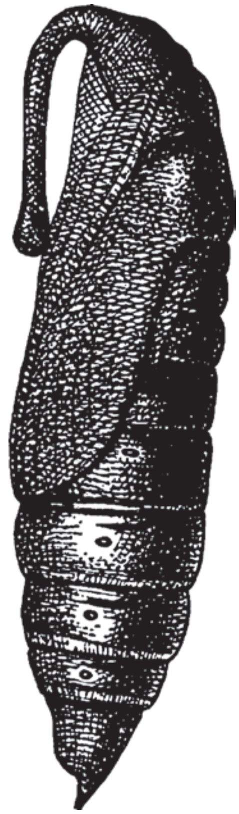


Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 80 Tobacco hornworm larva.

Mature larvae drop to the soil at maturity and burrow to a depth of 10–15 cm. There they form a pupal cell measuring about 7 cm long and 4 cm wide, and pupate within. The interval between entering the soil and pupation is usually 4–8 days. The pupa is large and elongate-oval in form, but pointed at the posterior end. It measures 45–60 mm in length and 13–14 mm in width. The pupa bears a pronounced maxillary loop, a structure that encases the mouthparts. The maxillary loop in tobacco hornworm extends back about one-fourth the length of the body, whereas in tomato hornworm it is longer, usually extending for about one-third the length of the body (Figs. 81 and 82). The color of the pupa is brown or reddish brown. Duration of the pupal stage is protracted and variable. Pupal duration often exceeds 100 days, even in the summer generations, but may be as short as 15 days, and 21 days is about average. Overwintering pupae do not emerge synchronously, with emergence spread from May to early August; a few even diapause through two winters.

The adults of both species are large moths with stout, narrow wings, and a wing span of 80–130 mm. The forewings are much longer than

Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 81 Tomato hornworm pupa.



Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 82 Tobacco hornworm pupa.

the hind wings. The females are larger than the males and can be differentiated from them by the narrower antennae. Both species are dull grayish or grayish brown in color, though the sides of the abdomen usually are marked with six orange-yellow spots in tobacco hornworm and five spots in tomato hornworm. The hind wings of both species bear alternating light and dark bands (Figs. 83 and 84). Adults become active at sunset, when they can be observed feeding at flowers. Though some adults remain active throughout the night, most activity occurs early in the evening and just before dawn. Both hornworm species likely produce sex pheromone, but only that of the tobacco hornworm has been identified. The preoviposition period of moths is about 2 days, and eggs are deposited for about 4–8 days.

Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 83 Tomato hornworm adult.

These insects feed only on solanaceous plants, particularly tomato and tobacco. They are recorded from other vegetables such as eggplant, pepper, and potato, but such feeding is unusual. Several

Tomato Hornworm, *Manduca quinquemaculata* (Haworth) and Tobacco Hornworm, *Manduca sexta* (Linnaeus) (Lepidoptera: Sphingidae), Figure 84 Tobacco hornworm adult.

solanaceous weeds are reported to serve as hosts, including groundcherry, *Physalis* spp.; horsenettle, *Solanum carolinense*; jimsonweed, *Datura stramonium*; and nightshade, *Solanum* spp.; but wild hosts are unimportant larval food sources relative to crops. Adults imbibe nectar from flowers of a number of plants such as catalpa, *Catalpa speciosa*; daylily, *Hemerocallis* sp.; hollyhock, *Althaea rosea*; jimsonweed; four o'clock, *Mirabilis jalapa*; mallow, *Hibiscus lasiocarpus*; mimosa, *Albissia julibrissin*; and tobacco.

A large number of natural enemies is known from tobacco and tomato hornworm. Natural enemies of the egg stage include *Trichogramma* sp. (Hymenoptera: Trichogrammatidae) and *Telenomus* sp. (Hymenoptera: Scelionidae), but these are thought to be of little importance. Of greater importance is the stilt bug *Jalysus spinosus* (Say) (Hemiptera: Berytidae) and other general predators such as bigeyed bugs (Hemiptera: Lygaeidae) and lacewings (Neuroptera: Chrysopidae).

Larvae often are parasitized by *Apanteles congregatus* (Say) (Hymenoptera: Braconidae), and larvae are sometimes seen bearing clusters of white pupal cases formed by this wasp, attached to their bodies. In North Carolina, 30–40% of hornworms may be parasitized by this wasp. In contrast to this one species of wasp accounting for most of the parasitism by Hymenoptera, a number of insects in the order Diptera, particularly the Tachinidae, attack tobacco and tomato hornworm. Records of tachinid parasitism from tomato hornworm include *Compsilura concinnata* (Meigen), *Drino incompta* (Wulp), *D. rhoeo* (Walker), *Lespesia frenchii* (Williston), *Winthemia leucanae* (Kirkpatrick), and *W. quadripustulata* (Fabricius). Records of tachinids from tobacco hornworm include *Carcelia* spp., *Drino incompta*, *D. rhoeo*, *Lespesia* spp., *Metavoria orientalis* Townsend, and *Winthemia quadripustulata*. In North Carolina, the proportion of hornworm larvae parasitized by tachinids increases during the season, sometimes attaining 100%. The number of tachinid eggs per hornworm larva also increases seasonally, indicating a greater abundance of flies. Also of great significance as a mortality agent of larvae is *Polistes* spp. (Hymenoptera: Vespidae). These wasps kill and consume, or sometimes carry away to provision their nest, a very high proportion of larvae. Apparently *Polistes* spp. is the most important larval mortality factor in North Carolina.

Pathogens sometimes affect hornworms. A bacterial disease that causes the larva to blacken and droop is sometimes reported to kill larvae, but this does not occur regularly, and is observed mostly at very high larval densities. Larvae also are susceptible to infection by the fungus *Entomophaga aulicae*, but this disease also does not occur widely.

Vertebrates may prey on the pupae. Skunks and moles are particularly important. Tachinids emerge from the prepupal and pupal stages, but attack only the larvae.

Damage

Although these insects are common, they are not serious pests in commercial agriculture because they are easily killed by insecticides. In home gardens they often cause considerable damage to tomato.

Larvae are defoliators, usually attacking the upper portion of plants initially. Rather than chewing holes in the leaf, they usually consume the entire leaf. Sometimes they attack green fruit. Because the larvae of hornworms attain such a large size, they are capable of high levels of defoliation. The consumption of tobacco foliage by larvae is 5.2, 9.7, 33.5, 175.4, and 1,941.4 cm^2 by instars 1–5, respectively, for a total of 2,165 cm^2. Note that about 90% of the foliage consumption occurs during the final instar, and although the exact value of foliage consumption would differ on tomato, the pattern would be the same. Larvae blend in with the foliage and are not easy to detect. Thus, it is not surprising that they often are not observed until they cause considerable damage at the end of the larval period.

Management

Moths are attracted to light and can be captured in light traps. Light traps have also been used to attempt suppression of hornworm populations, and although some reduction was noted, this approach has not proved practical. Isoamyl salicylate is attractive to both species of hornworms. Visual examination of foliage usually is recommended for monitoring of larval populations. Young larvae of tobacco hornworm tend to be found in the upper regions of the plant, whereas larvae of tomato hornworm tend to be lower; differential flight and oviposition behavior between the species is implicated.

Chemical insecticides or *Bacillus thuringiensis* are applied to the foliage for larval suppression. The mature caterpillars are more difficult to kill, so young larvae should be targeted. The pupae are large and not buried very deeply in the soil, so greater than 90% mortality is caused by normal soil tillage practices. Hand picking and destruction of larvae is often practical in the home garden.

To take advantage of the preference of *Polistes* wasps for hornworm larvae, wasp shelters or nesting boxes have been placed in tobacco fields to encourage the wasps, and wasp colonies were relocated into tobacco. Although wasp predation was inadequate to prevent damage to tobacco, this approach might be satisfactory for tomato.

Tobacco and tomato hornworm thrive on tobacco plants that are allowed to revegetate after harvest of the leaves, leading to high populations during the next year. Destruction of tobacco stalks, or inhibition of sprouting by application of plant growth regulators, greatly reduces hornworm populations in subsequent seasons. Though not documented, timely destruction of tomato crop residue likely would have similar beneficial effects.

A family of springtails in the order Collembola.

► Springtails

Tonic Receptors

Sensory neurons that are slow to adapt to continuing steady stimuli, with the receptor potential remaining elevated (contrast with phasic receptors).

Tooth-Necked Beetles

Members of the family Derodontidae (order Coleoptera).

► Beetles

Tormogen Cell

An epidermal cell that forms a depression in the integument and which contains a seta, often is a flexible socket. It typically is innervated and has sensory capabilities.

Torre-Bueno, José Rollin De La

José de la Torre-Bueno was born at Lima, Peru, on October 6, 1871. At the age of 14 he and his family moved to the United States. He attended Columbia University and graduated in 1894. He obtained employment with the General Chemical Company of New York, where some of his principal responsibilities involved editorial work. He was an active member of the Brooklyn Entomological Society, and helped revive the society's publications as the Bulletin of the Brooklyn Entomological Society, New Series, and of Entomologica Americana, New Series. He served as editor of both until he died. Torre-Bueno was a hemipterist, and published "Synopsis of the North American Hemiptera Heteroptera" in three parts (1939, 1941, 1946). In 1937 the Brooklyn Entomological Society published Torre-Bueno's "Glossary of Entomology." Though the "Glossary" was a revision of J.B Smith's "An explanation of the terms used in entomology," it became a classic publication. It was updated in 1989 by S.W. Nichols. Torre-Bueno died in Tucson, Arizona, on May 3, 1948.

Townes, Jr., Henry K

Henry Townes was born at Greenville, South Carolina, USA, on January 20, 1913. He received B.S. and B.A. degrees from Furman University in

1933, and then attended Cornell University where he attained the Ph.D. in 1937. He taught at Cornell and Syracuse Universities until receiving a fellowship in 1940 to work at the Philadelphia Academy of Natural Sciences in Philadelphia, where he prepared a catalog on the Nearctic Ichneumonidae. He also worked at the U.S. National Museum, where he was employed by the United States Department of Agriculture as a taxonomist. In 1949 he moved to North Carolina State University, where he worked on tobacco pests, and traveled to the Philippines to advise the government on pests of rice and corn. In 1956 he moved to the University of Michigan to work on Ichneumonidae. Henry and his wife Marjorie founded the American Entomological Institute in Ann Arbor, Michigan, in 1962 as an independent, nonprofit research institute. Henry also worked briefly at Michigan State University and Carleton University during the early stages of the institute, but it soon became a mecca for parasitic hymenopterists, and a full-time job. The Institute relocated to Gainesville, Florida, in 1985. Henry was passionate about the study of Ichneumonidae, became known as the world's foremost authority, and amassed the world's best collection. He published nearly 140 articles or books during his career, of which nine were at least 500 pages long. Along with colleagues, he established a firm knowledge of this group, one of the largest families of insects known. Henry Townes died at Gainesville, Florida, on May 2, 1990.

Toxemia

A condition produced by the dissemination of toxins in the blood, though the bacteria are confined to the gut (e.g., brachytosis).

Toxicant

A toxic substance, often the active ingredient in pesticide formulations.

► Insecticides
► Acaricides or Miticides

Toxicity

The ability of a toxin to harm or kill an organism.

► Insecticide toxicity

Toxicogenic Insects

Insects capable of producing disease in plants due to injection of saliva or other secretions, and in the absence of microbial pathogens.

Trachea (pl., Tracheae)

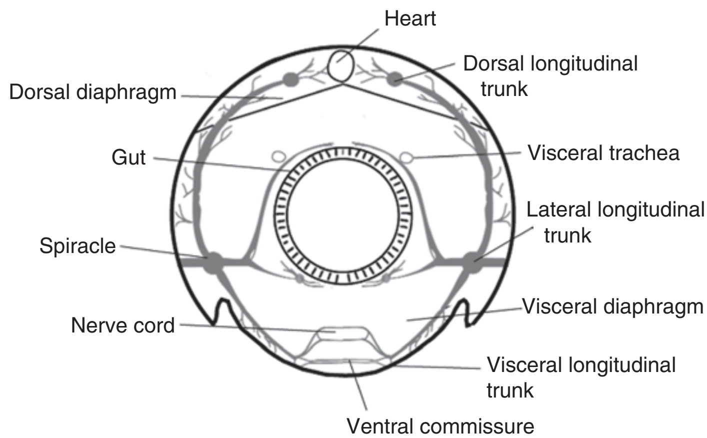
An internal tube that delivers air to tissues, and part of a system of large and small tubes. The external openings of the system are called spiracles, and the smaller tubes are called tracheoles. Air sacs, or dilated areas of trachea, are often found in the system (Fig. 85).

► Tracheal System and Respiratory Gas Exchange

Tracheal Gill

An extension of the insect's body that contains numerous tracheae and serves as a site for oxygen extraction from water. The heavily tracheated flaps or filaments of the body wall are usually lateral or ventral expansions of the thorax or abdomen, and gas exchange occurs across the body surface.

► Tracheal System and Respiratory Gas Exchange



Trachea (pl., Tracheae), Figure 85 Cross section of the abdomen of an insect, showing the principal trachea and tracheal connections (adapted from Chapman 1998, The insects: structure and function).

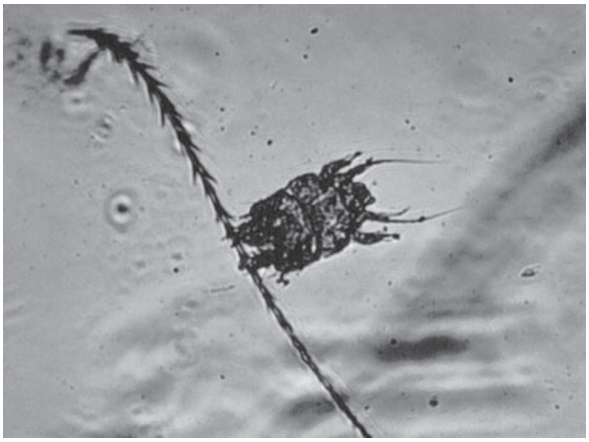
Tracheal Mite, *Acarapis woodi* (Rennie) (Acariformes: Tarsonemidae)

THOMAS C. WEBSTER
Kentucky State University, Frankfort, KY, USA

The tracheal mite is an internal parasite of honey bees. It feeds and reproduces inside the prothoracic tracheae of the adult bee. If a bee is heavily infested, its tracheae become scarred and filled with mites. Bees from heavily infested colonies may be seen crawling on the ground nearby, unable to fly.

Young bees are more susceptible to infestation than older bees. The female mite enters the tracheal tube at the spiracle, and lays eggs within several days of entry. The egg is followed by a larval and a pharate nymphal stage. The immature stages last 11–12 days for males and 14–15 days for the larger females. Immature and mature mites feed by piercing the host bee's tracheal wall with stylet mouthparts, and consuming the hemolymph. Male and female offspring mate in the trachea. Only mated females exit the spiracle to find another host bee (Fig. 86).

The means by which tracheal mites kill bees is not entirely clear. Some bees found crawling near infested hives have no mites or any apparent damage to their tracheae. Possibly, pathogen outbreaks in a bee colony are stimulated or mediated by the mite.



Tracheal Mite, *Acarapis woodi* (Rennie) (Acariformes: Tarsonemidae), Figure 86 Female tracheal mite clinging to a bee hair, in wait for a new host bee.

Dispersal from bee to bee is most rapid in winter when the bees cluster tightly. Since no bees are reared during winter, the proportion of bees which are infested rises considerably in winter. Consequently, a heavy infestation is often discovered on the first warm days of early spring, when many bees are found crawling on the ground near the hive. Tracheal mites spread from hive to hive when infested bees drift to, or rob honey from, other hives nearby.

An earlier name, the acarine mite, has been abandoned because it is meaningless and redundant. Two closely related mites, *A. externus* and *A. dorsalis*, live externally on the bees. They are not known to be harmful to their hosts.

History

The tracheal mite was first identified in 1919, when it was found in Scotland. Originally the mite was implicated in the "Isle of Wight disease," which had plagued the British Isles earlier in the century. However, more recent studies suggest that the disease was not caused simply by mite infestations.

Since then, the mite has been discovered in many other parts of the world. It is very well adapted to life as a honey bee parasite and is not found on hosts other than *Apis* species. Consequently, the host-parasite relationship must be very old.

Mexico was found to have the mite around 1980. In 1984 it was discovered in the United States, having apparently entered Texas from Mexico. Infestations were confirmed in Canada in 1986. By the late 1980s many thousands of hives in the United States and Canada were dying yearly. This parasite was rapidly dispersed by the shipment of queen and package bees, and migratory beekeeping operations. By the late 1990s, however, tracheal mite infestations had declined dramatically. Now the mite continues to be endemic in North America, as it is elsewhere. The decline of tracheal mite infestations is still not well understood.

Diagnosis and Control

Tracheal mites are identified by removing the prothoracic tracheae alone, or within the anterior portion of the bee's thorax. Thoracic muscle tissue is cleared with potassium hydroxide solution. Tracheal mites and scarring of the tracheae are easily seen by low power microscopy. Positive identification is not possible for those without a microscope.

Menthol, formic acid and chlorobenzilate have been used effectively as fumigants to control the mites inside the hive. Vegetable oil also has been used with success, mixed with sugar and placed inside the hive. Bees that walk over the oil preparation acquire a fine coating which seems to inhibit mite dispersal among bees in the hive.

Some bees groom themselves of mites. This trait is heritable, so selection for grooming behavior can be part of a breeding program for tracheal mite resistance.

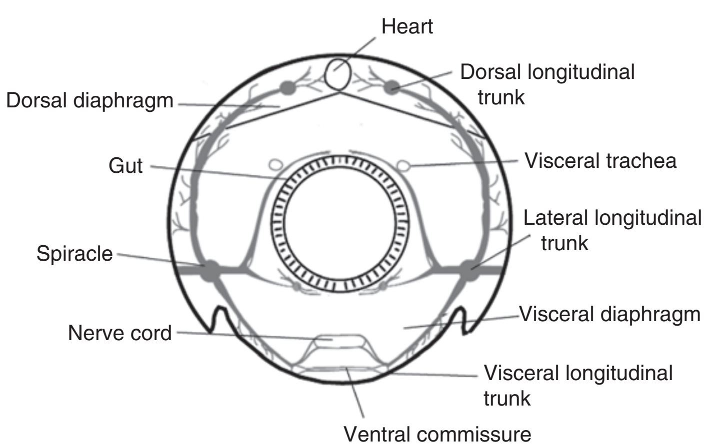
Tracheal System and Respiratory Gas Exchange

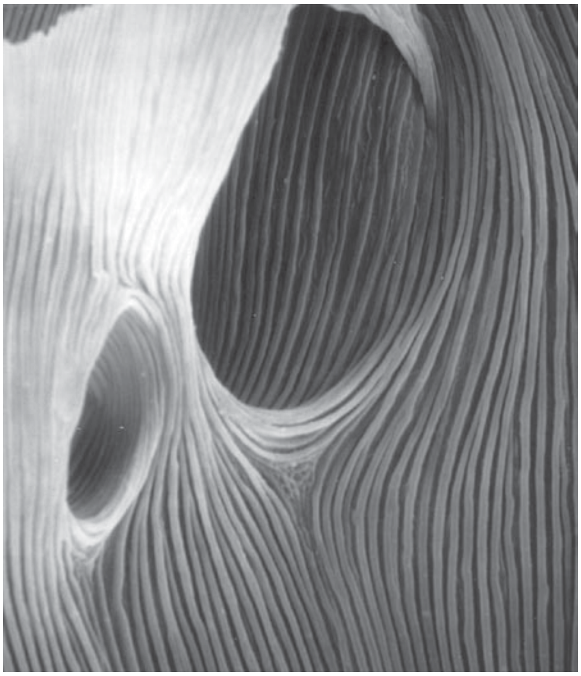
JAMES L. NATION
University of Florida, Gainesville, FL, USA

Insects breathe through a complex network of tubules, the tracheae. Large tracheae connect to spiracles opening at the surface of the body, where air enters and carbon dioxide exits. Spiracles usually occur on the pleural surface of the body, typically one on each side of each segment, but numerous variations have evolved. Airflow may be tidal, in and out of the same spiracles, or directed flow with inflow through anterior spiracles and outflow through posterior abdominal ones. Interconnecting longitudinal and transverse tracheal trunks make directed flow possible and more efficient than tidal flow because the system is constantly flushed and incoming air is not mixed with used air. Larger tracheal tubes send off branches that become smaller in diameter as they ramify to all tissues. The smallest diameter tracheoles (tubes 1 μm diameter or less) end blindly on the surface of most cells and even indenting some cells, like pushing a finger into a soft balloon, until they terminate within a few μm of mitochondria that actually use the oxygen. Tracheoles indented into a cell are said to be intracellular, although in reality they are not really within the interior of the cell, for the tracheal epithelium cell layer and the cell membrane separate the tracheole from the cytoplasm of the cell. The chitinous lining of tracheae are shed at each molt, but the lining of tracheoles is not molted. Spiracular valves at the body surface often can be closed to reduce water loss from the system. Although all parts of the tracheal system allow oxygen to diffuse out to the tissues and carbon dioxide to enter, most of the gas exchange occurs across the smaller tracheae and tracheoles because they are the parts of the system in intimate contact with cells. The extensive ramification of tracheae and tracheoles and their relationship to all cells are similar to the pattern of the vertebrate circulatory system, with the exception that tracheoles end blindly and vertebrate capillaries do not. The tracheal system is remarkably efficient for insects. Insects do not accumulate an oxygen debt during vigorous activity, such as flight. In some very small insects (smaller than a *Drosophila* fly), simple diffusion of gases through the tracheae may suffice, but most insects, large or small, actively ventilate the system by rhythmic compression of the abdomen. Muscular movements during flight or other vigorous muscular and body movements compress the tracheal system and act like a pump to ventilate the system (Figs. 87, 88, and 89).

Tracheae develop from embryonic ectodermal tissue, and all parts, including the smallest tracheoles, have an epicuticular lining or intima that is continuous with the external cuticle. In some larger insects one can see larger tracheal trunks that are pulled out and still attached to the old exoskeleton at a molt. Larger tracheae may contain a thicker endocuticle layer that gives more strength to the tubular structure. The internal surface of tracheae contains a hydrophobic substance that helps prevent water from entering the tracheae, and reduces evaporative water loss from the internal tracheal surfaces. Thickened, tight spirals of the cuticular intima, the taenidia, strengthen tracheae, provide elasticity, and help the tubes resist compression and collapse. Even tracheoles and air sacs show some evidence of taenidial reinforcements, but thickenings usually



Tracheal System and Respiratory Gas Exchange, Figure 87 Cross section of the abdomen of an insect, showing the principal tracheae and tracheal connections (adapted from Chapman 1998, The insects: structure and function).



Tracheal System and Respiratory Gas Exchange, Figure 88 **A view from inside a large trachea in a mole cricket. This scanning electron micrograph shows the branching of two smaller tracheae and the taenidial windings that strengthen all tracheae and keep them from collapsing.**

Tracheal System and Respiratory Gas Exchange, Figure 89 **A scanning electron micrograph view of a trachea (about 2 μm diameter) that branches several times into smaller tracheae and tracheoles that penetrate the salivary gland tissue of a male Caribbean fruit fly, *Anastrepha suspensa*.**

are widely spaced apart so that these parts of the system are more flexible.

Tracheae are not simply tubes and tubules; every part of the system contains living cells. Tracheal epithelial cells are thin and flattened, like many small pieces of ribbon glued together and wrapped around the tracheae. A tracheal epithelial cell encloses a tracheole. New tracheae and tracheoles develop as the insect grows. A new tracheole develops as a tubule or cavity within a tracheal epithelial cell that grows out, often in multiple finger-like shapes, from the surface of a larger trachea. The tracheole unites with the larger tracheal branch to which the parent tracheal cell is still attached.

Air sacs, dilated portions of tracheae, occur in many insects. They are variable in size, but frequently are large in flying insects such as honeybees, cicadas, many adult Diptera, and some scarab and buprestid beetles. The rhythmical squeezing action of working flight muscles pumps air sacs like a bellows and increases the flow of air through the system. Air sacs may collapse as growing tissues fill the body space, and by collapsing they make room for the new tissue, with little change in the general body shape. Air sacs serve a hydrostatic function in some aquatic insects, and allow more freedom in vibration of the tympanic membrane in some sound-producing insects. By taking up space and restricting hemolymph volume, air sacs increase solute concentration in the hemolymph without increasing total solute.

Hemocytes, the circulating blood cells, are the only cells in the body that do not have direct tracheal connections. Recently, it was shown that hemocytes tend to accumulate on very thin-walled tufts of tracheae near the last pair of abdominal spiracles and in the compartment at the tip of the abdomen called the tokus. It seems as if the highly branched tracheal system of the last segment and the tokus are sites where the hemocytes can become oxygenated; they probably pass their carbon dioxide directly into the hemolymph.

Discontinuous Breathing

Some insects regulate spiracle closing and opening, and keep the spiracles tightly closed and/or apparently closed for a high percentage of the time. Gas exchange occurs in three periods named the open, flutter, and closed periods (often designated as O, F, and C, respectively) because of the action of spiracles over the duration of a cycle. This functional pattern, variously known as discontinuous release of CO_2, passive suction ventilation, discontinuous ventilation cycle, and as the discontinuous gas exchange cycle (DGC) has been known in some insects for more than half a century. The earliest studies were in diapausing pupae of Lepidoptera, and initially DGC was thought to be limited to quiescent insects in a depressed state of metabolism. DGC patterns, however, have been observed in a number of different insects in various states of activity, including ants, the cockroach *Periplaneta americana*, a number of adult tenebrionid beetles, the locust *Schistocerca gregaria*, the lubber grasshopper *Romalea guttata*, and adults of additional species. DGC behavior also occurs in some arthropods other than insects. During DGC, accumulated CO_2 is discharged periodically in bursts during brief intervals when spiracles are open. After a burst, the spiracles are closed for some period of time that varies from species to species. During the closed interval, tissues use oxygen and intratracheal oxygen tension falls. Most insects that exhibit discontinuous gas exchange allow the spiracular valve to flutter with imperceptible amplitude to the unaided eye during a portion of a cycle. The fluttering (F) phase allows small amounts of O_2 to be sucked into the tracheal system by the slight negative pressure arising from O_2 consumption by the tissues. The F phase usually is considered to involve convective transfer of O_2. This has given rise to the name "passive suction ventilation" that sometimes is applied to the process. The slight internal vacuum retards the outward loss of water vapor and CO_2 during the fluttering phase, and the low influx of O_2 lengthens the time to full opening or "burst" of spiracles. Tissues produce CO_2 even when the spiracles are closed. The high solubility of CO_2 in aqueous solutions enables insects to accumulate bicarbonate ion, HCO_3^-, in the hemolymph. Buffering capacity of hemolymph aids in solubilizing CO_2 as bicarbonate, and this keeps gaseous CO_2 from building up rapidly in the tracheal system. At some point, probably different for different insects, the relationship between gaseous O_2 and CO_2, and HCO_3^- in solution reaches an equilibrium at which tracheal tension of CO_2 and O_2, and/or pH change in the hemolymph, trigger spiracle opening and release of CO_2 from the hemolymph as a gas. It often has been assumed, but not proven, that the functional benefit of discontinuous ventilation is conservation of water. In diapausing pupae that must pass a long winter under the soil, leaf litter, or other pupation site, water conservation seems quite necessary and a reasonable driving mechanism for the evolution of discontinuous ventilation, since the pupa is a closed (to food/water intake) system. Most adult insects that exhibit discontinuous ventilation do so only intermittently, and the rest of the time they ventilate the system continuously. Surprisingly, some insects do not show DGC respiration under conditions that might be expected (based upon assumptions) to promote the behavior. For example, the lubber grasshopper *Romalea guttata*, which discontinuously ventilates at times, tends to ventilate continuously when dehydrated, a physiological condition in when it presumably has a great need to conserve water. No good explanation has been provided for such behavior. The ant *Camponotus vicinus*, which exhibits discontinuous gas exchange, actually loses more water than CO_2 during the period when the spiracles are open. The harvester ant, *Pogonomyrmex rugosus*, and similar desert ants have a relatively high percentage (up to 13%) of body water loss through the tracheal system, even though they exhibit discontinuous ventilation at times. Whether the higher rate of water loss from the tracheal system in these ants is a significant stress for them may depend upon how much of the time the ants exhibit discontinuous gas exchange, how much access they have to food with high water content, and duration of exposure to environmental extremes. Although it seems somewhat intuitive that water loss might be high from the tracheal system, actual measurements in some insects indicate that more than 90% of total body water loss occurs through the cuticle, with only 2–5% typically lost from the tracheal system. In summary, a definitive selection mechanism for evolution of discontinuous gas exchange cycling is not evident, but the mechanism is fairly widespread in many insects including larvae, pupae, and large and small adults. Water conservation, ecological niche occupied by insects, and interactions of sensory components may be important factors.

Gas Exchange in Aquatic Insects

The tracheal system of most aquatic insects is structurally the same as that of terrestrial insects, i.e., with open spiracles and an extensive network of tracheae and tracheoles. These aquatic insects breathe air by coming to the surface. Water is prevented from entering the system by the hydrophobic surface of the tracheae, and in some cases, by spiracles that can be closed. Many aquatic larvae have a tracheal system with only one functional pair of spiracles near the tip of the abdomen. When the insect comes to the surface, it does so with the posterior end uppermost and only the tip of the abdomen bearing the spiracles is held above the surface. A large number of aquatic insects submerge with a bubble or film of air around a spiracle. These gas bubbles or films of air are called gas gills, and they may be temporary or permanent. Temporary ones must be replenished periodically as the oxygen is used. Permanent gas gills are called plastrons. They do not collapse and oxygen can be extracted from water into the gill (if the water is well aerated), allowing the insect to live underwater. A plastron consists of an extensive physical meshwork, either of fine hairs or setae, or a meshwork of small pores and channels that can hold a volume of air and can present a large water-air interface. Plastrons are common in aquatic insects and can take many physical forms. Some aquatic insects are able to capture and utilize gas bubbles of oxygen released by aquatic plants. Certain species of Diptera, Coleoptera, and Lepidoptera independently evolved modifications for piercing aquatic plants for air.

Some aquatic insects have a closed tracheal system without functional spiracles. The lack of functional spiracles eliminates any chance that water will enter the system, but oxygen must diffuse into the tracheal system through the cuticle, a breathing mechanism called cutaneous respiration. Some aquatic insects have tracheal gills, thin flaps of cuticle with many tracheoles just under the cuticle. Larvae of Trichoptera, Plecoptera, Odonata, and some Lepidoptera utilize cutaneous respiration, facilitated by extensive elaboration of thin hair-like or flap-like tracheal gills from the body surface. Internally these insects still have an extensive tracheal system, and gas transport through the tracheae and tracheoles to internal body tissues is the same as in terrestrial insects. Movement of water over the gill and body surface of aquatic insects is important in maintaining a fresh supply of oxygenated water in contact with the body, and most use undulations of the body and/or movements of the gills themselves to create ventilatory currents of water. Larvae of some dragonflies (Anisoptera) draw water into the rectum by elastic expansion of the body as dorso-ventral compressor muscles relax. Typically there are six main gill folds of the cuticular intima in the anterior part of the rectum with extensive tracheoles just beneath the intima that extract O_2 from the water. The water is pumped out by dorso-ventral compression of the abdomen. The rate of ventilation varies with several factors including the O_2 content of the water. About 85% of the water in the rectum is renewed during each pumping cycle, and 25–50 cycles/min have been recorded. Larvae also will come to the surface and ventilate the rectum with air when oxygen content of the water is very low.

Many hymenopterans and dipterans are parasitic on other insects, and have been little studied with respect to respiration, perhaps for the obvious reasons that they are usually small and hidden in the body of the host. Cutaneous respiration is probably very important. Many chalcid wasps and tachinid flies hatch from eggs laid on the surface of the host insect and they eat their way into the host. They orient the posterior pair of spiracles at the body surface of the host so that they breathe air directly. Bot fly larvae, *Hypoderma* spp., migrate to the skin of the vertebrate host where they bore a tiny opening to the surface through which gas exchange occurs. Respiration is cutaneous in earlier instars that are migrating through the body of the host.

Respiratory pigments occur in only a few insects. *Chironomus* spp. larvae have a small hemoglobin molecule composed of two chains with a MW of 31,400. The hemoglobin is not in the cells, but occurs as a circulating hemolymph protein. The molecule has extraordinarily high affinity for oxygen and is 50% saturated at a pO_2 of 0.6 mmHg at 17°C. This means that it will not give up its oxygen to tissues except under extremely low oxygen tension. Its principal function may be to aid recovery from anaerobic conditions and to provide limited O_2 to some critical tissues, such as the nervous system. Hemoglobin occurs in certain cells of *Gastrophilus* spp. (horse bots) and in larvae and adults of some beetles (Family Notonectidae, certain species of the genera *Anisops* and *Buenoa*). In contrast to the situation in *Chironomus* larvae, the hemoglobin of the beetle *Anisops pellucens* is only 50% saturation at a pO_2 of 28 mmHg at 24°C (i.e., it will give up half of its oxygen at 28 mmHg, a pressure that might occur in actively metabolizing tissues), giving it much more functional potential. The beetle may get up to 75% of the O_2 consumed during a normal dive from its hemoglobin. Increased temperature also causes the hemoglobin to release more oxygen, which could be important to actively working tissues such as muscles.

The embryo developing inside the egg must obtain sufficient oxygen for development. The majority of aquatic and semi-aquatic insects lay eggs with no special respiratory structures incorporated into the shell, while eggs of a majority of terrestrial insects contain special structures for respiration, including an extensive, inner chorionic meshwork that can function as a plastron when the egg is submerged in well aerated water. Gas exchange in eggs with no special respiratory structure occurs by simple diffusion through the egg shell.

Non-Respiratory Functions of the Tracheal System

Tracheae serve some important functions other than gaseous transport. Tracheae act as the connective tissue of insects, helping to tie cells and tissues together. Tracheae are important as a structural base for at least two important endocrine tissues (i) the prothoracic glands whose cells are attached to the tracheae near the prothoracic spiracle in larvae of Lepidoptera, and (ii) cells of the epitracheal glands attached to the surface of the major ventrolateral tracheal trunk to each spiracle in lepidopterous larvae. Air sacs lie behind sound producing organs in insects and are important to sound modulation. A large air sac backs up to the tymbal located on each side of the first abdominal segment of male cicadas. The size of the air sac varies with different species, and its size and tuning are partly responsible for the species-specific quality of the sound produced by male cicadas. The interconnected prothoracic tracheae extending across the prothorax and into the prothoracic legs of crickets act as a resonator of sounds. They aid the cricket in discriminating direction of sounds reaching the tympanal membrane located just below the joint of the femur with the tibia (i.e., the knee joint) on each prothoracic leg. Hissing cockroaches produce a hissing sound by expelling air forcefully from certain spiracles when they are disturbed. Lubber grasshoppers, *R. guttata*, release quinones from the tracheal system on the side of the attack when an ant attacks, or when stimulated by probing.

Tracheole

A very narrow trachea (1 µm or less in diameter) that serves as the actual site of gas exchange between the tracheal system and the body tissues because they penetrate organs and lie so close to the cells.

► Tracheal System and Respiratory Gas Exchange

Trachypachidae

A family of beetles (order Coleoptera). They commonly are known as false ground beetles.

► Beetles

Trade Name

The name given a product that is marketed by a company. The same product may be marketed by more than one company using different names.

Trail Pheromone

A pheromone that is deposited along the ground or other substrate that allows insects to maintain the group or to communicate to others in their group (usually nest- or tent-mates) directionality, often to a feeding location.

► Pheromones
► Sociality of Insects

Transcript

A mRNA copy of a gene.

Transcription

The process of producing a mRNA copy of a gene.

Transformation

The process of changing the genetic makeup of an organism by introducing foreign DNA. Transformation may be transient or stable (transferred to succeeding generations.)

Transgene

The DNA that is inserted into the genome of a cell or organism by recombinant DNA methods.

Transgenic Arthropods for Pest Management Programs

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Transgenic organisms contain genes that have been introduced into the genome using biotechnology (recombinant DNA) methods. Transgenic plants (including corn, rice, cotton and squash) have been developed using recombinant DNA methods and currently are grown commercially. Development of the tools to develop transgenic insects and mites has lagged behind that of plants and microorganisms, but genetic modification using recombinant DNA methods have been used to transform a number of pest and beneficial insects and mites. The successful transformation of the fruit fly *Drosophila melanogaster* by a genetically modified transposable element called the P element in 1982 stimulated subsequent research to genetically modify other insects (and mites) using similar methods. (See the entry on Transformation of *Drosophila melanogaster* by P elements for details of this method.)

Domesticated and semidomesticated insects have been modified by traditional breeding methods for hundreds of years. Genetic manipulation has improved disease resistance and silk production in silk moths, and disease resistance and pollination attributes in honey bees. More recently, natural enemies of insects and mites used in biological control programs in agriculture and forestry have been modified by traditional breeding methods and by hybridization of different strains to achieve hybrid vigor. A pesticide-resistant predatory mite (*Metaseiulus occidentalis*), developed with traditional breeding methods, was incorporated into a integrated mite management program in almonds in California. These predators provided effective control of spider mites, reduced the need for costly pesticides, reduced production costs and saved almond growers approximately $22 million per year, most of which was due to fewer applications of pesticides to control the spider mites. This project demonstrated that genetic improvement of natural enemies could result in improved pest management programs. Genetic improvement of natural enemies for biological control of pest insects and mites by traditional genetic methods has involved selecting for resistance to pesticides, lack of diapause, and increased tolerance to temperature extremes, although modification of other traits, such as sex ratio, theoretically could result in improved biological control.

During the past 40 years, a number of pest insects have been sterilized by irradiation or chemicals for use in genetic control programs. This approach to pest management has been called the sterile insect release method (SIRM) or the sterile insect technique (SIT). Male insects are mass reared and sterilized, usually by irradiation, and released in to control a number of serious pests, including the Mediterranean and Caribbean fruit flies, mosquitoes and the New World screwworm *Cochliomyia hominivorax*. The SIRM has been used to eradicate pests or to reduce pest populations.

Sex and the Sorted Insects: A Case Study

Genetic control of pest insects represents an attractive alternative to chemical control of some pests in terms of safety, specificity and the limited negative effect this control tactic has upon the environment. The screwworm (*Cochliomyia hominivorax*) eradication campaign demonstrates what can be achieved with mass releases of males sterilized by irradiation.

The genetic control method used to eradicate the screwworm was called the "sterile insect release method" (SIRM) or "sterile insect technique" (SIT), and involves mass rearing, sterilization of males by chemicals or irradiation, and their subsequent release to mate with wild females. Because females of the screwworm mate only once, any wild female mating with a sterile male fails to contribute progeny to the next generation. By releasing an excess of sterile males (compared to the number of wild males), populations decline in a predictable manner, ultimately becoming extinct. Because absolute population densities were often low in the USA, the number of sterile males that had to be released could be produced in "fly factories."

The screwworm eradication program in the USA was initiated in Florida with small scale trials on Sanibel Island in 1951. The results were promising and the project was geared up to cover the state of Florida and then the southeastern USA. The screwworm was declared eradicated from the southeastern USA in 1959, one year ahead of schedule. Eradication was achieved in a surprisingly short time due to the combined effects of a severe winter in Florida during 1957–1958, which greatly reduced the overwintering screwworm population, and a 17-month eradication program beginning in July 1958 that cost approximately $7 million and involved the release of almost nine billion sterile screwworm flies over an area of approximately 56,000 square miles.

Since 1959, the livestock industry of Florida and adjacent states have saved at least $20 million each year because the screwworm is no longer present; actual benefits are even greater in today's dollars. Furthermore, the elimination of losses due to the deaths of livestock and labor and control costs are only part of the benefits; loss of wildlife to screwworm attack also was eliminated.

The success of the SIRM program in the southeastern USA led the cattle growers of Texas to mount, in collaboration with the state and the USDA, a similar but much more ambitious program in the southwestern USA in the 1960s. This program required more time and effort because the area in which the screwworm was to be eradicated bordered on a front 2,400 km long, stretching from the Gulf of Mexico to the Pacific Ocean. Despite this challenge, and some setbacks with quality control and reinvasion of flies from Mexico, both Texas and New Mexico were declared "screwworm free" in 1964.

The SIRM program was moved into Arizona and California in 1965, and in 1966 the entire USA was declared free of screwworms. To reduce the likelihood that the screwworm would reinvade the USA from Mexico, the program was expanded into Mexico in 1972, with the goal of eradicating the screwworm all the way south to the Isthmus of Tehuantepec.

After successfully eliminating the pest in Mexico, the SIRM program was expanded to cover all of Central America. Screwworms were eliminated from Guatemala between 1988 and 1994, from Belize between 1988 and 1994, from El Salvador between 1991 and 1995, from Honduras between 1991 and 1996, from Nicaragua between 1992 and 1998, from Costa Rica between 1995 and 1999, and from Panama between 1997 and 2000. These eradication programs were carried out so that a barrier zone could be set up at the Isthmus of Panama, which is only 190 km wide as compared to the 2,400 km border that the USA and Mexico share. This barrier zone has been maintained by a combination of quarantines and mass releases of sterile screwworms.

Benefits of this massive, and expensive, screwworm eradication program are large. In 1996, the annual producer benefits in the USA, Mexico and Central America were estimated to be $796 million, $292 million and $77.9 million, respectively. These benefits were due to decreases in deaths of livestock, reduced veterinary services, medicines, insecticides, inspections, handling costs, and increases in meat and milk production. The estimated benefit to cost ratios for the eradication programs average 12.2:1 for Central America to 18:1 for the USA and Mexico.

The principle of sterile insect releases has been applied to other pest insect species, including the Mediterranean fruit fly (*Ceratitis capitata*), tsetse flies (*Glossina palpalis* and *G. morsitans*), mosquitoes (*Anopheles albimanus*), codling moth (*Cydia pomonella*) and ticks.

Sterile insect release programs usually require only males, but both sexes must be reared. Not only is it expensive to rear large numbers of "useless" females, but, in the case of species that vector disease or annoy or bite humans or domestic animals, it is undesirable to release any females, sterile or not! As a result, various genetic methods have been used to develop "genetic sexing strains." Slight differences in size or color of pupae have been used to sort out undesirable females during mass rearing. Most genetic sexing strains are based on maintaining the desired genes (such as *white pupa* or a temperature sensitive lethal) within translocations. However, because translocations can undergo recombination in the region between the translocation breakpoint and the sexing gene, the strains are not completely stable. As a result, if no practical means exist to remove the recombinants, an increasing number of the undesirable females will be reared and released.

Ideally, a genetic sexing method using recombinant DNA methods will become available that could produce only males of high quality and vigor to compete with wild males for female mates. Since an all-male colony will be difficult to maintain (!), this character ideally would be a conditional trait, perhaps dependent upon temperature or some other environmental cue. Because the released males would be sterile they could not persist in the environment, which could reduce potential risks. Other potential improvements using recombinant DNA methods could result in insects containing a marker gene, such as green fluorescent protein, that would allow the released sterile males to be identified readily in the traps used to monitor progress in the program; because such males would be sterile, risks associated with their release would also be low. Finally, recombinant DNA methods might be developed that would allow the insects to be sterilized without radiation; this could reduce the damage produced by irradiation to the entire body and allow fewer insects to be reared and released, resulting in considerable cost savings.

Why Use Transgenic Methods?

Traditional genetic methods have limitations, and recombinant DNA methods offer new opportunities for improving pest management programs (Table 13). For example, significant benefits could accrue if recombinant DNA methods allowed sterile insects to be produced without incurring the negative effects of irradiation. During the sterilization process, the insect's whole body is irradiated, which damages all tissues. As a result, the SIRM requires rearing very large numbers of males for release because the irradiated males are damaged by the sterilization process. Commonly, pest populations are first reduced by pesticide applications or through natural seasonal (winter) mortality to reduce the number of insects that have to be released. The number of males released is usually a

Transgenic Arthropods for Pest Management Programs, Table 13 Pest management goals that might be achieved with transgenic methods

Project type	Objective(s)
Biological control of insect and mite pests	
• Improve survival of natural enemies in environment	Enhance ability to control pests by introducing resistance genes; modify diapause or temperature tolerance traits
• Improve effectiveness of natural enemies	Alter traits such as sex ratio (more females), host/prey specificity; restrict ability to fly
Disease control method	
• Develop insects that introduce a vaccine into their hosts when taking a blood meal	Provide low cost vaccination against widespread, serious diseases such as malaria
Improve domesticated and semi-domesticated insects	
• Improve silk production in silkworms (*Bombyx mori, Philosamia, Anthaerea*)	Improve quantity, quality or type of silk, introduce disease resistance genes, introduce silk genes from spiders or other silk producing arthropods into moths to produce special types of silk
• Improve honey bees, *Apis mellifera*	Insert genes for resistance to bacterial, viral and fungal pest resistance; introduce resistance to mite (*Varroa*) pests; modify pollination behaviors, modify aggressive behaviors

Transgenic Arthropods for Pest Management Programs, Table 13 Pest management goals that might be achieved with transgenic methods (Continued)

Project type	Objective(s)
Population control methods	
• Population replacement	Eliminate traits that make a pest, such as make a pest unable to transmit diseases such as malaria, dengue, sleeping sickness or yellow fever, by altering ability of the pathogen to pass gut or salivary gland barriers; eliminate the need for a blood meal by vector mosquitoes; alter behavior so the vector feeds on only one host. Release altered strain to replace the pest population. Replacement will require some type of drive mechanism or a way to select for the released population in the field.
• Insert useful/deleterious genes	Release genetically modified individuals to mate with a "driver" such as wild individuals in correct ratio to insert genes transposable elements or *Wolbachia* into populations. Proposals include releasing (introgression model) insects with active transposable elements, lethal genes or genes that cause sterility, with the goal of causing so much genetic damage that the pest population crashes (as laboratory populations can do when a new transposable element invades)
Sterile insect release method (SIRM)	
• Sterilize males by recombinant DNA methods to reduce damage from radiation/chemosterilization	Introduce genes and regulatory sequences to cause sterility that can be stimulated by light, diet or other environmental cues during mass rearing, as needed, allowing colony to be reared normally until the transgene(s) is activated
• Mark released males with molecular such as green fluorescent protein, that can be detected in trapped dead males so that the effectiveness of the SIRM program can be assessed	Insert benign marker gene that is expressed or visible in dead insects
• Develop genetic sexing method so that females do not have to be reared, reducing program costs	Introduce a conditional lethal gene so that females can be killed during the mass rearing program when a particular cue is provided

multiple of the estimated density of wild males, with a 100:1 ratio of sterile to wild males commonly used. Rearing such huge numbers of insects is costly and difficult.

Recombinant DNA methods also could allow unique molecular markers to be inserted into the sterile insects, which would allow SIRM program managers to more easily discriminate between released sterile males and wild fertile males caught in the traps used in monitoring the progress of the program. Current marking methods using fluorescent dusts are unsatisfactory because they can reduce fitness of the insects and the dyes do not always adhere, which could falsely indicate that the program is not working well. Other significant benefits could be obtained if recombinant DNA methods make it possible to control the sex of insects being reared in SIRM programs, to introduce lethal genes or genetic loads into pest populations, or to produce vectors of human and animal diseases that are unable to transmit diseases such as malaria, dengue, yellow fever and sleeping sickness.

Recombinant DNA techniques could make genetic improvement of beneficial insects, such as silkworms (*Bombyx mori*), honey bees (*Apis mellifera*) or biological control agents, more efficient and less expensive. Once a useful gene has been cloned, it could be inserted into a number of beneficial species in a relatively short time. Furthermore, recombinant DNA methods broaden the number and type of genes potentially available for use; no longer is a project dependent upon the intrinsic genetic variability of the species under study.

Many have speculated about the role that recombinant DNA methods could play in the genetic control of insects that serve as the vectors of human and animal diseases or pests of agricultural crops. Some consider transgenic technology to be a new and vitally important pest management tool for the control of serious pests that cannot be controlled by any other means. Others have expressed reservations about the goals and methods suggested.

There are limitations to transgenic methods at present. For example, traits primarily determined by single major genes are most appropriate for manipulating insects by recombinant DNA techniques. Methods for manipulating and stabilizing traits that are determined by complex genetic mechanisms are not yet feasible with insects, although such methods could be developed using procedures similar to those developed by plant molecular geneticists.

Components of a Genetic Manipulation Project

Genetic manipulation with recombinant DNA methods requires methods for efficient and stable insertion of foreign genes into the genome of the target insect or mite, and the availability of useful genes and appropriate promoters and other regulatory elements to obtain effective expression of the inserted gene in the appropriate tissue at the appropriate time. Inserting cloned DNA into insects can be accomplished using several different techniques. If the inserted DNA is incorporated into the chromosomes in the cells that give rise to the ovaries and testes, the foreign gene(s) or transgenes could be transmitted faithfully and indefinitely to successive generations (stable germline transformation).

Initial research on stable transformation methods was accomplished with *Drosophila melanogaster* when it was discovered that the P element could be genetically manipulated to serve as a vector to carry foreign genes into the chromosomes of germ line cells. In molecular genetics, vectors are self-replicating DNA molecules that transfer a DNA segment between host cells. P-element vectors were investigated as possible gene vectors for insects other than *Drosophila*, but failed to function in other insects. Other transposable element vectors such as *mariner*, *piggy*-Bac, *Hermes* and *hobo* have been isolated from insects and genetically modified for use as vectors to transform insects other than *D. melanogaster*. Another approach to genetic modification involves the genetic engineering of insect gut symbionts. For example, a bacterial symbiont of the Chagas disease vector *Rhodnius prolixus* lives in the insect's gut lumen and is transmitted from adult to progeny by contamination of egg shells or of food with infected feces. The symbionts have been genetically engineered and transmitted to hosts lacking any symbionts. The goal is to reduce the ability of *Rhodnius* to transmit pathogens when it takes a blood meal, perhaps by infecting the bugs with gut bacteria that produce antibiotics that kill the Chagas disease agent. Likewise, gut symbionts of tsetse flies (*Glossina* species), which are vectors of both animal and human African sleeping sickness, also have been transformed. Proposals have been made to release tsetse flies carrying transgenic symbionts so the released flies could replace or out-compete native populations, but fail to transmit the disease.

The ability to introduce cloned genes into the germ line at a predictable chromosomal site is especially desirable, as it reduces the likelihood of "position effects" on gene expression. Genes introduced by transposable element and viral vectors insert more or less randomly into the chromosomes, making it difficult to predict how well the transgene will be expressed. One method for accomplishing precise insertion is based on a system found in the yeast *Saccharomyces cerevisiae*. A gene for yeast recombinase, called FLP recombinase, and two inverted recombination target sites (FRTs) that are specifically recognized by the FLP enzyme have been cloned. The FLP-FRT system has been modified to insert DNA into a specific site in a *Drosophila* chromosome. If the FRT sites can be inserted into other insects, the system could reduce concerns about unstable transformation that may be elicited by the use of transposable element vectors.

A few experiments have delivered linear or circular plasmid DNA into the genome of insects without using a specific vector. This approach has the advantage of eliminating potential risks of introducing vector sequences into the insect genome, which could result in increased stability of the inserted genes in the genome. This approach assumes that the inserted gene is no more likely than any other gene to be moved by "wild" transposable elements or viruses.

A variety of methods have been evaluated for delivering genes into insects in order to achieve transformation. These include microinjection of transposable element vectors and other vectors into dechorionated insect eggs, microinjection of plasmids directly into the abdomen of female mites or insects (maternal microinjection), soaking eggs in DNA, using sperm to carry foreign DNA into eggs of the honey bee, using microprojectiles (gene gun technology) to insert DNA into insect eggs, electroporation of DNA into insect eggs, transplanting nuclei and cells, and transformation of an insect microbial gut symbiont (which has been called paratransgenesis because the insect genome has not been modified).

What Genes are Available to Insert?

Cloned DNA can be isolated from the same or other species. It is technically feasible to insert genes from microorganisms into arthropods and have the DNA transcribed and translated, although coding sequences isolated from microorganisms must be attached to promoters (controlling elements) and other regulatory sequences derived from a higher organism so that the gene can be expressed in insects. The regulatory sequences determine when a gene will be transcribed, at what level, in what tissues, and how long the messenger RNA can be used for translation. Considerable research is under way to identify regulatory sequences that regulate genes in specific insect tissues, such as the salivary glands and gut. It also may be possible to isolate a gene from the species being manipulated, alter it, and reinsert it into the germ line, although this approach has not yet been attempted in insects other than *Drosophila* to date.

Project goals will dictate what type of regulatory sequences might be most useful to regulate transgene expression. In some cases, a low level constitutive production of transgenic proteins will be useful, while in other cases high levels of protein production will be required after inducement by a specific cue. Researchers may have to evaluate the trade-offs between high levels of protein production and the subsequent negative effects these could have on fitness of the transgenic arthropod strain based on the specific goals of each program.

After inserting the desired genes and regulatory elements, the next issue is how to detect whether the gene has in fact been incorporated into the germ line. Because transformation methods are relatively inefficient, a screening method is needed to identify transformed individuals. This process is relatively simple in *Drosophila*, where there is a wealth of genetic information and visible markers can be used to identify transgenic individuals. Most pest or beneficial arthropods lack such extensive genetic information or markers. Identifying transformed individuals could be achieved using a pesticide resistance gene as the selectable marker. However, the release of pesticide-resistant pests into the environment would create concerns about risk. Another option is to use antibiotic resistance genes as selectable markers to identify transgenic insects. However, horizontal movement of resistance genes into microbes in the environment could result in increased levels of antibiotic resistance; the likelihood of this potential risk has not been quantified. Antibiotic resistance gene markers are no longer considered safe for release into the environment in transgenic crops, and methods have been developed for their removal. Another potential marker is the β-galactosidase gene (*lacZ*) isolated from *E. coli*, which can be detected by an assay that produces a blue color in the transformed insects and mites. This construct has been present in a number of released organisms and it has been concluded that risks associated with their release are low. Eye color and green fluorescent protein (GFP) genes also are considered to be safe selectable markers if transgenic insects are to released into the environment. Unfortunately, transgenic insects with mutant eye colors may exhibit abnormal behavior, which could reduce their effectiveness in the field. The effects of GFP on vision could be important when the GFP gene is expressed in the eyes of insects. Normal behavior often is crucial to the function of released insects in pest management programs. It is probably desirable to eliminate unneeded marker genes from transgenic insect strains prior to their release into the environment.

Once transgenic strains have been produced, they should be contained in the laboratory using effective procedures and containment facilities until permits have been obtained from the appropriate governmental agencies that would allow the transgenic arthropods to be released into the environment in a pest management program. Transgenic strains must be evaluated for fitness and the expression of the desired traits should be stable in the laboratory. However, efficacy of the transgenic strain for the intended purpose will have to be evaluated eventually under field conditions. At present, transgenic strains are first evaluated in greenhouses, field cages, or some other contained environment to be sure that they perform as expected and do not exhibit unintended traits. Purposeful permanent releases of transgenic insects or mites have, as of winter 2004, not been requested.

Risk Assessments of Transgenic Arthropods

Risk equals the potential for damage and the likelihood of its occurrence. Risk estimates may be different for pest versus beneficial insects and may depend on whether the insect is expected to persist in the environment or is unable to reproduce and cannot persist. Risks also will vary with the specific transgene(s) inserted. At present, it is easier to identify potential types of harm than to quantify the likelihood of its occurrence.

Relative Risks

The least risky transgenic insects could be the domesticated silkworm (*B. mori*), which is unable to survive on its own in the wild. Transgenic *B. mori* are unlikely to have a negative effect on the environment because they should not be able to persist even if they were accidentally released. Also, transgenic pest or beneficial insects that are sterile and unable to reproduce should pose lower risk than insects that are able to reproduce and persist in the environment. Transgenic pest or beneficial insects that are unable to persist because the environment is unsuitable during a portion of the year also are likely to pose a lower risk. Honey bees, *Apis mellifera*, are only semi-domesticated and thus can escape human management to survive in the wild. Transgenic honey bees could pose a greater environmental risk than the domesticated silkworm for this reason.

Evaluating the risks associated with releasing insects and mites that have been manipulated with recombinant DNA techniques will likely change as we learn more about risk assessment procedures and gain experience. Current concerns can be summarized as:

- Is the transgenic population stable?
- Has its host or prey range has been altered?
- Does it have the potential to persist in the environment?
- Will the transgenic strain will have unintended effects on other species or environmental processes?

Another question we may need to ask is how far and how quickly can the transgenic strain disperse from the experimental release site? Less is known about dispersal behavior of many insects than might be needed. The first three questions are relatively easy to answer with a variety of laboratory experiments. The last issue is much more difficult to answer. For the near future, releases of transgenic arthropods in the USA will be evaluated by regulatory agencies on a case-by-case basis. Initial permits for releases will be for short term releases in controlled situations so that unexpected outcomes might be mitigated.

Horizontal Gene Transfer

One risk issue that is unusually difficult to quantify is the risk of horizontal transfer of transgenes or transposable elements, or of drive elements such as *Wolbachia*, to other organisms. Our knowledge of horizontal transfer and transposable elements only began in the 1950s when Barbara McClintock discovered transposable elements in maize. Horizontal gene transfer results in the movement of genes or transposable elements or drive elements from one insect population to another of the same species, from one insect species to another, or to other organisms in the environment. It is difficult to quantify this risk because we lack fundamental information on the frequencies and mechanisms of horizontal gene transfer; furthermore, the specific genes transferred will be important in determining potential harm as will the site into which the transgene or transposable element inserts. If the insertion is into noncoding DNA in the chromosome, no harm may occur to the recipient. If the insertion is into functional and essential gene(s), then the recipient may be harmed or killed. If the insertion is into somatic cells the effect, if any, may be minimal but if the insertion is into germ line cells then the unintended genetic modification could be transmitted to future generations. The whole topic of horizontal gene transfer in insects has received limited scientific attention until relatively recently.

We do know that horizontal transfer of genes may occur between insect species by movement of naturally occurring transposable elements. Horizontal transfer is thought to be rare, yet more than one such transfer has been observed within historical times in *D. melanogaster* and may have been missed in other species because no one was looking. The P element appears to have invaded *D. melanogaster* populations within the last 50 years, perhaps from a species in the *D. willistoni* group. Controversy exists as to whether P elements were transferred between *Drosophila* species by the semiparasitic mite *Proctolaelaps regalis*. Another transposable element, *hobo*, appears to have invaded natural populations of *D. melanogaster* around the 1960s, representing the second invasion of this well-studied insect in the past 40–50 years.

Transfer of transposable element vectors from insects to other organisms, including humans, is potentially feasible, although these transfers would be expected to occur very rarely. Recall that risk is determined by frequency of occurrence and the damage that might occur. In this case, the frequency is expected to be very low if natural invasions represent a realistic estimate of frequency in the case of purposeful releases of active transposable elements as drive mechanisms or of conversion of inactive transposable element vectors into active ones.

We are still discovering new aspects of the biology and ecology of transposable elements and this lack of knowledge makes it difficult to predict what would happen if insects were released that contained either active or inactive transposable element vectors. The safest course might be to remove any introduced transposable element vector sequences from a transgenic insect strain prior to its permanent release into the environment to reduce the probability that the transgene will move, either within the strain or horizontally between different populations or species.

Some questions to answer: When developing a genetic manipulation project if it is to be deployed successfully

PHASE I. Defining the problem and planning the project:

- What genetic trait(s) limit effectiveness of beneficial species or might reduce damage caused by the pest?
  - Do we know enough about the biology, behavior, genetics and ecology of the target species to answer this question?
  - Is the potential trait determined by single or multiple genes?
- Can alternative control tactics be made to work more effectively and inexpensively than genetic manipulation projects, and are they more environmentally friendly?
  - The costs of genetic manipulation projects are high and the time to develop a functional program can be quite long
  - Transgenic technology may not be appropriate if traditional genetic or other control methods can be used because issues surrounding risk assessment of releasing transgenic arthropods into the environment for permanent establishment have not been resolved.
- How will the genetically-manipulated strain be deployed?
  - Will releases be inoculative and some type of selection or drive system used to replace the wild strain?
  - Will the desired genes be introgressed (introduced) into the wild population?
  - What selection mechanism will be used?
  - Will augmentative releases of very large numbers be required?
  - Will multiple releases be required over many years?
- What risk issues, especially of transgenic strains, should be considered in planning?
  - If pesticide resistance genes are used as a selectable marker for beneficial species is there a possibility of the resistance gene moving to a pest?
  - What is known about the potential for horizontal gene transfer?
  - If transposable element or viral vectors are used in the transformation process, what risks might they pose if the transgenic strain is released into the environment?
  - What health or other hazards might be imposed on human subjects if the transgenic strain were released?
- What advice do the relevant regulatory authorities give regarding your plans to develop a transgenic strain?
  - Which agencies are relevent to consult for your project?

PHASE II. Developing the genetically-manipulated strain and evaluating it in the laboratory:

- Where will you get your gene(s)?
  - Should the transgene(s) sequence be modified to optimize expression in the target species if it is from a species with a different codon bias?
- Is it important to obtain a high level of expression in particular tissues or life stages?
  - Where can you get the appropriate regulatory sequences?
- How can you maintain or restore genetic variability in your transgenic strain?
  - Because both artificial selection and transgenic methods typically involve substantial inbreeding to obtain pure lines, how will you

outcross the manipulated strain with a field population to improve its adaptation to the field or otherwise increase genetic variability.

- What methods can you use to evaluate "fitness" in artificial laboratory conditions that will best predict effectiveness in the field?
  - Have life table analyses and laboratory studies of the stability of the trait under no selection been correlated with efficacy in the field?
  - Is it possible to carry out competitive population cage studies?
- Do you have adequate containment methods to prevent premature release of the transgenic strain into the environment?
  - Have these containment methods been reviewed by appropriate regulatory authorities?
- Do you have adequate rearing methods developed for carrying out field tests?
  - Are artificial diets available to reduce rearing costs?
  - Are quality control methods available to maintain quality during mass rearing?
- What release rate will be required to obtain the goals you have set?
  - Do you have an estimate of the absolute population density of the target species in your field test?
  - What release model are you applying: inundative, inoculative, introgressioin, complete population replacement?
- Have you tested for mating biases, partial reproductive incompatibilities or other population genetic problems?
- If the strain is transgenic, have you obtained approval from the appropriate regulatory authorities to release the strain into the greenhouse or small plot?
  - Can you contain it in the release site?
  - Can you retrieve it from the release site at the end of the experiment?
  - Can you mitigate if unexpected problems arise?
- How will you measure effectiveness of the modified strain in the field trials?

PHASE III. Field evaluation and eventual deployment in practical pest management project:

- If the small-scale field trial results were promising, what questions remain to be asked prior to the deployment of the manipulated strain?
  - Are mass rearing methods adequate?
  - Is the quality control program in place?
  - Is the release model feasible?
  - Were there unexpected reproductive incompatibilities between the released and wild populations?
- If permanent releases are planned, have relevant risk issues been evaluated?
- How will the program be evaluated for effectiveness?
- Will the program be implemented by the public or private secto?
- What did the program cost and what are the benefits?
- What inputs will be required to maintain the effectiveness of the program over time?

(Modified from Hoy 2000.)

Steps in Developing a Transgenic Arthropod

The above description indicates that a number of steps are involved in a program designed to control pest insects through transgenic methods. The target species probably should be identified as a significant pest for which conventional control tactics are ineffective because genetic manipulation is usually more expensive and difficult than other pest management approaches. Furthermore, genetic manipulation with recombinant DNA techniques may generate concerns about risk, requiring additional time and resources.

How best might our knowledge about the pest species' physiology, ecology, or behavior be used against it? How will the transgenic strain be deployed in a pest management program?

Once a target trait has been identified, it must be genetically altered using appropriate genes and genetic regulatory sequences to ensure that the new trait is expressed at the appropriate time and in appropriate tissues. After a modified strain has been developed, it must be evaluated in the laboratory for fitness and stability. If ultimate deployment requires mass rearing of very large numbers of high quality insects, mass rearing and release models will need to be developed. Eventually the manipulated strain must be released into greenhouses or small field plots in the field for evaluation.

Permission to release a transgenic insect will have to be obtained from (several) regulatory agencies. Short term releases initially will be made into small plots, perhaps in cages. Initial releases of transgenic insects into the environment in the USA are intended to be short term experiments, and current regulation of such releases by the U.S. Department of Agriculture require the researcher to retrieve all transgenic insects from the environment at the end of the experiment.

If the transgenic insect strain(s) perform well and risk assessments are completed satisfactorily, permanent releases into the environment may be allowed, but the guidelines for such releases are lacking as of spring 2002. Many pest management programs, especially those involving replacement of pest populations by the transgenic population, will require permanent establishment in the environment. The use of several "drive mechanisms" have been proposed for replacement. Analysis of the potential risks of such drive mechanisms has not been carried out.

Could "Gene Silencing" Reduce Program Effectiveness?

There is always the risk that a transgenic insect population could be released into the field and fail to function as expected due to a phenomenon called "gene silencing." Transgenic plants and mammals have been shown to be able to inactivate (silence) transgenes that overexpress proteins or are otherwise novel. Gene silencing is thought to be due to genetic systems that evolved as a means to prevent high levels of expression of transposable elements or viruses that can cause genetic damage when they invade new hosts. In fungi and plants, gene silencing is associated with several mechanisms, including methylation of the DNA or posttranscriptional or transcriptional processes. Multiple mechanisms of transgene silencing also occurs in *Drosophila melanogaster*. Thus, methods may have to be developed to eliminate transgene silencing in insects or this phenomenon could reduce the effectiveness of a pest management program. The use of genetic sequences called insulators or boundary elements may limit gene silencing.

Gene silencing might be turned into a positive attribute if specific genes in insects could be turned off. Gene silencing has purposefully induced in *D. melanogaster* by introducing a sequence that codes for an extended hairpin-loop RNA by P-mediated transformation. Perhaps endogenous gene expression and developmental processes could be modified in other insects by a similar genetic process.

The ultimate utility of transgenic insects and mites for pest management programs remains to be resolved in the coming years. Research on improved transformation methods, isolation of additional useful genes and regulatory elements and development of improved risk assessment methods based on an international consensus must be achieved before transgenic arthropods are widely used in pest management programs.

Transgenic Organism

An organism whose genome contains genetic material originally derived from an organism (not its parents) or from a different species. The transgene(s) can be transmitted to subsequent generations (stable transformation) or can be lost subsequently (unstable transformation).

Translocation

A type of mutation in which a section of a chromosome breaks off and moves to a new position in that or a different chromosome.

Transmission of Plant Diseases by Insects

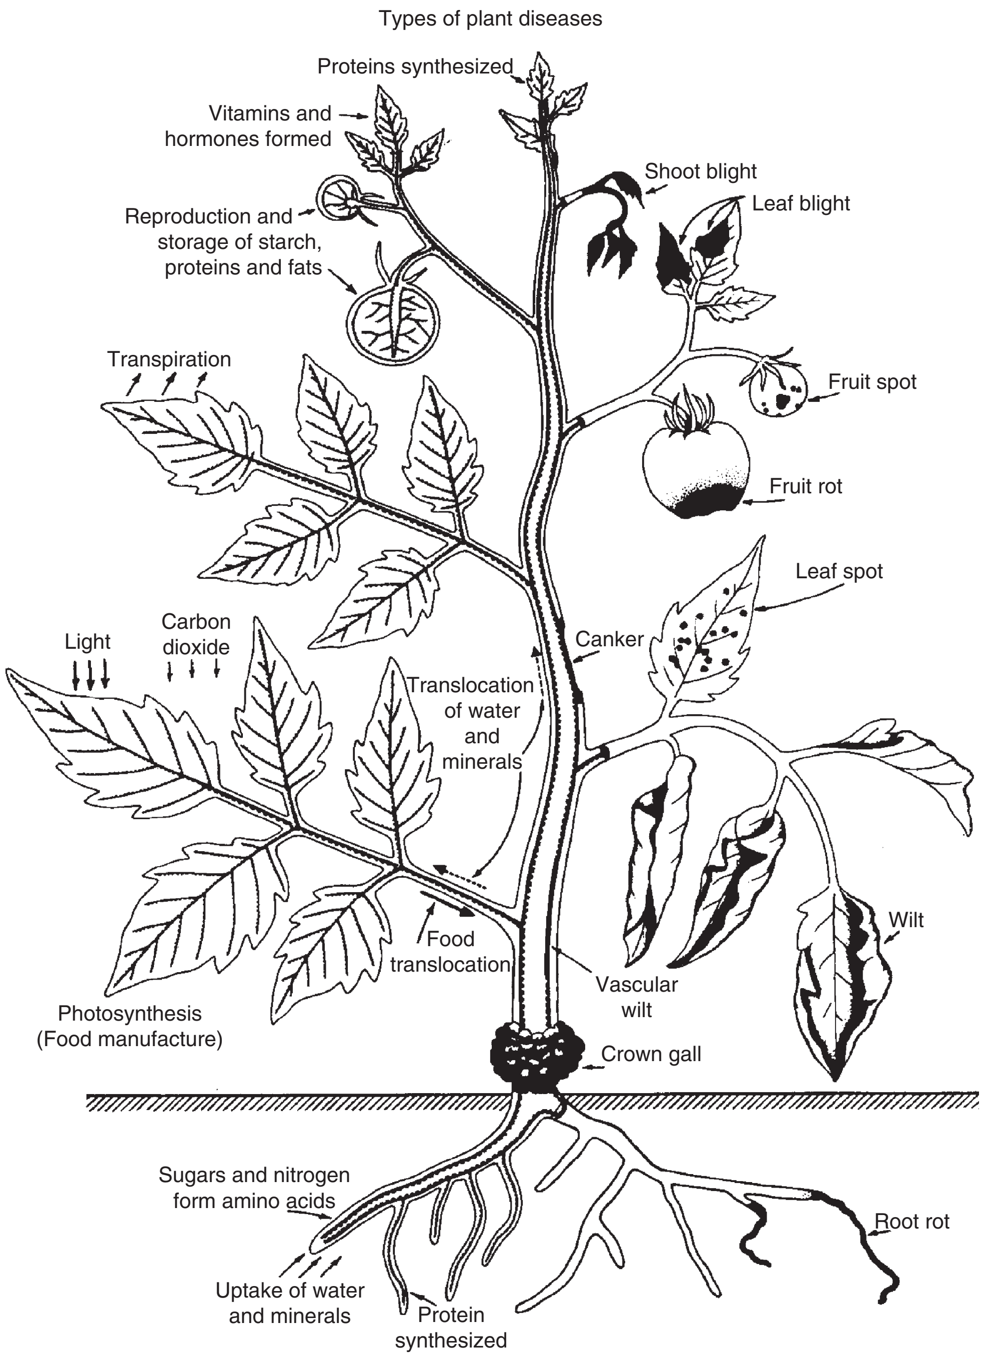
GEORGE N. AGRIOS
University of Florida, Gainesville, FL, USA

Plant diseases appear as necrotic areas, usually spots of various shapes and sizes on leaves, shoots, and fruit; as cankers on stems; as blights, wilts, and necrosis of shoots, branches and entire plants; as discolorations, malformations, galls, and root rots, etc. Regardless of their appearance, plant diseases interfere with one or more of the physiological functions of the plant (absorption and translocation of water and nutrients from the soil, photosynthesis, etc.), and thereby reduce the ability of the plant to grow and produce the product for which it is cultivated. Plant diseases are generally caused by microscopic organisms such as fungi, bacteria, nematodes, protozoa, and parasitic green algae, that penetrate, infect, and feed off one or more types of host plants; submicroscopic organisms such as viruses and viroids that enter, infect, spread systemically and affect the growth of their host plants; parasitic higher plants which range from about an inch to several feet in size and penetrate and feed off their host plants. Plant diseases are also caused by abiotic, environmental factors such as nutrient deficiencies, extremes in temperature and soil moisture, etc. that affect the normal growth and survival of affected plants.

Of the aforementioned causes of disease, many of the microscopic organisms and of the viruses are transmitted by insects either accidentally (several fungi and bacteria) or by a specific insect vector on which the pathogenic organism (some fungi, some bacteria, some nematodes, all protozoa causing disease in plants, and many viruses) depends on for transmission from one plant to another, and on which some pathogens depend on for survival (Fig. 90).

The importance of insect transmission of plant diseases has generally been overlooked and greatly underestimated. Many plant diseases in the field or in harvested plant produce become much more serious and damaging in the presence of specific or non-specific insect vectors that spread the pathogen to new hosts. Many insects facilitate the entry of a pathogen into its host through the wounds the insects make on aboveground or belowground plant organs. In some cases, insects help the survival of the pathogen by allowing it to overseason in the body of the insect. Finally, in many cases, insects make possible the existence of a plant disease by obtaining, carrying, and delivering into host plants pathogens that, in the absence of the insect, would have been unable to spread, and thereby unable to cause disease. It is offered as a guess that 30–40% of the damage and losses caused by plant diseases is due to the direct or indirect effects of transmission and facilitation of pathogens by insects.

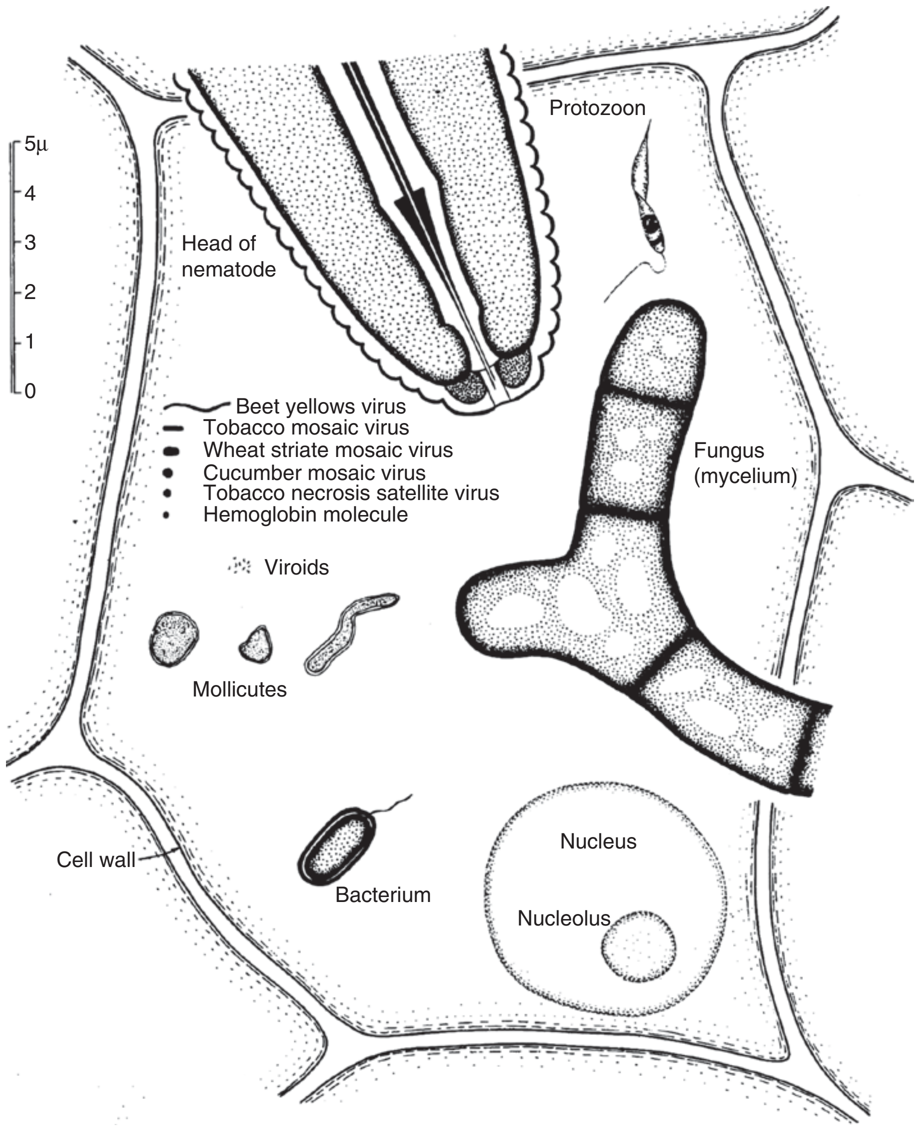
Insects and related organisms, such as mites, are frequently involved in the transmission of plant pathogens from one plant organ, or one plant, to another on which then the pathogens cause disease. Equally important is that insects can and do transmit pathogens among plants from one field to another, in many cases even when the fields are several to



Transmission of Plant Diseases by Insects, Figure 90 **Schematic representation of the basic functions in a plant (*left*) and the interference with these functions (*right*) caused by some common types of plant diseases (from Agrios 1997).**

many miles apart. Almost all types of pathogens, that is, fungi, bacteria, viruses, nematodes, and protozoa, can be transmitted by insects. Insects transmit pathogens, such as many fungi and bacteria, mostly externally on their legs, mouthparts, and bodies. Almost all plant pathogenic viruses, all phytoplasmas, xylem- and phloem-inhabiting fungi and bacteria, some protozoa, and some nematodes are also transmitted by insects, and they are usually carried by the insect internally. The insects that transmit fungi and bacteria externally on their bodies and legs belong to many orders of insects. On the contrary, the insects that transmit the other pathogens listed above internally are very specialized and specific for the pathogen they transmit and belong to a certain species or genus of insects (Fig. 91).

Insects transmit pathogens in three main ways. (i) Many insects transmit bacteria and fungal spores passively by feeding in or walking through an infected plant area that has on its surface plant pathogenic bacteria or fungal spores as a result of the infection. The bacteria and spores are often sticky, cling to the insect as it moves about, and are carried by it to other plants or parts of the same plant where they may start a new infection. (ii) Some insects transmit certain bacteria, fungi, and viruses by feeding on infected plant tissues and carrying the pathogen on their mouthparts as they

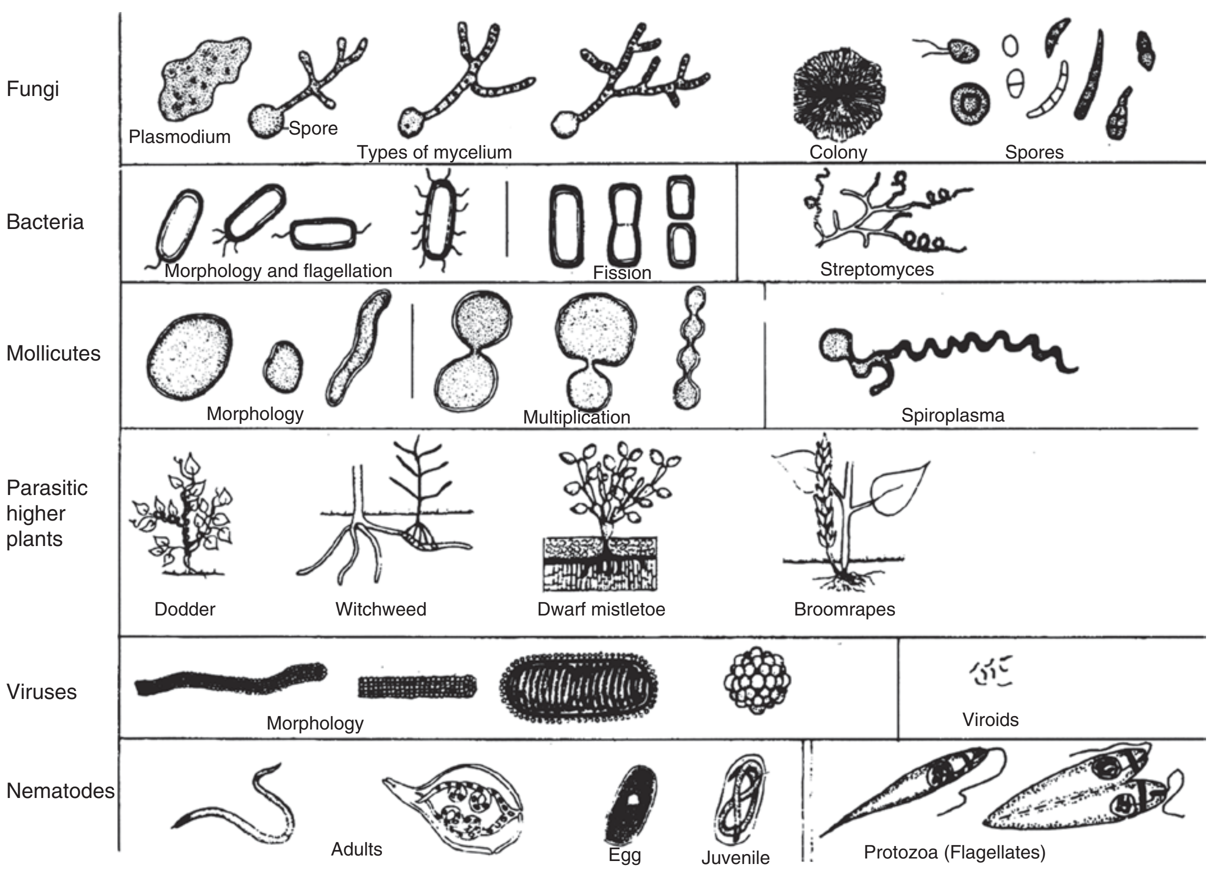


Transmission of Plant Diseases by Insects, Figure 91 **Schematic diagram of the shapes and sizes of certain plant pathogens in relation to a plant cell (from Agrios 1997).**

visit and feed on other plants or plant parts. (iii) Several insects transmit specific viruses, phytoplasmas, protozoa, nematodes, and xylem- and phloem-inhabiting bacteria by ingesting (sucking) the pathogen with the plant sap they eat. Subsequently, the pathogen circulates through the body of the insect until, with or without further multiplication in the insect, the pathogen reaches the salivary glands and the mouthparts of the insect through which it is injected into the next plant on which the insect feeds (Fig. 92).

Role of Insects in Bacterial Diseases of Plants

In most plant diseases caused by plant pathogenic bacteria (especially in those that cause spots, cankers, blights, galls, or soft rots, bacteria), which are produced within or between plant cells, escape to the surface of their host plants as droplets or masses of sticky exudates (ooze). The bacteria exudates are released through cracks or wounds in the infected area, or through natural openings such as stomata, nectarthodes, hydathodes, and sometimes through lenticells, present in the infected area. Such bacteria are then likely to stick on the legs and bodies of all sorts of insects, such as flies, aphids, ants, beetles, whiteflies, etc., that land on the plant and come in contact with the bacterial exudates. Many of these insects are actually attracted by the sugars contained in the bacterial exudate and feed on it, thereby further smearing their body and mouthparts with the bacteria-containing exudate. When such bacteria-smeared insects move to other parts of the plant or to other susceptible host plants, they



Transmission of Plant Diseases by Insects, Figure 92 **Morphology and multiplication of some of the groups of plant pathogens (from Agrios 1997).**

carry on their body numerous bacteria. If the insects happen to land on a fresh wound or on an open natural opening, and there is enough moisture on the plant surface, the bacteria may multiply, move into the plant, and begin a new infection. The same happens if the insects happen to create a fresh wound on the plant.

The type of insect transmission of bacteria is probably quite common and widespread among bacterial diseases of plants, but it is passive and haphazard, depending a great deal on the availability of wounds or moisture on the plant surface. In any case, there are few data on how frequently such transmission occurs, and many conclusions about it are the result of conjecture. A further point that has been made is that insects which, whether above or below ground, wound the host plant organs (roots, shoots, fruit, etc.) by feeding or by ovipositing in them, increase the probability of transmission of plant pathogenic bacteria. This occurs because such insects place the bacteria, with their mouthparts or the ovipositor, in or around wounded plant cells, where they are surrounded by a suspension of nutrients (plant cell sap) in the absence of active host defenses and where they can multiply rapidly and subsequently infect adjacent healthy tissues.

Numerous plant diseases could be listed among those in which bacteria are spread by insects passively as described above, for example, the bacterial bean blights, fire blight of apple and pear, citrus canker, cotton boll rot, crown gal, bacterial spot and canker of stone fruits, etc. In several bacterial diseases, however, the causal bacterium has developed a special symbiotic relationship with one or a few specific types of insects and depends a great deal on these insects for its spread from infected to healthy host plants. Some of the better known bacterium – insect associations are described briefly below.

Bacterial Soft Rots

Bacterial soft rots cause tremendous losses worldwide, particularly in the warmer climates and the tropics. They are caused primarily by the bacterium *Erwinia carotovora* pv. *carotovora*, to some extent by *Pseudomonas fluorescens* and *Ps. chrysanthemi*, and, occasionally, by species of *Bacillus* and *Clostridium*. The last two genera of bacteria cause rotting of potatoes and of cut fleshy leaves in storage while *Pseudomonas fluorescens* and *Ps. chrysanthemi* cause soft rots of many fleshy fruits and fleshy vegetables. The species *E. c.* pv. *carotovora* causes the vast majority of soft rots on fleshy plant organs of any type (leave, blossoms, fruit, stems, or roots), especially in storage and under cover or in plastic bags. Affected fleshy fruits are, for example, strawberries and other berries, cantaloupes, peaches, pears, etc.; vegetables, for example, tomatoes, potatoes, spinach, celery, onions, cabbage, etc.; and ornamentals, for example, cyclamen, iris, lily, etc. Nearly all fleshy vegetables are subject to bacterial soft rots. The soft rot bacteria enter the plant organ through a wound, sometimes in the field but more commonly during storage, and there they multiply rapidly, secrete enzymes that separate the cells from each other and macerate the plant cell walls, which causes the tissues to become soft and to rot. In many cases, these bacteria are accompanied in the rotting tissues by other saprophytic bacteria that further degrade the softened plant tissue and cause it to give off a foul odor. In all cases, rotting tissues become soft and watery, and slimy masses of bacteria ooze out from cracks in the tissues.

The soft rotting bacteria survive in infected fleshy organs in storage and in the field, in plant debris, in infected roots and other plant parts of their hosts, in ponds and streams from where irrigation water is obtained, and to some extent in the soil and in the pupae of several insects. The seedcorn maggot, *Delia platura* (Meigen) (Diptera: Anthomyiidae), was shown to play an important role in the dissemination and development of bacterial soft rot in potatoes both in storage and in the field. The soft rot bacteria are usually introduced into a potato field on infected or contaminated seed pieces but they can also live in all stages of the insect, including the pupae, and there they may survive cold or dry weather conditions. The insect larvae become contaminated with the bacteria as they feed in, or crawl about on, infected seed pieces; they also carry the bacteria to healthy plants and there they deposit them into wounds they create. Even when the plants or storage organs are resistant to soft rot bacteria and can normally stop the advance of the bacteria by developing a barrier of cork layers, the maggots destroy the cork layers as fast as they are formed and the soft rot continues to spread. Some other related flies, for example, the bean seed maggot *Delia florilega* (Zetterstedt), *Drosophila busckii* Coquillett (Diptera: Drosophilidae), and probably others, seem to have analogous relationship to the soft rot of potato and other fleshy organs. It has also been shown that several other flies have similar relationships with soft rot bacteria and the host plants on which they prefer to feed. Such relationships, for example, exist between the cabbage maggot, *Delia radicium* (Linnaeus) and soft rot in the Brassicaceae; the onion maggot, *Delia antiqua* (Meigen), the onion black fly, *Tritoxa flexa* (Weidman) (Diptera: Otitidae), the seedcorn maggot, and the onion bulb fly, *Eumerus strigatus* (Fallen) (Diptera: Syrphidae) and the soft rot of onion; and the iris borer, *Macronoctua onusta* (Grote) (Lepidoptera: Noctuidae) and soft rot of iris.

The exact relationship between soft rot in each host and each specific insect found to possibly be involved in the transmission of soft rot bacteria from one organ or plant to another is not clear. There is little doubt, however, that insect transmission of soft rot bacteria does occur, that insects help introduce the bacteria into wounds they open, and that the presence of insects in soft-rotting tissues inhibits the defense reaction of the plants against the bacteria. The insects also, by carrying the soft rot bacteria internally in their bodies, help the bacteria survive adverse environmental conditions. On the other hand, the bacteria seem to help their insect vectors by preparing for them a more nutritive substrate through partial maceration of the host plant tissues.

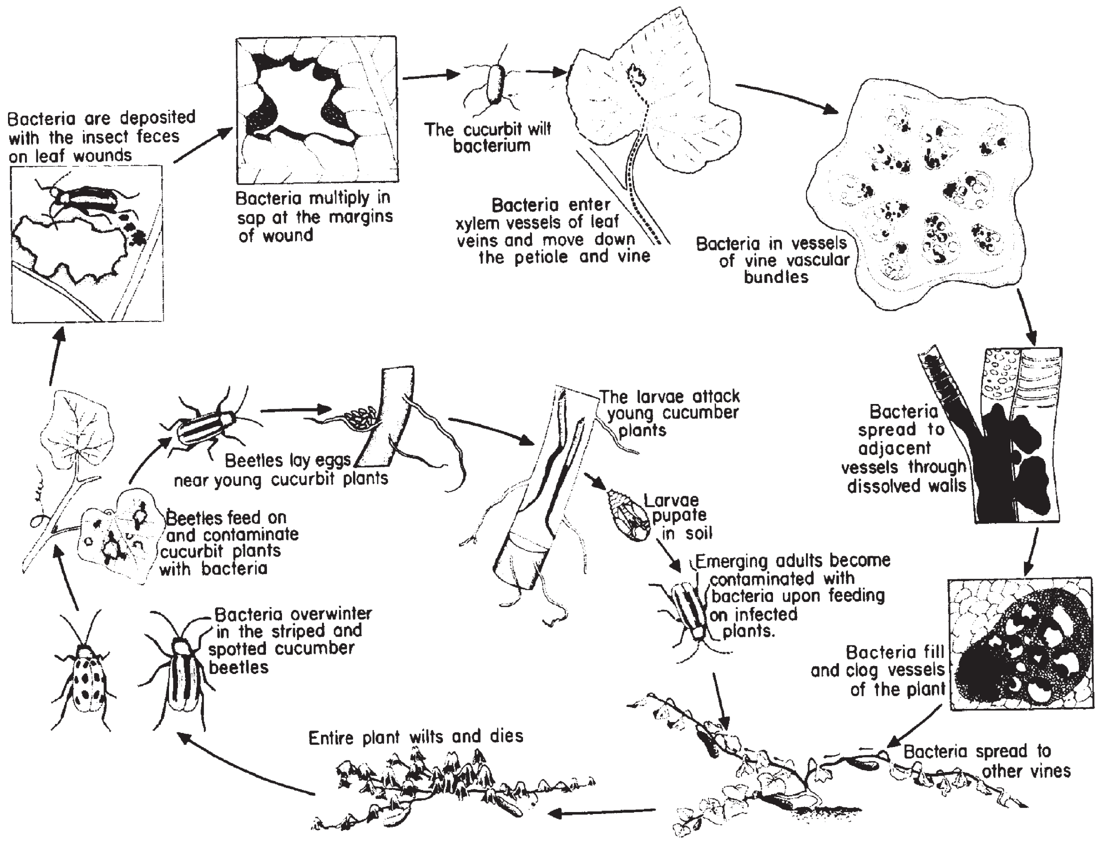
Bacterial Wilts of Plants

In several bacterial diseases of plants, the bacteria enter the xylem conductive system of the plant and there they move, multiply, and clog up the vessels. The clogging of the xylem vessels is further increased by substances released from cell walls by bacterial enzymes and interferes with the translocation of water through the stems to the shoots of the plant. As a result of insufficient water, the leaves and shoots loose turgor, wilt, and eventually turn brown and die. In some bacterial wilts, the bacteria destroy and dissolve parts of the xylem walls and move into the adjacent tissues where they form pockets full of bacteria from which the bacteria ooze out onto the plant surface through cracks or natural openings. In other bacterial wilts, the bacteria remain confined in the xylem and do not reach the plant surface until the plant is killed by the disease.

The wilt-causing bacteria overwinter in plant debris in the soil, in the seed, in vegetative propagative material, and in some cases, in their insect vector. They enter plants through wounds, and they spread from plant to plant through the soil, through tools and direct handling of plants, or through insect vectors. The most important bacterial wilts in which insects play a significant role in the transmission of the bacteria from plant to plant are described briefly below.

Bacterial Wilt of Cucurbits

Bacterial wilt of cucurbits has been reported from most developed countries but it probably occurs throughout the world. It affects many species of cucurbits, including cucumber, muskmelon, squash, and pumpkin. Watermelon is resistant or immune to bacterial wilt. Diseased plants develop a sudden wilting of their foliage and vines and eventually die. Diseased squash fruit develops a slimy rot in storage. Losses from bacterial wilt vary from an occasional wilted plant to destruction of 75–95% of the crop (Fig. 93).



Transmission of Plant Diseases by Insects, Figure 93 **Disease cycle of bacterial wilt of cucurbits caused by *Erwinia tracheiphila* and transmitted by the striped cucumber beetle (*Acalymma vittatum*) (from Agrios 1997).**

Bacterial wilt of cucurbits is caused by the bacterium *Erwinia tracheiphila*. The bacterium survives in infected plant debris for a few weeks but it survives over winter in the intestines of its two insect vectors, the striped cucumber beetle (*Acalymma vittatum* [Fabricius]) and the spotted cucumber beetle (*Diabrotica undecimpunctata* Mannerheim [Coleoptera: Chrysomelidae]). The bacterium depends on these two vectors for its transmission to and inoculation of new plants. In the spring, striped cucumber beetles and, to a lesser extent, spotted cucumber beetles, that carry bacteria, feed and cause wounds on the leaves of cucurbit plants. The insects deposit bacteria in the wounds through their feces and the bacteria enter the wounded xylem vessels in which they multiply rapidly and through which they move to all parts of the plant. In the xylem, the bacteria excrete polysaccharides, secrete enzymes that break down some of the cell wall substances, and induce xylem parenchyma cells to produce tyloses in the xylem. All of them together form gels or gums that clog the vessels, especially at their end walls, thereby reducing the upward flow of water in the xylem by up to 80% and causing the leaves and vines to wilt. Beetles feeding on infected cucurbit plants pick up bacteria on their mouthparts and when they feed onto healthy plants they deposit the bacteria in the new wounds they have made. Thus, the bacteria start a new infection. Each contaminated beetle can infect several healthy plants after one feeding on an infected plant. It appears that a relatively small percentage of beetles become carriers of the bacteria through the winter. Spotted cucumber beetles transmit the wilt bacteria rather late in the season, therefore they are considered less important vectors of this disease than the striped cucumber beetles.

Bacterial Wilt of Corn

This disease is also known as Stewart's wilt of corn. It is caused by the bacterium *Pantoea* (formerly *Erwinia*) *stewartii*. It occurs in North and Central America and also in Europe and China. It is more severe in the northern states. The bacterium invades the vascular tissues but it also spreads into other tissues. When sweet corn plants are affected at the seedling stage they may wilt rapidly and may die, or they develop pale green wavy streaks on the leaves, become stunted, wilt, and may also die. If infected plants survive, they often tassel prematurely, the tassels become bleached and may die, and produce deformed ears. Bacteria also enter the stalk pith, which they macerate in places near the soil line and form cavities. From there the bacteria invade all vascular tissues and spread throughout the plant. Field corn is more resistant to early infection but becomes more severely infected later in the season. Some hybrids are susceptible and their symptoms parallel those of sweet corn. Later infections, after tasseling, produce irregular streaks on the leaves that originate at feeding points of the corn flea beetle, *Chaetocnema pulicaria* Melsheimer. The corn wilt bacteria are also transmitted by the toothed flea beetle (*Chaetocnema denticulata* Illiger), the spotted cucumber beetle (*Diabrotica undecimpunctata howardi* Barber), and by the larvae of the seed corn maggot (*Delia platura* Meigen), wheat wireworm (*Agriotes mancus* Say), and the May beetle (*Phyllophaga* sp.). It appears, however, that overwintering and spread of the bacteria in the field is carried out primarily by the corn flea beetle.

These beetles cause direct damage to corn leaves and seedlings but their main damage comes from harboring and transmitting the bacteria from plant to plant. The beetles pick up the bacteria when they feed on infected corn plants. The bacteria survive in the digestive tract of the insect as long as the latter lives. The insects are also the main place where the bacteria overwinter. The corn flea beetles overwinter as adults in the upper 2–3 cm of soil in grass sod. They are rather sensitive to low temperatures, however. In mild winters, when the sums of mean temperatures for December, January, and February are above 3–4°C, large numbers of beetles survive. When the soil warms up to about 17–20°C, they begin to feed on corn seedlings, which they infect with bacteria. Following mild winters, bacterial wilt of corn is spread rapidly by corn flea beetles, and corn losses can be quite severe. During cold winters that average temperatures below 0°C, many of the beetles do not survive and the incidence and spread of bacterial wilt of corn the following spring and summer are quite limited.

Southern Bacterial Wilt of Solanaceous and Other Crops

This vascular wilt is caused by the bacterium *Ralstonia solanacearum*. It occurs in the warmer regions around the world and is particularly severe in the tropics. It is known by different names in different hosts, for example, southern wilt or brown rot in potato and tomato, Granville wilt in tobacco, and Moko disease in banana. Insects, primarily bees (*Trigona corvine* Cockerell, Hymenoptera: Apidae), wasps (*Polybia* spp., Hymenoptera: Vespidae), and flies (*Drosophila* spp., Diptera: Drosophilidae) have been implicated as vectors. Because these and other insects visit infected stem wounds and natural abscission sites oozing out bacteria, they are considered as playing a role in the transmission of the bacteria to natural infection courts and in providing wounds for bacterial entry, but their importance as vectors has not been documented.

Fire Blight of Pears, Apples and Other Rosaceous Plants

The disease is caused by the bacterium *Erwinia amylovora*. Fire blight occurs in North America, Europe and countries surrounding the Mediterranean Sea, and in New Zealand. It continues, however, to spread into new countries. Fire blight is the most devastating diseases affecting rosaceous plants. The symptoms consist of infected blossoms and young shoots becoming discolored and water-soaked, then being killed rapidly and appearing brown to black as though scorched by fire. The disease spreads rapidly into larger twigs and branches, which it also kills, and parts of or entire trees may be killed. At the base of twig or branch infections, cankers develop at the margins of which the bacteria overwinter. Fruit also become infected and ooze droplets of bacteria. The bacteria kill and macerate the contents of primarily parenchyma cells on flowers and in the bark of young shoots and twigs, but as they destroy these cells they move on mass in the bark. The bacteria also enter the phloem and xylem vessels through which they may move over relatively short distances.

The fire blight bacteria overwinter at the margins of cankers of twigs and branches. In the spring, the bacteria around cankers multiply and their byproducts absorb water and build up internal pressure. This results in droplets of liquid containing masses of fire blight bacteria oozing out of the cankers. The bacteria in the ooze are disseminated by splashing rain and also by flying and crawling insects, several of which are attracted to the bacterial ooze, and their legs, bodies, and mouthparts become smeared with bacteria. More than 200 species belonging to many insect groups, including aphids, leafhoppers, psyllids, beetles, flies, and ants, have been shown to visit oozing cankers and healthy blossoms, although bees and wasps seem not to visit oozing cankers routinely. Insects smeared with bacteria oozing out at cankers carry the bacteria to young shoots where they deposit them in existing wounds or in fresh wounds they make upon feeding, or in the nectar of the flowers. Once the fire blight bacteria are transmitted to blossoms by rain or insects, they enter the flower tissues through nectarthodes or wounds, multiply rapidly in them, and ooze out of them and commingle with the nectar in the flower. The same kinds of insects apparently can transmit fire blight bacteria from infected to healthy flowers but flower to flower transmission of fire blight bacteria is carried out so much more efficiently by pollinating insects, namely bees, that the contribution of other insects to that type of transmission seems to be relatively insignificant. As honeybees, wild bees, bumblebees, wasps, and other insects visit pear, apple, and other flowers infected with fire blight bacteria, their mouthparts, legs, and other body parts become smeared with the bacteria in the nectar. The insects then carry the bacteria and deposit them in the nectar of healthy flowers they visit and there the bacteria start new infections. The bacteria, however, do not survive on or in the insects for more than a few days and do not appear to overwinter in association with the insects.

Olive Knot

Olive knot is caused by the bacterium *Pseudomonas savastanoi*. It occurs in the Mediterranean region, in California, and probably the other parts of the world where olive trees grow. The disease occurs as rough galls of varying sizes developing on leaves, branches, roots, on leaf and fruit petioles, and on wounds in tree branches and trunks. Sometimes the galls are so numerous on twigs that the twigs decline and may die back. The galls are the result of growth regulators being produced by the bacteria, which grow and multiply in the intercellular spaces of the outer cells of the galls. In California, the bacteria are spread by running and splashing rain water that carries the bacteria to existing wounds, pruning wounds, and leaf scars. In other parts of the world, however, such as the Mediterranean region, the olive knot bacteria are also spread by the olive fly or olive fruit fly, *Bactrocera* (formerly *Dacus*) *oleae* (Gmelin) (Diptera: Tephritidae), which is the most destructive pest of olive in its own right.

The bacterium and the olive fly have developed a close symbiotic relationship that contributes to the transmission of the olive knot bacteria from tree to tree. The bacteria are carried by all stages (larvae, pupae, and adults) of the olive fly. The adult olive flies, and related fly species, have specialized structures along their digestive tract that are filled with bacteria. There is even a connection of the digestive tract with the oviduct that insures contamination of the eggs before oviposition. Transmission of the bacteria by the insect takes place during feeding and oviposition into olive tissues. The bacteria actually penetrate the egg through the micropyle, thereby ensuring that when the larvae hatch they are contaminated with the bacteria. It appears that while the olive fly plays a significant role in the transmission of the olive knot bacteria, the bacteria contribute to the insect by hydrolyzing proteins and making available to the insect certain amino acids needed by the insect for survival of the larvae and for development of adults.

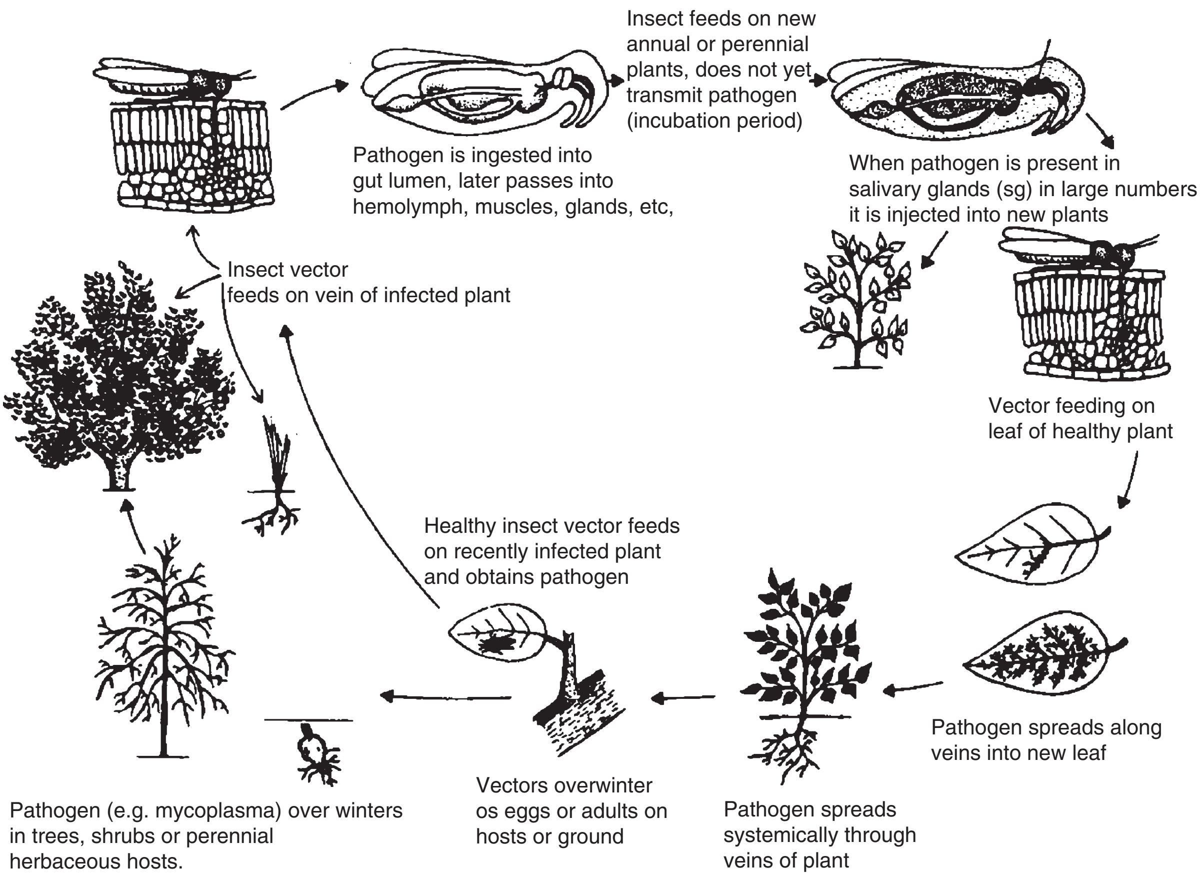
Insect Transmission of Xylem-Inhabiting Bacteria

Quite a few important bacterial diseases of plants, primarily trees, are caused by the fastidious bacterium *Xylella fastidiosa*. These bacteria inhabit the xylem of their host plants and are rather difficult to isolate and to grow on the usual culture media. The diseases they cause differ from the vascular wilts caused by conventional bacteria in that instead of wilt they cause infected plants to decline, some of their twigs to die back, and in some cases the whole plant to die. The xylem-inhabiting fastidious bacteria are transmitted in nature only by xylem-feeding insects, such as sharpshooter leafhoppers (Cicadellidae: Cicadellinae) and spittlebugs (Cercopidae). *Xylella* bacteria seem to be distributed in tropical and semitropical areas worldwide. Among the most important diseases caused by *Xylella* are Pierce's disease of grape and citrus variegated chlorosis. Other diseases caused by xylem-inhabiting bacteria include phony peach, plum leaf scald, almond leaf scorch, bacterial leaf scorch of coffee, oak leaf scorch, and leaf scorch diseases of oleander, pear, maple, mulberry, elm, sycamore, and miscellaneous ornamentals, as well as the alfalfa dwarf disease (Fig. 94).

Pierce's Disease of Grape

Pierce's disease is a devastating disease of European-type grapevines (*Vitis vinifera*). It is caused by the xylem-inhabiting bacterium *Xylella fastidiosa*. It occurs in the Southern United States and in California, in Central America, and parts of northwestern South America. The presence of Pierce's disease in an area precludes the production of European-type grapes in that area but some muscadine grapes and hybrids of European grapes with American wild grapes are tolerant or resistant to Pierce's disease. The Pierce's disease bacterium moves and multiplies in the water-conducting (xylem) vessels of shoots and leaves, some of which become filled with bacteria and reduce the flow of water through them. Leaves beyond such blocked vessels become stressed from lack of sufficient water and develop yellowing and then drying or scorching along their margins. During the summer, the scorching continues to expand toward the center of the leaf, while some or the entire grape clusters begin to wilt and dry up. Scorched leaves fall off leaving their petioles still attached to the vine, while the vines mature unevenly and have patches of brown (mature) and green bark. In the following season(s), affected grapevines show delayed growth and stunting. The leaves and vines repeat the symptoms of the first year and both, the top of the plant as well as the root system, decline and die back.

The bacterium that causes Pierce's disease of grape is *Xylella fastidiosa*. The bacterium apparently consists of various host specific strains. The strain that causes Pierce's disease of grape also causes alfalfa dwarf disease and almond leaf scorch. Apparently related but different strains of the bacterium cause citrus variegation chlorosis, the other related leaf scorch diseases of fruit and forest trees and of ornamental trees and



Transmission of Plant Diseases by Insects, Figure 94 **Sequence of events in the overwintering, acquisition, and transmission of plant viruses, mollicutes, and fastidious bacteria by leafhoppers (from Agrios 1997).**

shrubs. The identity and taxonomy, as well as the host range and vector preference of the possible strains of *Xylella fastidiosa*, are unknown. In all cases, the bacterium is transmitted from plant to plant through vegetative propagation, such as cuttings, budding, and grafting, and by one or more of several closely related insects. The known vectors of *Xylella fastidiosa* are sharpshooter leafhoppers (family Cicadellidae, subfamily Cicadellinae) or spittlebugs (family Cercopidae). It is possible that other or all sucking insects that feed on xylem sap, for example, the cicadas (family Cicadidae), are also vectors of *Xylella fastidiosa*. In California, there are at least four important sharpshooter leafhopper vectors of *Xylella*: The blue-green (*Graphocephala atropunctata*), the green (*Draeculacephala minerva*), the red-headed (*Carneocephala fulgida*), and the glassy-winged (*Homalodisca coagulata*) sharpshooters. The vectors may be different in other parts of the world. All vector insects acquire the bacteria when they feed on infected plants. Ingested bacteria seem to adhere to the walls of the foregut of the insect and when the insect moves to and feeds on the next healthy plant, the insect transmits the bacteria into the xylem vessels of that plant where they multiply and cause a new infection. Once a vector acquires bacteria from a diseased plant, it remains infective indefinitely. When, however, infective insects shed their external skeleton by molting, they loose the bacteria and must feed on a diseased plant again before they can transmit the bacteria to healthy plants.

Insect Transmission of Phloem-Inhabiting Bacteria

At least four plant diseases are caused by bacteria that inhabit only the phloem of their host plants. These diseases include the destructive citrus greening disease, the severe papaya bunchy top disease, the cucurbit yellow vine disease, and the infrequent clover club leaf disease. The bacteria causing these diseases have not yet been grown on nutrient media and so far many of their properties remain unknown. All of them, however, are transmitted from plant to plant only by specific insect vectors. The citrus greening bacterium is transmitted by a psyllid, while the papaya bunchy top disease bacterium and the clover club leaf bacterium are transmitted by leafhoppers, and the cucurbit yellow vine disease bacterium is transmitted by the squash bug. In the psyllid and leafhopper vectors, the bacterium also multiplies in and is passed from the mother insect to its offspring through the eggs (transovarial transmission). It is not known what happens to the bacteria transmitted by the squash bug.

Citrus Greening Disease

Citrus greening is a very destructive disease of all types of citrus. It occurs in most citrus producing areas of Asia, including the Arabian Peninsula, and in Africa. The disease is caused by the bacterium *Liberobacter asiaticum* in Asia, and *L. africanum* in Africa. Both bacteria are limited to the phloem of the host plants, and have yet to be cultured. The disease first appears as a chlorosis and leaf mottling on one shoot or branch, which it has given it the name "huanglongbing," or "yellow shoot," in Chinese. Later on, entire trees become chlorotic as though they are suffering from zinc deficiency, their twigs die back, and the trees decline rapidly and become non-productive. Fruit on diseased trees is small, lopsided, and does not color uniformly as it ripens but large parts of it remain green even when mature, thereby the "greening" name of the disease. Diseased fruit is also quite bitter.

Citrus greening is spread by vegetative propagation with buds and grafts, and by at least two citrus psyllids: *Diaphorina citri* Kuwayama, which is the principal vector of the more severe and more destructive Asian form of the citrus greening bacterium that occurs at higher temperatures (30–35°C), commonly found at lower elevations; and *Trioza erytreae* Del Guercio, which is the principal vector of the milder, less severe, lower temperature (27°C) African form of the bacterium, which is normally found at higher elevations. Both vectors, however, can transmit both forms of the bacterium. Asian psyllids acquire the bacterium within 30 min of feeding while African psyllids require 24 h. The bacterium apparently multiplies in the vector and can be transmitted within 8–12 days from acquisition.

Infected plants and vectors have been introduced into several citrus-producing countries but in most cases it was eradicated before it could become established. The vector of the greening bacterium *Diaphorina citri* was introduced in Brazil in the early 1980s and in Florida in 1998 but, so far, the causal bacteria apparently have not been introduced and no trees have been found in either place to be infected with citrus greening.

Bunchy Top of Papaya Disease

Bunchy top is a devastating disease of papaya. It occurs in most or all islands of the Caribbean Basin and, probably, also in Central America and in the northern part of South America. Young leaves of infected plants show mottling, then chlorosis and marginal necrosis, and become rigid. Internodes become progressively shorter, further apical growth stops, and the plant develops a "bunchy" top. Older leaves may fall off, any fruits that are set are bitter, and the entire plant may die.

Bunchy top of papaya is caused by a rickettsia-like phloem-limited bacterium that moves and multiplies in the phloem elements of the plant. The bunchy top bacteria are transmitted from diseased to healthy papaya plants by the leafhoppers *Empoasca papayae* Oman and *E. stevensi* Young. Symptoms appear 30–45 days after inoculation.

Cucurbit Yellow Vine Disease

Yellow vine disease affects watermelon, melon, squash, and pumpkin. It was first reported in the Texas–Oklahoma area and has since been found in Massachusetts, New York, and Tennessee. Affected plants show vines with yellow leaves, the phloem of leaves and vines becomes discolored, and the leaves and vines collapse and die. The disease has been severe in the Texas and Oklahoma areas where it annually destroys thousands of acres of cucurbits costing millions of dollars.

Cucurbit yellow vine disease is caused by a phloem-limited bacterium that has been placed in the species *Serratia marcescens* and its properties are still being characterized. The bacterium is most probably transmitted by insect vectors. The squash bug, *Anasa tristis*, is considered to be a vector of this bacterium, but its involvement in transmitting this bacterium has been questioned.

Insect Transmission of Plant Diseases Caused by Mollicutes

Mollicutes are prokaryotes (bacteria) that lack cell walls. In nature, plant pathogenic mollicutes are limited to the phloem of their host plants. Plant pathogenic mollicutes are generally classified as belonging to the genus *Phytoplasma*. Most phytoplasmas have an irregular spherical to elongated shape and have been obtained and maintained on complex nutrient media, although they do not readily grow or multiply on them. A few plant pathogenic mollicutes typically have spiral morphology and belong to the genus *Spiroplasma*. Spiroplasmas grow and multiply readily on specialized nutrient media. Plant diseases caused by mollicutes appear as yellowing of leaves, proliferation of shoots (witches' brooms) and of roots, stunting of shoots and whole plants, greening of flowers, abortion of flowers and fruit, dieback of twigs, and decline and death of trees. Numerous important diseases of annual crops are caused by mollicutes, mostly phytoplasmas, for example, aster yellows of vegetables and ornamentals, tomato big bud (stolbur), corn stunt, etc. Phytoplasmas cause even more, and more severe, diseases on trees, including X-disease of peach, peach yellows, apple proliferation, elm yellows, pear decline, and lethal yellowing of coconut palms. Spiroplasmas also cause severe diseases, for example, corn stunt, and citrus stubborn disease.

All mollicutes, that is, phytoplasmas and spiroplasmas, are spread from plant to plant through vegetative propagation and, in nature, these pathogens depend for their transmission on phloem-feeding, sap-sucking insects, mainly leafhoppers, planthoppers, and psyllids. These insects can acquire the pathogen after feeding on appropriate infected plants for several hours or days, or if they are artificially injected with extracts from infected plants or insects. More insects become vectors when they feed on young leaves and stems of infected plants than on older ones. The insect vector cannot transmit the pathogen immediately after feeding on the infected plant but it begins to transmit it after an incubation period of 10–45 days, depending on the temperature. The quickest transmission (10 days) occurs at about 30°C, while the slowest (45 days) takes place at about 10°C.

The reason for the incubation period is that the acquired phytoplasmas or spiroplasmas must first multiply in the intestinal cells of the insect vector and then move through the insect by passing into the hemolymph, then infect internal organs and the brain, and finally reach and multiply in the salivary glands. When the concentration of the pathogen in the salivary glands reaches a certain level, the insect begins to transmit the pathogen to new plants and continues to transmit it with more or less the same efficiency for the rest of its life. Insect vectors are not generally affected adversely by the phytoplasmas or spiroplasmas multiplying in their cells, but in some cases they show severe pathological symptoms. Phytoplasmas and spiroplasmas can be acquired as readily or better by nymphs than by adult leafhoppers, etc., and they survive through subsequent molts of the insect. The pathogens, however, are not passed from the adults to the eggs and to the next generation. For this reason, young insects of any stage must feed on infected plants in order to become infective vectors.

Some of the most important plant diseases caused by mollicutes and their insect vectors are described briefly below.

Aster Yellows

Aster yellows is caused by phytoplasmas and occurs worldwide. It affects numerous annual crops, mostly vegetables and ornamentals, for example, tomato, lettuce, carrot, onion, potato, chrysanthemum, aster, and many others, on which it causes severe symptoms and serious losses, in some crops amounting to 10–25% of the crop and occasionally up to 80–90% of the crop. Plants infected with aster yellows develop general chlorosis (yellowing) and dwarfing of the whole plant, abnormal production of shoots and, sometimes, roots, sterility of flowers, malformation of organs, and a general reduction in the quantity and quality of yield. The aster yellows phytoplasma is transmitted by several leafhoppers, one of which is the aster leafhopper *Macrosteles fascifrons*. The various leafhopper vectors have a wide host range, as does the aster yellows phytoplasma. The phytoplasmas survive in perennial ornamental, vegetable, and weed plants. The vector leafhopper acquires the phytoplasmas while feeding by inserting its stylet into the phloem of infected plants and withdrawing the phytoplasmas with the plant sap. After an incubation period, when the insect feeds on healthy plants it injects the phytoplasmas through the stylet into the phloem of the healthy plants where they establish a new infection and multiply. The phytoplasmas move out of the leaf and spread throughout the plant causing the symptoms characteristic of the host plant.

Tomato Big Bud

The disease occurs in many parts of the world but except for a few areas, it is of little economic importance. It affects most Solanaceous vegetables and lettuce. The symptoms include small, distorted, yellowish green leaves and production of numerous thickened, stiff, and erect apical stems that have short internodes. The flower buds are excessively big, green, and abnormal looking, and fail to set fruit. Fruit present when infection takes place becomes deformed.

Tomato big bud is caused by a phytoplasma that is transmitted by several leafhoppers, the main one of which is the common brown leafhopper *Orosius argentatus*. The insect feeds and breeds on infected weed hosts and when they become undesirable the insects move into tomato or other crops bringing with them the big bud phytoplasmas.

Apple Proliferation

It is the most important insect transmitted disease of apple in most of Europe. It may also occur in South Asia and South Africa. Depending on prevalence in an orchard, apple proliferation may cause economic losses of 10–80% due to reduction in fruit size, total yield, and vigor of trees. The most conspicuous symptoms of apple proliferation are the production of witches' brooms or of leaf rosettes, and of enlarged stipules at the base of leaves. Affected trees leaf out earlier in the spring but flowering is delayed. The leaves, fruit, and entire trees are smaller, and fruit color and taste are also poor. Proliferating shoots are often infected with powdery mildew.

Apple proliferation is caused by a phytoplasma that also infects other wild and ornamental apple species, and possibly pear and apricot.

The phytoplasma is spread in nature by several leafhoppers, including *Philaenus spumarius*, *Aphrophora alni*, *Lepyronia coleoptrata*, *Artianus interstitialis*, and *Fieberiella florii*. The leafhopper vectors acquire the phytoplasmas when they feed on the phloem elements of young leaves and shoots of infected apple trees and, after an incubation period, transmit the phytoplasmas into healthy apple trees. The time between inoculation and appearance of symptoms varies with the size of the inoculated tree. Young nursery trees may develop symptoms within a year while large established trees may do so 2 or 3 years after inoculation.

Pear Decline

It is a serious disease of pear resulting in significant crop losses and also in stunting and death of affected pear trees grown on certain rootstocks. The disease, which is caused by a phytoplasma, occurs in North America and in Europe, and probably in many other parts of the world where pears are grown. The symptoms of pear decline may develop as a quick decline, that is, sudden wilt and death of a tree within a few days or weeks, with or without first showing reddening of leaves, or a slow decline. Quick decline usually develops on trees propagated on certain hypersensitive rootstocks in which a brown necrotic line develops at the graft union of the tree. Slow decline also occurs on trees grafted on the same or other rootstocks, and appears as a progressive weakening of the tree of varying severity. Slow declining trees have reduced or no terminal growth, have few, small, leathery, light green leaves whose margins are slightly rolled up and may be yellow or red in the autumn. Such trees may or may not die a few years after infection. Some infected pear trees, however, show primarily a reddening of the leaves in late summer or early autumn, and mild reduction in vigor.

The pear decline phytoplasma is transmitted from tree to tree by grafting and by the pear psylla (*Psylla pyricola* Forster) and in Europe, probably by *P. pyri* and *P. pyrisuga*. Pear psylla acquires the phytoplasma after feeding on infected trees for a few hours and remains infective for several weeks. Young trees inoculated with phytoplasma by the insect show symptoms the same or the next year, while older trees may take longer. The phytoplasma is sensitive to low temperatures and dies out in the above-ground parts of the tree but survives in the tree roots. In the spring, the phytoplasma recolonizes the stem, branches and shoots and from the latter it can be acquired and transmitted again by the insect vectors.

Lethal Yellowing of Coconut Palms

Lethal yellowing is a blight that kills coconut and some other palm trees within 3–6 months from the time the trees show the first symptoms. It occurs in Florida, Texas, Mexico, most Caribbean islands, in West Africa, and elsewhere. The disease appeared for the first time in Florida in 1971 and killed 15,000 coconut palm trees the first two years, 40,000 by the third year, and by the fourth year (1975), 75% of the coconut palms in the Miami area were dead or dying from lethal yellowing. The disease appears as a premature drop of coconuts followed by blackening and death of the male flowers. Subsequently, first the lower and then the other leaves turn yellow and then brown and die, as does the vegetative bud, and the entire top of the tree falls off leaving the palm trunk looking like a telephone pole.

Lethal yellowing is caused by a phytoplasma that lives and multiplies in the phloem elements of the plant. The main means of spread of lethal yellowing from tree to tree is through the planthopper *Myndus crudus*, although other vectors are also possible. As with the other phytoplasma diseases, the vector acquires the phytoplasma while sucking juice off the phloem of palm leaf veins, the phytoplasma multiplies in the vector during an incubation period, and the insect then transmits the phytoplasma when it visits and feeds on leaf veins of healthy palm trees.

Corn Stunt

Corn stunt causes severe losses where it occurs although losses vary from year to year. It occurs in the southern United States, Central America, and northern South America. Symptoms consist of yellow streaks in young leaves followed by yellowing and reddening of leaves, shortening of internodes, stunting of the whole plant, and sterile tassels and ears.

Corn stunt is caused by the spiroplasma *Spiroplasma kunkelii*. The spiroplasma invades phloem cells from where it is acquired by its leafhopper vectors *Dalbulus maidis*, *Dalbulus eliminatus*, and other leafhoppers after feeding on infected plants for several days. The vectors transmit the spiroplasma after an incubation period of 2–3 weeks, during which the spiroplasma moves and multiplies in the insect.

Citrus Stubborn Disease

It is present and severe in hot and dry areas such as the Mediterranean countries, the southwestern United States, Brazil, Australia, and elsewhere. It is one of the most serious diseases of sweet orange and grapefruit. It is hard to diagnose but reduces yield, quality, and marketability of fruit dramatically. Infected trees grow upright but are stunted. There is less fruit and it is smaller, lopsided, green, and sour, bitter, and unpleasant.

Citrus stubborn disease is caused by the spiroplasma *Spiroplasma citri*, which is found in the phloem of affected orange trees. It is transmitted by budding and grafting and, in nature, by several leafhoppers such as *Circulifer tenellus*, *Scaphytopius nitrides*, and *Neoaliturus haemoceps*. Role of insects on fungal diseases of plants.

Insect Transmission of Fungi

As with bacteria, many insects are involved in the transmission of numerous plant pathogenic fungi from diseased to healthy plants. Insects are also involved in plant diseases by breaking the epidermis and other protective tissues of plants with their mouthparts or with their ovipositor and thereby allowing the fungus to enter. Most of the insect transmissions of fungi are accidental, that is, they occur because the insects happen to become externally or internally contaminated with the fungus or its spores when they visit infected plants and then carry the spores with them to the plants or plant parts they visit next. In some cases, insect transmission of a fungus occurs as the insect visits blossoms during pollination, in others it occurs while wounding plants during oviposition, and in other and most frequent cases, transmission occurs while wounding the plant during feeding. In relatively few cases, the insect and the fungus it transmits develop a symbiotic relationship in which each benefit from its association with the other.

Root-Infecting Fungi

It should be pointed out that there are innumerable cases for which there is circumstantial evidence that insects are apparently involved in the transmission of many plant pathogenic fungi and in the development of disease by them, but this has not been proven experimentally. In this category belong, for example, root infections by fungi such as *Pythium*, *Fusarium*, and *Sclerotium*, being facilitated by billbugs such as *Calendra parvula* and *Anacentrus deplanatus*, by the Hessian fly *Phytophaga destructor*, and by the southern and northern corn root worms *Diabrotica undecimpunctata howardi* and *Diabrotica longicornis*, respectively. In the black stain root disease of pines, hemlock, and Douglas fir is caused by the fungus *Leptographium wageneri*, the teliomorph of which is *Ophiostoma wageneri*, and is transmitted by the root-feeding bark beetle *Hilastes nigrinus* and two root and crown weevils, *Steremnius carinatus* and *Pissodes fasciatus*.

Stalk or Stem-Infecting Fungi

Many fungi infecting stalks or stems, for example *Gibberella*, *Fusarium*, and *Diplodia* in corn, are apparently aided by various insects, for example, the widespread European corn borer, *Pyrausta nubilalis*.

Trunk and Branch Canker-Causing Fungi

Many fungi, such as species of *Neofabrea*, *Nectria*, *Leucostoma* (*Cytospora*), *Ceratocystis*, and *Leptosphaeria*, causing tree cankers, are apparently also often associated with and assisted by insects in the initiation and development of the cankers. The insects involved vary with the particular host and fungus. For example, the fungus *Neofabrea perennans* (Gloeosporium perennans), the cause of the perennial canker of apple, is transmitted by the wooly aphid *Eriosoma lanigerum*. The woolly aphids feed on the bark at the base of the trunk where they cause the formation of galls within which they multiply. In early spring the galls burst, the aphids come out and the fungus attacks the injured tissue and from it advances into healthy tissue and produces a canker. In the summer, the apple tree produces callus tissue and seals off the fungus and the spread of the canker stops. The aphids, however, grow into the callus tissue and form a new gall, and the process is repeated.

The spittlebug *Aphrophora saratogensis* seems to be involved in the *Nectria* canker of pines, the nitidulid beetle *Carpophilus freemani* and the drosophilid fly *Chymomyza procnemoides* in the *Ceratocystis* cankers of stone fruit trees, while the tree cricket *Oecanthus niveus* and the raspberry midge *Thomasianna theobaldi* are involved in the tree cricket canker of apple and the midge canker of raspberry, respectively. Many more such insect-pathogen associations could be mentioned.

In the beech bark canker, caused by the fungus *Nectria coccinea* var. *faginata*, the fungus is transmitted to some extent by the scale insect *Cryptococcus fagi* but the main effect of the insect is in weakening the tree and reducing its defenses to the fungus. Thus, after beech trees have been heavily infested by scale insects for about 3–5 years, the fungus invades and kills the bark and the tree forms a canker that may girdle the tree partially or completely and may kill it.

In the birch constriction disease, the lower parts of shoots become constricted at the point where the apical birch woodwasp (*Pseudoxiphydria betulae* Ensl.) feeds on the shoots. The leaves above the constriction wither and die but cling to the twigs past the autumn. Almost all (92%) of the constrictions are also infected with the anthracnose fungus *Melanconium bicolor*.

A similar case in which twig canker initiation and development are facilitated by insects is the cacao dieback disease in which the fungi *Calonectria* (*Fusarium*) *rigidiuscula* and/or *Botryodiplodia theobromae* enter the twigs through wounds created by the feeding of the capsid insects *Sahlbergella singularis* and *Distantiella theobroma*. In isolated infections the tree defenses take over, isolate the fungus, and its further spread stops. In trees massively infested with the insect, however, the fungus develops unchecked in the insect-infested tissues and causes a chronic dieback of twigs. Control of the insects also halts the invasion by the fungus and the tree recovers.

In mango malformation disease, presumably caused by the fungus *Fusarium moniliforme*, the fungus is transmitted by the eriophyid mite *Aceria mangifera*, while other fungi seem to be carried in the digestive tract of certain termites.

Sooty Molds

These are black-colored fungi that grow on the surfaces of mostly leaves of plants, especially in the tropics and subtropics. Sooty mold fungi do not penetrate and infect plants but cause disease by blocking the light from reaching the leaves. Sooty mold fungi do not parasitize plants but feed off the honeydew excreted by insects such as whiteflies, scales, mealybugs, aphids, etc. The sooty mold fungi are disseminated through their spores being blown about by wind. However, they are also spread by the honeydew-producing insects and, also, by several other types of insects such as flies, wasps, bees, and ladybug beetles, all of which seek honeydew as a source of food and in the process become smeared with fungus spores which they carry about.

Wood Rots

Rotting of wood is carried out primarily by wood-rotting basidiomycete fungi. The shelf or conk-shaped fruiting bodies of many of these fungi are visited routinely by many types of insects and it is believed that many of these insects act as vectors of the wood-rotting fungi. Insects and mites have also been implicated in the spread of some pine rust diseases, while at least three common scolytid beetles have been shown to be involved in the transmission of the scleroderis canker of pine and spruce.

Wood-Stain Diseases

Wood stain or wood discoloration diseases occur in conifer trees and felled timber. They are caused by the so-called blue-stain fungi, of which the most common are species of *Ceratocystis* and *Ophiostoma*. The blue-stain fungi are associated with several species of bark beetles, such as *Dendroctonus ponderosae*, *Ips pini*, etc., which serve as vectors of the fungi and provide them with wounds for penetration. On the other hand, the fungi reduce the water content of the tree and otherwise improve the microenvironment for the developing brood of insects. Such a fungus-insect relationship is described as true mutualistic symbiosis. In other blue-stain diseases, like the ones caused by the fungi *Trachosporium tingens* and *T. t.* var. *macrosporum*, the fungi are constantly associated with their bark-beetle vectors *Myelophilus* (*Blastophagus*) *minor* and *Ips acuminatus*, respectively, and are found regularly in the breeding places of the insects in pine stems. Such fungal-insect associations are known as symbiotic ambrosia cultures.

In the Southern United States, attacks of short-leaf pines by beetles like *Dendroctonus frontalis* are quickly followed by heavy fungus infection soon after the beetles tunnel through the bark and outer wood. Several fungi, including *Ceratocystis pini*, *Saccharomyces pini*, *Dacryomyces* sp. and *Monilia* sp. can be isolated from the infected wood and are carried by the same insects both externally and internally. A similarly complex association seems to occur in spruce attacked by *Dendroctonus engelmani*, followed by the fungi *Leptographium* sp., *Endoconidiophora* sp., or *Ophiostoma* sp. infecting the wood and causing a gray stain in the sapwood of the infected trees.

Vascular Wilts

Several vascular wilts affect trees and some of them cause extensive death of trees, because the fungus responsible for the disease is transmitted from diseased to healthy trees by specific insect vectors. The spores produced by the causal fungi are sticky and are produced primarily inside the tree, therefore, they can be spread by no other means but only by certain insects closely associated with the disease. These vascular wilts include (i) persimmon wilt, a devastating disease caused by the fungus *Cephalosporium diospyri* which enters through all kinds of wounds but is also transmitted by the powder-post beetle. *Xylobiops basilaris* and the twig girdler beetle *Oncider cingulatus*, and (ii) mango wilts, one caused by the fungus *Diplodia recifensis* and transmitted by the beetle *Xyleborus affinis*, and another caused by the fungus *Ceratocystis fimbriata* and transmitted by the scolytid beetle *Hypocryphalus mangiferae*. The other two vascular wilts are oak wilt and the Dutch elm disease and will be discussed in some detail below.

Oak Wilt

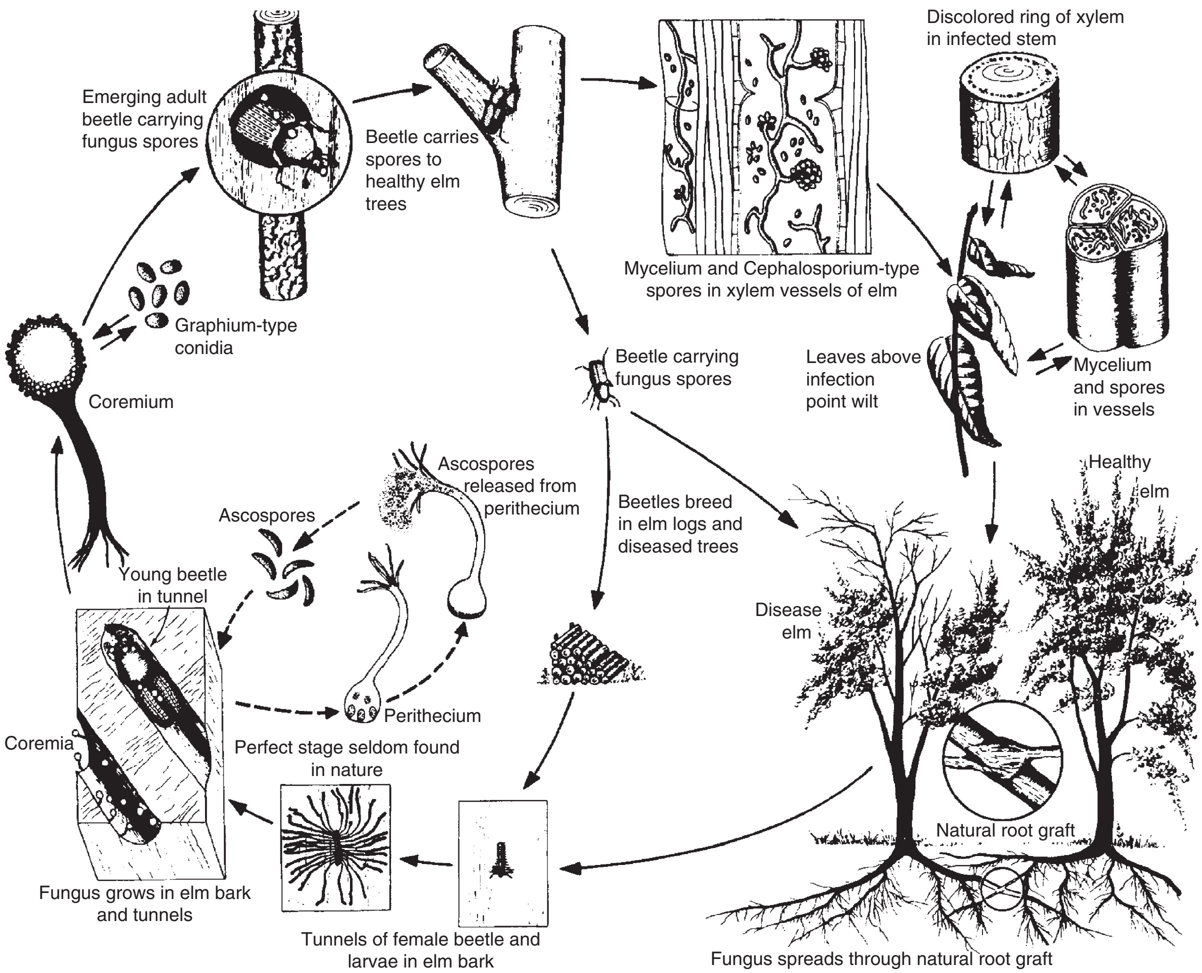
It is caused by the fungus *Ceratocystis fimbriata* and is one of the most important diseases of forest trees. The fungus enters the xylem vessels of trees through fresh wounds to which it is carried by air or insects, and through natural root grafts. Tree parts beyond the point of infection wilt, turn brown and die while newly infected wood shows dark streaks. The fungus is spread to healthy trees by nitidulid beetles such as *Carpophilus lugubris*, *Colopterus niger*, *Cryptarcha ample*, and several species of *Glischrochilus*. These fungi breed in the mycelial mats of the fungus between the bark and wood and carry the fungus both externally on their bodies and internally through their digestive tract. In addition to the nitidulid beetles, several scolytid beetles, such as *Monarthrum fasciatum* and *Pseudopityophthorus minutissimus*, the brentid beetle *Arrhenodes minuta*, the buprestid *Agrillus bilineatus*, the flat-headed borer *Chrysobothrys femorata*, and others, have been shown to carry the spores of the fungus, both externally and internally, when they emerge from the tunnels in diseased trees in which they breed and overwinter and to carry them to susceptible trees in the spring. Transmission of the oak wilt fungus by insects not only spreads the fungus and the disease to new trees and into new areas, it also increases the ability of the fungus to produce new variants and new races more virulent than the existing ones. This is accomplished by the insects bringing together in the same tree the compatible self-sterile mating types which results in the production of perithecia containing the sexual spores ascospores. The latter express any new characteristics brought together during the formation of the spores, some of the characteristics possibly being increased virulence.

Dutch Elm Disease

It is caused by the fungus *Ophiostoma ulmi* and the most recent variant *Ophiostoma novo-ulmi*, which is replacing the earlier species. The disease was first described in the Netherlands in 1921, found in Ohio and New York in the 1930s, and has since spread throughout the United States and much of the rest of the world. It kills elm tree twigs, branches and whole trees by clogging their xylem vessels and blocking movement of water from the roots to these parts. Dutch elm disease has been particularly devastating in the United States where the native elm tree *Ulmus americana* is extremely susceptible to the pathogen. The disease has killed almost all trees in its path, especially elm trees planted along streets and parks. Elm trees in forests have also been killed but many of them have escaped infection so far (Fig. 95).

The fungus causing Dutch elm disease is spread from diseased to healthy trees by the European elm bark beetle *Scolytus multistriatus* and the native elm bark beetle *Hylurgopinus rufipes*, and by natural root grafts. The fungus overwinters in the bark of dying or dead elm trees and logs as mycelium and spores. The elm bark beetles lay their eggs in galleries they make in the intersurface between bark and wood of weakened or dead elm trees. If the tree is already infected with the Dutch elm disease or if the insects carry with them spores of the fungus, the fungus grows and produces new spores in the tunnels. After the eggs hatch, the larvae make tunnels perpendicular to that made by the adult female and pupate. The adults emerge, carrying thousands of fungal spores on their body. The emerging adults prefer to feed on young twigs of trees and the crotch of small branches. As the beetles burrow into the bark and wood for sap, the spores they carry on their body are deposited in the wounded moist tissues of the tree. There the spores germinate and grow into the injured bark and wood and the fungus reaches the xylem vessels of the tree in which it grows producing mycelium and spores. The latter are carried upward by the sap stream where they can start new infections. Shoots beyond the infected areas turn brown, wilt, and die, and as their number increases the tree shows more browning and more wilted branches. Eventually large parts of or entire trees wilt and die, while the fungus continues to grow and spread in the dead tree. Such trees are then visited by adult female beetles that lay their eggs in them and the cycle is repeated.

In Dutch elm disease there is a clear dependency of each organism, the fungus and the insect, on the other. Probably more than 99% of the elm



Transmission of Plant Diseases by Insects, Figure 95 **Disease cycle of Dutch elm disease caused by the fungus *Ophiostoma ulmi* and transmitted by the European and the American elm bark beetles (from Agrios 1997).**

tree infections are caused by the fungus being carried to the elm trees by the elm bark beetles. On the other hand, the elm bark beetles depend on the fungus for causing many elm trees to weaken and die, thereby becoming available as breeding grounds for the two species of elm bark beetles that transmit the fungus. The interdependence of the two organisms has provided the most effective means of managing the Dutch elm disease by burning or debarking dead elm trees and logs, thereby denying the insects the breeding ground they need and, through the reduced number of insects produced, reducing the number of elm trees to which they spread the disease.

Foliar Diseases

Many foliar diseases are probably spread by various insects visiting and moving about on leaf surfaces that are exhibiting infections by spore-producing fungi. Spores or the spore containers of many such fungi are sticky or have appendages that cling to the legs or other body parts of such insects and are carried by them to other plants or plant parts they visit next. A few examples of foliar diseases in which insect transmission of the fungal pathogen has been shown to occur are described briefly below.

Powdery Mildews

These are diseases that affect most annual and perennial plants. They are characterized by white superficial mycelial growth and sporulation by a small group of fungi that cause symptoms on leaves, shoots, blossoms and fruit of their host plants. Powdery mildews serve as food for many mycophagous fungi and produce large numbers of loosely attached spores. Such spores become attached to, and are disseminated by, insects with which they come in contact. Examples include the feeding of thrips on and the transmission of spores of the fungi *Sphaerotheca panosa* and *Uncinula necator* that cause powdery mildew on rose and grape, respectively. Although these fungi are disseminated readily by wind, it is likely that transmission is aided by insects.

Rust Diseases

Most rust diseases produce several types of superficial spores on their host plants that, like those of the powdery mildews, are easily disseminated by air currents but are also visited, eaten, and transported by a wide variety of insects. Furthermore, many rust fungi produce spermatia and receptive hyphae in the same spermagonium but they are self-sterile. Many insects, when visiting such spermagonia become smeared with sticky spermatia. When the insects visit successive spermagonia, they transfer to the receptive hyphae spermatia from the opposite, compatible type. These spermatia can fertilize the receptive hypha which then produces dikaryotic mycelium and spores that contain two nuclei. These dikaryotic spores have entirely different properties. For example, they can infect an entirely different host plant from the plant on which they were produced. The involvement of insects in rust diseases is, therefore, important in both the dissemination of the spores to new hosts and, more importantly, in the fertilization of the fungus and, thereby, in increasing the potential of the fungus to produce more new and possibly more virulent races.

Some other examples of foliar diseases in which insects have been shown to play a role in their transmission include: red pine needle blight caused by the fungus *Pullularia pullulans* and transmitted and aided in penetration of pine needles by a cecidomyiid midge; cucurbit anthracnose, caused by the fungus *Colletotrichum lagenarium* and transmitted and aided in penetration by the spotted cucumber beetle *Diabrotica undecimpunctata*; oil palm leaf spot, caused by the fungus *Pestalotiopsis palmarum* and transmitted and aided in penetration by the oviposition punctures of a tinged of the genus *Gargaphia*.

Diseases of Buds and Blossoms

Insects often overwinter in buds of plants and many also visit blossoms to feed on the nectar they produce. Buds also often contain mycelium and spores of plant pathogenic fungi, and blossoms are often the first plant organ such fungi attack in the spring. Examples of bud infections in which insects have been implicated to play a role include: bud-blast disease of rhododendron, caused by the fungus *Pycnostyamus azalea* and aided by the leafhopper *Graphocephala coccinea*; bud rot disease of carnations caused by the fungus *Fusarium poae* and aided by the mite *Siteroptes graminum*.

Several diseases of blossoms have been associated with insect vectors. In most cases, transmission of the fungus by the insect is related to the activities of the insect during pollination. Some of the better-known examples include:

Anther Smut of Carnations

This is caused by the fungus *Ustilago violacea*. In this disease, the pollen is replaced by the teliospores of the fungus but the petals remain unaffected and continue to attract insects. The visiting insects become smeared with the smut spores, which they transfer to previously healthy flowers.

Blossom Blight of Red Clover

This is caused by the fungus *Botrytis anthophila* and is transmitted primarily by pollinating bees.

Ergot of Cereals and Grasses

This is caused by the fungus *Claviceps purpurea*, which develops in the flowers and produces spores that are contained in a sweet and sticky substance. That substance is attractive to many insects, particularly flies and beetles. The insects feed on the spores and also become smeared with them externally and carry them, externally and through their feces, to healthy flowers. Although primary infections by the ergot fungus are primarily from ascospores produced by sclerotia overwintering on the ground and carried via air currents, insect transmission of conidia is important for secondary transmission of the disease and for transmission over long distances. Some beetles, however, feed on ergot sclerotia on the ground and may carry mycelium and ascospores on their bodies to healthy plants and through them may cause primary infections.

Anthracnose Disease of Musa Balsamiana

This is caused by the fungus *Gloeosporium musarum* and is transmitted by the hymenopterans *Polybia occidentalis*, *Synoeca surinama*, and *Trigona* sp. The fungus infects the floral parts of the plant but these are dropped while still producing conidia and sweet exudate. The insects are attracted to the exudate on the fallen flowers and there they become smeared with conidia, which they subsequently carry to healthy flowers, which the spores infect.

Flower Spot of Azalea

This is caused by the fungus *Ovulina azaleae* and is transmitted by several species of bees, thrips, and ants. The insects carry spores on their bodies and drop them off on healthy flowers they visit which, in addition, may injure directly and facilitate penetration and infection by the fungus.

Diseases of Fruit and Seeds in the Field

Fruits and seeds are the source of food and the breeding grounds of many insects. Insects puncture fruit and seeds to obtain food and to lay their eggs in them. Although insects often cause direct damage to fruits and seeds that make them unsalable, the damage increases manifold when the insects also carry to the fruits and seeds fungi that infect and cause these organs to rot or to develop other symptoms. Numerous examples of fruit-insect-pathogen interactions could be cited, although in many cases no hard data of such interactions exist. Some of the better-studied cases are described briefly below.

Rots of Fleshy Fruits

Fig Rots

Several kinds of fungi attack figs and cause rotting of fruits in the field. In most such cases, certain types of insects play a more or less important role in the transmission and introduction of the fungus into the fig.

Endosepsis of Figs

This is caused by the fungus *Fusarium moniliforme*, and results in the entire fruit content turning into a pulp. The fungus is transmitted from fruit to fruit by the fig wasp *Blastophaga psenes*, which also plays a crucial role in the pollination of figs. Fig trees, being dioecious, have male trees that produce staminate flowers around the opening and gall flowers in the cavity, and female trees that produce only pistilate flowers. The fig wasp lays its eggs in the ovules of the gall flowers of male plants, which are thereby stimulated to grow. The eggs hatch and the larvae parasitize the galls until they pupate. The adults emerge from the pupae and the females are fertilized while still in the male fig. When they come out of the fig, the females brush against the staminate flowers that surround the opening and become smeared with pollen. The female wasps carry the pollen to male and female flowers they subsequently visit for oviposition. In female flowers, however, because of the length of styles, oviposition fails but pollination is nevertheless successful and the fruit develop into edible figs. If, however, as the female wasp visits some infected figs it becomes smeared with spores of the fungus, it transmits the spores to male and female figs it visits, and the fungus then causes endosepsis of the female figs.

Souring of Figs

This is caused by yeast fungi that cause fermentation, and appears as discoloration and wateriness of the fig contents which then exude from the fig opening. Such figs shrivel, dry, and cling to the tree. The fermenting yeasts are transmitted to figs externally and internally on the bodies of the two most common visitors of figs still in the tree, the sap beetle *Carpophilus hemipterus* and the fruit fly *Drosophila melanogaster*.

Fig Smuts and Molds

These are caused by the black mycelium and spores of *Aspergillus niger* and the variously colored growths of other fungi. These fungi are carried into green figs on the bodies of predatory mites and, to a lesser extent, by thrips.

Brown Rot of Stone and Pome Fruits

This is caused by the three related fungi *Monilinia fructicola*, *M. fructigena*, and *M. laxa* and affects all the stone fruits and, to a lesser extent, the pome fruits. The fungi are aided in their penetration of the fruit by the feeding and oviposition wounds made by the insects plum curculio (*Conotrachelus nenuphar*) and the oriental fruit moth (*Grapholitha molesta*), and the feeding wounds of the dried fruit beetle (*Carpophilus hemipterus*) and two nitidulid beetles (*Carpophilus mutilatus* and *Haptonchus luteolus*). The insects also become smeared with spores of the brown rot fungi which they carry on their bodies and deposit at the wounds they make on the fruits they visit. In pome fruits, the fungus is facilitated in penetrating the fruit by the feeding holes made by the earwig *Forficula auricularia* at the beginning of ripening of the fruit, at which time they are susceptible to brown rot.

Gray Mold of Grapes

This is caused by the fungus *Botrytis cinerea*. The fungus spores are generally spread by air currents. Penetration of the grapes and shoots, however, seem to be increased by the wounds made on them by the larvae of the lepidopterans *Argyrotaenia pulchellana* and *Lobesia botrana*.

Black Pod of Cacao

This is caused by the fungus *Phytophthora palmivora* and results in devastating losses of yield. Insects of several different families play a role in the transmission of this disease. At least 10 species of ants, especially *Crematogaster striatula* and to a lesser extent *Camponotus acvapimensis* and *Pheidole megacephala*, appear to spread the fungus vertically within the tree, especially during the rainy season, when they carry spore-containing soil particles up the cacao tree for nesting purposes. Certain coleoptera, such as the nitidulid beetle *Brachypeplus pilosellus*, and certain dipterans, such as the fly *Chaetonarius latifemur*, colonize black pods in the field and may carry the fungus internally or externally on their bodies to healthy pods. Because of their large numbers on cocoa trees, their habit of visiting wounded pods, and their proven efficiency to transmit the fungus, these insects are considered the main vectors of the fungus locally and over long distance.

Boll Rots of Cotton

These are caused by several fungi including *Fusarium moniliforme*, *Alternaria tenuis*, *Aspergillus flavus*, and *Rhizopus nigricans*. Various insects are apparently involved in the transmission of these fungi and they seem to use different mechanisms of transmission. Thus, in boll rot due to *Fusarium* and *Alternaria*, the fungi penetrate cotton bolls through feeding and oviposition wounds made by the boll weevil (*Anthonomus grandis*), the cotton bollworm (*Heliothis zeae*), and the tarnished plant bug, *Lygus lineolaris*, or they are brought to and penetrate through the nectarines by nectar feeding flies such as *Drosophila* and cabbage looper, *Trichoplusia ni.* In boll rots caused by *Aspergillus flavus* and other aflatoxin-producing species, the fungus is primarily wind disseminated but is also carried internally and externally by insects, such as the lygus bug *Lygus hesperus* and the stink bug *Chlorochroa sayi*, that frequently visit cotton bolls. The latter fungus, however, seems to depend for entrance on the presence of large wounds like the large exit holes made by the mature larvae of the pink bollworm, *Pectinophora gossypiella*. On the other hand, boll rots by *Rhizopus stolonifer* occur when wounds made by the bollworm *Earias insulana* and by the pink bollworm are available. In the lint rot of cotton, caused by the fungus *Nigrospora oryzae*, the fungus is transmitted very efficiently by the mite *Siteroptes reniformis*. In Stigmatomycosis or internal boll disease, caused by the fungus *Nematospora gossypol*, the cotton fibers are stained in the absence of external symptoms. This disease is associated with the feeding of several species of plant bugs primarily of the genus *Dysdercus*, often referred to as cotton stainers. The insects carry the fungus spores externally on the mouthparts and internally in their deep stylet pouches and introduce it via their proboscis through the wall of young cotton bolls.

Coffee Bean Rot

This is caused by the related fungi *Nematospora corylii* and *N. gossypii*, which cause berries to turn black and subsequently to rot. The fungi are introduced into the berries through the feeding wounds made by the insects *Antestia lineaticolis* and *A. faceta*. The insects feed on small and large berries and if they carry the fungus the latter causes infection of the bean. The number of infected berries is proportional to the number of insects, approximately 300 insects per tree resulting in infection of all the berries on the tree.

Molds and Decays of Grains and Legumes

Numerous decays and molds affect the various grains and legumes while still in the field and their frequency and severity increase as the number of insects infesting the crops, and feeding on the seeds, increases. In corn, for example, seed rots can be caused by species of the fungi *Fusarium*, *Gibberella*, *Diplodia*, *Cephalosporium*, *Nigrospora*, *Physalospora*, *Cladosporium*, *Penicillium*, *Aspergillus*, *Rhizopus*, *Trichoderma*, and others. The insects most commonly involved in transmitting and facilitating infection of corn kernels by these fungi are the corn earworm, *Heliothis zea*, and the European corn borer, *Pyrausta nubilalis*, but other borers and other insects also play important roles as vectors and, most importantly, as facilitators of infection by these fungi by creating wounds that allow the fungus to enter the seed. In seed infections by *Aspergillus* and by *Fusarium* there is the added adverse effect of production of debilitating mycotoxins. Similar, although less studied situations have been reported for rice infections by fungi, e.g., *Nematospora corylii*, transmitted and facilitated by wounds made by the rice stinkbug *Oebalus pugnax*; wheat and corn infections by *Nigrospora* sp. and *Fusarium poae*, transmitted by large numbers of *Peliculopsis* mites feeding on and transporting spores of the fungus in their abdominal sacs; and in various legume infections by the fungi *Nematospora*, *Cladosporium*, *Aureobasidium*, etc., transmitted and facilitated in their penetration and infection of the seeds by the stinkbugs

Acrosternum hilare and *Thyanta custator*, the lygaeid *Spilostethus pandurus*, by thrips, aphids, and other insects.

Molds and Decays of Harvested Fruits and Seeds

Generally little is known definitively about the roles of specific insects on the transmission and facilitation of rots of specific fruits and vegetables, and of molds and decays of seeds of specific grains, legumes, or nuts by specific fungi. It is generally accepted, however, that postharvest infections of plant products are greatly increased in numbers and in severity if insects are also present in the same or adjacent containers. There is agreement that insects moving about among stored fruits, seeds, etc., transport externally and internally on their bodies spores of fungi infecting such fruits and seeds and deposit such spores on the next fruit or seed they feed on. There is also agreement that by creating feeding or oviposition wounds on harvested fruit and seeds, the insects create openings through which the fungi can penetrate and release sap and additional nutrients. The fungi then can grow and build momentum to eventually infect and rot the entire fruit or seed.

The fungi that cause most rots of fleshy fruits and vegetable after harvest include *Penicillium*, *Fusarium*, *Botrytis*, *Rhizopus*, *Alternaria*, *Sclerotinia*, *Monilinia*, and *Colletotrichum*, while the molds and decays of grains and legumes involve primarily *Aspergillus*, *Fusarium*, and *Penicillium*. The insects involved in transmission and facilitation of infection of fleshy organs after harvest include larvae and adults of various Lepidoptera such as the oriental fruit moth, *Grapholitha molesta*, Diptera such as the apple maggot, *Rhagoletis pomonella*, the Mediterranean fruit fly, *Ceratitis capitata*, the house fly, and others. The insects involved in the transmission and facilitation of infection by fungi causing molds and decays of grains and legumes are the larvae and adults of various Coleoptera such as the rice weevil *Sitophilus oryzae*, the granary weevil *Sitophilus granarius*, and the confused grain beetle, *Tribolium confusum*, and also Lepidoptera such as the Angoumois grain moth, *Sitotroga cerealella*, the European corn borer, *Pyrausta nubilalis*, the ear cornworm, *Heliothis zea*, and other insects.

Insect Transmission of Plant Pathogenic Nematodes

Two very serious plant diseases caused by nematodes of the genus *Bursaphelenchus* are transmitted by insects. In both diseases there is a symbiotic relationship between the fungal pathogen and the insect vector.

Pine Wilt

This is a lethal disease of many species of pines and other conifers. It is caused by the nematode *Bursaphelenchus xylophilus*, known as the pinewood nematode. The nematode is about 800 μm long by 22 μm in diameter and it develops and multiplies rapidly, each female laying about 80 eggs and completing a life cycle in as short as 4 days. The nematode produces the four juvenile stages and the adults. The juvenile stages develop in the resin canals of infected pine trees, feeding at first on plant cells and later on fungi that invade the dying or dead tree. Later, the nematode produces special fourth-stage dispersal juveniles that are adapted to survive in the respiratory system of the cerambycid beetles *Monochamus carolinensis* and *M. alternatus* by which they are transmitted to healthy pine trees.

The pinewood nematode overwinters in the wood of infected dead trees, which also contain larvae of the beetle vectors of the nematode. Early in the spring, the larvae dig small cavities in the wood in which they pupate. As the adult beetles emerge from the pupae later in the spring, large numbers of fourth-stage juvenile nematodes enter the beetles and almost fill the tracheae of the respiratory system of each insect with about 15,000–20,000 juveniles. These nematode-carrying adult beetles emerge and fly to young branch tips of healthy pine trees where they feed for several weeks. As the beetles strip the bark and reach the cambium, the nematode juveniles emerge from the insect and enter the pine tree through the wound. The juveniles in the tree then undergo the final molt and produce adult nematodes. The latter migrate to the resin canals, feed on their cells and cause their death, and then they move in the xylem and in the cortex where thy reproduce quickly and build enormous populations of nematodes and kill twigs, branches and entire trees.

After the adult *Monochamus* beetles, the vector of the pine wilt nematode, have fed on young twigs for about a month, they are ready to breed and look for stressed and dead pine trees, including trees showing symptoms or dying from infection by the pinewood nematode. The female beetles deposit their eggs under the bark of such trees where the first two instars develop and feed. The third instar penetrates the wood where it undergoes the next molt and produces the fourth instar, which overwinters there. In early spring, the fourth instar digs a cavity in the wood where it pupates and to which numerous third-stage nematode juveniles are attracted and congregate. The juvenile nematodes undergo the next molt and produce the fourth-stage dispersal juveniles, which by the thousands infect the tracheae of the adult insects as soon as they emerge from the pupae and are carried by them to healthy pine trees, thus completing the cycle.

Red Ring of Coconut Palms

This disease kills coconut palm trees from Mexico to Brazil and in the Caribbean islands. It is caused by the nematode *Bursaphelenchus cocophilus*, which is transmitted from palm to palm by the American palm weevil, *Rhynchophorus palmarum*, the sugarcane weevil, *Metamasius* sp., and probably other weevils. The nematodes infect, discolor, and kill the palm tissues in a ring 3–5 cm wide about 5 cm inside the stem periphery over the length of the stem.

The nematode pathogen lays its eggs and produces all its juvenile stages and the adults inside infected palm trees, completing a life cycle in about 9–10 days. Female weevil vectors are attracted to red ring-diseased trees but they also lay eggs on healthy or wounded palm trees. If the female carries red ring nematodes, it deposits them in its feeding wounds at bases of leaves or at internodes. The nematodes then enter the palm tissues and undergo repeated life cycles and spread intercellularly in the parenchyma cells of the petioles, stem, and roots, where the cells break down and form a flaky, orange to red discolored tissue with cavities. Red ring nematodes do not invade xylem and phloem tissues but cause tyloses to develop in xylem vessels within the red ring that block the upward movement of water and nutrients. In the meantime, the weevil larvae of the insect vector feed on the red ring tissue and swallow several hundred thousand nematode third-stage juveniles. Of these, however, only a few hundred of the nematodes survive and pass through the molt, internally or externally, to the next stage weevil larvae and to the adult weevil. As weevil females emerge from rotted palms, a small percentage of them carry with them third-stage juveniles of the nematodes. Nematode populations increase rapidly at first but later they decline and about 3–5 months after infection there are hardly any red ring nematodes or their eggs left in decomposed stem tissue of infected, dead palm trees. The nematodes, however, survive in newly infected palm trees and, briefly, in their insect vector.

Insect Transmission of Plant Pathogenic Protozoa

Three plant diseases: phloem necrosis of coffee, heartrot of coconut palms, and sudden wilt of oil palms, are caused by flagellate protozoa of the genus *Phytomonas*. In all three diseases, protozoa invade the phloem elements of infected plants and multiply in them, reaching populations of varying densities. Some of the sieve tubes become plugged by protozoa. Generally, the more severe the symptoms of infected plants, the higher the populations of protozoa in their phloem. The pathogen is transmitted from infected to healthy plants occasionally through natural root grafts, and primarily by stink bugs (Pentatomidae) such as the genera *Lincus* and *Oclenus*, and possibly others.

Insect Transmission of Plant Pathogenic Viruses

Plant viruses cause many and severe diseases of plants, their number and importance being second only to fungal diseases of plants. Most viruses infect their host plants systemically, that is, the virus multiplies internally throughout the plant. Almost all viruses enter and multiply in phloem and in parenchyma cells. Viruses do not produce spores, nor do they come to the surface of the plant. All plant viruses are transmitted to new plants that are propagated from infected plants vegetatively (that is, by grafting or budding, by cuttings, by bulbs, corms, roots, tubers, etc.), and many can be transmitted artificially by mechanical inoculation, that is, by rubbing sap from infected plants onto leaves of healthy plants. Some plant viruses can be transmitted from diseased to healthy plants by pollen or seed produced by infected plants, some by the parasitic higher plant dodder when it is infecting both virus-infected and healthy plants, and some plant viruses are transmitted from plant to plant by certain plant pathogenic fungi, nematodes, or certain mites. More than half of the plant viruses, numbering more than 400, are transmitted from diseased to healthy plants by insects.

The number of insect groups that are vectors of plant viruses is relatively small. The most important vector groups, with the number of vector species and viruses transmitted, are listed below. Hemiptera, which includes the aphids (Aphididae, 192 species, 275 viruses), leafhoppers (Cicadellidae, 49 species, 31 viruses), the planthoppers (Fulgoroidea, 28 species, 24 viruses), the whiteflies (Aleurodidae, 3 species, 43 viruses), the mealybugs (Pseudococcidae, 19 species, 10 viruses), and some treehoppers (Membracidae, 1 species, 1 virus), contain by far the largest number and the most important insect vectors of plant viruses, but the true bugs (Hemiptera, 4 species), the thrips (Thysanoptera, 10 species, 11 viruses) and the beetles (Coleoptera, 60 species, 42 viruses) also are implicated. Grasshoppers (Orthoptera, 27 species) seem to occasionally carry and transmit a few viruses. Unquestionably, the most important virus vectors are the aphids, leafhoppers, whiteflies, and thrips. These and the other groups of Hemiptera have piercing and sucking mouthparts, although several thrips have rasping, sucking ones. Beetles and grasshoppers have chewing mouthparts, but many beetles are quite effective vectors of certain viruses. Generally, viruses transmitted by one type of vector are not transmitted by any other type of vector.

Aphids and Aphid-Transmitted Viruses

Aphids have evolved as the most successful exploiters of plants as a food source, particularly in the temperate regions. Many species of aphids alternate between a primary and a secondary host, although there are many variations of aphid life cycles depending on the aphid species and on climate. Some aphids overwinter as parthenogenetic viviparous forms while others go through their life cycle on one host species or on several related species. On the other hand, there are several aphid species, such as *Myzus persicae*, that have as many as 50 primary and alternate species of host plants.

Aphids have mouthparts that consist of two pairs of flexible stylets held within a groove of the labium. During feeding, the stylets are extended from the labium and, through a drop of gelling saliva, the stylets rapidly penetrate the epidermis. Penetration may stop at the epidermis or it may continue into the middle layers of leaf cells with a sheath of saliva forming around the stylets. The stylets move between the cells until they reach and enter a phloem sieve tube from which the aphids obtain their food. Individual aphids vary in their ability to transmit the virus to individual plants. Infection of a plant with a virus often makes the plant more attractive for aphids to grow on and to reproduce. Both acquisition and transmission of virus by aphids are affected by temperature, humidity and light.

Virus–Vector Relationships

Insect vectors that have sucking mouthparts carry plant viruses on their stylets, and such viruses are known as stylet-borne, externally borne, or non-circulative, because they do not pass to the vector's interior. The remaining viruses are taken up internally within the vector and are called internally borne persistent circulative or persistent propagative viruses.

Stylet-Borne Non-Persistent Transmission

Most externally borne viruses can be transmitted in the typical stylet-borne non-persistent manner. In such a transmission the virus is assisted in its transmission by a specific configuration of its coat protein or by a non-structural virus-encoded protein. The insect acquires the virus from the plant by feeding on it for only seconds or, at most, minutes. The insect can transmit the virus immediately after the acquisition feeding, that is, without any incubation period required for transmission. The insect retains the virus and is usually able to transmit it for only a few minutes after it acquired it. Most of the nearly 300 known aphid-borne plant viruses are stylet-borne non-persistent. Some of the most important groups of plant viruses, such as those in the genera *Potyvirus*, *Cucumovirus*, *Alfamovirus*, and the *Caulimovirus* transmitted by *Myzus persicae* are stylet-borne non-persistent viruses. In the few seconds in which aphids acquire the virus, the aphid stylet usually penetrates only the epidermal cell. Actually, deeper penetration of the stylet into leaf tissues reduces the ability of aphids to transmit the virus. Aphids vary greatly in their ability to transmit viruses, each particular virus being transmitted by one or a few species of aphids. Sometimes, certain virus strains are transmitted by distinct aphid species. Also, even individual aphids in a population vary in their ability to transmit the same virus, some of them being incapable of transmitting the virus.

All non-persistently transmitted viruses have simple structures of elongated or isometric particles with the nucleic acid encapsidated by one or more kinds of coat proteins. In some viruses, the coat protein interacts directly with the binding site of virus retention in the aphid. In other viruses, the virus encodes a non-structural protein which interacts with the aphid-virus retention binding site and forms a bridge between the virus and the aphid stylet. However viruses are bound to the aphid stylet, there must also be a mechanism for release of the virus when the aphid feeds on the next plant. It appears that saliva alone may carry out this function.

Semi-Persistent Viruses

Some externally borne non-persistent viruses are known as semi-persistent because they reach but do not seem to go past the foregut of the vector; the vector must feed on an infected plant (acquisition period) for several minutes or hours before it can transmit the virus; and the vector can then retain (retention time) and transmit the virus to healthy plants for several hours. Semi-persistent viruses are also assisted in their transmission by a transmission helper protein or coat protein configuration. The best known semi-persistent viruses are caulimoviruses, which occur in most cell types, and the closteroviruses beet yellows virus and curly top virus, which are found primarily in phloem cells. In several of the semi-persistent viruses, a helper component seems to be involved in their transmission. In cauliflower mosaic virus, the helper component consists of two non-capsid proteins, one of which is associated with the virus particles and the other has two binding domains that interact strongly with microtubules. In some cases, certain viruses can be transmitted only in the presence of a second virus which acts as the helper virus.

Persistent Viruses

Internally borne viruses are either persistent circulative or persistent propagative. Persistent circulative viruses are acquired from the plant by the vector after an acquisition feeding period of several hours to several days, and then they are retained by the insect vector and can be transmitted by it for several days or weeks. Persistent circulative viruses require a latent period of several hours to several days beyond the acquisition time before they can be transmitted by the insect vector, they reach the hemolymph of the vector, and pass through the various stages of the insect, but not through the ovaries to the egg. Persistent propagative viruses are acquired by the insect after a feeding period of several hours to several days, are retained by the vector for several weeks to several months, they multiply in the vector, they have a latent period of a few to several weeks, and can pass through the various stages of the insect, including transovarial passage to the egg. Persistent viruses are generally transmitted by one or a few species of aphids and cause symptoms characterized by leaf yellowing and leaf rolling.

Persistent Circulative Viruses

These include primarily the luteoviruses, such as barley yellow dwarf virus, and the nanoviruses, such as banana bunchy top virus. The luteoviruses are acquired after a feeding period as short as 5 min but it usually takes 12 h. After an incubation period of an additional 12 h, the vector can transmit the virus within a 10–30 min inoculation feeding and can continue transmitting it for several days or a few weeks. In the vector, the virus particles seem to associate only with the hind gut of the aphid, entering its cells by endocytosis into coated pits and vesicles and accumulating in tubular vesicles and lysosomes. Virus particles are then released into the hemolymph by fusion of the vesicles with the plasmodesmata and enter the salivary glands of the aphid via invaginations with two plasma membranes on the hemocoel side of the salivary gland accessory cells. It appears that persistent circulative viruses do not require a non-capsid protein for helper component but they require a protein produced via a read-through of the coat protein stop code if they are to advance beyond the hemocoel. Some persistent circulative viruses also require a helper virus to be present for them to be transmitted by their aphid vector.

Persistent Propagative Viruses

Propagative viruses are transmitted primarily by leafhoppers and planthoppers but several members of the Rhabdoviridae multiply in and are transmitted by their aphid vector. These bacilliform viruses replicate in the nucleus and the cytoplasm of cells in the brain, salivary glands, ovaries, and muscle of the insect vector. The virus goes through the egg to about 1% of the nymphs. Infection of aphids with rhabdoviruses results in increased mortality of the aphids.

Leafhoppers and Planthoppers, and Transmission of Plant Viruses

Leafhoppers lay eggs that hatch to nymphs which pass through several molts before becoming adults. Some of them overwinter as eggs, some as adults, and some as immature forms. They all feed by sucking sap from phloem elements of plants. Their feeding behavior is similar to that of aphids in that the mouthparts, surrounded by the salivary sheath, penetrate the phloem of host plants.

Virus–Vector Relationships

All hopper-transmitted viruses are persistent circulative or persistent propagative, and are transmitted by only one or by a few closely related species of the hopper vectors. Only two of the 60 sub-families of leafhoppers (Cicadellidae) contain species that are vectors of viruses: the Agalliinae feed on herbaceous dicotyledonous hosts and the Deltocephalinae that feed on monocots. Of the 20 planthopper families (Fulgoroidea), only one, the Delphacidae, have species that are vectors of viruses all of which infect monocotyledonous plants and many of them cause severe diseases on cereal crops such as rice, wheat, and corn.

Semi-Persistent Transmission

Two viruses, maize chlorotic dwarf virus (MCDV) and rice tungro spherical virus (RTSV), are acquired by their vectors (*Graminella nigrifrons* and *Nephotettix virescens*, respectively) from their hosts within about 15 min and are retained by their vectors for one to a few days. MCDV particles have been seen in the foregut and a few other tissues but not beyond. Hoppers egest material from the foregut once in a while during feeding and it is thought that transmission occurs during this ingestion-egestion process.

Persistent Transmission

This involves the internal movement of the virus obtained from the plant to the salivary glands of the insect vector. Some of these viruses are circulative while others are propagative.

Circulative Viruses

Only two genera of geminiviruses (*Mastrevirus* and *Curtovirus*) are transmitted by leafhoppers in the persistent circular manner. The viruses are acquired by the vector after feeding for a few seconds to an hour. There is a latent period of about a day, presumably for the virus to reach the salivary glands. The internal movement of these viruses is determined by the viral coat protein and by receptor-mediated endocytosis.

Propagative Viruses

There are four families and genera of plant viruses that replicate within the cells of their insect vectors as well as the cells of their host plants. Two of these families, Rhabdoviridae and Reoviridae, contain viruses that infect animals, and their virus members that infect plants have been considered as animal viruses that infect plants. The propagative viruses have a latent period of about 2 weeks. During this period the virus replicates and invades most tissues of the insect vector. When the virus reaches the salivary glands of the vector, the latter can transmit the virus to new plants and can continue to transmit it for the rest of their life. Only a small percentage of the hoppers feeding on infected plants become vectors and of these only about 1% pass the virus through their eggs to the next generation. Various capsid proteins seem to be necessary for passage of viruses through the organs of the vector and are required for transmission.

The two genera that have propagative viruses are Tenuivirus, members of which are transmitted by delphacid planthoppers, and Marafivirus, which is vectored by the leafhopper *Dalbulus maydis*. These viruses have an acquisition feeding period of 15 min to 4 h, a latent period of 4–31 days, inoculation periods as short as 30 s, and can transmit the virus for as long as they live. Almost all of these viruses are transmitted transovarially to the egg.

Whitefly Transmission of Plant Viruses

Whiteflies transmit the viruses in the genus *Begomovirus* of the family Geminiviridae, and all the viruses in the genus *Crinivirus* and some in the genus *Closterovirus* of the family Closteroviridae. Whitefly adults are winged but only the first instar among the larvae is mobile. Whiteflies produce many generations in a year and reach high populations. Only a few species of whiteflies transmit viruses, mostly in the tropics and subtropics, but the viruses they transmit cause very severe diseases. Begomoviruses are transmitted by *Bemisia tabaci* whiteflies, while the criniviruses and the whitefly-transmitted closteroviruses are vectored by the whiteflies *Trialeuroides vaporariorum*, *T. abutilonea*, *B. tabaci*, and the type B of *B. tabaci* (also referred to as *B. argentifolii*). Whitefly mouthparts and feeding behavior resemble those of aphids.

Begomoviruses are bipartite geminiviruses and are transmitted by whiteflies in the persistent circulative manner. A helper factor coded by the virus seems to be involved in the transmission. The whitefly-transmitted monopartite closteroviruses and the bipartite criniviruses reach only the foregut of the vector and are transmitted in the semi-persistent manner. These viruses are retained in the vector for about 3–9 days. Two capsid proteins help the virus in its transmission by the vector.

Thrips Transmission of Plant Viruses

About 10 species of thrips of the family Thripidae are the vectors of about a dozen viruses belonging to four genera (*Carmovirus*, *Ilarvirus*, *Sobemovirus*, and *Tospovirus*) of four families. Thrips are polyphagous insects that have many hosts. Some of the vector species reproduce mainly parthenogenetically. The larvae are rather inactive but the adults have wings and are very active. Thrips adults feed by sucking the contents of subepidermal cells. Adults live up to 3 weeks and there may be as many as 20 generations per year. The tospoviruses are transmitted in the persistent propagative manner, while the viruses of the other genera are transmitted in the pollen carried by the thrips vectors and by mechanical damage during feeding of the vector.

By far the most important thrips-transmitted viruses are the tospoviruses, which include the widespread and severe tomato spotted wilt virus and the impatience necrotic spot virus. In tospoviruses, only the larvae but not the adults can acquire the virus, and their ability to acquire it decreases with age. Larvae sometimes acquire the virus after feeding on a diseased plant for as little as 5 min, but usually they must feed for more than an hour both in acquiring and in inoculating the virus. There is a latent period of 3–4 days before the larvae can transmit the virus. The virus is passed from the larvae to the adults which can transmit it, although erratically, for as long as they live. These viruses appear to multiply in the vector but are not passed through the egg. Several structural proteins of the virus seam to be associated with the acquisition, passage through, and inoculation of the virus by its larval and adult insect vector.

Mealybug and Other Bug Transmission of Plant Viruses

Mealybugs are important as virus vectors primarily on some perennial plants in the tropics and subtropics. They move slowly on plants and therefore are not as efficient virus vectors as those discussed previously. They move from plant to plant, mostly as crawling nymphs, through leaves of adjacent plants being in contact with each other; by ants tending the mealybugs and moving them from one plant to the other; and occasionally by wind.

Mealybugs feed on the phloem and they are vectors of the badnaviruses, such as the cacao swollen shoot virus (CSSV), several closteroviruses, such as grapevine leafroll associated viruses and the pineapple mealybug wilt associated virus, and the trichoviruses, such as grape viruses

A and B. Mealybugs acquire the viruses after feeding on diseased plants for only a few, about 20 min and retain the virus for a few, up to 24 h, so the transmission resembles the non-persistent or semi-persistent mechanism of transmission by aphids.

Other bugs that transmit plant viruses include the mirid bugs, which transmit some sobemoviruses in manners that have characteristics of non-persistent, semi-persistent, and beetle-like transmission, and the piesmatid bugs, which transmit beet leaf curl virus in a persistent propagative manner.

Virus Transmission by Insects That Have Biting/Chewing Mouthparts

Although there are a few vectors in the orders Orthoptera and Dermaptera, there are more than 60 vector species in the order Coleoptera (beetles), 30 of them in the family Chrysomelidae. Most beetle vectors tend to eat plant cells between the leaf veins and regurgitate during feeding, thereby bathing their mouthparts with sap and virus. Virus transmission by beetles, however, is specific between each virus and its vector. Beetle-transmitted viruses belong to the genera *Tymovirus*, *Comovirus*, *Bromovirus*, and *Sobemovirus*. Most of these viruses are small (25–30 nm in diameter), stable, reach high concentrations, and are easily transmitted by sap. These viruses can also be translocated through the xylem of the plant. Beetles can acquire and can transmit the virus after feeding for a few seconds and they can retain the virus from 1 to 10 days.

Virus Transmission by Mites

Several members of the mite family Eriophyidae transmit viruses of the genus *Rymovirus* which cause many serious diseases in grain crops. Two mite species of the family Tetranychidae transmit two plant viruses, one of them transmitting the peach mosaic virus. All mites in these families feed by piercing plant cells and sucking their contents.

Eriophyid mites are small (0.2 mm long), move little by themselves and, instead, they are spread by wind. They have two nymphal instars followed by a resting pseudopupa. They complete a life cycle within 2 weeks. Mites can acquire virus from infected host plants within 15 min from the start of feeding and can transmit it to healthy plant within a similar duration. Mites acquire the virus as nymphs but not as adults. They carry the virus through molts and remain infective for 6–9 days.

Tetranychid mites are larger (0.8 mm long). Pre-adult mites readily acquire the virus and they, as well as the adults, transmit the virus efficiently.

Virus Transmission by Pollinating Insects

Honey bees and other pollinating insects seem to play a role in distributing virus-infected pollen from infected plants to healthy ones. It appears, however, that no special mechanisms or involvement of the insect are present in such virus transmission.

Summary

Insects play various roles in the transmission of plant pathogens, and in the initiation and development of disease in plants. In some diseases, the insects incidentally carry pathogens on their bodies or in their feces and deposit them on healthy plants where they cause disease, without developing any special relationships with the pathogens. In several cases, the insects weaken the plants on which they feed and make them much more susceptible to attack by pathogens. In other cases, the pathogens depend on the insects to carry them to healthy plants and to deposit them on fresh wounds through which they penetrate and infect the plants. While pathogens seem to be the beneficiaries of these actions, insects also derive advantages by the pathogen making the diseased plant more attractive to the insect for feeding or breeding purposes, and in some cases, by the insect feeding on the

pathogen growing in the cavities made by its insect vector. Also, while in most cases the pathogen does not affect its insect vector directly, there are several plant viruses and mollicutes that multiply in the insect vector as well as in their plant host, and such vector insects often show histopathological symptoms, reduced reproduction, and shorter life span. Most of the insect/pathogen associations are highly specific and involve sophisticated molecular mechanisms that regulate the uptake, retention, and transmission of the pathogen by its insect vector.

Transmission of *Xylella fastidiosa* Bacteria by Xylem-Feeding Insects

ALEXANDER H. PURCELL
University of California, Berkeley, CA, USA

Insects that feed predominantly on the sap of plants' water-conducting systems (xylem) can transmit bacteria that are specific parasites of the plant xylem. Most xylem sap-feeders are spittlebugs (families Cercopidae and Machaerotidae) or sharpshooters (subfamily Cicadellinae) belonging to the leafhopper family (Cicadellidae) in the order Hemiptera (Fig. 96). Xylem sap is extremely low in nutrition, and xylem sap-feeders have the highest feeding rates of any terrestrial animals, consuming up to 1,000 times their body weight per day.

The best known xylem-limited bacterium that causes plant diseases is *Xylella fastidiosa*. Various strains of *X. fastidiosa* cause disease in grape, peach, almond, orange, alfalfa, and numerous tree species (Table 14). The bacteria and associated gums plug the xylem system, leading to discoloration and killing or stunting of leaves and fruits. Pierce's disease of grape, phony disease of peach, and citrus variegated chlorosis are among the best known and most economically damaging of these diseases. For example, Pierce's disease is so severe and widespread in the southeastern United States that it has prevented commercial viticulture there using susceptible European grapes. Less appreciated, but economically and ecologically important, are the numerous and more widespread leaf scorch diseases caused by *X. fastidiosa* in numerous forest trees such as oak, sycamore, maple, and elm. This bacterial species has an enormously wide range of plant species – about 75–90% of all plant species tested – in which it can multiply, but it causes symptoms in relatively few. Except for a leaf scorch disease of pear in Taiwan, these diseases appear to be limited to the Americas. However, in 1996, Pierce's disease was confirmed to occur in southeastern Europe. Numerous other bacterial pathogens invade the xylem system, but not exclusively. The widespread *Leifsonia (Clavibacter) xyli*, a xylem-limited bacterium that causes ratoon stunt disease of sugar cane, is not transmitted by insects.

The great majority of insect species that are xylem sap-feeding specialists that have been tested as vectors (transmitters) of *X. fastidiosa* have been shown to be able to transmit this bacterium to plants. Only a small fraction of the species that are xylem sap-feeding specialists have been tested as

Transmission of *Xylella fastidiosa* Bacteria by Xylem-Feeding Insects, Table 14 Examples of plant diseases caused by strains of the bacterium *Xylella fastidiosa*

Crop	Disease	Where found
Grape (*Vitis vinifera* and other *Vitis* species)	Pierce's disease	Southern North America, Central America (northern South America?)
Citrus	Variegated chlorosis	South America
Peach	Phony disease (dwarfing)	Southeastern United States
Oak, sycamore, elm, others	Leaf scorch diseases	Southeastern United States
Pear	Leaf scorch	Taiwan
Alfalfa	Dwarf	California, probably other locations in North and Central America
Coffee	Leaf scorch	South America, possibly Central America

Transmission of *Xylella fastidiosa* Bacteria by Xylem-Feeding Insects, Figure 96 The glassy-winged sharpshooter (*Homalodisca coagulata*) a vector of the xylem-limited bacterium *Xylella fastidiosa*. Drawing by and with permission of Rosser Garrison.

vectors, so several thousand species are probably vectors of *X. fastidiosa*. This broad degree of vector specificity, as well as other characteristics of vector transmission point to the method by which insects transmit the bacterium. There is no time delay (latent period) between a vector's acquiring the bacterium by feeding on infected plants and its introducing the bacterium to other plants. Once infective, a vector can transmit for the rest of its life, but immature vectors lose the ability to transmit when they shed their skin. All of these characteristics can be best explained if the bacteria are transmitted from the foregut of the vector. The exact location in the foregut from which the bacteria are transmitted is not yet known. The lack of a latent period and the persistence of infectivity in vectors makes control of diseases caused by *X. fastidiosa* especially difficult. Because a few infective insects can quickly transmit the bacterium to susceptible plants, insecticides to kill vectors within vineyards has not proven to be effective.

Transmission Threshold

The level of abundance of a parasite, or the abundance of its vector, that is necessary for disease to spread.

Transovarial Transmission

Passage of a material through the ovariole and within the egg.

Transovum Transmission

Passage of a material on the surface of the egg.

Transpiration

The evaporation of water from the surface of plant foliage.

Transposable Element

An element that can move from one site to another in the genome. Transposable elements have been divided into two classes, those that transpose with an RNA intermediate, and those that transpose as DNA.

Transposon

A transposable element carrying several genes including at least one coding for a transposase enzyme. Many elements are flanked by inverted repeats. *Drosophila melanogaster* contains multiple copies of 50–100 different kinds of transposons.

Transstadial Transmission

The transmission of pathogens or parasites through successive stages of the host's life cycle, as from the egg to the larva, pupa and adult.

Trap Crop

A crop or portion of a crop that is intended to lure insects away from the main crop.

Traps for Capturing Insects

NANCY D. EPSKY[1], WENDELL L. MORRILL[2]
RICHARD W. MANKIN[3]
[1]USDA/ARS, Subtropical Horticulture Research Station , Miami, FL, USA
[2]Montana State University, Bozeman, MT, USA
[3]USDA/ARS Center for Medical, Agricultural, and Veterinary Entomology, , Gainesville, FL, USA

Traps developed for capturing insects are as varied as the purpose for the trapping, the insects targeted, and the habitats in which they are used. Traps are used for general survey of insect diversity, and these usually are simple interception devices that capture insects moving through an area. Traps also are used for detection of new invasions of insect pests in time and/or space, for delimitation of area of infestation, and for monitoring population levels of established pests. This information is used to make decisions on the initiation of control measures or to measure effectiveness of a pest management program. Traps may be used as direct control measures, for example, by mass trapping (use of a high density of traps throughout the infested area) or by perimeter trapping (use of traps as a barrier around a pest-free area to intercept insects moving into the area) to remove a large number of individuals, with the goal of preventing or suppressing population buildup. Traps can be used as direct control measures if they are highly effective, if they capture a high percentage of females (especially if they capture them before they have a chance to lay eggs), and if they are integrated with other pest management approaches. Factors such as cost per trap, the need to service the traps frequently and the high reproductive rate of individuals that escape capture, however, prevent widespread use of traps as a stand-alone pest control measure (Figs. 97 and 98).

Traps for specific insect species or pest groups may use combinations of cues to lure the target insect and exploit aspects of the insect's behavior to facilitate movement of insects into the trap. Several factors influence the effectiveness of a specific trap. The ability of the trap to mimic and present those cues to the insect, the strength of those cues in influencing the insect's behavior, and the proper placement of the trap in the habitat are important.

Following is an overview of the basic trap types, and variations of those basic trap types for specific uses. Traps may be used with or without attractant cues, and may use a combination of cues, including visual (color, light, shape), chemical (food/host, pheromone, parapheromone, oviposition) and acoustic stimuli to make them more specific and/or more effective. Automated monitoring systems exist that will transmit information on trap capture to an offsite station. Insect traps are an important part of insect pest management programs. Although a number of trapping systems are discussed, the intent is to provide a general framework of types of traps that are used with some representative examples. It is not intended to be a complete listing of all traps that have been developed or are in use. Representative literature is presented at the end of the section that will provide additional information on insect traps and specific uses.

Trap Types

There are a few basic designs that describe almost all insect traps. They may be a surface that is presented flat or is formed into baffles or cylinders; containers with holes on the sides, top or bottom; and funnels leading up or placed over the container to hold captured insects. However, different types of traps are used for insects moving through air (that is, flying or wind-borne insects), ground-dwelling or walking insects, subterranean insects, or aquatic insects. A number of these are described below.

Traps for Flying Insects and Wind-Blown Insects

Interception Traps

Interception traps are commonly used for faunal surveys in ecological studies, although they can also have pest management applications. In its simplest form, it is a suspended net with an invagination along the top that leads to a collecting tube. The Malaise trap is an example of an interception trap. Fixed interception traps have been used to study insect migration, with separate collecting tubes for north-bound versus south-bound insects. Or, the trap may be used with a wind vane attachment so that the flat surface of the net swivels to face into the wind. Large, funnel-shaped nets have been mounted on moving trucks for sampling flying insects such as biting midges (Ceratopogonidae) or attached to a suction device to sample Russian wheat aphids, *Diuraphis noxia* (Mordvilko).

Sticky Traps

Panels, cylinders or spheres covered with sticky material are probably the most commonly used traps for faunal surveys in agricultural studies. In the simplest form, they may be clear panels that are coated with a material that will retain insects that are blown onto the panel or fly into it. Panels may also be used with a color and/or a shape and a chemical attractant. Very small insects will be retained by a thin coating of motor oil, but larger insects may escape this substance. To capture both small and

large insects, sticky material such as Tangle-trap is applied to the surface. The traps can be serviced by using a small tool to scoop insects of interest off the trap and onto a card, or the entire trap can be replaced. For transport, the panel with sticky material can be covered with clear plastic wrap or the panel can be placed in a box with spacers to keep panels from touching other surfaces. To reuse the trap, a paint scraper or thinner can be used to remove sticky material from the surface so that new material can be applied. The advantage of this trap is that it is inexpensive and will capture a variety of insects that are moving through the area. The surface area and trap orientation can be increased by using two panels that are crossed into baffles. The primary disadvantage is the trap can be very messy, can become coated with dirt or debris and will no longer capture insects, and the sticky material is difficult to remove from the captured insects. These traps, as well as other traps for flying insects described below, are usually placed above the ground at the height of the vegetative growth. When used in row crops, the traps usually are attached to a wooden or metal stake, and the traps are moved higher as the plants grow over the season. When used in trees, traps are normally hung within the canopy. Trap placement and orientation within the canopy, as well as amount of vegetation near the trap, will vary among the trap types and target species.

Three-Dimensional Triangular Traps, Diamond Traps and Wing Traps

This group is another set of fairly inexpensive traps that are used with an attractant. These are basically sticky traps with the sticky surface protected on the interior of the trap and are either disposable or used with a sticky component that is replaced at servicing. Delta traps are small and light-weight triangular (tent-shaped) traps that are easy to hang in trees and to transport. The Jackson trap is a delta trap used for a number of tropical tephritid fruit flies. It has a removable base coated with sticky material that can be replaced at time of sampling. Diamond-shaped (in profile) traps are used to monitor indoor pests in public areas, such as stores and supermarkets. Wing traps composed of a roof and a floor are used for pest Lepidoptera. These are larger and more cumbersome than delta traps, but the larger surface is more suitable for larger pest moths. Because the sticky surface is enclosed, these traps are less susceptible to dirt and dust and capture fewer non-target insects than sticky traps, but the surface still may be coated with dust or debris that gets blown into the trap.

Water Pan Traps

A simple collection method for aphids and other small flying insects is a water pan trap. Insects flying over the trap are attracted to the reflective surface of the water and are captured. The traps are made from rectangular baking pans, storage containers, or dish-washing pans partially filled with aqueous solutions of soap or car antifreeze. Care should be used in selecting soap to be used so that it does not contain odors that may be repellent to target insects or that the antifreeze is environmentally safe. (Most antifreeze solutions are poisonous, and traps containing antifreeze should be placed so that animals are unable to gain access to them.) These traps are open containers, so there may be problems with movement in wind, evaporation during dry periods or overflowing during periods of heavy rain.

Bucket Traps

Another simple and inexpensive trap is a bucket trap. The bucket trap may be used without a lid, or as a closed container with holes on either the top or sides for insects to enter. Small drainage holes may be placed near the bottom of the trap to allow trapped water to drain out. The Nadel trap and Mission trap are examples of bucket traps that are translucent closed containers with entrance holes around the periphery. The corn rootworm trap has a large dome-shaped top and a gap between the top and the container. Size of the container and placement, diameter and number of entry holes is dictated by the targeted insect. These usually are used with a chemical lure of some type. These may be used without a killing agent so that live insects can be recovered, however captured insects may escape through the entrance openings. A variety of retention devices can be used with bucket-type traps. A pesticide such as dimethyl 2,2-dichlorovinyl phosphate (DDVP, mothballs) can be used inside, but if the concentration is too high it may prevent insects from entering. Aqueous solutions of soap or car antifreeze or surfactants such as triton may also be used. Again, care should be used in selecting soap that does not contain odors that may repel target insects and/or environmentally safe antifreeze should be used. Sticky material may also be used on either the interior or exterior surface. When used on the exterior, this may increase effectiveness of lure-baited traps because usually only a proportion of the insects attracted to the trap will proceed to enter the trap. However, the same problems outlined above for sticky panels will apply to sticky-coated bucket traps. Open-bottom cylindrical traps are essentially bucket traps used upside down. The Phase 4 trap is a green cylinder that uses a yellow panel as a sticky insert to retain captured insects. Clear versions of the trap have also been used. In addition to the opening on the bottom of the trap, entrance openings also are located around the periphery of the cylinder.

Bucket Traps with Funnels

Probably the most common traps for agricultural use are combinations of bucket traps with funnels. They are more costly than simple bucket traps and they are often used with some type of odor attractant. The funnel essentially provides an enlarged hole that directs movement of the attracted insect into the bucket. There are differences among this group of traps in orientation of the funnel and size of the funnel in relation to size of the bucket. The Steiner trap is a clear plastic horizontally oriented cylinder with small funnels centered on the flat sides of the cylinder. For insects that approach from the underside of the trap and move upward, the funnel is used with the large opening facing downward and the small opening leading up into a bucket or other container. Because it is difficult for the insect to find the top of the funnel for exiting, and these insects tend to move upward, they can be used with or without a pesticide or liquid to retain the insects. A well-known example of the downward facing trap is the McPhail trap, which is a bell-shaped invaginated trap that is used for tephritid and drosophilid fruit flies. The original trap was made from glass and there are several plastic versions of McPhail-type traps available including dome fruit fly traps, International Pheromones McPhail traps and Multilure traps available that typically have a clear top and a yellow base. Another example is a wasp trap, such as the Victor yellowjacket trap. This trap has holes around the sides of the base for wasps to enter, and then a funnel that leads to a separate upper container that retains the wasps.

Other insects approach from the top and either move or fall downward. For these insects, bucket traps with funnels that have the large opening facing upward and the small opening leading down into the bucket are appropriate. The universal moth trap (unitrap) and Multipher trap are examples of this trap and they commonly are used for Lepidoptera adults. These traps have lids held above the funnel opening to shelter the contents from rain and are available in a variety of colors. A trap developed for the Japanese beetle, *Popillia japonica* Newman, uses a funnel with the large opening facing upward and the small opening over a container, but the funnel is topped by two panels crossed to form a baffle. Insects are intercepted by the baffles, fall into the funnel and are captured in the container. The boll weevil trap is a version of a bucket trap that contains a funnel mounted on a cylinder. Insects land on the cylinder and move up the sides of the trap, enter the funnel and move into the small collection bucket above the small funnel top. The Lindgren funnel trap consists of 4, 8 or 12 plastic funnels stacked vertically over the container. It is used for ambrosia beetles and bark beetles. Fast-flying beetles hit a funnel and are deflected down into the collection container.

Cone Traps

Cone traps are essentially bucket traps with funnels, but the funnel is very large in relation to the size of the bucket or collecting tube. These are used with the large opening of the funnel oriented toward the ground and the top of the funnel leading up to a container. Examples of these traps include *Heliothis* traps and butterfly bait traps. These traps are made from a light cloth or mesh material and the design takes advantage of the moth or butterfly's tendency to move upward. The butterfly bait traps have a large container for the butterfly to move into so that the insect is undamaged.

Traps for Walking Arthropods and Soil-Dwelling Insects

Pitfall Traps

Pitfall traps are useful for collecting insects and other arthropods that are walking across a surface. This surface is usually a soil surface, for capturing beetles, spiders and other ground-dwelling organisms, although they also may catch flying insects that are walking across the soil surface. Pitfall traps placed into the top of stored grain also have been used to sample stored product insects. Pitfall traps consist of a container that is buried in the substrate, and into which insects and arthropods fall and are captured. The traps used in soil consist of an upper funnel, a collecting container, and perhaps a liner that makes servicing easier. Upper funnels can be made from disposable plastic funnels with the bottoms removed to enlarge the hole. Collecting containers can be made from plastic cups, and can be designed for dry catches with screens in the bottom to permit rain water to flow through, or can be made to hold a glycol (antifreeze)/water/detergent solution. Dry containers need to be serviced several times a week to minimize destruction of the sampled insects from other insects entering the trap. They have the advantage of providing live specimens for further studies. Wet containers can be serviced at longer intervals, but have the disadvantage of filling with rain water. Traps should be designed to produce minimal impact on the nearby soil, because insects may be repelled or attracted to the disturbance. To do this, holes can initially be cut with golf-hole cutters and lined with 4″diameter polyvinylchloride (PVC) pipe. The top of the pipe should be carefully leveled with the soil, and the traps serviced without disturbing the soil. Covers can be installed over the top to prevent rainfall from entering. Enhancement-fences or guides can be installed to guide insects to the trap. A cone with a gradual slope and smooth edge is necessary because insects may back away from the void of a direct hole. Captured insects should be removed at least weekly (wet) or twice weekly (dry).

Grain Probe Traps

Grain probe traps are a special modification of a pitfall trap for use in stored grain. Grain probe traps consist of an elongated cylinder with holes drilled into the sides that are above a funnel and insect receptacle. An early version of the trap was machined from solid brass and included a hollow cylinder made from 14 gauge brass sheet. Subsequently, probe traps have been made from clear polycarbonate (Lexan) plastic and from a perforated section of tubular polyethylene. The receptacle is coated with liquid Teflon (polytetrafluoroethylene) to prevent captured insects from escaping, however, insects remain alive for a while and may damage previously captured insects. These traps may be used at any depth within the grain mass, with long rods used to push the traps into place. A rope connected to the trap is affixed to the roof of the grain bin to allow removal of the grain probe trap and to prevent loss of the trap during grain bin filling and emptying operations. Traps should be inspected at 1–2 week intervals to remove the trapped insects. The PC trap is a cone-shaped trap that usually is used on grain mass surface, although it too can be pushed into the grain mass as long as it remains in an upright position. The top is covered by a convex lid that is covered with concentric circles of small holes to allow insects to enter the trap. When used at the grain surface, the traps are easy to remove for servicing, but webbing produced by larvae of lepidopteran grain pests, such as the Indianmeal moth, may block the openings into the trap and render them ineffective.

Shelter Traps

Shelter traps are used for insects that prefer a dark harborage and are useful in areas where it is preferred that the trap be inconspicuous. These are usually used to intercept insects as they walk over a surface and have small openings that encourage insects to enter the trap. Roach motels are the most well-known examples of such traps. They usually have a sticky material inside to trap insects that have entered or contain an oil or other substance to retain attracted insects. Shelter traps are used for stored product insects, and designs include dome traps, stealth traps and corner traps. The PC floor trap has been modified from the PC trap for use as a shelter trap by replacing the cone-shaped bottom with a flat container, which allows the trap to be placed on the ground or hung on a wall. Swarm traps are shelter traps that are used to capture unwanted swarms of domestic honey bees and to detect invading swarms of Africanized honey bees. These traps are fairly large bucket-shaped traps made of molded fiber material, have a single entrance hole, and are hung at least one meter above the ground. They provide a nesting site for bees, and the captured bees can be kept alive and moved to standard bee hives for honey production or pest bees can be identified and destroyed.

Emergence Traps

Emergence traps are a type of cone trap used for capturing adults that have subterranean larval and/or pupal stages. These traps are made from aluminum screening shaped into a funnel, with the top opening leading to a collecting tube or vial. The trap is placed flush with the ground and soil is pushed up around the edges to seal the trap to the ground. Adults emerging from below-ground stages move up into the trap and are captured in the collecting tube. The number of insects per unit area can be determined and the source of infestations can be identified. However, these traps may interfere with ground maintenance activities that prevent use in certain situations. Circle traps are another type of emergence trap. They are wire cone traps that are attached to the trunk or branch of a tree. Insects moving up a tree are captured, and because the traps are off of the ground, they do not interfere with ground maintenance activities.

Solar Bait Stations

The above traps can be used to capture the above-ground stages of subterranean insects, however the below-ground stages of wireworms (Elateridae), and false wireworms (Tenebrionidae) can be captured with solar bait stations. These are used to estimate wireworm populations and to make decisions on seed treatment/non-treatment. Larvae of these insect groups can be concentrated by creating microenvironments that have favorable moisture, temperatures, and food. A handful of grain (wheat, etc.) is buried a few inches below the surface of the soil. The bait is covered with a mound of soil, about 18″ high, and is covered with clear plastic. Edges of the plastic should be covered with soil to prevent them from blowing away. Stations should be constructed in the fall before soil freezes, and they can be examined in the spring before planting time. Surveyors' flags can be used to mark sites for easy location.

Traps for Aquatic Insects

Interception Traps

Interception traps capture aquatic insects moving through the water and are generally similar to interception traps used for wind-borne insects. Often, these traps are tapered nets with either round or rectangular openings which can be fixed in place to sample insects in moving water or pulled through the water manually. The size of the mesh governs the size of insects retained, but use of too fine a mesh may impede movement of water through the trap and retain too much debris.

Emergence Traps

Floating emergence traps are used to capture insects with aquatic larval stages when they emerge as adults. Construction and use is similar to that for emergence traps used for soil-dwelling insects.

Attractant Cues

Attractant cues are signals that are used by insects to locate resources for feeding, members of the opposite sex for mating, and oviposition sites for egg laying. Cues are added to traps to increase insect specificity and effectiveness of the traps. Attractive cues from natural substrates may be perceived by one or several of the senses including sight, sound, and smell. Semiochemicals are naturally occurring, message-bearing chemicals that are used by insects (and other organisms) for communication and for perception of their environment. Semiochemicals that have a behavioral effect on insect orientation, that is, chemicals that cause an insect to move toward the source, are used in insect traps. Of specific interest are kairomones, which are signals emitted and received by members of different species (interspecific) that give an advantage to the receiving species, and pheromones, which are signals emitted and received by members of the same species (intraspecific). Traps may use single cues to lure insects, but often a combination of cues is used to improve insect capture. For each cue and each insect species being targeted, there is usually an optimal range of stimulus intensity, below which attraction is minimal and above which attraction is reduced. Control of the stimulus level is particularly important for semiochemical cues, and considerable research has been conducted to optimize emission rates and ratios of semiochemical blends. This effect seems less important for acoustic cues, where it has usually been determined that the greatest capture rates are found for traps with the highest sound levels.

Visual Cues

Color

Color can serve as a strong attractant for use in a trap. Insects may use a specific color to locate host fruit or plant material, with both hue and intensity affecting insect response. Contrasts between light and dark can also play a role, with either the trap in contrast with the background color or through the use of lines with insects orienting to an edge between a light and dark area on a trap. Most sticky traps use a color to target certain insects. Yellow is the most commonly used attractant color, and is used to capture hemipterans such as whiteflies and aphids, but is also used for almost every order of flying insects. The Rebell trap is constructed from two yellow panels as baffles, and is used for walnut husk flies, *Rhagoletis completa* Cresson, and cherry fruit flies, *Rhagoletis cingulata* (Loew). A disadvantage of using yellow for sticky traps is that it also attracts beneficial insects such as hymenopteran parasitoids, and the traps may fill up with these and other non-target insects. Yellow-colored pan traps are used to capture Hymenoptera, especially the parasitoid species. Orange sticky traps are used for carrot rust fly, *Psila rosae* (Fabricius), and blue sticky traps for western flower thrips, *Frankliniella occidentalis* (Pergande). Blue is also highly attractive to tsetse flies (Glossinidae). White sticky traps are used as panels and as trunk wraps for capture of tarnished plant bug, *Lygus lineolaris* (Palisot de Beauvois), and eastern apple sawfly, *Hoplocampa testudinea* (Klug), and red trunk wraps for apple blotch leafminer, *Phyllonorcycter crataegella* (Clemens). Use of contrasts may increase insect capture, such as the use of insect silhouettes added to the surface of white sticky panels to increase capture of house flies, *Musca domestica* L.

Shape

Shape can be used as an attractant, although it is combined with appropriate color for the target insect. Spheres commonly are used as traps for tephritid fruit flies. Red spheres are used for apple maggot flies, *Rhagoletis pomonella* (Walsh), small green spheres for blueberry maggot flies, *Rhagoletis mendax* Curran, and large green spheres for papaya fruit flies, *Toxotrypana curvicauda* Gerstaecker. A Ladd trap is a red sphere that is mounted on a yellow panel and is used for apple maggot flies and cherry fruit flies, *Rhagoletis cingulata* (Loew). Black spheres have been used to capture biting flies in the family Tabanidae, which are attracted to the movement of the black ball hanging in a tree. A tree silhouette is mimicked by a Tedders trap, which is a baffle constructed from two dark isosceles triangles, with the unequal side forming the base. The size of the Tedders trap can be adjusted to optimize capture of tree-dwelling beetles. Root-infesting weevils, such as pecan weevils, *Curculio caryae* (Horn) and several citrus root weevils, as well as wood-boring beetles, may be captured by these traps. Beetles emerging from soil or moving along the soil surface respond to the trap as if it were the trunk of a tree. The insect moves up the baffles and is captured in a small collection container at the top of the trap.

Light

Attraction of insects to light is easily observed by standing next to a porch light or street light during the night. A commonly accepted explanation of this phenomenon is that insects have evolved mechanisms to travel straight paths at night by orienting at a constant angle to the light of the moon. Artificial light produced by man-made devices interferes with this response. Moving at a constant angle to a light source always directs the insect toward the source of the light, once it comes within a few meters. Lights that include ultraviolet (UV) frequencies may also be attractive because insects in a confined area can use UV light as a cue to the direction of an opening into a clear area. A variety of insect traps have been developed and used that are based on a light as the attractant. Lights used include mercury lamps and black lights (UV) for moths, incandescent lights for flies and mosquitoes, green lights for stored product insects and cyalume lightsticks for aquatic light traps. Light traps, also called electric traps, are typically bucket traps with funnels. When used with fluorescent bulbs, the traps have baffles alongside the bulb that knock insects attracted to the light down into the trap. The Pennsylvanian light trap is an example of this design. Rothamsted and Robinson-type traps use incandescent bulbs with a reverse funnel over the light bulb. The New Jersey trap and the CDC trap are light traps developed for mosquito surveillance. They use incandescent bulbs, a fan that creates a suction to draws attracted mosquitoes down into the bucket and a filter to prevent larger insects from entering the trap. Lights may also be used with sticky traps to retain attracted insects. These more commonly are used for control of indoor pests such as house flies, stored product insects and fleas. A LED-CC trap for whiteflies uses a green light-emitting diode (LED) to attract insects into an open-bottom clear cylindrical trap with a yellow ring on the bottom.

Chemical Cues

Food/Host Lures

Volatile chemicals emitted from host plants, animals and other materials are used by insects to locate food sources. These chemicals are referred to as kairomones, that is, chemicals produced by a plant or animal that are advantageous to the receiving individual of a different species. Host material can be used to bait traps for insect capture, and the spectrum of use of food-based baits for insect control and pest management are covered in separate chapters. Examples of use of host material in a trap include use of carrion in pitfall traps or fruit in butterfly bait traps as survey tools, or fruit and meat in traps for yellowjackets (Hymenoptera). Grain or grain products (e.g., wheat germ, wheat germ oil, corn oil, etc.) are used for stored product insect pests, and grain oils used in shelter traps provide both an attractant and a method to kill attracted insects. However, host material may rapidly decay or may release attractive chemicals for only a short time period after initial placement. The insect may be using only a few of the sometimes numerous volatile chemicals emitted by a host and traps baited with synthetic chemical versions of the host can be used to lure an insect into a trap. The quality and quantity of the chemical can be controlled by the method of formulation, providing a standard release rate for a known time period, which improves trap performance. Carbon dioxide is used by mosquitoes to locate vertebrate hosts, and addition of dry ice to a trap can be used to survey blood-feeding mosquitoes. Octenol (1-octen-3-ol) is a naturally occurring chemical emitted by oxen and cows because they ingest large amounts of vegetable matter, and combinations of octenol and carbon dioxide are used to bait traps for mosquitoes, biting midges and no-see-ums (Ceratopogonidae). To make these chemicals more attractive, they can be combined with heat and moisture in a trap such as the Mosquito Magnet. Host kairomones are used with blue sticky traps to capture tsetse flies and in rootworm traps for corn rootworm adults. Floral cues are used in traps for Japanese beetles, and for nectar-feeding female moths (Lepidoptera). These are used in bucket traps with funnels. Fruit lures that provide volatile chemicals emitted from apples and plums are used in traps for apple maggot flies and for plum curculio, *Conotrachelus nenuphar* (Herbst). Fruit lures for apple maggot flies are hung near red sphere traps; fruit lures for plum curculio are used in a variety of traps, including Tedders, circle and boll weevil traps. McPhail-type traps can be used with a variety of liquid baits. They have been used with fermenting sugar solutions to capture small fruit flies (Drosophilidae) and moths (Lepidoptera), and with aqueous protein solutions for fruit-infesting fruit flies (Tephritidae). Ammonia has been found to be the primary chemical responsible for attraction of tephritid fruit flies to protein solutions, and ammonia alone or in combination with other synthetic volatile chemicals emitted from protein baits are used in sticky panels, sticky spheres or McPhail traps to catch these fruit flies.

Pheromone Lures

There are two main types of pheromones that are used with insect traps. Sex pheromones are produced by one sex to attract the opposite sex. The sex pheromones most commonly used in traps are ones that are produced by females. These are used in either wing traps or bucket with funnel traps, and there are lures available for numerous species of pest Lepidoptera and for sweetpotato weevils, *Cylas formicarius elegantulus* (Summers). The moths tend to be active at night, so visual cue is less important, however, the contrast of a white or light colored trap versus the dark background often increases capture. The advantage of traps baited with these sex pheromones is that they are highly specific and very effective, however, they capture only males and so no information on or samples of females are obtained. Some male tephritid fruit flies produce a sex pheromone that is attractive to female flies, and the papaya fruit fly pheromone increases capture of both male and female flies on green sticky sphere traps.

Aggregation pheromones are used with insect traps also. These are attractive to both sexes and are used to bring both sexes to a common location for both feeding and mating. Although both males and females can be captured in traps baited with aggregation pheromones, they tend to be less effective lures than sex pheromones or they need to be presented with other cues. Exceptions are the pheromone produced by boll weevils (Grandlure), *Anthonomus grandis grandis* Boheman, and the lesser and larger grain borers, *Rhyzopertha dominica* (Fabricius) and *Prostephanus truncatus* (Horn). Sticky, shelter and wing traps baited with these pheromone lures capture both sexes of these borers. Aggregation pheromones are often produced by males in conjunction with feeding, thus since both insect pheromone and host kairomones are emitted as signals, both are needed to elicit attraction. Combinations of synthetic aggregation pheromone and host material as source of kairomones are used in shelter traps for stored product beetles and cockroaches, in Lindgren or panel traps for bark beetles, and in bucket traps for palm weevils. A combination of honey bee pheromones is used in swarm traps to increase bee capture. This includes honey bee queen mandibular pheromone (BeeBoost) and an orientation pheromone produced by worker bees (Nasonov).

Parapheromone Lures

Parapheromones are a special group of lures that are used to trap some species of tephritid fruit flies. They act as sex pheromones because they are highly attractive to male fruit flies, similar to female-produced sex pheromones. However, these are not insect-produced compounds and do not appear to play a dominant role in the biology of the responding species. They may be synthetic kairomones, as they are similar in structure to some plant compounds, and access to the synthetic or natural versions of these compounds have been shown to increase sexual competitiveness of males. These compounds include trimedlure for Mediterranean fruit flies, *Ceratitis capitata* (Wiedemann), cuelure for melon flies, *Bactrocera cucurbitae* (Coquillett), and methyl eugenol for oriental fruit flies, *Bactrocera dorsalis* (Hendel). These lures are most commonly deployed in white Jackson traps (triangle traps) or on yellow sticky panels.

Oviposition Lures

Oviposition lures are chemicals that attract egg-laying (gravid) females. A gravid mosquito trap uses a baited water solution to attract and capture the adult females. A trap and bait also has been developed for navel orangeworms, *Amelyois transitella* (Walker), on which the female moth lays eggs.

Acoustic Cues

Just as many insect species produce volatile chemicals to attract members of the opposite sex, some species use sound alone or in combination with chemicals for this purpose. Such cues have been incorporated successfully into panel or bucket traps of several different shapes. The different sounds broadcast as attraction cues have included songs recorded from conspecifics of the targeted insect and synthetic mimics of the songs. A variety of different speaker systems have been used, including standard loudspeakers, piezoelectric boards with extensive surface areas, and piezoelectric cylinders.

The most successful use of acoustic traps has been for mole cricket (Gryllotalpidae). Sound traps have been developed that produce highly amplified synthetic or recorded calls of male mole crickets. A bucket or bucket with funnel trap is placed under the sound emitter to capture responding crickets. These traps also capture tachinid flies that parasitize adult crickets and that locate them by responding to the call. Sticky traps broadcasting the recorded male lesser wax moth, *Achroia grisella* (Fabricius), calling song have been used to attract virgin females. Many tephritid fruit flies perform wing-vibration behaviors during courtship, and there have been a few attempts to attract female fruit flies by broadcasting songs recorded from courting males. Such songs have been demonstrated to be attractive to Mediterranean fruit flies over distances of 50 cm or less, but the traps are noisy and require electric power. Jackson traps broadcasting the recorded male Caribbean fruit fly, *Anastrepha suspensa* (Loew), calling song have been demonstrated to attract virgin females.

Another use of acoustic cues is as an attractant for males of some midge and mosquito species that form swarms to attract females. When females fly into a swarm, the males are attracted by their wingbeats, which are of distinctly lower frequencies than those of the males in the swarm. Consequently, males can be attracted in great numbers by placing a black cloth or other swarm marker on the ground and broadcasting recorded or synthetically generated female wingbeats from a speaker inside or at the edge of a sticky panel, cylinder, or cup hung about 1 m above the swarm marker. Acoustic traps can greatly reduce male populations of sedentary mosquito species, and also have been used to chemosterilize and re-release males rather than killing them. However, they are not yet in common use in isolated field environments because they require electricity and some technical skill to operate, and the sound that must be broadcast at high amplification for optimal trap catch can be a nuisance.

Automated Monitoring Systems

Advances in information technology, computer technology, and remote sensing are adding to the field of precision agriculture; that is, use of computers to aid in management decisions. The ability to rapidly move data from traps into computer databases or spreadsheets is an integral component of precision agriculture, and will facilitate making pest management decisions in a timely manner. Bar codes can be added to traps and a bar code scanner can be taken to the field to expedite data entry on trap type, trap location, etc., so that only insect counts need to be entered manually. In addition, data can now be transmitted by cable or wireless devices directly to a local computer for later downloading, or data can be transmitted to an off-site computer. Ideally, the tasks of species identification and counting would be automated to eliminate expensive, time consuming labor. This ideal has not yet been realized to any practical extent, although it is a goal of considerable interest to agricultural engineers and entrepreneurs.

A potential method for automating the insect identification process is to analyze the wingbeats of insects coming into a trap or flying overhead. Fourier transforms, nearest neighbor classification, and artificial neural network classification schemes have been tested in feasibility studies with aphids and mosquitoes, and species classification accuracies of up to 70–90% have been reported. If the costs of hardware needed to detect and transmit wingbeat sounds continue to decrease, automated identification will soon emerge from the laboratory as a practical option in environments where traps are difficult to service or labor costs are prohibitive. An example of counting insects where traps might be difficult or dangerous to service is a device to evaluate the intensity of honey bee defensive attacks near a hive. The device includes a microphone set inside a plastic target, connected to a datalogger with an amplifier, tone decoder, and a microcontroller that times and stores information from the decoder continuously, and later transfers data to a personal computer. For operation, the target is moved next to the hive and the hive is disturbed. The bees attack the target with sharp blows that are counted and saved for downloading after the attack is over.

Another already existing approach to automated off-site monitoring is the use of gravimetric analysis of flight trap captures of red flour beetles, *Tribolium castaneum* (Herbst). Beetles responding to cone-shaped flight traps fall into a small container coated with liquid Teflon which rests on the weighing pan of a digital pan balance. Signals from the balance are sent over a cable to a personal computer, and the weight, which is recorded at sequential intervals, is used to estimate the numbers of insects captured over time. Insect movements that interrupt an infrared light beam can be counted by a computer that monitors fluctuations in the beam intensity. Infrared beams can be used in actigraphs to monitor insect movement in activity chambers. Infrared beams also are used in a recently developed electronic grain probe insect counter system. The beams are located below the bottom of the funnel in a cylindrical grain probe trap. Insects falling through the funnel are counted electronically and time-stamped data is transmitted to off-site computers. Counts from electronic traps along with information from automated temperature and relative humidity probes can be collected together and used for management decisions.

Trap Uses in Integrated Pest Management (IPM)

The goals of trapping are highly variable. Traps may be used for general survey of biota, for detecting the start of population increase in infested areas, for identifying the source of stored product pest infestation in a store or warehouse, or for detecting invasion by exotic invasive insect pests in previously uninfested areas. Trapping systems for insects are important components in integrated pest management programs. Trapping data can be used to make decisions on the initiation or termination of control measures, as well as to assess efficacy of control approaches that have been implemented. Detection trapping is used to alert personnel to the presence of a new insect pest in a previously pest-free area so that control measures can be implemented in a timely manner. Early detection and targeting the locations of small infestations will facilitate pest management strategies such as biological control or sterile insect technique that are most effective when pest populations are low. With the availability of sufficiently effective traps that capture both female and male pest insects, trapping systems may be used as control measures, and thus could be added to the growing list of biologically based technologies for insect control. Traps can be used as toxicant delivery systems, with insects that visit the trap taking a slow-acting poison back to the rest of the population. This approach is used with social or gregarious insects such as termites, ants and cockroaches. Mass-trapping is the use of large numbers of traps in an effort to suppress the population. Sticky traps are usually used in this approach as a high percentage of responding insects are captured. This approach has been used to suppress populations of a pest such as apple maggot flies and papaya fruit flies, which spend part of their life cycle away from the host and can be intercepted by traps placed around the periphery of the orchard. However, these traps require frequent servicing to maintain activity. An alternate approach is the development of attract-and-kill systems, sometimes called attracticides. In this approach, insects responding to traps consume or contact a toxicant, but then exit the trap and die away from the trap. Examples include addition of insecticide to artificial cows for control of tsetse flies, methyl eugenol mixed with insecticide for control of oriental fruit flies, addition of insecticide to pheromone to control codling moth in apples, and addition of insecticide to feeding stimulant in corn rootworm traps. All of these control approaches should be combined with other pest management strategies to be fully successful.

Traumatic Insemination

A form of insemination practiced by bed bugs (Hemiptera: Cimicidae) and some other bugs wherein the male punctures the female's abdomen with his needle-like penis and deposits sperm within her hemolymph; they then migrate to her ovary to fertilize the eggs. This is also called "hemocoelic insemination."

► Bed Bugs

Tree Crickets

A subfamily of crickets (Oecanthinae) in the order Orthoptera: Gryllidae.

► Grasshoppers, Katydids and Crickets

Trehalose

A polysaccharide found in insects that is one of the two most common carbohydrate stored reserves (the other is glycogen) for insect flight. It occurs principally in the hemolymph, fat body, and gut tissues. Trehalose is usually the first metabolite used when energy is needed. Each molecule of trehalose is hydrolyzed into two molecules of glucose. Trehalose also is rapidly synthesized from glucose as it is absorbed in the midgut. Glucose is not usually present in high concentrations in the hemolymph because of this synthesis, so glucose absorption is easily accomplished.

Treherne, John E

John Treherne was born on May 15, 1929, near Swindon, England. He was educated at Bristol University. After military service he was invited by Vincent Wigglesworth the join the Unit of Insect Physiology at Cambridge. Treherne did so, and also served as lecturer and reader at the University. Upon Wiggleworth's retirement, Treherne headed up a new Unit of Invertebrate Chemistry and Physiology at Cambridge. Treherne's reputation was based on research of insect neurobiology, the blood-brain barrier of insects, gut physiology, circadian rhythms, hormones, cuticle permeability, osmoregulation, and other physiological subjects. His subjects were not just insects, as he worked on molluscs and annelids. Indeed, he was a physiologist first and foremost, and never pretended to be an entomologist in the classic sense. Nevertheless, he enjoyed field entomology, especially marine and salt marsh insects, and made insightful behavioral and evolutionary contributions in this area. Treherne served as editor of "The Journal of Experimental Biology," and edited "University Reviews of Biology," "Advances in Insect Physiology," and others. He served as president of Downing College from 1985 to 1988. Treherne also wrote popular novels, some of which included entomological elements. He died on September 23, 1989.

Treehoppers (Hemiptera: Membracidae)

CHRIS H. DIETRICH
Illinois Natural History Survey, Champaign, IL, USA

Most treehoppers are readily distinguished from their close relatives, the leafhoppers, by their enlarged pronotum, which extends posteriorly over the remaining thoracic segments and often bears horns, spines, bulbs, or other projections. A few treehoppers have a pronotum that is more modest in size; these differ from leafhoppers in that the scutellum is enlarged with either a median longitudinal keel, or a distinct median longitudinal groove or notch (Fig. 99).

Order: Hemiptera
Infraorder: Cicadomorpha
Superfamily: Membracoidea
Family: Membracidae

Membracidae, a large and diverse family of plant-feeding insects, comprises approximately 3,100 described species in 400 genera. Their closest living relatives are Melizoderidae (a small group of treehopper-like insects endemic to Chile) and Aetalionidae (a small, mostly neotropical family with one endemic southeast Asian genus). Aetalionidae, Melizoderidae and Membracidae together constitute a specialized lineage apparently derived from leafhoppers (Cicadellidae). Treehoppers are mainly a tropical group, but a sizeable fauna of mostly oak-feeding species occurs in temperate North America. Most of the subfamilies of Membracidae are endemic to the new world. Centrotinae, the only treehopper subfamily that occurs worldwide, is well represented in tropical and subtropical regions of Africa, Asia and Australia, but the palearctic fauna is extremely depauperate. The oldest fossil treehoppers are known from Tertiary-age Dominican and Mexican amber.

External Morphology

Adult treehoppers range from 3 to 30 mm in length. In addition to differences in coloration and the shape of the pronotum, genera and species of treehoppers differ in the shape and proportions of the head, the wing venation, the arrangement of setae on the legs (particularly the hind tibia), the shape of the female ovipositor and the male genitalia. Sexual and seasonal dimorphism in pronotal shape and color is common in many species. Treehopper nymphs are often even more bizarre than the adults. some species have large spines on the head, thorax and abdomen; others are well adapted for crypsis, being strongly depressed with the flattened tibiae fitting like puzzle pieces into notches in the sides of the thorax.

Life History and Habits

Details of the life cycle vary from species to species. The female deposits several eggs on the bark or into the living tissue of a woody host plant and may cover the eggs with a frothy substance that hardens when dry. The eggs either remain dormant for a period ranging from a month to over a year, or they develop and hatch within a few weeks. The young, known as nymphs, feed on plant sap by inserting their mouthparts into the phloem vessels of the host plant and go through a series of five molts reaching the adult stage after a period of several weeks. The adult males and females seek each other out for mating, locating each other through vibrational signals made by sound producing organs at the base of the abdomen called tymbals. These signals are transmitted through the substrate and are usually too faint to be heard by human ears. Some treehoppers exhibit anointing behavior similar to that of their relatives, the leafhoppers, but, unlike leafhoppers, treehoppers do not produce brochosomes (a hydrophobic, granulated coating).

As implied by their name, most treehoppers are strong jumpers as adults. However, treehopper nymphs cannot jump and avoid predation through crypsis, ant-mutualism, or parental care. Although many species are solitary as nymphs and adults, numerous treehopper species are gregarious and exhibit various degrees of parental care (or presocial) behavior. In the most advanced form of parental care, females guard their eggs and remain with the nymphs throughout their development, repelling invertebrate predators by kicking with the legs or buzzing the wings.

(Photos by C. H. Dietrich.)**

Predators and Parasites

Treehoppers are a food source for vertebrate predators such as birds and lizards, as well as invertebrate predators such as spiders, assassin bugs, wasps and robber flies. Treehoppers also are attacked by various parasitoids such as dryinid and mymarid wasps, epipyropid moths, pipunculid flies and strepsipterans. They also are attacked frequently by entomopathogenic fungi.

Economic Importance

Several treehopper species are minor pests, particularly of tropical fruit trees such as papaya, cacao and palm. A few species are known to transmit plant pathogens. The buffalo treehopper (*Stictocephala bisonia* Kopp & Yonke), a North American species that injures apple and related fruit trees, was introduced accidentally into Europe and now is well established in the temperate zone of the palearctic region as far east as central Asia.

Control

Treehoppers rarely inflict economic damage on crops, but when they do, control usually involves the use of conventional contact insecticides.

Trench Fever

A bacterial disease of humans transmitted by the body louse, *Pediculus humanus*. The disease agent is *Bartonella* (*Rochalimaea*) *quintana*. The organism does not affect lice, and is defecated after a few days within the louse. Humans contract the disease primarily by scratching and rubbing the organism into wounds (bites, scratches) but possibly also through inhalation. Formerly known mostly as a war-related illness, particularly among soldiers lacking in sanitation, it has also appeared in modern times within urban settings among the homeless, drug abusers, political refugees, and others lacking adequate access to shelter and sanitation. Recovery may require a few days to over a month. It is treated with antibiotics. Symptoms include rash, malaise, headache and bone pain; mortality is not attributed to trench fever. Only humans are known to host this malady.

► Chewing and Sucking Lice

Triassic Period

A geological period at the beginning of the Mesozoic era, extending from about 250 to 213 million years ago.

► Geological Time

Trichobothrium (pl., Trichobothria)

Small spots or depressions on the cuticle that bear setae or bristles. The number and location is often used for identification of immature insects.

Trichoceridae

A family of flies (order Diptera). They commonly are known as winter crane flies.

► Flies

Trichodectidae

A family of chewing lice (order Phthiraptera). They sometimes are called mammal chewing lice.

► Chewing and Sucking Lice

Trichogrammatidae

A family of wasps (order Hymenoptera).

Trichomes

Hairs or small spines on the surface of a plant, and an important morphological defense against attack by insects.

► Trichomes and Insects

Trichomes and Insects

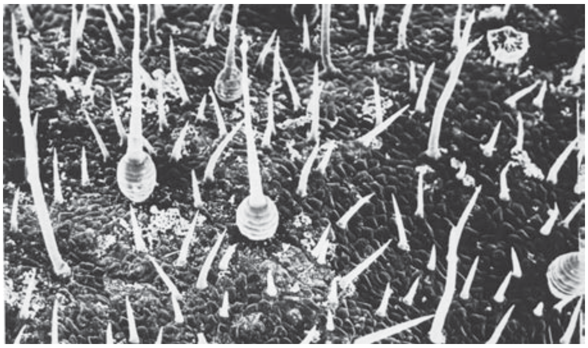
THOMAS G. SHANOWER
USDA-Agricultural Research Service, Sidney, MT, USA

Trichomes, also called plant hairs, are found on vegetative and reproductive structures in all higher plant families. They have evolved independently in a number of plant families. In general, monocotyledons are less pubescent (hairy) than dicotyledons, but trichome production can be induced in many glabrous (hairless or smooth) plant species. Several factors, including various light and temperature regimes, moisture availability and soil conditions affect the development and expression of trichomes. Trichomes are the first structure an insect encounters when landing on a plant, and provide the initial arena for complex and varied plant-insect interactions.

Types and Functions of Trichomes

The structure and function of trichomes are highly variably within and among plant species. There are two general types of trichomes: glandular, which produce, secrete or contain chemicals, and non-glandular, which are simple hairs and do not produce or contain chemicals. Trichomes have also been classified morphologically. Various morpho-types have been observed including: simple unicellular, multicellular uniseriate, multicellular multiseriate, two to five branched, stellate, dendritic or arboriform, and peltate. Several different classifications have been proposed and there is much variation and overlap in the description of trichome types. Developing a generalized classification system based on trichome morphology has not been possible because of their highly polymorphic nature (Fig. 100).

Trichomes may have either or both physiological and defensive functions for the plant, though may be utilized for a different purpose by an insect. For example, a dense covering of hairs on a leaf may have a physiological role for the plant but may provide a preferred ovipositional surface for an insect. The following physiological functions have been identified for trichomes: altering optical properties of the leaf surface, deflecting solar radiation and thus reducing leaf



Trichomes and Insects, Figure 100 Trichomes on the surface of a pigeonpea (*Cajanus cajan*) pod. Three types of trichomes are visible: short and long non-glandular (simple hairs), and a multicellular glandular trichome with a bulb-like base. temperature, maintaining water balance, acquiring nutrients and water from the atmosphere, and excreting excess salts. The focus of this discussion is insect/trichome interactions; therefore, the physiological functions of trichomes will not be considered further. Trichomes can affect both primary (herbivores) and secondary (predators and parasitoids) consumers.

The impact of trichome density, length, and orientation on insect behavior and performance has been well documented. Trichome density is perhaps more important than length or orientation but all three characteristics have been shown to impact insect behavior and/or performance. Wild relatives are often good sources of pubescence and have been utilized to develop insect resistant crop cultivars.

Trichomes as an Ovipositional Substrate

Oviposition has been positively correlated with increasing trichome density in many herbivorous species. For example, more eggs have been observed on trichome-dense cotton cultivars compared to smooth cotton cultivars for several insects including *Lygus hesperus*, *Helicoverpa* spp., *Earias fabia* and *E. vitella*. A similar situation has been noted for *Laspeyresia glycinivorella* and *Ophiomyia phaseoli* on soybean pods and leaves, respectively. Hairy surfaces can also positively alter egg and larval development and survival by ameliorating environmental factors such as increasing humidity levels. Conversely, trichomes inhibit oviposition in some insect species. At least one species of bruchid, *Callosobruchus chinensis*, prefers smooth as opposed to hairy pigeonpea (a tropical legume) pods for laying eggs. The cereal leaf beetle, *Oulema melanopus*, lays fewer eggs on wheat genotypes with highly pubescent leaves compared to genotypes with glabrous leaves. Both egg laying and larval survival are lower on cultivars with relatively longer and/or denser trichomes.

Impact of Trichomes on Herbivores

Trichomes interact with insect herbivores in many ways. The role of trichomes in providing defense against insect herbivores has been well documented and has been the topic of considerable investigation. Trichomes provide protection to the plant by acting as a physical barrier limiting an insect herbivore's contact with the plant, or as a chemical barrier by producing toxic compounds that poison the insect or by producing gummy, sticky or polymerizing chemical exudates which impede the insect. The effectiveness of the first mechanism, as a simple physical barrier to reaching the plant surface, is dependant on the length, density, and orientation of the trichomes, and on the insect's size, mode of locomotion, and type of mouthparts. In general, longer, denser and/or more erect hairs provide a better barrier to insect herbivores than shorter, sparser or recumbent hairs. As a purely physical phenomena, trichomes may also interfere with the insect digestion.

Wild relatives of cultivated plant species often have higher densities of trichomes than the cultivated relatives. A wild relative of pigeonpea possesses twice the density of small, non-glandular trichomes on pods as cultivated pigeonpea pods. When newly emerged pod borer (Helicoverpa armigera) larvae are placed on pods of both species, mortality is increased by 85% relative to the cultivated pigeonpea. The high density of non-glandular trichomes prevent the larvae from reaching the pod surface and they starve or desiccate before feeding.

Trichomes have been used to develop soybean cultivars with resistance to several insect pests. Soybean leaves possess simple non-glandular trichomes and cultivars vary in their degree of pubescence. Feeding and survival of at least four different caterpillars and two species of beetles were lower on pubescent leaves than on smooth leaves. Trichome length and shape are also important, especially for small-bodied insects such as the potato leafhopper. Potato leafhopper populations decreased with increasing trichome length, regardless of trichome density. The irregular shape produced by the highly pubescent accessions prevents potato leafhopper from attaching normally for feeding and oviposition.

Reduced movement of first instar larvae of pink bollworm on cotton has been observed on highly pubescent versus glabrous leaves. Larvae pause regularly to swing their heads and sample the substrate while moving. This resulted in higher larval mortality due to starvation or desiccation. The larvae of *Heliothis virescens* are also more likely to die from biotic (predators and parasites) and abiotic (high temperature and insecticides) factors because of slower movement on pubescent genotypes.

In contrast to non-glandular trichomes, glandular trichomes can act as both physical and chemical barriers to insect herbivores. The fluidity and volume of the exudates, whether toxic or sticky, may vary with weather, time of day and age of the plant. There is also tremendous diversity in the structure of glandular trichomes and the composition of glandular exudates.

Glandular trichomes confer resistance to several phytophagous insects and, because of the toxic and deterrent properties of their exudates, are often more effective than non-glandular trichomes in providing resistance to insect pests. Glandular trichomes secrete and/or accumulate a variety of compounds that generally act either as insect repellents or immobilize insects by entrapment. In addition to protecting plants by deterring herbivores, glandular trichomes may also attract pollinators; these structures contribute to the flavor and aroma of many plants.

The commercial potato, *Solanum tuberosum*, and its wild relatives, *Solanum* spp., possess two types of glandular trichomes. Type A is short, globular, and releases exudates after rupturing; Type B is longer, more hair-like, and continuously exudes a viscous fluid. After landing, an insect first encounters Type B exudates. In struggling to escape from the sticky coating, the insect disturbs and ruptures Type A trichomes. The exudates in Type A trichomes combine with the Type B exudates to harden the sticky exudate. Thus, small bodied insects such as aphids and leafhoppers are trapped and starve to death. The Type B exudates also increase the mortality rate and inhibit settling and probing behavior of some aphids. These trichomes provide greater resistance to wild *Solanum* spp. than in the cultivated *S. tuberosum*. In general, wild species are more pubescent and have more glandular trichomes, and are hence more resistant to insect pests than the cultivated relatives.

Another type of glandular trichome are those found on chickpea. They secrete highly acidic (pH = 1) exudates, containing primarily malic and oxalic acids. The quantity of malic acid in the exudate reportedly confers resistance to the leafminer, *Liriomyza cicerina*, and the pod borer, *H. armigera*, though others have reported an antibiotic effect of oxalic acid, but not malic acid.

Impact of Trichomes on Parasitoids and Predators

Trichomes can have a direct negative impact on the predators and parasitoids that attack insect herbivores. The efficacy of these natural enemies can be impaired by (i) increasing search time, (ii) decreasing residence time in the host/prey habitat, (iii) chemical and/or physical entrapment, and (iv) chemical repellents. As with herbivores, small bodied natural enemies are generally more affected by trichomes than larger ones.

The time parasitoids and predators spend searching for hosts/prey is directly related to their walking speed; more hosts/prey are encountered when parasitoids and predators walk faster. Trichomes, even simple non-glandular hairs, interfere with movement and reduce walking speed. Faster walking speeds of several egg parasitoids (*Trichogramma* spp.) have been measured on smooth versus hairy cotton leaves and pigeonpea pods. In addition, parasitoids which walk on the plant surface can be slowed by exudates secreted by glandular trichomes. Predators are similarly hindered by glandular and non-glandular trichomes. The walking speed of coccinellid larvae are inversely related to the density of trichomes on potato and tomato.

On pigeonpea, eggs of an important pest (*Helicoverpa armigera*) are readily parasitized (>55%) by an egg parasitoid (*Trichogramma chilonis*) when placed on leaves but are rarely attacked (<1%) when placed on pigeonpea pods. Parasitoids walked significantly faster on leaves than on pods, where their movement was inhibited by long trichomes. The higher density of glandular trichomes on pods compared to leaves resulted in the parasitoids being trapped by glandular exudates. The same pest (*H. armigera*) feeds on chickpea, but is never attacked by the egg parasitoid, *T. chilonis*. The highly acidic trichome exudates secreted by vegetative and reproductive parts of chickpea deter, and may entrap, the egg parasitoid. Other examples of *Trichogramma* spp. being trapped by sticky trichome exudates have been reported from tomato and potato.

The negative effects of glandular trichomes on natural enemies may not be as strong under field conditions as often observed in greenhouse or laboratory experiments. Glandular trichome exudates may be dried by the sun or wind, washed off by rain, or even be rendered ineffective by dust under field conditions.

Conclusions

Trichomes are found on vegetative and reproductive structures in many plant species. There are two types, non-glandular and glandular; both are found in a variety of shapes and forms. Trichomes and insects interact in numerous ways. Trichomes on a number of plants have evolved a defensive function and may protect plants from insect herbivores. Plants are protected from insect feeding when trichomes form a chemical or physical barrier, preventing herbivores from reaching the surface. Trichomes may also provide a preferred oviposition site and/or may interfere with an insect's movement on the plant surface. Both positive and negative interactions, from the insect's point of view, have been documented. Generalizing about the role and function of trichomes and how these structures interact with insects is difficult because trichomes vary greatly across plant species and because the interactions may be specific or unique to the plant-insect association.

Trichomycetes

CHARLES E. BEARD
Clemson University, Clemson, SC, USA

Trichomycetes are obligate symbiotic organisms that typically live in the guts of arthropods. They are generally viewed as commensals, having little effect on the host, but in stressful environments they might confer an advantage to colonized hosts; in some cases they act as pathogens. In the broad sense, trichomycetes (designated by a lower case t) includes the fungal class Trichomycetes (designated by an upper case T) and some historically similar protists that were earlier considered fungi. Most trichomycetes colonize freshwater and marine arthropods, but some colonize terrestrial arthropods. Hosts are filter feeders, detritus feeders, or aquatic grazers, but not predators or fluid feeders (e.g., Brachycera) (Fig. 101).

Non-Fungal Trichomycetes

The first trichomycetes were described by Joseph Leidy in 1849 from millipedes. Initially, Leidy thought trichomycetes were colorless algae. Later, trichomycetes were placed in various fungal groups. Because of similar lifestyles, all trichomycetes were placed in the fungal class Trichomycetes until the 1990s. The non-fungal trichomycetes constitute the orders Amoebidiales and Eccrinales. Recent molecular analysis has shown that these trichomycetes are protists in the Mesomycetozoa group.

Order Amoebidiales

The thalli of these trichomycetes are coenocytic (one large multinucleate cell not divided into cells by septae or cross walls) and unbranched. They are usually associated with freshwater larval Diptera or Crustacea. They are most common with filter feeders and grazers, but might occur externally on predatory insects. A secreted holdfast is usually evident. Many workers had suspected that organisms in the order Amoebidiales were not fungi, because they produce amoeboid dispersal cells and lack chitin (or have very little). This order includes two genera: *Amoebidium* and *Paramoebidium*.

Amoebidium parasiticum attaches to the external cuticle of freshwater arthropods (e.g., Diptera, Ephemeroptera, and Crustacea). *Amoebidium* spp. are usually restricted to still-water (lentic) environments. Although not pathogenic, this fungus has a life cycle that is closely coordinated with that of the host. During the intermolt period of the host, the thallus produces asexual spores that can attach to other areas of the cuticle. Prior to molting or at host death, production of amoeboid cells rather than spores begins. The amoebae swarm from the thallus, encyst, and produce spores. These then form new thalli upon external contact with hosts. Sexual reproduction has not been verified.

Paramoebidium species live in the hindgut of aquatic insect larvae, usually hosts from the orders Diptera, Ephemeroptera, and Plecoptera. They do not produce spores directly, as do *Amoebidium* spp., but produce amoebae upon molting or death of the host. The amoebae swarm and then produce cysts that produce spores. Spores in this genus are presumed to germinate in the gut after ingestion. Sexual reproduction is unknown.

Order Eccrinales

The thalli are coenocytic and unbranched; however, in some species (e.g., *Leidyomyces attenuatus* in passalid beetles), multiple thalli share a common attachment point and appear branched at the base. The holdfast is a secreted material and can be large. These trichomycetes are found in the foregut or hindgut of Crustacea, Diplopoda, Insecta and Isopods. Eccrinales is the only trichomycete group in terrestrial insects (Passalidae and Scarabaeidae), other than *Orchesellaria* (see Asellariales below) in Collembola. Various asexual spore types are formed depending on taxon. The spores are usually formed by division within the tips of vegetative thalli. Fusion of adjacent cells has been reported, but confirmation of subsequent sexual spores is lacking.

Fungal Trichomycetes (Class Trichomycetes)

Trichomycetes are a class in the fungal division Zygomycota and include the trichomycetes most encountered in insects. Sexual zygospores are produced in many of the taxa.

Order Asellariales

Thalli of these fungi are branched and septate. The septation produces endogenous (inside the thallus) spores. The holdfast area (basal cell) often appears bulbous or branched (digitate). The order consists of two genera. The genus *Asellaria* inhabits isopods (Crustacea) and the genus *Orchesellaria* inhabits springtails (Collembola). Zygospore production following conjugation of thalli has been reported in this order.

Order Harpellales

The thalli produce large cells with septa. The spores are produced exogenously. Many spores have nonmotile appendages that are usually longer than the spore proper. The length and number of appendages have taxonomic value. Harpellales in the midgut are unbranched (Harpellaceae), whereas the species in the hindgut (Legeriomycetaceae) have a branched growth pattern. These Trichomycetes are common in aquatic insect larvae, especially Diptera. No Trichomycetes have been found in predatory insects, and most occur in filter-feeding or grazing insects.

Harpellales exhibit three reproduction types in their life cycle. The most common type is the production of asexual spores that are shed in the feces and ingested by hosts. When in the proper gut environment, asexual spores quickly germinate. Germination is a complex process involving extrusion of the spore protoplast from the spore wall and attachment to the host gut. The second type of spore is the sexual zygospore, which is produced by fusion of nuclei from adjacent cells of the same thallus or of neighboring thalli. Conjugation tubes between thalli are sometimes detected in the latter, whereas the sexual apparatus might not be evident in the former. The zygospores are usually characterized by a thickened end wall on one or both poles of the spore. The role of the zygospore in the natural history has not been determined, but because of the biomass investment, it presumably plays an important survival role. A third type of spore is the pathogenic spore, often referred to as a cyst (not to be confused with the cysts of Amoebidiales). These spores proliferate in the ovaries of adult females and are deposited as if they were eggs. The cysts produce spores (smaller than other asexual spores) that presumably colonize new larvae from adjacent eggs as the clutch hatches. This cycle helps explain how trichomycetes can colonize upstream hosts as the spores in feces are washed downstream, because infected females can carry the cysts upstream. The cyst stage is documented in a few locations (due to insufficient geographic sampling) (e.g., eastern Canada), but is expected to be common at a site on a temporal basis.

Harpellales are the Trichomycetes most likely to be encountered by entomologists; therefore, a few specific examples are presented. *Harpella melusinae* is common in larval black flies (Diptera: Simuliidae) on all continents except South America and Antarctica. Different species of *Harpella* are found in South America and black flies are not known from Antarctica. *Harpella melusinae* inhabits the midgut of the larva, where the pH is very high (up to pH 11.3) in Diptera. The fungal thalli attach to the peritrophic matrix and grow in this seemingly hostile environment. Asexual spores form on the unbranched thalli, usually absorbing the protoplast from the vegetative thallus and leaving empty cell walls. These spores continue through the hindgut unaltered and exit with the wastes. Sexual conjugations between adjacent vegetative thalli occur in some populations. When conjugations are occurring, large numbers of thalli in a locality might be sexual. Zygospores are seldom seen in fresh dissections, but in nature zygospores likely are produced by these conjugations. Other larval Diptera have Trichomycetes in the midgut. Species of *Stachylina* are common in chironomids and occasionally in Blephariceridae. No Trichomycetes have been reported from mosquito midguts.

Smittium species are the most commonly cultured Trichomycetes. These branched hindgut-dwelling species are known from larval Diptera such as Chironomidae, Culicidae, Simuliidae, and Tipulidae. Often, a species can inhabit larvae of different host families, a degree of host plasticity not seen in most Harpellales. Asexual spores are produced on branched thalli and have one hair-like appendage. When ingested, the spores react to gut pH changes and potassium levels to avoid germinating in the midgut (high pH) where they do not grow, but delay germination until until they pass to the hindgut with its lower pH. Zygospores are formed after conjugation of thalli and can be quite large. Zygospores of *Smittium megazygosporum* can be up to 150 μm long. Pathogenesis has been reported in the species *Smittium morbosum*. This species appears to mechanically interfere with molting of the hindgut lining and thus leads to mortality.

Stoneflies are hosts of several genera, including *Capniomyces*, *Ejectosporus*, *Genistelloides*, *Orphella*, and *Paramoebidium*. The stonefly genus

Allocapnia has been of particular interest because of its hypothesized biogeography and use in dating symbiotic associations. Two of the species of Trichomycetes (*Genistelloides hibernus* and *Ejectosporus spica*) that colonize *Allocapnia* have a wide distribution. Based on hypothesized host origins, the association is dated from the Pleistocene, and must have been in the host from this time (early in its evolution) and before dispersal. One trichomycete species (*Capniomyces stellatus*) had restricted distribution and was hypothesized to have evolved after *Allocapnia* dispersal.

Organisms that Might Resemble Trichomycetes

Insects host a variety of organisms that can be confused with trichomycetes. Among the nonfungal forms is a bacterium called *Arthromitus*. This bacterium forms chains of cells attached at a common point, so they appear as tufts or clusters. Molecular evidence has shown that many of these are an alternate growth form of the soil bacterium *Bacillus cereus*.

External fungi that resemble Amoebidiales include chytrid fungi and Laboulbeniales. The chytrid fungi resemble *Amoebidium*, but they produce flagellated zoospores for reproduction. The names *Harpochytrium* and *Oedogoniomyces* have been associated with these fungi. These fungi are probably incidentals, and are usually expected on other substrates. The Laboulbeniales can be distinguished by thick cell walls and septate thalli that are often branched. Also, Laboulbeniales are usually restricted to terrestrial insects and often have a tan color. Trichomycetes are usually colorless or white.

Passalid beetles host an ascomycete fungus that grows in a trichomycete-like form in the gut. The septate filaments form tufts on the hindgut lining. These fungi have a yeast-growth form in culture. They belong to the genus *Pichia* or *Enteroramus* (synonym). They have the ability to digest xylose, which can be beneficial to wood-feeding organisms.

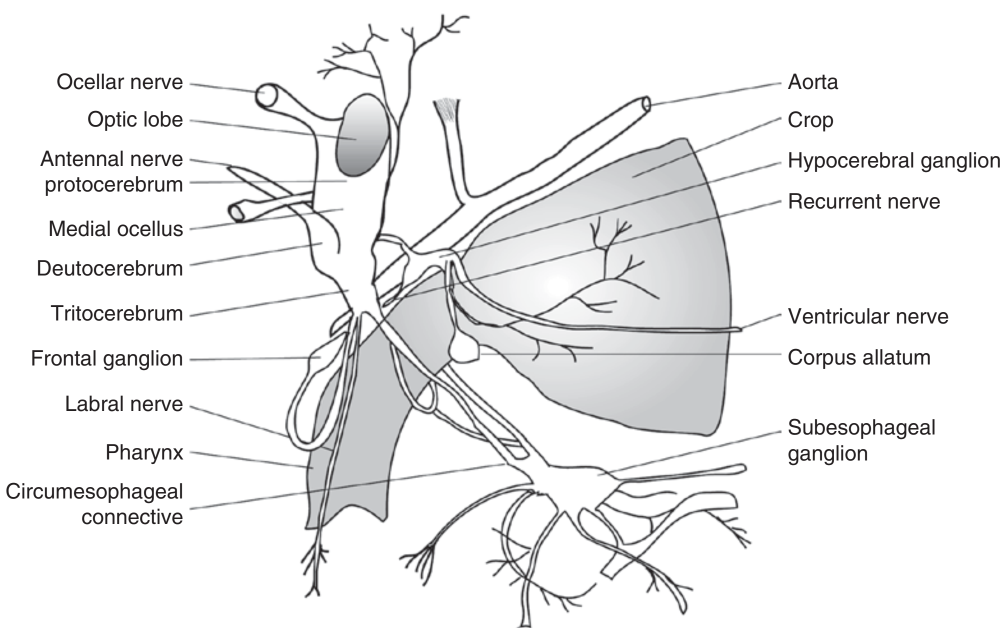
Tritrophic Interactions

MARCEL DICKE
Wageningen University, Wageningen, The Netherlands

Two central issues in ecology are (i) how do organisms interact with their environment, and (ii) what interactions determine the composition and dynamics of communities. Ecologists have long debated the relative importance of bottom-up and top-down effects on communities. An example of a bottom-up effect is that nutrient availability to plants can affect the composition of insect communities and this can subsequently influence top-down forces. Top-down



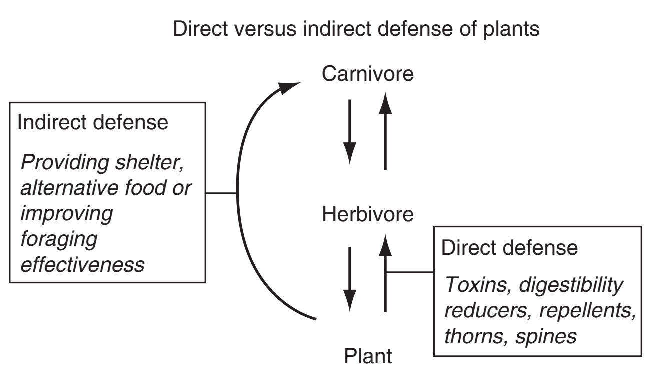
Tritocerebrum, Figure 102 **Diagram of the insect brain, lateral view (adapted from Snodgrass, Insect morphology).**

effects comprise, for instance, the effects of carnivores on herbivore populations with consequences for plant population biology. However, it is becoming more and more clear that this is not an either/or issue, but rather one of the degree to which bottom-up and top-down forces are integrated. Bottom-up forces, such as nutrient availability to plants, can affect the composition of animal communities and this can subsequently influence top-down forces. Furthermore, plants have many characteristics that influence the effectiveness of carnivores in reducing herbivore numbers, i.e., bottom-up and top-down forces can be linked.

Although it is long-known that food webs are composed of more than two trophic levels, it was Price and coworkers who, in 1980, pointed to the important effects of plants on interactions between herbivores and carnivores, and of carnivores on herbivore-plant interactions. They introduced the term "three-trophic level interactions" or "tritrophic interactions." With this term, they indicated that apart from food web considerations where one trophic level feeds on another (lower) level, there are interactions between alternate trophic levels that can be of decisive importance to the outcome of interactions between two subsequent trophic levels. Thus, within a tritrophic context, indirect interactions in a community are considered in addition to direct interactions.

To obtain a sound ecological understanding of each bitrophic interaction (one between plants and herbivores and the other between herbivores and carnivores), it is essential to consider at least three trophic levels and all their interrelationships. For instance, plant defense may be aimed directly against herbivores, but, in addition, carnivores may be a component of the plant's battery of defense. Thus, there are two distinct kinds of plant defense (i) direct defense where plant characteristics have a negative effect on herbivores, and (ii) indirect defense that affects herbivores by promoting the effectiveness of their carnivorous enemies. Direct defense may consist of such elements as repellents, toxins or digestibility reducers, while indirect defense may consist of the provision of shelter, alternative food, or chemical information that promotes the abundance and/or activity of carnivores (Fig. 103).

The majority of research has been done on plants and arthropods and, therefore, this discussion concentrates on these organisms. The arthropods involved are herbivorous arthropods and carnivorous arthropods, i.e., predators and parasitoids (parasitic wasps). Tritrophic interactions between plants, herbivores and carnivores will be addressed. However, tritrophic interactions are not restricted to these three trophic levels; they may also encompass interactions between, for example, herbivores, first order carnivores and second order carnivores.



Tritrophic Interactions, Figure 103 **Direct and indirect defenses of plants in a tritrophic context.**

Plant Characteristics that Affect Herbivores and Indirectly Affect Natural Enemies of the Herbivores

Any plant condition that reduces the growth rate of an herbivore makes the herbivore available to natural enemies for a longer period of time and, thus, raises the probability of mortality. This is especially true for mortality from parasitoid attack, because parasitoids are usually stage-specific and, thus, prolongation of the vulnerable growth stage may be essential for the parasitoid to find that stage. For instance, digestibility reducers have growth-retarding effects. This theory was tested using several soybean varieties, the Mexican bean beetle (*Epilachna varivestis* Mulsant) as the herbivore and some predatory pentatomid bugs. It was found that the herbivores that grew more slowly were more effectively regulated by the predator than those on the soybean variety that was more favorable for herbivore growth. In addition, it was found that the reduced growth rate of the herbivore also affects the functional response of the predator (the relationship between predation rate and prey density) because more small prey are needed for satiation than large prey, and small prey are usually easier to handle by the predator.

Digestibility reducers produced by plants may affect herbivore-natural enemy interactions in several ways:

1. Prolonged developmental time of herbivores and, thus, prolonged risks of attack by carnivores.
2. Reduced resistance of herbivores to pathogens and natural enemies.
3. Reduced herbivore body size and, thus, fecundity, resulting in a lower rate of population increase. This may determine the ability of natural enemies to exterminate the herbivore population.

The influence on enemy effectiveness through a direct influence on herbivores is not limited to digestibility reducers. Any plant characteristic that can affect growth, resistance to disease, or fecundity can have an influence. Variation in plant nutrient composition is probably important in this regard. While such variation probably seldom involves complete presence or absence of essential nutrients, changes in their proportions appear to be commonplace. Effects that are sublethal should, therefore, also be commonplace. Negative effects of imbalanced diets on insect survivorship, growth, and development, not surprisingly, have been demonstrated in controlled artificial diets for a number of insects and nutrients.

On the other hand, retardation of herbivore growth may hamper some predators or parasitoids. For instance, some predators do not take small prey because of a low energetic (nutritional) reward in combination with high capture costs. For example, an insectivorous bird, the European Great Tit, rejects small insect prey when large prey are available.

Another effect of growth rate and size results from the minimum size of an herbivore that is acceptable to its natural enemies; however, this critical size is different for different natural enemy species. Luck and colleagues at the University of California showed that host size is a very important factor in the coexistence of *Aphytis* parasitoid species attacking Californian red scale, *Aonidiella aurantii* (Maskell). *Aphytis lignanensis* needs larger hosts for female progeny than *Aphytis melinus* DeBach. Thus, *A. melinus* can attack hosts before they become available to *Aphytis lignanensis* Compere. In addition, host size depends on plant part. Host size is smallest on wood, largest on fruits and intermediate on leaves. Thus, many more scales are available to *A. melinus* than to *A. lignanensis*, and the degree of this difference is dependent on the location in the tree. As a consequence, *A. melinus* can effectively replace *A. lignanensis* in many citrus areas where red scale is a problem. It is simple to imagine that the three plant parts (wood, leaves and fruits), actually represent different "cultivars" of a species with different levels of defense, and their different impacts on host-parasitoid interactions.

Retardation of growth can also result from induced resistance in plants. In many cases, plant defense is not active prior to herbivore infestation. The damage inflicted by herbivores may induce the defensive actions of plants. Thus, the production of phytoalexins in response to infestation by pathogens is well known. Such induced responses also may occur after an herbivore attack. For instance, tomato plants that are damaged, either by herbivores or by mechanical means, produce proteinase inhibitors that reduce the digestibility of the plant material. These proteinase inhibitors are produced systemically throughout the damaged plant. Induced resistance (or induced direct defense) appears to be rather nonspecific. Infestation with one species of herbivore often affects the performance of other herbivore species as well. Induced resistance lasts for some time after the herbivores are gone. It may last for hours or days, but in some cases (e.g., for perennial plants such as trees), induced resistance has been reported to last for one to several years. Thus, previous and current herbivory may affect the growth rate of other herbivores and, thus, their vulnerability to parasitoids and predators. In addition, mechanical characteristics of plants can be subject to induction also (e.g., trichomes of nettles).

Plant Characteristics that Directly Affect the Effectiveness of Natural Enemies of Herbivores

Mutualisms between plants and animals have been known for a long time but, until the 1980s, the focus had been almost exclusively on mutualisms between plants and herbivores, e.g., involving pollination or seed dispersal. The best and longest (more than 100 years) known mutualism between plants and members of the third trophic level is that between *Acacia* plants and protective ants. The *Acacia* plant provides sugar-containing secretions from extrafloral nectaries and other macronutrients from food bodies on their stems, leaves, or buds. Some *Acacia* species even provide hollow stems, thorns, or bulbs that the ants penetrate to use as shelter for their colonies. The ants guard the source of nutrients and simultaneously defend the plant against herbivorous insects or even encroaching vegetation. Recently, it was shown that ants may even reduce the feeding by large herbivores such as giraffes. Also, less conspicuous structures, such as pits and pouches at vein cross-sections, can function as shelter for carnivorous enemies of herbivores. Such structures are called "domatia" (Greek for "little rooms") and are usually inhabited by predatory or fungivorous mites, whose activities can be important in reducing the abundance of plant attackers.

The protection of plants by ants is far more general than the well-known example of *Acacia* suggests. Many plant species have well-developed nectaries on stems, stipules, or leaves, or they secrete sugar-rich liquid from unopened flower or leaf buds. Such nectaries attract virtually any sugar-loving ants, most of which also eat insects. In temperate climates, seedlings and developing buds often secrete nectar, and are defended by ants. For example, seedlings of cherry trees (*Prunus* sp.) secrete nectar that encourages their defense by a variety of opportunistic ants.

Ants are generalist protectors that can defend a plant against a wide variety of herbivores. However, recent evidence shows that mutualisms between plants and members of the third trophic level also involve much more specialized predators and parasitoids. When a plant is attacked by an herbivore, the plant starts to produce and emit volatiles that attract natural enemies of the herbivore. This appears to be a common phenomenon among plants and many different herbivore species have been shown to induce carnivore attractants in plants (Fig. 104). Herbivory is not always necessary. Hilker and colleagues of the Free University of Berlin showed that even the deposition of herbivore eggs can induce a plant to emit induced volatiles that attract egg parasitoids. It has been shown for several tritrophic systems that the natural enemy discriminates between different plant species infested by the same herbivore species and between different herbivore species on individuals of one plant species. Chemical analyses have shown this specificity on

Herbivore-induced carnivore attractants:
a *common* phenomenon

Plants	Herbivores	Carnivores
• 8 families	• 13 families	• 8 families
• 23 species	• 27 species	• 28 species
Monocots and dicots mostly agricultural plants	e.g. mites, thrips, aphids, butterflies and months	e.g. parasitic wasps and predatory mites and bugs

Tritrophic Interactions, Figure 104 The induction of carnivore attractants by herbivory has been reported for a wide variety of tritrophic systems.

the molecular level. The composition of the blend is determined to the greatest extent by the plant species/cultivar. Not only natural enemies of the herbivore seem to use the herbivore-induced synomone, herbivores may respond also; spider mites avoid locations with high concentrations of induced plant volatiles that are related to conspecific damage. In addition, for a tritrophic system consisting of lima bean or cotton plants, spider mites and predatory mites, it was recorded that downwind, uninfested neighbors of infested plants are more attractive to predatory mites than upwind neighbors or other control plants.

Apart from mutualistic interactions, plants also may hamper the performance of natural enemies. For instance, a thick bark hinders parasitoids that attack herbivores that forage under the bark. The same holds true for the effect of gall thickness on parasitoids of gall-forming herbivores. Hairs on stems and leaves may affect the locomotion and the survival of natural enemies of herbivores (in addition to adverse effects on herbivore performance). For instance, cucumber leaves have many long, non-flexible hairs that interfere with parasitoid movement. In addition, herbivore products, such as honeydew, may adhere to these hairs, which enhances the adverse effects on parasitoid performance. The capability of the parasitoid *Encarsia formosa* Gahan to reduce populations of the greenhouse whitefly (*Trialeurodes vaporariorum*) on cucumbers depends on the density of these hairs. Also, trichomes that hamper herbivore survival may have strong adverse effects on the survival of natural enemies. Hairs, usually seen as a component of direct defense against herbivores thus may be incompatible with natural enemies that are a component of indirect defense.

Effect of Dietary Specialization

An animal's degree of dietary specialization is an important characteristic frequently used in comparative ecological and evolutionary studies. This concept also has been applied to herbivores and their natural enemies, although knowledge on herbivore range used by natural enemies is generally sparse. Dietary specialization of herbivores is assigned to the plant level, while dietary specialization of natural enemies can be assigned to both the herbivore and the plant level.

Specialist herbivores are usually better adapted to plant defenses, such as toxins, than are generalized herbivores. Specialist herbivores can usually tolerate higher levels of toxins and can sequester the defensive plant chemicals. As a result, they usually are much better protected against their natural enemies such as pathogens, predators and parasitoids. For example, consider the interactions between the nicotine in tobacco, the specialist herbivore *Manduca sexta* L. (tobacco hornworm), the generalist herbivore *Trichoplusia ni* (Hübner) (cabbage looper), and a pathogenic bacterium, *Bacillus thuringiensis*. The generalist herbivore is adversely affected by the nicotine in the plant, while the nicotine has only minor effects on the fitness components of the specialist herbivore. Higher nicotine concentrations in the plant are actually beneficial to the specialist herbivore because infection by the pathogen *B. thuringiensis* is reduced. Among predators and parasitoids, the specialists also are better adapted to the defenses of their prey/host. Thus, specialist herbivores are better protected against generalist natural enemies than against specialist natural enemies. This example shows that tritrophic interactions also may extend to pathogens of herbivores. The following example relates to the dietary specialization of parasitoids. Nicotine may be sequestered by *Spodoptera frugiperda* (J. E. Smith) (the fall armyworm), and adversely affects the development and survival of the polyphagous wasp parasitoid, *Hyposoter annulipes* (Cresson). In contrast, the specialist wasp parasitoid, *Cotesia congregata* (Say), is much less affected by the sequestered nicotine.

The first step in the chain of events leading to interactions between an herbivore and its predators or parasitoids is the location of an herbivore-containing habitat from a distance by its natural enemies. Predators and parasitoids are faced with a great variety of stimuli they may use to locate their victim, even when considering only one sensory modality, i.e., chemoreception. Both plants and herbivores produce odors and, thus, potential information. The appropriateness and usability of information ultimately depends on two factors (i) its reliability in indicating herbivore presence, accessibility and suitability, and (ii) the degree to which stimuli can be detected. It is assumed that the use of information that is both reliable and easy-to-detect enhances searching efficiency and consequently, Darwinian fitness.

Stimuli derived from the herbivore itself are generally the most reliable source of information. Ideally, the infochemicals should reliably tell natural enemies whether a herbivore is present, to which species it belongs, whether there is more than one individual and, if so, how many, whether it is suitable to be parasitized or eaten, and whether it is readily accessible or hidden. For parasitoids, whose host continues to develop, and for predators that search for an oviposition site, there is the additional need to know whether the food plant is suitable for the development of their offspring. In fact, the more intimate the herbivore-carnivore interaction, the more specific the information that the carnivore needs.

However, the use of herbivore-derived stimuli often is limited by low detectability, especially at longer distances. Stimuli from plants, on the other hand, are usually more readily available because of the plants' relatively larger biomass, but are less reliable predictors of herbivore presence. Reliability of plant cues depends on the predictability of plant infestation over space and time. So, natural enemies are challenged to combine the advantageous characteristics of information from both trophic levels. It has been hypothesized that detectability of stimuli from the second trophic level puts a major constraint on the evolution of herbivore location by their natural enemies. Natural enemies may approach the reliability-detectability problem in three ways (i) by resorting to the use of infochemicals from herbivore stages different from the one under attack, that are more conspicuous in their infochemical release (infochemical detour), (ii) by focusing their responses to herbivore-induced plant volatiles (HIPV) that originate from specific interactions of the herbivore and its food, and (iii) by learning to link easy-to-detect stimuli (plant cues) to reliable but hard-to-detect stimuli (herbivore cues). Which of these options is/are employed is dependent on the ecological context in which the parasitoid has evolved, and the degree of dietary specialization is an essential aspect of this.

By using the comparative approach, one can speculate whether and, if so, how the natural enemy species' use of herbivore-induced synomones correlates with their dietary specialization. The more natural enemies are specialized at a certain trophic level, the more they innately use infochemicals from that trophic level. In contrast, polyphagy at a trophic level is expected to result in more plastic responses to infochemicals from that trophic level. Thus, it is hypothesized that (i) natural enemies that are specialists on specialist herbivores have strong fixed responses to kairomones from their victims, to uninduced plant volatiles and to HIPV, (ii) natural enemies that attack several herbivore species on one host plant species have fixed responses to general kairomone components shared by the different herbivores and strong fixed responses to uninduced plant volatiles and HIPV, (iii) natural enemies that are specialists on a polyphagous herbivore have strong fixed responses to kairomones and have to learn to respond to plant volatiles and HIPV, and (iv) natural enemies that are extremely polyphagous on polyphagous herbivores are not expected to use infochemicals in finding their prey or hosts. These four categories are extremes in a continuum. The ecological settings of many natural enemies are intermediates along the continuum. The way these species use infochemicals will depend on the relative importance of the diet breadth at each trophic level.

Relative Importance of Plant and Natural Enemies to Herbivore Fitness

Herbivorous arthropods are affected by both their food plants and by predators and parasitoids. They have to deal with plant defenses such as toxins and digestibility reducers, but also with predator attacks. In general, it seems that there is a wide variation in effects of plants and natural enemies on the fitness of herbivores. This has led to speculation on which effects are the most important: "top-down effects" (effects of natural enemies) or "bottom-up effects" (effects of plants). The answer to this question is not likely to receive a general answer. It seems that the relative importance of the two effects is dependent on system-specific characteristics and the two effects are integrated, rather than alternatives.

The discussion about top-down and bottom-up effects is remarkable with respect to herbivore specialization. Two main selective forces have been mentioned: plant secondary chemicals have long been assumed to be the selective force determining the high degree of specialization among herbivores. More recently, natural enemies of herbivores have been mentioned as another important selective.

The role of toxic plant secondary chemicals has centered on the so-called "arms race" of plants and herbivores. Less than 10% of all herbivorous insects are polyphagous species that feed on plants in more than three different plant families. The high degree of specialization of insect herbivores usually is explained by the existence of secondary plant chemicals. However, this has received criticism by L. Bernays and colleagues at the University of Arizona who argue that generalist natural enemies, especially predators of the herbivores, may be an important factor in the evolution of narrow host range. Bernays and colleagues argue that oviposition choice and/or host utilization ability can be significantly altered within only 10–16 generations, which implies that current patterns of host use should probably be seen as ecologically dynamic, and not as an end result of co-evolutionary processes over millennia. Moreover, host shifts by insects with a restricted host range often are to unrelated plant species, suggesting that behavioral barriers do not simply reflect a need to avoid toxins. Plant secondary chemicals tend to provide the proximate, mechanistic bases for narrow host range, but do not necessarily provide the ultimate, functional basis for the patterns presently seen. An important aspect in their arguments is the concept of "enemy-free space," which indicates that, on some plants, an herbivore is not, or is less, affected by natural enemies compared to other plant species. Within a given place and time, preference for a plant less likely to be visited by natural enemies could evolve rapidly. Specializations for continued avoidance of predators also may then be rapidly selected and established. For example, it is self-evident that the most effective insect crypsis is developed on specific substrates, and the most celebrated instances of sequestration of compounds toxic to vertebrates from plants are reported for insects with specialized feeding habits. Both of these specializations are predator related. Because many parasitoids are relatively restricted in host range, or restricted in the ranges of plants searched, they might be more important in causing host switches or broadening herbivore host range. This could leave the predator element as the most important factor in pushing insect herbivores toward narrow host range and the specializations that can then follow.

The Plant's Perspective: A Paradox in Its Defense Against Herbivores and the Answer in a Tritrophic Context

The previous section considered the herbivore's viewpoint of being in between plant defense and natural enemy attack. When taking the plant's perspective of defense against herbivores, a bitrophic view may yield a paradox. If plants affect herbivore fitness by reducing the food quality through digestibility reducers or nutrient composition (e.g., low nitrogen content), the herbivores will respond by inflicting more damage to compensate (e.g., by prolonged feeding, or more intense feeding). Natural enemy attack may be the essential factor needed to turn digestibility reducers into a positive trait. Digestibility reducers result in longer duration of herbivore stages. This may affect attacks by parasitoids that are usually rather restrictive as to the herbivore instar they attack, or attacks by (insect) predators that consume more small prey than large prey. However, experimental evidence for this often-mentioned scenario is still limited.

Plants also may face another dilemma. If the secondary chemicals the plants produce are sequestered by specialist herbivores, that means the herbivores exploit the plant's defense for their own protection against carnivores, and the plant faces a net ecological cost. Many plants only start the (increased) production of these secondary metabolites in response to herbivory. A recent example shows that the induction can be dependent on the herbivore that feeds on the plant. Wild tobacco plants initiate nicotine production in response to wounding by such factors as rabbit feeding or mechanical wounding. However, Kahl and colleagues at the Max Planck Institute for Chemical Ecology showed that when caterpillars of a specialist herbivore, i.e., tobacco hornworm (*M. sexta*), feed on the plant, the plant does not initiate a high nicotine biosynthesis, but rather, initiates the production of volatiles that attract carnivorous enemies of the specialist herbivore.

Hidden Players

Currently, tritrophic interactions are mostly considered for above-ground interactions of plants, and herbivorous and carnivorous arthropods. However, it is increasingly apparent that microorganisms play an important role in communities in general, and in plant-insect communities in particular. Microorganisms may compete with insects for food, and microorganisms may be symbionts or pathogens of insects. Therefore, all interactions in tritrophic systems can be affected by microorganisms. Research in this area is rapidly increasing.

Moreover, most knowledge on tritrophic interactions relates to above-ground systems, especially because they are more easily investigated than below-ground interactions. However, above-ground and below-ground interactions cannot be considered individually because they are intimately linked. Intensified research on below-ground interactions, as well as their link to above-ground interactions, is foreseen for the near future.

Theories on Plant Defense

Classical plant defense theory describes the evolution of secondary plant substances in direct defense against herbivores as the result of an arms race between plants and herbivores: plants evolve secondary metabolites in response to attacks by insects, while insects meet the challenge by evolving new detoxification systems. In the 1970s, P. Feeny of Cornell University, and D. Rhoades and R. Cates at the University of Washington, developed a theory that centers on plant "apparency," which emphasizes the herbivore's perspective. A third plant defense theory is the "resource availability theory," developed by P. Coley and colleagues at the University of Utah. This theory emphasizes the plant's perspective and centers around the possibilities of defense as affected by the availability of nutrients and energy.

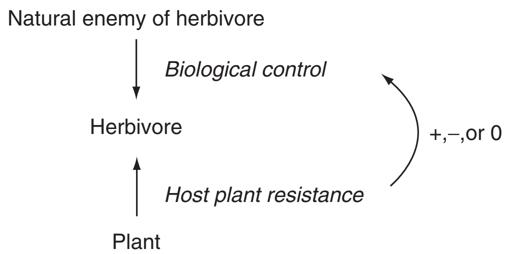
The relatively young field of three-trophic-level interactions has not been the subject of many theoretical considerations. Yet, Price at Northern Arizona University has integrated the plant apparency theory with the actions of natural enemies (indirect defense). He argues that many of the broad patterns relating to natural enemies discovered to date relate to gradients from herbs to shrubs to trees, from unstable to stable environments, and from herbivores with external to concealed feeding habits. When using plant succession as a starting point, and concentrating on parasitoids as natural enemies, Price notes five patterns:

1. With plant succession, the number of parasitoid species per host species increases.
2. With plant succession, the prevalent parasitoid species becomes more generalistic.
3. With an increase in the number of parasitoid species per host species, host mortality increases; this has not been well-studied.
4. With an increase of the number of parasitoid species per host species, the probability increases that herbivore populations are regulated.
5. Host-specific parasitoids (that are more often present in early succession stages) have innate and strong responses to kairomones and plant volatiles, whereas generalistic species (more frequently present in later successional stages) have more plastic responses that are subject to learning.

Price then theorizes on the differences in plant defenses in early and late succession. In early succession, plants are unapparent to herbivores and defend themselves through specific toxins. Thus, host location by parasitoids is constrained and the parasitoids need specialized enzymes to cope with the sequestered toxins in the herbivores. Thus, selection will favor specificity of the parasitoids. It is exactly host-specific parasitoids that are predicted to use specific synomones and kairomones in host location in a genetically fixed pattern. In late succession, plants are apparent and defend themselves in similar ways (convergence) through digestibility reducers. This increases the chance that an herbivore will include a new plant species in its diet; herbivores are less plant-specific. Parasitoid species may be more generalistic than in early successional stages. For these parasitoids, the recognition of, and innate response to, a large number of specific synomones and kairomones is less likely (physiological constraint) and, thus, learning will be more important.

Applied Aspects

The importance of considering interactions between insects and their food and enemies in a multitrophic context has been realized since the beginning of the 1980s. Thus, the field of tritrophic interactions is a relatively young one. However, developments in this field are quick and the knowledge gained is not only important from a scientific point of view, but also from an applied point of view. For instance, in environmentally benign pest control, herbivores can be controlled through plant breeding for resistance and through biological control (Fig. 105). The combination of these two methods may be explicitly exploited, or may occur without special intervention, because naturally occurring, carnivorous arthropods often play an important, but unnoticed, role in the reduction of pest populations. Therefore, it is important that these two methods are synergistic rather than antagonistic. However, synergistic interaction between host plant resistance and biological control is by no means self-evident. If certain plant characteristics are selected because they have a negative influence on herbivores in the absence of biological control agents, this does not automatically mean that the plant contributes to pest control in the presence of biological control agents. A remarkable example was recorded for cabbage plants. Two cabbage varieties differed in resistance against the cabbage aphid, *Brevicoryne brassicae* (L.), which resulted in reduced aphid populations when parasitoids had been excluded. However, the susceptible cultivar emitted larger quantities of a parasitoid-attracting volatile and, therefore, under conditions where biological control was applied, aphid densities were lower on the susceptible variety than on the resistant variety.



Tritrophic Interactions, Figure 105 Durable and environmentally benign pest management can incorporate host plant resistance and biological control. Host plant characteristics may affect biological control positively, negatively, or not at all. Which of these interactions between host plant resistance and biological control occurs can be important for the success of environmentally benign pest control.

Along similar lines, current developments should be considered in the field of transgenic insect-resistant plants. So far, the main emphasis is on the effects of the transgenic plants on pest insects, without much emphasis on tritrophic effects. However, an important question is: Do plants that have been engineered to express certain toxins affect non-target organisms, including non-target herbivores and carnivorous arthropods that attack target and/or non-target herbivores?

Agricultural plants have to produce under conditions where they are members of a community. Agroecosystems harbor a diverse community – even when they are usually less diverse than the community in a natural ecosystem – and if important carnivores are eliminated or hampered by introducing crop plants that have different characteristics, the result may be that pest control is hampered rather than improved. This is a lesson that is older than the research on tritrophic interactions. The dusting of crop plants with broad-spectrum pesticides in the 1960s and 1970s can be seen as an artificial alteration of plant characteristics that had severe impacts on pest control, where even novel pests were induced as a result of the elimination of carnivorous arthropods.

Conclusion

Interactions in communities comprise direct and indirect interactions. Characteristics of community members can have effects on interactions with their direct enemies or resources, but also on non-producer/consumer interactions. Indirect interactions are by no means less important than direct interactions between producers and consumers. Indirect interactions can decisively influence producer-consumer interactions. Tritrophic interactions show that the debate on the role of bottom-up versus top-down forces in shaping communities is not an either/or debate, but rather one of the degree of integration of the two forces. Considering tritrophic interactions is not only interesting from a basic point of view, it is also important from an applied point of view (for example, in developing novel methods of environmentally benign pest control). Finally, the study of tritrophic interactions is not an endpoint but only a beginning. After initiating studies on interactions among plants, herbivores and carnivores (not exclusively insects), it is now clear that microorganisms can play important roles in these interactions. Moreover, second-order carnivores and interactions with organisms that cannot be exclusively linked to a single trophic level, such as omnivores, should be included as well. Therefore, the study of tritrophic interactions is evolving into the research area of multitrophic interactions.

Triungulin

The active first instar of stylopids (Strepsiptera) and certain beetles (Coleoptera) that undergo hypermetamorphosis, becoming less active after they find a host and commence feeding (contrast with planidium).

Triunguloid Larva

A larval body form with minute, active, spiny first instars, and found in certain predaceous beetles and stylopids.

► Triungulin

Trochanter

A small leg segment found between the coxa and femur. The second segment of the leg (Fig. 106).

► Legs of Hexapods

Trochantin

The basal part of the trochanter when it is subdivided. In Coleoptera and some other groups, it refers to a structure present on the outer side of the coxa.

Trochiliphagidae

A family of chewing lice (order Phthiraptera).

► Chewing and Sucking Lice

Troctopsocidae

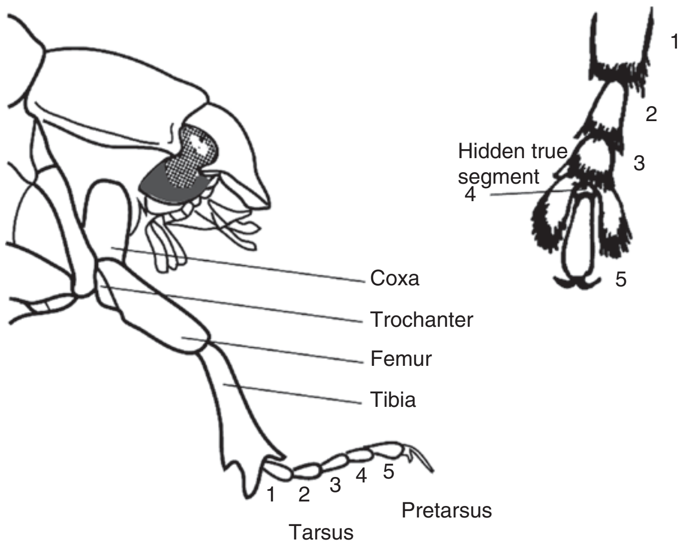
A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice and Psocids

Trogidae

A family of beetles (order Coleoptera). They commonly are known as skin beetles.

► Beetles



Trochanter, Figure 106 **Leg of a beetle (Coleoptera: Scarabaeidae) leg showing its component parts, and a close-up of one type of beetle tarsus (foot).**

Trogiidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice and Psocids

Trophallaxis

A behavior found in social insects involving the exchange of food between members of the colony, or among colony members and guests. The food may originate from the mouth (stomodeal trophallaxis) or from the anus (proctodeal trophallaxis).

Trophic Egg

A degenerate egg that is inviable, and used to feed other members of the colony.

Trophic Level

The classification of organisms in a community according to their feeding relationships. The first trophic level usually is green plants. The second tropic level includes herbivores, and insects are a principal component. However, insects also are carnivores, parasites, and detritivores, so they appear in various tropic levels (Table 15).

Trophic Structure

Organization of a community in terms of energy flow through the constituent trophic levels.

Trophobiosis

The indirect stimulation of reproduction through plant conditioning following the host plant's exposure to insecticides. Normally the insecticide affects the nutrient condition in a favorable manner. This phenomenon is best documented in aphids.

Trophogenic Polymorphism

Polymorphism in social insects due to differential feeding of the larvae, or different sized eggs.

Tropical Burnet Moths (Lepidoptera: Lacturidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tropical burnet moths, family Lacturidae, total 138 species, mostly Indo-Australian but with a few in the southern United States; actual world fauna probably exceeds 250 species. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small to medium size (11–65 mm wingspan), with head scaling average; haustellum naked; labial palpi upcurved; maxillary palpi small, 1- to 2-segmented; antennae filiform. Wings elongated. Maculation usually colorful, especially with orange, red and yellow colors, and with various bands or spots, and with darker hindwings. Adults nocturnal but some may be crepuscular. Larvae are leaf skeletonizers and are colorful, but most are not known biologically; somewhat slug-like, with concealed head. Host plants include families Celastraceae, Moraceae, and Sapotaceae.

Tropical Carpenterworm Moths (Lepidoptera: Metarbelidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tropical carpenterworm moths, family Metarbelidae, include 103 species, mainly Afrotropical and

Oriental, with one species in the Palearctic region; actual world fauna likely exceeds 150 species. The family is in the superfamily Cossoidea (series Cossiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Some recent views place the group as a subfamily of Cossidae. Adults small to medium size (21–48 mm), with head small and rough scaled; labial palpi upcurved; maxillary palpi minute; antennae short and bipectinate; legs short. Body robust. Wings elongated and rounded (frenulum-retinaculum usually absent). Maculation mostly shades of brown and gray, even nearly white background, with dark spotting (often also with a preapical darker forewing discal spot); hindwings darker. Adults may be crepuscular. Larvae nocturnal borers on tree bark or in tree trunks, but most species remain unknown biologically. Host plants include various trees in Anacardiaceae, Guttiferae, Lauraceae, Leguminosae, Myrtaceae, Rhamnaceae, Rutaceae, Sapindaceae, and Sterculiaceae. A few have minor economic status.

Tropical Ermine Moths (Lepidoptera: Attevidae)

John B. Heppner
Florida State Collection of Arthropods, Gainesville, FL, USA

Tropical ermine moths, family Attevidae, include 48 species, mostly tropical and in the genus *Atteva* (the single partially non-tropical species known occurs across the southern United States and into the Caribbean and Mexico); actual fauna probably at least 60 species. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium size (20–34 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi upcurved; maxillary palpi 1- to 2-segmented. Wings elongated with termens rather rounded. Maculation usually colorful (many with red or orange forewings), with various spots on the forewings (Fig. 107). Adults diurnal or crepuscular. Larvae are leaf webbers and leaf skeletonizers on Araliaceae and Simaroubaceae. Minor economic species occur on *Ailanthus* trees in India and the United States.

Tropical Fruit Pests and their Management

Jorge E. Peña
University of Florida, Homestead, FL, USA

Tropical fruits are important in several production areas of south and southeast Asia, Australia,

Tropical Ermine Moths (Lepidoptera: Attevidae), Figure 107 Example of tropical ermine moths (Attevidae), *Atteva niveigutta* Walker from India.

Africa, the Mediterranean, the Americas and the Caribbean region. Tropical fruits are regularly grown in different climates from latitude 23°27″N to 23°27″S of the equator, while some are grown to approximately 37°N in Spain. Proximity to the sea, sea currents, altitude, direction of prevailing winds, rainfall and air humidity all have modifying effects on these crops. Most tropical fruits are perennial plants which persist for several years without abrupt, major changes other than seasonal leaf formation, flowering, and fruit development. However, pineapple, papaya, and passion fruit are grown for shorter periods of time and their arthropod management is influenced by their persistence in the field.

In general, tropical fruit crops provide a relatively stable environment over many years, offering continuing habitats for both pests and natural enemies and providing opportunities for biological control and effective pest management programs. Avocado, mango, pineapple, banana, passion fruit, litchi, guava, *Annona* spp., durian, mangosteen, rambutan, acerola and carambola, and their most common pests are included here.

Annona Fruits (Annonaceae Family)

The genus *Annona* embraces several valuable fruit trees and is centered in the Neotropics, with about 110 species. The most common species are *A. muricata* L., *A. montana* McFadden, *A. glabra* L., *A. cherimola* P. Miller, *A. squamosa* L., *A. reticulata* L., and *A. longiflora* Watts. Fruits of Annona are fleshy aggregates that arise from coalesced carpels and contain large seeds with reticulate endosperm.

Most species of Annona have specific climatic requirements for growth, flowering, and fruit maturation. The origins of the tropical species, such as the sugar apple (*A. squamosa*), are the warm lowland regions of Brazil, Guyana, Venezuela, Mexico, and the West Indies. A distinctly subtropical species is the cherimoya (*A. cherimola*), which originates from the cool Andean valleys of Peru and Ecuador at elevations of around 2,000 m. The hybrid atemoya (*A. cherimola* × *A. squamosa*), which appeared spontaneously when parent trees were cultivated side by side and also through manual pollination, exhibits intermediate climatic requirements for growth and fruiting.

Within the family Annonaceae, fruits of the cherimoya, sugar apple, atemoya, and soursop (*A. muricata*) have the greatest potential for utilization and export in the American, Caribbean, Asian and Australian countries. Much of the production of commercially grown species has spread from their indigenous areas to tropical and subtropical parts of Australia, New Zealand, Asia and around the Mediterranean. Thus, production methods vary from more sophisticated systems to less intensive, small farm or backyard type production. The key pests are the annona seed borers, *Bephratelloides* spp., *B. cubensis* (Ashmead), *B. pomorum*, *B. paraguayensis* (Crawford), and *B. petiolatus* Grissell and Schauff (Hymenoptera: Eurytomidae), destroying seeds and pulp; fruit borers, *Cerconota anonella* Sepp (Lepidoptera: Oecophoridae), *Talponia batesi* Heinrich (Lepidoptera: Tortricidae) and *Thecla ortyginus* (Lepidoptera: Lycaenidae); fruit flies, the Queensland fruit fly, *Bactrocera tryoni* (Froggatt), *Anastrepha* spp., and *Ceratitis capitata* (Diptera: Tephritidae); and recently, the pink hibiscus mealybug, *Maconellicoccus hirsutus* (Green), causing defoliation.

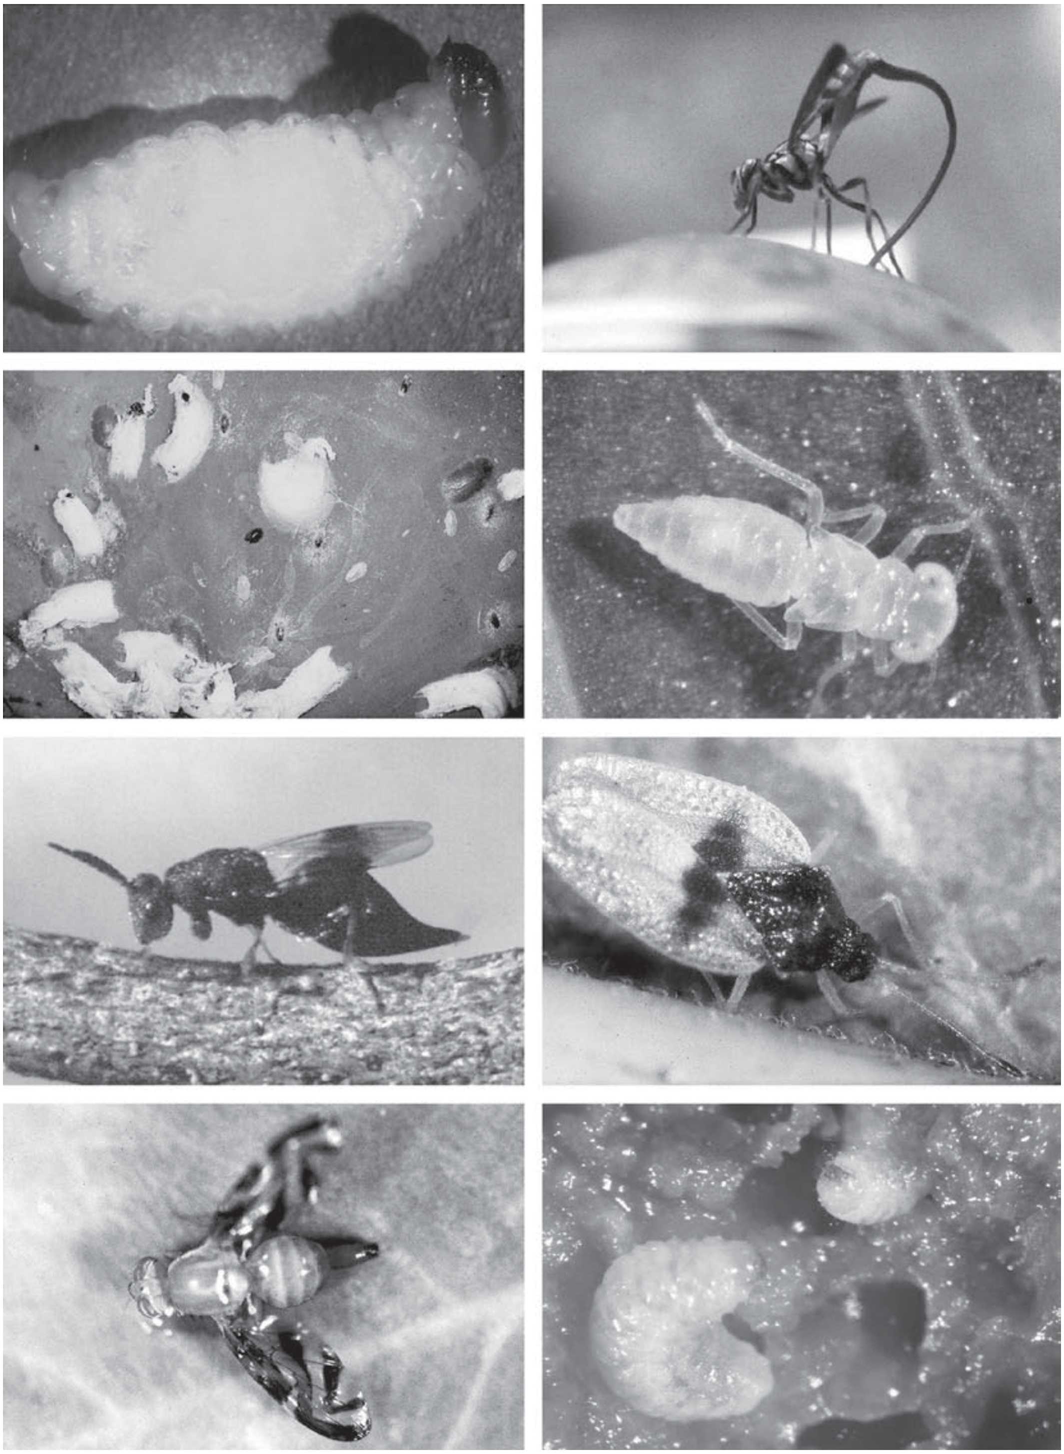
Avocado, *Persea americana* Mill. (Lauraceae family)

The avocado, *Persea americana* Mill. (Lauraceae), is of Central American origin and well known to the native inhabitants of Mexico, Central America and northern South America. Today, avocado is grown commercially not only in North America and throughout tropical America and the larger islands of the Caribbean, but also in Polynesia, the Philippines, Australia, New Zealand, Madagascar, Mauritius, Madeira, the Canary Islands, Algeria, tropical Africa, South Africa, southern Spain, southern France, Sicily, Crete, Israel and Egypt. The most important pests include the tea red mite, *Oligonychus coffeae* (Nietner), avocado brown mite, *Oligonychus punicae* (Hirst), the persea mite, *Oligonychus perseae* (Tuttle, Baker and Abbatiello), and the avocado red mite, *Oligonychus yothersi* (McGregor) (Acari: Tetranychidae), as well as the eriophyid mite *Tegolophus perseaeflorae* (Keifer) (Acari: Eriophyidae). Severe damage to the leaves can be produced by the psyllids *Trioza anceps* Tuthil and *Trioza perseae* Tuthill (Hemiptera: Psyllidae), and by the large blacktip wilter, *Anoplocnemis curvipes* F., injuring new flush, and by the leaffooted bugs, *Amblypelta nitida* Stål and *A. lutescens* lutescens (Distant) (Hemiptera: Coreidae), attacking fruits. Other important species are the avocado lace bug, *Pseudacysta perseae* (Heidemann) (Hemiptera: Tingidae) (Fig. 108), causing leaf chlorosis and necrosis, the mirids, *Dagbertus fasciatus* (Reuter), *D. olivaceous* (Reuter), and *Rhinacloa* sp. (Heteroptera: Miridae), affecting flowers and fruitlets, the thrips, *Scirtothrips aguacatae* Johansen and Mojica and *Scirtothrips kupae* Johansen and Mojica, *Scirtothrips perseae* Nakahara, the red-banded thrips, *Selenothrips rubrocinctus* (Giard) (Thysanoptera: Thripidae), affecting leaves and sometimes fruits. Among lepidopterans, several species affect production, including the avocado seed moth, *Stenoma catenifer* Walsingham (Lepidoptera: Oecophoridae), the western avocado leaf roller, *Amorbia cuneana* Walsingham (Lepidoptera: Tortricidae), and the avocado loopers *Anacamptodes defectaria* (Guenée), *Epimeces detexta* (Walker), *Epimeces matronaria* (Guenée), *Oxydia vesulia transponens* (Walker), and *Sabulodes aegrotata* Guenée (Lepidoptera: Geometridae), which consume foliage and eventually chewing on small fruit.

Other important pests are the weevils, *Conotrachelus perseae* Barber, *Conotrachelus aguacatae* Barber, *Conotrachelus serpentinas* (Klug) and *Heilipus lauri* Bohemann (Coleoptera: Curculionidae), boring into fruits and seeds.

Banana and Plantain, *Musa* spp. (Musaceae Family)

Bananas and plantains (*Musa* spp.) are among the most important crops in tropical and subtropical climates. The genus *Musa* evolved in Southeast Asia where numerous undomesticated *Musa* species still grow as opportunistic weeds. Edible bananas (*Musa* spp., *Eumusa* series) originated within this region from two wild progenitors, *Musa acuminata* and *M. balbisiana*, producing a series of diploids, triploids and tetraploids through natural hybridization. Additionally, man has selected for parthenocarpy (development of fruit without pollination or seeds). Hybridized bananas may be divided into six genome groups (i.e., AA, AAA, AAB, AB, ABB, ABBB) based on the relative contributions of *M. acuminata* and *M. balbisiana*. Domesticated bananas include a wide range of dessert, cooking and brewing cultivars. The most extensively grown bananas are triploids. In terms of gross value of production, bananas and plantains are the fourth most important global food crop. Bananas grown for export are almost exclusively of one variety, "Cavendish"; this cultivar accounts for slightly more than 10% of global production. Bananas are rhizomatous herbaceous plants ranging in height from 0.8 to 15 m. A mat (=banana stool) consists of an underground corm (rhizome) from which one or more plants (shoots) emerge. Adventitious roots spread extensively 4–5 m from the parent and downward 75 cm or more; however,



Tropical Fruit Pests and their Management, Figure 108 Some tropical fruit pests: *upper left*, banana weevil larva (photo Rita Duncan); *upper right*, papaya fruit fly (photo R. Swanson); *second row left*, papaya scale (photo M. Shepard); *second row right*, papaya leafhopper (photo Rita Duncan); *third row left*, Annona seed borer (photo H. Nadel); *third row right*, avocado lacebug (photo J. Peña); *bottom left*, Caribbean fruit fly (photo Rita Duncan); *bottom right*, Acerola weevil larva (photo Rita Duncan).

most roots are near the soil surface. Plants represent a single shoot (pseudostem, stem, leaves, flower and bunch). Yield is normally expressed in kg/area/year reflecting both number and size of bunches harvested.

Pests of the corm and pseudostem include the banana weevil, *Cosmopolites sordidus* (Germar), banana pseudostem borer, *Odoiporous longicollis* (Olivier) and the West Indian sugarcane borer, *Metamasius hemipterus sericeus* (Olivier) (Coleoptera: Curculionidae). The following are pests of flowers and fruits: banana thrips *Hercinothrips bicinctus* (Bagnall), *Caliothrips bicinctus* Bagnall, *Chaetanaphothrips orchidii* (Moulton), *C. signipennis* (Bagnall), *Thrips hawaiiensis* (Morgan) and *Tryphactothrips lineatus* Hood (Thysanoptera: Thripidae), while the banana fruit scarring beetles, *Colaspis hypochlora* Lefebre (Coleoptera: Chrysomelidae) and the "Irapua" bee, *Trigona spinipes* Fabricius (Hymenoptera: Apidae), are considered troublesome in some areas in the Neotropics. The banana moths, *Opogona sacchari* Bojer, *Opogona glyciphaga* (Meyrick) (Lepidoptera: Tineidae), the banana scab moth, *Nacoleia (Notarcha, Lamprosema) octasema* (Lepidoptera: Pyralidae) damage flowers and sometimes bunches. Important pests of foliage include the bagworm, *Oiketikus kirbyi* Guilding (Lepidoptera: Psychidae), *Caligo* spp., *Opsiphanes* spp. (Lepidoptera: Nymphalidae). The banana aphid, *Pentalonia nigronervosa* Coquerel. (Heteroptera: Aphidae) is important as the sole vector of the bunchy-top disease.

Barbados Cherry or Acerola, *Malpighia glabra* (L.) (Malpighiaceae Family)

Barbados cherry is a tropical fruit native to the West Indies, Central America, and South America. Recently, the Barbados cherry has received attention because its fruits are exceptionally high natural source of ascorbic acid (vitamin C). Its cultivation has extended throughout the subtropics and tropics and some of the largest plantings are in Brazil. Estimated commercial acreage in the Caribbean region is more than 400 acres with a potential crop value of several million U.S. dollars. Flowering and fruit set occurs almost continuously from April through November in Florida, and fruits mature in approximately 30 days. Acerola's most important pests are the acerola weevil, *Anthonomus macromalus* Gyllenhal (=*A. flavus*, =*A. bidentatus*, =*A. malpighia*) (Coleoptera: Curculionidae), injuring fruits and flowers; fruit flies, *Anastrepha* spp., and the Mediterranean fruit fly, *Ceratitis capitata* Wiedemann (Diptera: Tephritidae), and the coreids, *Leptoglossus* spp., *Crinocerus* spp. (Hemiptera: Coreidae), and the stink bug, *Nezara viridula* L (Hemiptera: Pentatomidae), causing fruit deformation.

Carambola, *Averrhoa carambola* L. (Oxalidaceae Family)

Known as carambola, star apple, or five corner, this fruit tree is a 5–12 m high evergreen tree native to southern Asia. Leaves imparipinnate, flowers in axillary or cauliflorous panicles, pentamerous. The fruit is a large berry, ovoid to ellipsoid in outline, with five pronounced ribs, stelate in cross section. The tree grows well in tropical or subtropical lowland conditions and flowers abundantly. Most of the information on pests of carambola comes from southeastern Asia and Australia. Important arthropods include the carambola fruit fly, *Bactrocera carambolae* Drew and Hancock (Diptera: Tephritidae), whose larvae feed on the fruit and make tunnels in the fruit; fruit piercing moths, *Gonodonta* spp. and *Eudocima* spp. (Lepidoptera: Noctuidae), pierce the skin of the ripe or ripening fruit with their strong proboscis, the damage resulting in crop loss or unmarketable fruit; the armored scale, *Morganella longispina* (Morgan) (Hemiptera: Diaspididae), feeds on buds and bark causing severe die back; the stink bug, *Nezara viridula* (L.), extracts fruit fluids leaving a small puncture and eventual fruit deformation; and the false spider mite, *Brevivalpus phoenicis* (Geijskes) (Acarina: Tenuipalpidae), causes bronzing of the fruit.

Durian, *Durio zibethinus* Murray (Bombacaceae Family)

Durian, a common fruit in Southeast Asia, originated in Borneo and Sumatra, and is held in high esteem from Sri Lanka and southern India to New Guinea. The ripe fruits, or rather the arils which form the edible part, are generally eaten fresh. Its strong and unmistakable smell is present in every market and street stall during the fruiting season. The fruit also can be preserved, deep frozen or consumed in ice creams, cakes and cookies. The fruit is a globose, ovoid or ellipsoid capsule, up to 25 cm long and 20 cm diameter, green to brownish, covered with numerous broadly pyramidal, sharp, up to 1-cm-long spines; usually with five thick, fibrous valves. Seeds are up to 4 cm long and completely covered by a white or yellowish, soft, very sweet aril. The tree is propagated by seeds, or superior cultivars by budding on seeding stock. Thailand is the largest producer with 444,500 tons in 1987, followed by Indonesia.

The key pests of durian are *Hypomeces squamosus* F. (Coleoptera: Curculionidae), a polyphagous weevil in which the adult stage feeds on leaves, causing extensive defoliation of young plants; the durian psyllid, *Allocaridara malayensis* (Crawford) (Hemiptera: Psyllidae), inserts eggs into young leaves, and both nymphs and adults feed on the underside of the leaf; the durian borer, *Conogethes punctiferalis* (Guenée) (Lepidoptera: Pyralidae), damages both young and mature fruits by boring into the pulp. The newly hatched larva of the durian seed borer, *Mudaria luteileprosa* Holloway (Lepidoptera: Noctuidae), feeds initially on the skin of the fruit and later bores into the husk and then into the seeds. The mite *Eutetranychus africanus* (Tucker) (Acari: Tetranychidae) feeds on the upper side of the leaf, especially along the mid-vein, causing withering spots that later spread over the whole leaf.

Guava, *Psidium guajava* L. (Myrtaceae Family)

The guava, *Psidium guajava* L., occurs naturally from southern Mexico to South America and the Caribbean. The guava is a small tree that is grown worldwide in the tropics and warm subtropics for its edible fruit. Guavas can flower and bear fruit continuously in the tropics, however, there are normally two crops a year. In Florida and Puerto Rico, there is a large crop in early to mid-summer (June and July), and a smaller crop in late winter (February). In Hawaii, the small harvest peak occurs in April to May and the heavy peak in September and November. In India and Malaysia, the main crop is in mid-winter and the lesser crop during the rainy season (July–September). Fruits mature 90–150 days after flowering depending on the variety or clone of the fruit and cultural and weather conditions. The large white flowers attract a large variety of pollinating insects including many species of bees. In many tropical regions the honey bee, *Apis mellifera* L., is the most important pollinator species.

Guavas are either eaten fresh, or used in juice, ice cream, jellies, pastes or preserves. Key pests involve fruit flies of the genera *Anastrepha* and *Bactrocera*, and several species of fruit boring weevils, such as *Conotrachelus psidii* Marshall. Fruit flies injure the fruit by ovipositing eggs and the developing larvae consume the pulp, leaving the fruit unmarketable. A secondary pest is *Heliopeltis theobromae* Miller (Miridae), which feeds on many parts of the plant, including the fruit. Damage to the fruit results in necrotic lesions which render the fruit unmarketable. Many species of mealybugs, including *Ferrisia virgata* (Cockerell), *Planococcus citri* (Risso), *Planococcus pacificus* Cox, *Pseudococcus citriculus* Cox, *Pseudococcus nipae*, *Planococcus minor* (Maskell), and *Pseudococcus* *lilacinus* Cockerell affect guava. Normally these insects do not damage the host severely, but large populations cause the fruit to become misshapen and deformed. For instance, honeydew produced by mealybugs often results in sooty mold, which lowers the fruit's market value. The red-banded thrips, *Selenothrips rubrocinctus* (Giard) and *Scirtothrips dorsalis* Hood, also attack guavas by feeding on the leaves and fruit and cause russetting or bronzing of the plant surface.

Mites can cause serious damage, and they include *Oligonychus yothersi* (McGregor), *Panonychus* sp., *Eotetranychus* sp., and *Oligonychus biharensis* (Hirst). These mites are reported to feed on leaves, causing leaves to become dull green, and then bronzed. The mites, *Tegolophus guavae* and *Brevipalpus* spp., cause damage to fruits and tender leaves.

Litchi and Longan (Sapindaceae Family)

The litchi (*Litchi chinensis* Sonn.) and longan (*Dimocarpus longan* Lour.) are closely related species belonging to the family Sapindaceae. Of Southeast Asian origin, they thrive in subtropical areas with cool dry winters and warm wet summers, but may be grown in tropical areas at high elevation. Around the world, litchis have been successfully grown commercially in latitudes from 15° to 35°. The litchi is a traditional fruit in China, and it occupies a special place in Chinese culture. Indo–China is the center of origin for this species and many old specimen trees have been identified. Litchi and longan fruits are best when eaten fresh, but they also can be processed by canning, juicing or drying into litchi nuts. In Asia they are usually harvested as whole panicles in order to maintain freshness, and are sold in street markets or at roadside stalls within a few days of harvest.

Apart from China and India, large litchi industries have been developed in Taiwan, Thailand, Vietnam, Madagascar, South Africa and Réunion. Smaller but expanding industries exist in Australia, Bangladesh, Mauritius, Mexico, the Seychelles, Spain and the USA (California, Florida and Hawaii).

In general, longans can be grown successfully wherever litchis are cultivated. Although both species flower at about the same time, longans take longer than litchis to mature. Major world producers are China (400,000 tons), Thailand (150,000 tons) and Vietnam (20,000 tons).

Litchi and longan are adapted to the warm subtropics and produce the best crops when winters are short, dry and cool, but frost-free. Such climatic conditions initiate the development of flower panicles. The inflorescences emerge during late winter and the flowers open in early spring. Most cultivars set fruit far in excess of what an individual tree can carry through to maturity and will shed the excess at various times during fruit development. Longan flowers about 2–3 weeks later than litchi, and matures 4–8 weeks later. Harvesting fruit as whole panicles has the effect of pruning and stimulates new leaf growth after harvest. It also reduces tree size. Ideally, trees should produce one or two vegetative flushes after harvest. The aim is to have the second or third flush commence in winter. If conditions are cool during the early part of the flush, development of the new growth will be floral. However, if warm weather is encountered, the new growth will produce leaves. Litchi and longan often are cultivated in the same geographical areas, and many pests are common to both crops.

Pests include the fruit borers *Conopomorpha sinensis* Bradley, *Conopomorpha litchiella* Bradley (Lepidoptera: Gracillariidae), *Cryptophlebia peltastica* Meyr., *Cryptophlebia leucotreta* Meyr., *Cryptophlebia bactrachopa* Meyr. (Lepidoptera: Tortricidae), and in the New World, *Crocidosema* n. sp. (Lepidoptera: Tortricidae). These insects lay new eggs on the fruit anytime after fruit set, as well as on new leaves and shoots. Larvae can bore into leaf buds and fruits. Fruit-piercing moths (Lepidoptera: Noctuidae) attack a range of fruits throughout Southeast Asia, the South Pacific and Australia. The larvae of fruit-piercing moths develop on a variety of host plants. In the Pacific Islands, *Eudocima (Othreis) fullonia* (Clerck), *Eudocima salaminia* (Cramer) and *Eudocima jordani* (Holland) are primary feeders on litchi fruit on the wet tropical coast of Queensland in Australia. Unlike most lepidopterous pests, of which the larva is the damaging stage, in this case it is the adult that causes the damage through its feeding on the fruit. The loopers *Oxyodes scrobiculata* F. and *Oxyodes tricolor* Guen. (Lepidoptera: Noctuidae) occupy similar niches in Thailand and Australia, respectively. The caterpillars feed on the foliage of litchi trees and can cause severe defoliation. Although they will eat leaves of any age, they prefer the younger ones. The litchi longicorn beetle, *Aristobia testudo* (Voet), is a serious pest of both litchi and longan in Guangdong Province in China. In Taiwan, the white spotted longicorn beetle, *Anoplophora maculata* (Thomson), has a one year life cycle. These beetles girdle branches by chewing 10 mm strips of bark. The larvae bore into the xylem and create tunnels up to 60 cm long in the wood. Several bugs belonging to the family Tessaritomidae attack litchis and longans throughout China, Southeast Asia and Australia. *Tessaritoma papillosa* Drury occurs in southern China, Vietnam, Thailand, Burma, the Philippines and India, although there are reports that *Tessaritoma javanica* Thunberg and *Tessaritoma quadrata* Distant are the species found on litchi in India. In litchis and longans, adults and nymphs feed on terminals, which may be killed, and also on flowers and fruit, causing these to fall.

The litchi erinose mite, *Aceria litchii* (Keiffer), also known in China as litchi hairy mite, hairy spider, or dog ear mite, occurs throughout China and Taiwan, India, Pakistan, Hawaii and Australia. The litchi erinose mite attacks new growth, causing a felt-like erineum to be produced on the leaflets. This may form as several blisters, but if the infestation is severe, it may eventually cover the entire leaflet, causing it to curl. Whole terminals may be deformed. The erineum is at first silver-white, changing as it ages to light brown and then dark reddish brown. The longan erinose mite, *Aceria longana* Boczek and Knihinicki, is a sporadic but major pest of longan in Thailand. *A. longana* is specific to longan, severely affecting the terminals and flowers. The longan gall mite, *Aceria dimocarpi* (Kuang), is associated with longans in China where it is recorded as causing erineum on leaves and also witches' broom symptoms. The litchi leaf midge, *Dasyneura* sp., is regarded as one of the major pests of litchi in China, and *Litchiomyia chinensis* Yang and Luo has been reared from galls collected on litchi leaves in Guangdong.

Mango, *Mangifera indica* L. (Anacardiaceae Family)

The mango most likely originated in Southeast Asia, particularly in the Malay Archipelago. However, it was probably first grown as a food crop in India, where its cultivation is thought to have commenced at least 4,000 years ago. Mangoes are now grown as an important crop all over the world, in both tropical and subtropical areas. Mangoes may be eaten ripe or green, or the fruit is juiced or processed into preserves, chutney, frozen puree, or dried. World production of mangoes in 2000 was estimated to be about 24.5 million tons. Worldwide, mango is affected by many pests. For instance, mango flowers are attacked by a variety of insects such as midges, leafhoppers, caterpillars and thrips. These include leafhoppers (Hemiptera: Cicadellidae) infesting mango flowers throughout Asia, such as *Idioscopus clypealis* Lethierry, *Idioscopus niveosparsus* Lethierry, *Idioscopus magpurensis* Pruthi and *Amritodius atkinsoni* Lethierry. The mango blister midge or mango gall midge (Diptera: Cecidomyiidae), *Erosomyia mangiferae* Felt, infests mangoes in the West Indies. Five cecidomyiid species, including *Erosomyia indica* Grover and Prasad, are reported to attack mango flowers and to cause severe damage in India, while *Dasyneura mangiferae* (Felt) does the same in Hawaii.

Numerous species of lepidoptera have been found to infest mango flower panicles in all production areas, but in few cases have the species involved been identified. In Florida, *Pococera atramentalis* Lederer (Pyralidae) and *Platynota rostrana* (Walker) (Tortricidae) are the two most damaging species of a complex that also includes *Pleuroprucha insulsaria* (Guenée) (Geometridae), *Tallula* spp. (Pyralidae) and *Racheospilla gerularia* (Hübner). In the Philippines, the tip borer, *Chlumetia transversa* Walker (Noctuidae), is second only to mango hoppers as a pest of flowers. The geometrids, *Eupithecia* sp., *Chloropteryx glauciptera* Hampson and *Oxydia vesulia* (Cramer), as well as *Penicillaria jocosatrix* Guenée (Noctuidae), also can be found feeding on mango panicles. Other blossom pests are *Frankliniella bispinosa* (Morgan) and *Frankliniella kelliae* (Sakimura) in Florida, the western flower thrips, *Frankliniella occidentalis* (Pergande), in Israel, and the chili thrips, *Scirtothrips dorsalis* Hood, in Thailand.

Because of the high price paid for unblemished fruit, fruits need to be protected from a range of insects that may cause physical damage or loss, or merely affect its outward appearance. Flies of the Tephritidae are pests of mango in many parts of the world. In the Neotropics, *Anastrepha* spp., *A. obliqua* (Macquart), the Mexican fruit fly, *A. ludens* (Loew), *A. serpentina* (Wiedemann), *A. striata* Schiner, *A. suspensa* (Loew), *A. ocresia* Walker, *A. distincta* Greene, *A. fraterculus* Wiedemann, and *A. chiclayae* Greene are considered important pests. *Bactrocera tryoni* (Frogatt), *B. neohumeralis* (Hardy), *B. jarvisi* (Tryon), *B. zonata* (Saunders), *B. frauenfeldi* Schiner and *B. dorsalis* (Hendel) are all reported to attack mango. The Mediterranean fruit fly, *Ceratitis capitata*, is reported to attack mango throughout the world, whereas the marula fruit fly, *Ceratitis cosyra* (Walker), and the Natal fruit fly, *Ceratitis rosa* Karsch, are important in Africa.

The mango seed weevils, *Sternochetus mangiferae* (F.) (Coleoptera: Curculionidae), are widely distributed in Africa, Asia, Australia, the Pacific Islands and in some Caribbean islands, whereas *Sternochetus gravis* (F.) and *Sternochetus frigidus* (F.) occur in India and Bangladesh. Seed weevils generally lay eggs in small green fruit, and the larvae tunnel to the seed, where they feed and develop. *Deanolis sublimbalis* Snellen (Lepidoptera: Pyralidae), the mango seed borer, is also an important pest of mango fruits in the Philippines, Vietnam, China, Thailand, Indonesia and Papua New Guinea. The distinctive red-banded larvae feed on and bore through the pulp to the seed.

Fruitspotting coreid bugs, such as the yellowish-green coreid bugs *Amblypelta lutescens lutescens* (Distant) and *Amblypelta nitida* Stål, and the tip wilter, *Anoplocnemis curvipes* (Fabricius), can be serious pests of young mango trees in South Africa. *Amblypelta lutescens* feeds on the young fruit, causing black lesions to develop and the fruit to fall.

Pest of leaves and buds include gall midges (Diptera: Cecidomyiidae) such as *Protocontarinia matteiana* Kieffer and Cecconi, *Erosomyia* spp., *Procontarinia schreineri* Harris, *Amradiplosis echinogalliperada* Mabi and *P. matteiana*. The galls dry up and fall out, leaving a typical "shot-hole" effect. Red-banded thrips, *Selenothrips rubrocinctus* (Giard), and the Mediterranean mango thrips, *Scirtothrips mangiferae* Priesner, feed on the leaf, especially adjacent to the midrib, where they cause a silvering that develops into necrosis, eventually leading to leaf drop. The mango bud mite, *Aceria mangiferae* Sayed is reported to attack the buds of terminals, and spider mites belonging to the genus *Oligonychus* (*O. mangiferae* Rahman and Sapra, *O. punicae* (Hirst), and *O. yothersi* McGregor) feed on the upper surface of mango leaves.

The mango scale, *Aulacaspis tubercularis* (Newstead), is regarded as a key pest mostly because it infests the fruit. Among the mealybugs, *Rastrococcus invadens* Williams, and the margarodid *Drosicha stebbingii* (Green) (Margarodidae) remain as important pests of leaves in different mango growing areas.

Mangosteen, *Garcinia mangostana* L. (Guttiferae Family)

Mangosteen is known only as a cultivated species, although there have been occasional observations of wild specimens in Malaysia. The scarcity of mangosteen orchards, limited fruit supply and the fruit's short shelf life are major marketing problems. The long juvenile period of 10–15 years, which discourages commercial production, contributes to much of the limited fruit supply. The mangosteen fruit is a globose and smooth berry, turning dark purple at ripening. It is a crop of the humid tropics, often found in association with durian. The fruit has a diameter of 4–7 cm. The edible part is the sweet white aril that envelops the seeds within the pericarp.

Floral initiation to anthesis takes about 25 days and the fruit ripens 100–120 days later. The most serious pests are *Hyposidra talaca* (Walker) (Lepidoptera: Geometridae), a highly polyphagous insect. *Hyposidra talaca* is a typical looper, causing defoliation in tropical lowlands and highlands. The citrus leafminer, *Phyllocnistis citrella* (Lepidoptera: Phyllocnistidae), mines leaves of mangosteen, causing leaf deformation and often leading to early fall. *Sictoptera cuculloides* Guenée (Lepidoptera: Noctuidae) is reported to feed voraciously on young flushes of mangosteen.

Papaya, *Carica papaya* L. (Caricaceae Family)

Papaya, *Carica papaya* L., is a major tropical fruit cultivated through the tropical and Neotropical regions of the world between 32°N and 32°S. Although papaya was probably cultivated by early civilizations in the New World, no botanical records are available prior to the arrival of Columbus to America. This herbaceous plant is also known as papaw, paw paw, kapaya, kepaya, lapaya, tapaya, papayao, papaya, papaia, papita, lechosa, fruta bomba, mamon, mamona, mamao, and tree melon. Papaya is cultivated mainly for its edible fruit, but medicinal and industrial uses also have been documented.

Fruit flies (Diptera: Tephritidae) are the only group of insects that actually penetrate the pulp or seeds. Twenty-six species from seven genera, *Anastrepha* (two species), *Bactrocera* (17 species), *Ceratitis* (three species), *Dacus*, *Euphranta*, *Myoleja*, and *Toxotrypana* (one species each) attack papaya fruits. *Toxotrypana curvicauda* Gerstaecker is the most important fruit fly species attacking papaya in the Americas and Caribbean Basin, whereas *Bactrocera papayae* (Drew and Hancock) is one of the most threatening pests to papaya in Australia. *Anastrepha* spp., *C. capitata* (Wiedemann), *C. catoirii* Guerin-Meneville, and *C. rosa* Karsch also are known to attack papaya.

Arthropods affecting the foliage and trunk of papaya include the white peach scale, *Pseudaulacaspis pentagona* (Targioni-Tozetti), the papaya scale, *Philephedra tuberculosa* Nakahara and Gill, and the papaya mealybug, *Paracoccus marginatus* Williams and Granara de Willink. Several species of mites feed on papaya. They include the carmine mite, *Tetranychus cinnabarinus* (a key pest), the red and black flat mite, *Brevipalpus phoenicis* (an occasional pest), and the papaya leaf edge roller mite, *Calacarus brionese*. Damage by the broad mite, *Polyphagotarsonemus latus* (Banks) (Tarsonemidae), is confused with virus-like symptoms. Nine cicadellid species from three genera (*Empoasca*, *Poeciloscarta* and *Sanctanus*) can affect papaya, such as *Empoasca papayae* Oman, which transmits bunchy-top, *E. stevensi* Young, and *E. insularis* Oman. Aphids do not colonize papaya plants and are considered minor pests, but several species, *Aphis coreopsidis* (Thomas), *Aphis nerii* Boyer de Fonscolombe, *Aphis gossypii* Glover, *Aphis spiraecola* Patch, *Myzus persicae* (Sulzer), and *Toxoptera aurantii* (Boyer de Fonscolombe), can be found on papaya plants. Several aphid species [*M. persicae*, *M. euphorbiae*, *A. spiraecola* (=*A. citricola*), *A. gossypii*, *A. craccivora*, *A. nerii*, *R. maidis*, and *T. auranti* (Boyer de Fosc)] are capable of transmitting papaya ringspot virus. Among the defoliators, hornworms (Lepidoptera: Sphingidae), *Eryinnis alope* (Drury), *E. ello*, and *E. lassuxi merianae* Grote, are considered important.

Passion Fruit (Passifloraceae Family)

Passion fruits belong to the genus *Passiflora* (family Passifloraceae), which has a wide genetic base. While some species are undomesticated, others are cultivated as ornamental plants, for nourishment and for medicinal purposes. The majority of Passiflora are indigenous to the tropical and subtropical regions of South America. Of the 400 known species of Passiflora, about 50 or 60 bear edible fruits. A few species are economically important, e.g., *Passiflora edulis* Sims., botanical form *flavicarpa* Deneger, the yellow passion fruit, whose juice and pulp are used extensively as ingredients of beverages, salads, fruit cocktails and desserts. The major producers of passion fruits are found in South America, mainly Brazil, Colombia, Peru and Ecuador. Commercial plantations of passion fruits are found also in Australia, Hawaii, India, New Guinea, Kenya, South Africa, Sri Lanka and Costa Rica. *Passiflora edulis f. flavicarpa*, *P. edulis* (purple passion fruit), and *P. alata* (sweet passion fruit) are the main species cultivated in the world. *Passiflora ligularis* (granadilla) and *P. quadrangularis* (badea) are cultivated in the Andean region of South America and in Central America.

Although the passion fruit crop has great economic potential, its establishment and expansion have been hindered by various problems. For example, passion fruit is attacked by a wide host range of diseases, insects and mites. Some pest species cause significant losses, reaching the status of key pests or secondary pests. They include lepidopterous defoliators such as three heliconiine species, *Dione juno juno* Cramer, *Agraulis vanillae vanillae* Linnaeus, and *Eueides isabella huebneri* Ménétries (Nymphalidae). Many species of bugs attack passion fruit; the majority belong to the Coreidae (leaf-footed bugs), such as *Diactor bilineatus* Fabricius, *Leptoglossus* spp., and *Holhymenia* spp. *Diactor bilineatus* is the most common species in Brazil and Venezuela, and is known as the passion fruit bug because it feeds only on fruit of *Passiflora* spp. Among the *Holhymenia*, *Holhymenia clavigera* (Herbst.) and *H. histrio* (Fabricius) are reported attacking passion fruit. *Leptoglossus gonagra* Fabricius and *L. australis* Fabricius are reported from several passion fruit producing regions.

Flies of the genera *Anastrepha* Schiner (Tephritidae) and *Lonchaea* Fallén (Lonchaeidae) cause economic losses. *Anastrepha consobrina* (Loew), *A. ethalea* (Walker), *A. grandis* (Macquart), *A. kuhlmenni* Lima, *A. lutzi* Lima and *A. pseudoparallela* (Loew) are the most frequent species followed by *Anastrepha pallidipennis* Guerne on yellow passion fruit. The oriental fruit fly, *Bactrocera dorsalis* (Hendel), melon fly, *Dacus cucurbitae* Coquillett, and the Mediterranean fruit fly, *Ceratitis capitata* Wiedemann, are known to attack passion fruit in Hawaii. The Queensland fruit fly, *Dacus tryoni* (Froggatt), is the most important insect pest of passion fruit in Australia.

Neosilba pendula (Bezzi) and *Dasiops* sp. (Lonchaeidae) attack flowers and buds of passion fruit. The species of *Dasiops* include *D. curubae* Steykal, *D. inedulis* Steykal and *D. passifloris* McAlpine. Other flies that may also feed upon flower and buds are *Lonchaea cristula* McAlpine (Lonchaeidae) and *Zapriothrica salebrosa* Wheeler (Drosophilidae).

Several species of mites have been reported from passion fruit including *Brevipalpus phoenicis* (Geijskes) (Tenuipalpidae) and the red spider mites, *Tetranychus mexicanus* (McGregor) and *T. desertorum* Banks (Tetranychidae), causing general discoloration of the leaves and necrosis, culminating in leaf drop. The broad mite, *Polyphagotarsonemus latus* (Banks), induces malformations in developing leaves, which later dry and drop. It may attack flowering buds, causing a reduction in the number of flowers.

Pineapple, *Ananas comosus* (L.) Merr. (Bromeliaceae Family)

The pineapple, *Ananas comosus* (L.) Merr., is a self-sterile herbaceous, perennial, monocotyledonous plant originating in the New World. The commercial cultivars are placed in five distinct groups, i.e., "Cayenne," "Spanish," "Queen," "Pernambuco" and "Perolera." It is currently grown in many countries with tropical and subtropical climates. Most pineapple pests are endemic to the new countries and adapted to utilize the pineapple to support their life-cycles.

More than 100 species of plant-parasitic nematodes have been recorded in association with pineapple roots, and between three and five species are usually found in most pineapple fields. The key nematode pests include the root-knot nematode (*Meloidogyne javanica* and *M. incognita*), the reniform nematode (*Rotylenchulus reniformis*) and the lesion nematode (*Pratylenchus brachyurus*). The key nematode pests of pineapple are all endoparasites. They either establish a permanent feeding site within the root and become sedentary, e.g., root-knot and reniform nematodes, or they live inside roots but remain migratory, e.g., lesion nematodes. Key arthropod pests are the pineapple leathery pocket mite/pineapple fruit mite, *Steneotarsonemus ananas* (Tryon), *Dolichotetranychus floridanus* (Banks), and the symphylids *Hanseniella* (Symphyla: Scutigerellidae), e.g., *H. unguiculata*, *H. ivorensis*, and *Scutigerella sakimurai* (Symphyla: Scolopendrellidae). *Steneotarsonemus ananas* is important because of its association with the fruit diseases, interfruitlet corking, leathery pocket and fruitlet core rot/black spot. The pineapple flat mite, *D. floridanus*, attacks plants of all ages. Damage is primarily to the whitish leaf bases, which develop brown/black necrotic lesions and appear progressively dehydrated, with feeding mites around lesion peripheries, or as orange patches on leaf bases.

The symphylids *H. unguiculata*, *H. ivorensis* and *S. sakimurai* feed on young meristematic tissues causing newly established plants to stop root development and causing severe witches' broom symptoms. Other important pests are the onion thrips or yellow spot thrips, *Thrips tabaci* Lindeman, responsible for yellow spot disease of pineapples, the pink pineapple mealybug, *Dysmicoccus brevipes* (Cockerell), associated with the devastating disease, pineapple mealybug wilt, the pineapple scale, *Diaspis bromeliae* (Kerner), infesting the lower pineapple leaves, the pineapple caterpillar, *Thecla basilides* (Geyer), causing larval galleries and rendering the fruit unmarketable, and the white grubs, *Lepidiota grata*, *Rhopaea magnicornis*, *Adoretus ictericus*, and the melolonthids, *Macrophylla ciliata* and *Asthenopholis subfasciata*, destroying the root system.

Rambutan, *Nephelium lappaceum* Blume (Sapindaceae Family)

Rambutan is a tropical relative of litchi, with a distribution that ranges from southern China through the Indo-Chinese region, Malaysia, and Indonesia to the Philippines. As the name suggests (the Malay word "rambut" meaning hair), the fruit is glabrous, resembling a burr. Rambutan, while highly prized in its region of origin, remains a minor fruit internationally. The fruits are consumed fresh or canned. The rambutan fruit is an ellipsoid to subglobular schizocarp, up to 7 cm × 5 cm, usually consisting of one nutlet. The skin color varies from yellow to purplish red. The seed usually is covered by a thick, sweet, juicy, white to yellow, translucent sarcotesta, which is the edible part.

The main flowering period occurs during the dry season. Fruits ripen about 110 days after bloom. The most important pests are the durian borer, *Conopomorpha* (=*Acrocercops*) *cramerella* (Snellen) (Lepidoptera: Gracillariidae). This insect tends to damage only the part of the fruit next to the fruit stalk. The cockchafer beetle, *Adoretus* (=*Lepadoretus*) *compressus* (Weber) (Coleoptera: Scarabaeidae), feeds on the interveinal areas close to the center of the leaf. Adults of *Apogonia cribricollis* Burmeister (Coleoptera: Scarabaeidae) are active at night, feeding on foliage from the leaf margin inwards. *Chalcocelis albiguttatus* (Snellen) and *Parasa lepida* (Cramer) (Lepidoptera: Limacodidae) cause severe defoliation of rambutan trees.

Integrated Pest Management (IPM) for Tropical Fruit

Tropical fruit crops provide a relatively stable environment over many years, offering continuing habitats for both pests and natural enemies, and providing opportunities for biological control and effective pest management programs. Any attempt to develop integrated control programs in fruit crops must take into account the following: (i) knowledge of native or resident arthropod fauna; (ii) arthropod fauna affecting the tree crop in its area of origin or domestication; and (iii) presence of natural enemies. The basis for integrated pest management includes the pest's biology and ecology, sampling and monitoring techniques, economic thresholds and the application of management tactics, i.e., chemical, biological, autocidal, plant resistance, etc.

Sampling and Monitoring

Sampling and monitoring methods for tropical fruits are well established for some direct pests such as fruit flies and fruit borers, as well as for some indirect pests (i.e., banana weevil) and defoliators. However, the inability to relate results of sampling to infestation of the fruit at the time of harvest is still a problem. Attempts have been made to develop sampling techniques for several pests of mango, avocado and banana; however for some pests and crops, adequate sampling techniques are not available. This, of course, may be a reflection of the place where the crop is grown, the purpose of tree cultivation (export vs. internal consumption) and grower economic solvency (Australia, USA, South Africa, Israel) vs. growers from other regions of the world.

Economic Thresholds

As export commodities, tropical fruit crops have a consistently high value, with highest prices for undamaged fruit of high quality; thus, the lack of knowledge of economic thresholds, or the low existent economic thresholds, requires control programs to focus on preventing damage by these pests.

Chemical Control

Pesticides have been significant for protecting tropical fruit from insect attack and increasing tropical fruit productivity, therefore the control of fruit and foliar insect pests tends to be heavily dependent on chemical insecticides/acaricides. Information regarding proper timing, spray volumes, and knowledge of the pest complex is available for some crops such as pineapple, and scarce for others such as papaya. Regular, heavy sprays for controlling fruit flies and leafhoppers in papaya can cause heavy outbreaks of mites and other pests. Widespread use of nonselective pesticides continues to be the rule, but currently there is a trend toward evaluating a new generation of pesticides, adoption of selective spraying, timing of spray applications, and determining the effect of pesticides on predators and parasitoids. In contrast, there is minimal to nonexistent information on the effect of pesticides on pollinators. For instance, the deleterious effects on pollinators can be reduced by timing spray applications in passion fruit, according to the cultivar. Purple passion, whose flowers open during the morning hours, should be sprayed during late afternoon, while the yellow cultivar, whose flowers open in the afternoon, should be sprayed in the morning.

Attractants (Pheromones)

Use of sexual attractants (pheromones) is mostly limited to fruit flies, while little information is available for other insect groups, such as curculionids and Lepidoptera.

Crop Sanitation

Crop sanitation is an important factor for maintaining low banana weevil densities in banana farms, and is used as a tentative effort to control important pests of avocados (i.e., weevils), annona (annona seed borer) and mango (mango seed weevil).

Biological Control

Biological control has great potential as a major tactic for regulating pest populations in fruit orchards. The ability to apply biological control effectively has increased in recent decades because of greater knowledge of the arthropod fauna of some tropical fruits (citrus, avocado, pineapple and mango). While biocontrol agents are recorded for most pests of other tropical fruit crops, concentrated efforts to use bio-regulators are rarely observed. For instance, efforts toward developing systems for biocontrol of pink mealybug, *Maconellicoccus hirsutus*, and carambola fruit fly, *Bactrocera carambolae*, in the Caribbean were not initiated until these pests were major threats to crops such as citrus. If a stenophagous insect (i.e., avocado weevils, papaya fruit fly, avocado thrips and annona fruit moths) is the major constraint to a single commodity, efforts for biological control are half-hearted. The exception to this rule is the current strong effort toward biocontrol of banana weevil and the search for natural enemies of avocado thrips. With time, it is likely that more extensive use will be made of biological agents to control pests of tropical fruit crops.

Host Plant Resistance

Host plant resistance offers considerable promise as a tactic in pest management. Even though it appears that most efforts are concentrated toward plant pathogens, use of this tactic merits attention for some crops and some pest species. Resistance to arthropods in tropical fruit germplasm collections should be a high priority. Most efforts are directed at insect vectors (papaya and pineapple) and pests of avocado, mango and guava. Several fruits, i.e., durian and acerola, continue to be largely unnaturalized, and improved selections are rare.

Cultural Practices

Untreated backyard trees and neglected plantings are considered to be major sources of pests, such as fruit flies. For instance, in Australia, hygiene and attention to alternative host plants that can increase pest pressure on the custard apple orchard are important. Mature fruit infested with yellow peach moth or with fruit fly should be collected and destroyed. Preferred fruit fly hosts like guava and loquat should not be planted in or near the orchard. Cultural practices generally do not offer a direct means for controlling pests, but used properly they can enhance natural enemy activity or retard pest population growth to a degree that is important in integrated control programs.

Florida State Collection of Arthropods,
Gainesville, FL, USA

Tropical fruitworm moths, family Copormorphidae, are a small family of 58 species, mostly tropical; actual fauna probably exceeds 100 species. The family is part of the superfamily Copromorphoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium size (12–37 mm wingspan), with head somewhat smooth-scaled; haustellum naked; labial palpi prominent and porrect; maxilary palpi 3- to 4-segmented (rarely 1-segmented). Wing venation with forewing veins long and typically equidistant near the termen; wings typically rounded along forewing termen. Maculation mostly dull gray with dark markings, and many have forewing scale tufts. Adults nocturnal. Larvae are leaf feeders using a leaf web, or are borers (one feeds beneath bark), but few biologies are known. Host plants include Berberidaceae, Ericaceae, Moraceae, Podocarpaceae, and Rubiaceae.

Tropical Lattice Moths (Lepidoptera: Arrhenophanidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tropical lattice moths, family Arrhenophanidae, total 30 species, mostly Neotropical but recently with some Southeast Asian additions; actual fauna probably exceeds 50 species. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium size (12–69 mm wingspan), with robust bodies and roughened head scaling; haustellum reduced or absent; maxillary palpi absent; antennae serrate to bipectinate. Maculation varies from light colored (often yellow) with translucent and colored wing marks, to dark and somber colored. Adult activity nocturnal but some are diurnal (e.g., species in Taiwan). Biologies are unknown except for one Neotropical species with casebearing larvae that feed on fungi.

Tropical Longhorned Moths (Lepidoptera: Lecithoceridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Tropical longhorned moths, family Lecithoceridae, total about 1,038 described species, mostly tropical Oriental, but also with one group in the Palearctic; actual fauna probably exceeds 1,500 species. There are four subfamilies: Ceuthomadarinae, Oditinae, Lecithocerinae, and Torodorinae. The family (previously known as Timyridae) is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Most species are in Lecithocerinae (475 sp.). The most colorful and largest species are in the tropical subfamily Torodorinae. Adults small (5–30 mm wingspan), with head mostly smooth-scaled, and antennae mostly long; haustellum scaled; labial palpi long; maxillary palpi 4-segmented and folded over haustellum base (rarely reduced to one segment). Maculation varies from dull to brightly colored and variously marked. Adults are mostly diurnal and many have the habit of holding the antennae together to the front when at rest. Larvae may mostly be leaf litter feeders or leaf tiers, but few species are known biologically. A few varied host plants are recorded, such as Fagaceae, Myrtaceae, Rosaceae, and Rubiaceae (Fig. 109).

Tropical Plume Moths (Lepidoptera: Oxychirotidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Tropical plume moths, family Oxychitoridae, include only six species, all Indo-Australian and South Pacific. Some specialists include this family as part of the Tineodidae. The family is in the superfamily Pterophoroidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (10–12 mm wingspan), with head scaling average; haustellum naked; labial palpi porrect; maxillary palpi 4-segmented. Wings extremely linear, with long fringes, or wider and with both wings split into two plumes each. Maculation shades of brown or gray, with coordinated spotting or banding in the split-wing species. Adults may be crepuscular. Larva of one species feeds on seeds of white mangrove (Avicenniaceae); the remainder are unknown biologically.

Tropical Slug Caterpillar Moths (Lepidoptera: Dalceridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tropical slug caterpillar moths, family Dalceridae, include 84 Neotropical species (only one sp. occurs north of Mexico, in southern Arizona). Two subfamilies are known: Acraginae and Dalcerinae. The family is in the superfamily Cossoidea (series Limacodiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Adults small to medium size (11–50 mm wingspan), with head small and scaling roughened; labial palpi 2-segmented and very short; maxillary palpi vestigial; antennae short and bipectinate. Body robust. Wings quadratic and rounded; hindwings notably ovoid (Fig. 110); frenulum sometimes absent. Maculation mostly brown hues with few markings but can be colorful, with yellow, orange, or pink, or lustrous white and silvery. Adult activity uncertain; possibly only nocturnal or crepuscular. Larvae slug-like, often with translucent gelatinous wart-like surface; feeding as leaf feeders (early instars as leaf skeletonizers), but few are known biologically. Various host plants are used and some larvae are polyphagous. Few have any economic status.

Trumpet Leafminer Moths (Lepidoptera: Tischeriidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Trumpet leafminer moths, family Tischeriidae, total 81 known species from all regions except Australia, but the Nearctic has most of the known species (48 sp.). The family forms a monobasic superfamily, Tischerioidea, in the section Nepticulina, of the division Monotrysia, infraorder Heteroneura. Adults small (6–11 mm wingspan), with head rough-scaled, with very large head tuft (no eye-caps on the antennal bases); haustellum is short, scaled basally; labial palpi 3-segmented, short and porrect; maxillary palpi minute and 1-segmented. Wing venation is very reduced, with frenular bristles as the wing coupling. Maculation is generally somber but often with iridescences. Adults are diurnally active. The few larvae known are leafminers, usually trumpet-shaped mines or blotch mines, on a variety of host plants.

Trypanosomes

CLARENCE M. LEE[1], EARLENE ARMSTRONG[2]
[1]Howard University, Washington, DC, USA
[2]University of Maryland College Park, MD, USA

Trypanosomes are microscopic unicellular protozoa that are ubiquitous parasites of plants, invertebrates, and vertebrates. These parasites have existed for more than 300 million years and have evolved with their natural hosts. Most of the trypanosomes cause no harm to their hosts and are found in locations throughout the world. Some, however, cause serious diseases in their hosts and are of major medical and veterinary significance. Only a few species of trypanosomes are pathogenic to man. These trypanosomes are not only found in sub-Saharan Africa, where they infect both man and livestock, but also occur in Canada, Latin America, and extend to the southern borders of the United States.

The pathogenic trypanosomes of mammals are called hemoflagellates. These trypanosomes require the blood of their host (human, livestock, etc.) in order to undergo changes pertaining to their life cycles. In addition, the parasite may be transmitted to its host by various techniques, depending on the species of the parasite. For example, *Trypanosoma equiperdum*, a trypanosome known to infect horses, is transmitted via venereal contact. However, the vast majority of the different species of trypanosomes affecting mammals are transmitted via an insect vector.

The most important insect vectors associated with trypanosomiasis (disease caused by protozoa belonging to the genus *Trypanosoma*) in vertebrates are the tsetse flies belonging to the genus *Glossina*. There are 33 known and recognized species of this genus. These vectors can be further divided ecologically into three major groups: the riverine flies of the *palpalis* group; the savanna flies of the *morsitans* group; and the forest flies of the *fusca* group.

Tsetse flies can be distinguished from other flies by the presence of a needle-like forward projecting proboscis, a hatchet-like cell in the middle of the wings and a lateral plumose like arista on the antennae. They are closely related to the muscoid (i.e., house flies, stable flies) flies but may be given their own family name, Glossinidae.

Unlike most flies that are oviparous, the female tsetse fly retains the larva in the uterus and gives birth to one 3rd instar larva at a time. During gestation, the larva is fed from so-called uterine milk-like glands found in the body. When the female larviposits, the larva burrows quickly in the soil and transforms quickly into a pupa. Adult emergence is dependent on the soil temperature and moisture conditions. Adult tsetse flies mate only once and a female produces about 10 offspring during her life span. Both sexes are active bloodsuckers.

Rarely are tsetse flies found in open country because all need some tree/vegetation cover. They are mostly confined to a specific type of habitat and the physical conditions prevailing therein. The flies feed on those animals most readily available in their specific habitat, and therefore carry trypanosomes harbored by their preferred hosts. As a result, infection rates and kinds of trypanosomes vary from one fly habitat to another.

Another important insect vector associated with trypanosomiasis in vertebrates is the assassin bug, cone-nose bug, or kissing-bugs belonging to the family Reduviidae of the order Hemiptera (true bugs). They are characterized by having two pairs of wings; the forewings have leathery basal portions and a membranous distal portion. The second pair of wings is membranous. Hemiptera belonging to this family have piercing sucking mouthparts adapted for feeding on other arthropods or blood. The most important genera of reduviid bugs with some medical importance are *Triatoma*, *Panstrongylus*, and *Rhodnius* which serve as vectors of *Trypanosoma cruzi*, the causative agent for Chagas' disease.

General Life Stages of Trypanosomes

Trypanosomes appear in four basic forms or stages as they undergo changes in the life cycle. These forms or stages differ from species to species, in that some species may exhibit only 2 of the four forms and others may exhibit all four forms. Each form has specific structures that enable it to adapt to its environment. One form is the amastigote or leishmanial stage. This stage has a kinetoplast, which is a structure that is always located at the place of entry into the cell of the flagellum and is opposed to the basal body of the later. The kinetoplast is further composed of a blepharoplast and parabasal body. This structure is analogically similar to the structure of the mitochondria, which is the powerhouse of most types of cells. In addition to a kinetoplast, the amastigote stage has a nucleus. Although the orientation of the kinetoplast can be detected by using the flagellum as a landmark, the leishmanial stage does not have a flagellum. A second stage is the promastigote or leptomonad stage. This stage is found within the tissues of the infected host. In this stage, a flagellum is present. From this stage, the parasite can and does change back and forth between the amastigote and the leptomonad stage in a phenomenon known as transition or morphogenesis. A third stage is the epimastigote or the crithidial stage. The unique characteristic or defining feature of this stage in the history of hemoflagellates is that its undulating membrane or flagellum originates anteriorly to the nucleus. Finally, the last stage is the trypomastigote or trypanosomal stage. The unique or defining feature of this stage is that its undulating membrane originates posterior to the nucleus.

In addition to the morphological differences, these stages can also show metabolic differences. For example, another interesting aspect to the life cycle of the trypanosomes involves the cytochrome oxidase system. The cytochrome oxidase system is one that requires the presence of the metal iron (Fe) in order to work. The only stage that uses this system (i.e., the cytochrome oxidase system) is the epimastigote stage or form. Once the epimastigote stage is placed in a culture that contains other sources of nutrients apart from iron, there is an immediate change or transformation that occurs. The epimastigote form of the parasite immediately changes to the trypomastigote stage, which does not use the cytochrome oxidase system. The trypomastigote stage then use the other forms of nutrients in the culture in order to survive.

Pathogenic Trypanosomes in Humans

The three major species of this parasite that are extremely pathogenic to humans are *Trypanosoma rhodesiense*, *Trypanosoma gambiense*, and *Trypanosoma cruzi*. These parasites were named based on, or according to, either the region they were first found or by the person who first found them. All are hemoflagellates, and thus require the blood of their host in order to undergo their life cycles. Furthermore, the three species also have one or two of the same life cycle stages or forms present. Notwithstanding, different vectors transmit them and all three parasites run a totally different course of infection in man.

T. rhodesiense and *T. gambiense* are found primarily in Africa while *T. cruzi* is located throughout Latin America and extends to the southern borders of the United States of America.

Trypanosoma rhodesiense

Trypanosoma rhodesiense is the causative agent for East African sleeping sickness or *Rhodesian trypanosomiasis* and is found primarily in the eastern region of Africa. It produces a virulent form of sleeping sickness and often results in death within a matter of weeks if not treated.

The principal insect vectors (tsetse flies) responsible for the transmissions of *T. rhodesiense* are *Glossina morsitans*, *Glossina pallidipes* and *Glossina swynnertoni*. When feeding on an infected host, the flies obtain the trypanosomal stage of the protozoa, which undergoes a period of development in the midgut region and eventually transforms into the epimastigote stage. The epimastigote stage then migrates to the insect's salivary glands and then changes to the elongated infective (metacyclic) trypanosomal stage. This stage can now be passed to another host during a blood meal and can initiate infection or disease. The transformations usually are completed in about 3 weeks.

Once in the human blood, the parasite multiplies rapidly. In most infected individuals, there is an enlargement of the lymph nodes (Winterbottom's sign) in the post-cervical region. Irregular fever, headache, joint and muscle pains, and a rash characterize the disease. *T. rhodesiense* may be found in is the blood, lymph nodes and tissues of humans.

Trypanosoma gambiense

Trypanosoma gambiense is the causative agent of the disease known as West African sleeping sickness and is found in the western part of Africa. *T. gambiense* is essentially transmitted between humans and tsetse flies sharing riverine vegetation habitats. In the case of *T. gambiense*, two tsetse flies (*Glossina palpalis* and *Glossina tachinoides*) serve as the primary vectors and are capable of transmitting the trypanosome.

West African sleeping sickness runs a more chronic course of infection in humans. In the first or early phase of the disease, infected individuals show similar clinical and pathological symptoms when infected with *T. rhodesiense*. However, the second or late phase of the disease is unique to *T. gambiense*. This phase involves severe damage to the central nervous system, and may be accompanied by other physical and mental impairment (mental retardation, speech impediments, swelling of the brains, etc.). At this time, the terminal sleeping stage develops and gradually the patient becomes more and more lethargic.

A person can be infected for months or even years without expressing obvious symptoms of the disease. When symptoms do appear, the disease is already at an advanced stage and, without treatment can lead to death. During the early or febrile stage of the sleeping sickness caused by *T. gambiense*, the organism occurs in the blood and lymph node of the infected individual. In the late stages where there is a development of cerebral symptoms, and the organisms can be found in the cerebrospinal fluid.

In infections with *T. rhodesiense* or *T. gambiense*, the presence of trypanosomes in chancre fluid, lymph node aspirates, blood, bone marrow, or, in the late stages of infection, cerebrospinal fluid (in the case of *T. gambiense*), using microscopic examination and other assays (such as testing for specific antibodies in the blood) are helpful in diagnosing trypanosomiasis.

In trypanosomiasis with *T. rhodesiense* or *T. gambiense*, treatment should be started as soon as possible and is based on the infected person's symptoms and laboratory results. The drug regimen depends on the infecting species and the stage of infection. Pentamidine isethionate and suramin (under an investigational New Drug Protocol from the CDC Drug Service) are the drugs of choice to treat the hemolymphatic stage of West and East African Trypanosomiasis, respectively. Melarsoprol is the drug of choice for late disease of *T. gambiense* with central nervous system involvement.

Tsetse flies do not normally fly far from their breeding sites (i.e., streams, lakeshores, lowland forests with dense growth of shrubs and trees, etc.) and are attracted to moving objects during the day. Control methods for the tsetse flies have included the removal of breeding sources, the use of a variety of insecticides, and well as traps.

Trypanosoma cruzi

Trypanosoma cruzi was first discovered in 1909 in Brazil by the scientist Carlos Chagas, in the midgut of its insect vector the kissing bug (*Triatoma infestans*). It is known to infect man and a wide range of domestic and wild species, including dogs, cats and rodents.

Chagas disease (named after Dr. Chagas) or American Trypanosomiasis is caused by *Trypanosoma cruzi* and is mostly prevalent in Brazil, Argentina, Uruguay, Chile, Venezuela, Central America and the Caribbean and afflicts approximately 15–20 million people. It is a disease primarily affecting low-income people living in rural areas. Chagas disease is also the leading cause of cardiac failure for men age 20–40 years in Brazil due to population and workforce movements into area infested with the insect vector. Houses built of adobe, mud, or thatch with cracks in the walls provides a suitable habitat and breeding habitat for the insect vectors.

Transmission of the trypanosomes depends on the presence of the parasite, vectors, reservoirs, and the host being present in the same location. Important reservoir animals in the United States are raccoons, opossums and armadillos. Also, in addition to animal reservoirs, insect vectors (*Triatoma infestans*, *Panstrongylus megistus*, *Rhodnius prolixus*) belonging to the family Reduviidae may also transmit the parasite. These bugs tend to inhabit cool, dark and damp areas, which makes underdeveloped communities with dilapidated, inadequate or simply unsanitary housing especially at risk for the infection.

Transmission of the parasite occurs when reduviids or kissing bugs that live in the cracks and crevices of substandard housing ingest the parasite in the blood from infected humans or animals. The protozoan *Trypanosoma cruzi* multiplies in the digestive tract of the insect and is eliminated in the feces on a person's skin, usually while the individual is sleeping at night. The individual often rubs the contaminated feces into a bite wound, an open cut, the conjunctiva or other mucous membranes. In addition, transmission through blood transfusion and the placenta have been reported. Animals may also become infected with the protozoa via similar methods, or by actually eating infected bugs. Transmission does not occur through the bite of the insect vector.

Some individuals may be infected and not show any symptoms of the disease until many years after infection (chronic form). The most recognized symptom of acute Chagas disease (especially in children) is the Romana's sign, or the swelling of the eye on one side of the face. Other symptoms may include fever, fatigue, enlarged liver and spleen and swollen lymph nodes, followed by convulsions and cardiac involvement. In infants and very young children with acute Chagas disease, cardiac arrest and death may result.

Beside the Romana's sign, and because many individuals do not show symptoms of the disease, xenodiagnosis (process whereby a small sample is injected into the body of an animal and after a period of time, the animal is tested for the amastigote form) may be able to determine the presence of the protozoan. Another form of laboratory diagnosis involves the culture of tissue aspirates especially from the lymph nodes on culture plates (N.N.N. culture plates).

No vaccination or drug is both safe and effective in the prevention and treatment of Chagas disease. Some drugs (anti-inflammatory doses of glucocorticoids and other supportive measures) may help to alleviate the symptoms associated with Chagas disease.

The usual method of insect control is the application of residual insecticides to the interior surfaces and roofs of the houses. In rural areas where the bugs may live and breed in substandard housing, plastering the walls to cover up cracks and crevices, or replacing homes with bricks and cement blocks can significantly contribute to the elimination of the insects inside of the home. The use of bed nets while sleeping has also shown to be effective in preventing bites from the bug. Outside, removal of the breeding sites of animals where the insects are found may also help to reduce the population of the insect vector, thereby reducing possible contact with the human host.

Trypanosomes in Animals

Some trypanosome species have been reported from wild and domesticated animals. These trypanosomes may be transmitted biologically or mechanically by various biting insects. *Glossina* or tsetse fly have been shown to transmit *Trypanosoma rhodesiense*, *T. gambiense*, *T. brucei*, *T. congolense*, *T. vivax*, *T. evansi* and *T. suis*. While insects such as tabanids have been shown to mechanically transmit *T. evansi* in animals, *T. equiperdum* in horses and camels is transmitted by direct blood contact during copulation. Some other trypanosomes, such as *T. thelieri* and *T. cervi*, are found in animals in the United States, but these species of the parasite are not pathogenic.

Of the various diseases associated with trypanosomes in which wild and domesticated animals are involved, *T. brucei* produces a disease called nagana which infects a wide range of animals, especially cattle. This trypanosome normally produces chronic infections in animals and may also produce different clinical signs. A severe acute case may be seen in horses, donkeys, dogs, goats and camels. In cattle, a chronic but sometimes fatal form of infection exists when the animals are infected by *T. brucei*.

When livestock are infected with *T. brucei*, they are mass-treated with drugs such as ethidium, isomethamidium or berenil. These drugs are effective, both for treatment and for prophylaxis, but may also be mutagenic. Slaughtered cattle fed these drugs may only be used for human consumption several months after drug treatment in order to avoid any residual effect of the drugs.

Recent Findings and Issues Associated with the Trypanosomes

Despite some progress with the trypanosomes, resurgence of the parasite remains a concern. During the nineteenth and twentieth centuries, trypanosomiasis was among the vector-borne diseases that prevented the development of large areas in the tropics, especially Africa. Fortunately, by 1910, it was shown that trypanosomes require blood sucking insect vectors, and over the next 50 years prevention and control programs were applied to curb the vectors. These programs placed emphasis on the elimination of the vector breeding sites, environmental hygiene and the limited use of chemical insecticides. However, the success of curbing the vectors was short lived, because by 1970 a reemergence of the vectors was seen and later intensified, over the next 20 years. Trypanosomes now infect over two million people each year.

Several factors have been implicated for the increase and reemergence of trypanosome related diseases. These factors include the following:

Civil and Political Unrest

Many of the affected African countries are currently experiencing wars, leading to the disruption of the available forms of controlling both the spread of the vector, and the parasite. War has also aided in the disruption of the ecosystem, and the displacement of the vectors from their native breeding grounds. In addition, many of the citizens of the affected countries have also been displaced, and are affected by the ongoing poverty.

Competing National Health Priorities

Currently, most of the available local resources are being put into research involving the prevention and cure of AIDS and malaria. Due to the efforts to solve the problems related to these diseases, funding for trypanosomiasis is limited.

Lack of Funding Support to Aid in the Availability of New Drugs, Vector Control and Diagnostic Tests

There has been very limited funding to support new drugs, vector control, and diagnostic tests. Due to the high level of poverty in most of the affected countries, most individuals cannot afford to buy the drugs to treat their illnesses. It is estimated that less than 10% of the infected individual are treated. Furthermore, there are no vaccines to protect the uninfected population from the parasite, because the parasite is able to mutate in order to evade the immune system.

Recently, several organizations including the World Health organization, the World Bank and some pharmaceutical companies have decided to look into the problem of the reemergence of trypanosomiasis. They have decided to employ the following methods to control the disease: increase research on vaccines, provide environmentally safe insecticides, educate the masses on the parasite and how to deal with it, and increase the availability of drugs to the infected areas so that people can afford them. Only by these concerted efforts will we be able to have a significant affect on trypanosomiasis.

Tsetse flies (*Glossina* spp.), pronounced "set-see" or "tet-see," are found only in Africa where they range discontinuously from coast to coast, limited primarily by environmental and ecological factors. They infest 37 countries and about 10 million km^2 of sub-Saharan Africa. Their negative impact on the potential for economic development is immense, and they often have been blamed for the widespread poverty that exists in tropical and sub-tropical Africa.

Tsetse flies have a significant impact on human activities because they are obligatory blood feeders (Fig. 111) and they transmit blood parasites of the genus *Trypanosoma*, which cause sleeping sickness. When untreated or treated too late, sleeping sickness is a fatal disease. Because many tsetse species feed on humans and domestic animals, as well as on the wild animals that serve as immune reservoirs of the parasites, the potential for transmission can be very high. The incidence in fly populations of trypanosomes that cause animal trypanosomosis (trypanosomiasis), for example, often exceeds 20% and sometimes is as high as 90%.

Animal Sleeping Sickness

The major impact of animal sleeping sickness, nagana, is to preclude maintenance of domestic animals. Thus, this disease has restricted cattle

Tsetse Flies, *Glossina* spp. (Diptera: Glossinidae), Figure 111 Adult tsetse fly, *Glossina morsitans*, engorged with blood. (Photo by D.F. Lovemore.)

production in the tsetse-infested areas to less than 15% of the carrying capacity of the land. Without draught animals, inhabitants have been limited to subsistence level farming because it is necessary to till the land by hand. Without cattle and other domestic animals, severe protein deficiency is widespread. The estimated annual cost and losses in potential animal and crop production is $4 billion.

Preventive or curative drugs for control of nagana in livestock are only partially effective and often uneconomical due to the development of resistance. Trypanotolerant livestock, such as the N' Dama cattle in western Africa, have provided partial relief, but under heavy fly challenge these small cattle also succumb to the parasite. Immunization against trypanosomes has not as yet been successful due to the antigenic plasticity of the parasites. Thus, the primary means of preventing transmission is by elimination of contact between vectors and hosts by control of the vectors. Tsetse flies are the only significant vectors of trypanosomosis, although some limited mechanical transmission results from the feeding activities of other biting flies (*Stomoxys, Tabanus,* etc.).

Human Sleeping Sickness

Human sleeping sickness, transmitted by tsetse flies from man to man in western and central Africa (*Trypanosoma gambiense*) and from animal reservoirs to man in eastern and southern Africa (*Trypanosoma rhodesiense*), has a lower incidence than animal trypanosomiasis. This is because of the relatively fewer encounters between flies and humans than between flies and livestock, and also because of the much lower rate of *T. gambiense* and *T. rhodesiense* infections in fly populations. In 1999, over 45,000 new human cases were reported, but due to incomplete reporting it is estimated that the actual human incidence was probably closer to 300,000–500,000. Historically, millions have been killed by trypanosomosis. Curative drugs are harsh, but can be effective with early diagnosis. Neurological disorders are common following recovery from infection. Due to civil unrest and disruption, combined with reduced control effort in many infested regions, the 60 million individuals estimated to be at risk of infection are subject to increased likelihood of severe disease outbreaks.

Tsetse Biology

Vector control is complicated by such a wide distribution of the flies, which usually are found in broad belts that are more or less continuous and often cross international boundaries. They can be difficult to detect in areas where the fly populations are advancing or at low density. Furthermore, there are over 20 distinct vector species, although not all are important vectors and often several species co-exist in the same areas (Table 16).

Members of the *morsitans* group, which inhabits savannah grasslands, and the palpalis group, which is generally found in lacustrine and riverine situations, are the primary vectors of both human and animal trypanosomosis. Because of ecological requirements, the palpalis group is generally restricted to areas near the dense vegetative cover found in aquatic situations, whereas species of the *morsitans* group have a wider range of ecological niches and are more widely dispersed.

All species are larviparous, not laying eggs but producing living young that have been nurtured in the uterus of the female fly for several days. They deposit only one offspring at a time and, even though the adults occasionally survive for as long as 90–100 days in nature, their biotic potential is quite low compared to that of other dipteran species (Fig. 112). The larvae usually burrow into the soil or other suitable substrate, where they pupate and develop for 3–4 weeks or more before emerging as adults. Thus, at any given time a significant portion of the fly population is underground, a fact that plays an important role in control strategy.

The adults move about in a diurnal pattern, governed to a great extent by temperature. For example, in the summer in southern Africa, *G. m. morsitans* feeds in the mornings when the temperature is moderate, seeks shelter during midday when the temperature is high and the insect exhibits negative phototaxis, and resumes feeding as the temperature declines in the latter part of the day. At night the flies rest. Nutritional requirements cause the flies to seek blood meals about every third day, and the males also actively visit host animals in search of mates feeding there. In this process, the sexually appetitive males move about several times daily, often resting on host animals grazing or traversing the bush. In the course of these activities, the flies alight on numerous resting sites in their preferred habitat. The preferred resting sites vary somewhat for the different species.

Tsetse Behavior and Ecology in Relation to Control

The association of tsetse flies with particular vegetation types has played a major role in determining control practices. Riverine species of the palpalis group are generally found within a short distance of their breeding sites, in or close to the riverine vegetation canopy that provides protection from sunlight, high temperature, and lower humidity of the surrounding, more open

Tsetse Flies, *Glossina* spp. (Diptera: Glossinidae), Figure 112 Adult female tsetse fly depositing fully developed larva.

vegetation. This habitat affords the fly an environment replete with a variety of hosts, and incidentally provides direct contact with humans and domestic animals when they come to the water. Partial or complete removal of the riverine vegetation results in the reduction or elimination of these tsetse flies. However, in more humid areas, species of the *palpalis* group may be found well away from surface water. *Glossina tachinoides*, for example, has been observed to breed in peridomestic habitats, where bush encroachments around villages have allowed flies to find suitable resting and larviposition sites well away from the typical riverine situation. Similar observations with species of the morsitans group have revealed their preferences for selected resting sites and their dependence upon certain characteristics of the habitat for survival. Ruthless removal or discriminative clearing of selected portions of the habitat results in major reductions of fly density because the flies cannot then find suitable protective cover when environmental stresses are maximal.

Similarly, feeding behavior characteristics of the tsetse fly have provided a means for reducing population density with a corresponding reduction in the risk of trypanosomosis. Most tsetse species feed on a variety of animals but prefer certain hosts, sometimes riverine. For example, in Zimbabwe, *G. m. morsitans* feeds on numerous hosts, but prefers bushpig, warthog, bushbuck, and kudu. Thus, by selective reduction of these four species, the fly density could be reduced along with the incidence of trypanosomosis.

However, for economic, environmental and aesthetic reasons, game reduction and wide-scale bush clearing are no longer acceptable control measures.

Awareness of specific tsetse resting niches spurred the development of selective application methods for the organic insecticides that first became readily available in the 1940s. Because most species have well defined resting site preferences, such as the lower boles of trees of certain diameters, application of persistent insecticides to these sites provided excellent control without resort to broadspread applications. Furthermore, since the flies have a long life span, during which the majority probably move less than 1,000 m from their origin, not all resting sites needed to be sprayed to achieve a high level of control. Flies below ground in the pupal stage eventually emerge and sooner or later come to rest on a treated surface. Treatment of 10–20% of the preferred resting sites in some tsetse habitats was sufficient to eliminate or substantially reduce the fly population when the toxicant persisted for several months.

Approaches to Fly Management

Glossina spp. are extremely susceptible to insecticides. Aerial applications of very low rates of nonpersistent aerosols repeated at 2–3 week intervals have been used to initially control the ambient fly population and then the flies that have recently (0–15 days) emerged, thereby precluding reproduction and eliminating the fly population after six or seven spray cycles. Alternatively, selectively placed helicopter applications of persistent insecticides have been used with dramatic results. These applications were discriminative in that they included only those habitats that offer refuge for the fly in the dry season, when tsetse fly distribution typically is more restricted. Most of the application was deposited on the leaves of the upper canopy, where tsetse rest at night. These residual types of application were particularly effective in areas with discrete wet and dry seasons.

But the broadspread application of pesticides has given way to the use of attractants and trapping to expose the flies to spot treatments of pesticides. Both visual and olfactory components are involved in tsetse host-seeking behavior. In the 1970s, animal emanations attractive to tsetse flies were found to be highly effective for trapping several species of tsetse, especially when combined with suitable visual attractants. By utilizing a persistent insecticide in conjunction with attractant devices, significant population reductions can be achieved in a matter of months. Such trapping provides a relatively inexpensive method of control, and because the pesticide is incorporated into the attracting device the probability of environmental contamination is low.

However, the attractant approach does not guarantee elimination of the vector, and thus the disease, even though fly population density in most situations can be reduced to well below the threshold level necessary to maintain regular transmission. Extensive study and operational level trials of the sterile insect technique have demonstrated the feasibility of this approach for area-wide elimination of tsetse where geographically isolated fly populations already have been reduced to low density. Used to eliminate *Glossina austeni* from the main island in Zanzibar, the inhibition of natural reproduction with sterile fly releases after reducing fly density by trapping is an environmentally friendly method of control that has potential application for most of Africa.

Tube-Making Caddisflies

Members of the families Polycentropodidae and Psychomyiidae (order Trichoptera).

► Caddisflies

Tubercle

A small raised area or extension of the integument. In caterpillars, a hair often originates from these raised areas.

Tube Moths (Lepidoptera: Acrolophidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tube moths, family Acrolophidae, total 270 species in the New world, mostly in the large genus

Acrolophus; actual fauna likely exceeds 350 species. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Two subfamilies are used: Amydriinae and Acrolophinae (formerly included in Tineidae). Adults small to medium size (9–60 mm wingspan), with rather robust bodies and roughened head scaling and usually large recurved labial palpi; haustellum naked (unscaled); maxillary palpi minute, 2-segmented. Maculation is mostly somber hues of brown or black, sometimes with some spotting and other markings. Adults are mostly nocturnal, but some may be crepuscular. Larvae are root feeders, mostly of grasses, and construct long silken tubes to feed on host-plant roots. A few are economic, mainly as turf grass pests (Fig. 113).

Tube Moths (lepidoptera: Acrolophidae), Figure 113 Example of tube moths (Acrolophidae), *Acrolophus plumifrontellus* (Clemens) from Florida, USA.

Turgor

The distension of living tissue, usually plant tissue, due to internal pressures (hydration).

Tullgren Funnel

An extraction devise used to separate and extract small arthropods from leaf litter or similar material. A Tullgren funnel normally consists of a funnel with a wire mesh insert that supports the plant material above a reservoir containing alcohol or another preservative. An incandescent light bulb is suspended above the funnel to provide a source of heat and drying, encouraging the movement of the arthropods. As the arthropods move about, particularly as they move deeper into the funnel to escape drying of the plant material, they slip down the funnel into the reservoir containing liquid, where they are retained for identification. This technique is useful for many arthropods, but not for those that may fly to escape, or those that are very fragile and perish from desiccation before they can escape the plant material. A cover is often provided to eliminate escape by insects capable of flight, and to more efficiently direct the heat generated by the light bulb. A Tullgren funnel is a modified Berlese funnel, with the difference being the light bulb, but the distinction is not usually appreciated and most Tullgren funnels are called Berlese funnels.

Tularemia

Also known as rabbit fever, this is a serious infectious disease caused by the bacterium *Francisella* *tularensis*. The disease is endemic in North America, and parts of Europe and Asia. The primary vectors are ticks and deer flies, but occasionally the disease can also be spread through other arthropods. Animals such as rabbits and muskrats serve as reservoir hosts. The disease is named after Tulare County, California, where in 1911 the disease was studied in squirrel and human populations.

Turfgrass Insects of the United States: Biology and Management

R. Chris Williamson[1], Rick Brandenburg[2]
Sarah Thompson[2]
[1]University of Wisconsin, Madison, WI, USA
[2]North Carolina State University, Raleigh, NC, USA

Turfgrasses are grown throughout the United States, covering over 30 million acres (12.2 million hectares). As urban environments have grown, the use of turfgrass in the U.S. has increased over the past several decades. Subsequently, large areas of land have been developed with dense, dark green, uniform turf providing numerous practical, recreational, and ornamental uses. Uses for turfgrass include dense turf for soil stabilization and erosion prevention; runways for rural airports; cemeteries; parks and recreational facilities for relaxation, picnics and general family activities; sports facilities and complexes including baseball, cricket, football, lawn bowling, polo, soccer, tennis and, especially, golf courses. Turfgrasses often are considered the most intensively managed plantings in urban landscapes. It is estimated that $45 billion is spent per year in the U.S. for turfgrass culture in its many forms.

Turfgrass can be designated as either cool-season or warm-season grasses depending on their climatic adaptations. These two categorical designations can be further divided into four distinct turfgrass adaptation zones in the U.S. including (i) cool, humid; (ii) cool, arid or semi-arid; (iii) warm, humid; and (iv) warm, arid or semiarid. Despite these partitioned zones, there is considerable overlap of the species of turfgrass grown in various regions of the U.S. As a result, it is rather difficult to effectively provide an accurate description for the boundaries of specific insect pests and nearly impossible to give a comprehensive classification for all turfgrass pests including disease pathogens, insects and weeds.

Some insect pests are host specific, feeding only on certain turfgrass species or types, while others are non-discriminate, infesting a diversity of grass and broadleaf plant materials. An insect pest such as the European chafer typically only infests cool-season areas, whereas mole crickets and fire ants infest warm-season turfgrasses. Preference of an insect pest can be either for a host (e.g., turf-type or species) or it may be a reflection of the geographic range of the pest. Destructive turfgrass insects can be divided into three primary groups according to the habitat in which the destructive life stage spends its life in the turfgrass ecosystem. They include (i) leaf and stem, (ii) thatch, and (iii) root zone/soil. This method of grouping is highly valuable because specific control tactics or strategies implemented for each group have a direct bearing on the effectiveness or satisfaction of control for the respective insect pest. Some insects are capable of occupying more than one habitat during its development, and may even occupy all three habitats during its various life stages. Thus, a modified designation of turf habitats has been suggested including (i) foliage and stem, (ii) crown and thatch, and (iii) soil.

Effective control of any pest (plant pathogen, insect or weed) can be accomplished successfully only with a comprehensive understanding of both the host and the pest. Factors such as growth habits and cultural requirements of the host (turfgrass) must be understood. Knowledge of the biology, behavior, ecology, life history for the host and pest are critical for making decisions. Symptomology or type of damage caused by the pest(s), accurate identification of the pest, information regarding the time of year, growth stage of the host and the pest, and environmental conditions under which pest damage is most likely to occur are all important factors that also should be understood. This information is the foundation for the Integrated Pest Management (IPM) philosophy. IPM is a commonsense approach to pest management that is effective and environmentally responsible. IPM relies on a combination of preventative and corrective measures to keep pest densities below levels that would cause unacceptable damage. IPM includes sampling and monitoring, accurate pest identification, decision-making, appropriate intervention, follow-up, and detailed record keeping. In terms of the appropriate intervention tactic, several control options are available including biological, chemical, cultural, and plant resistance. IPM is a decision-making process that does not preclude the use of pesticides, however, it does not rely upon chemical control as its first line of defense. The ultimate goal of IPM is to manage pests effectively, economically, and with minimal risks to people and the environment. For this reason, turfgrass managers must constantly be aware of potential pest problems that they may experience. The listing that follows provides vital information for the major insect and mite pests affecting turfgrass in the US (Figs. 114 and 115).

Foliar and Stem Inhabitants: Surface Chewing and Sucking Insects

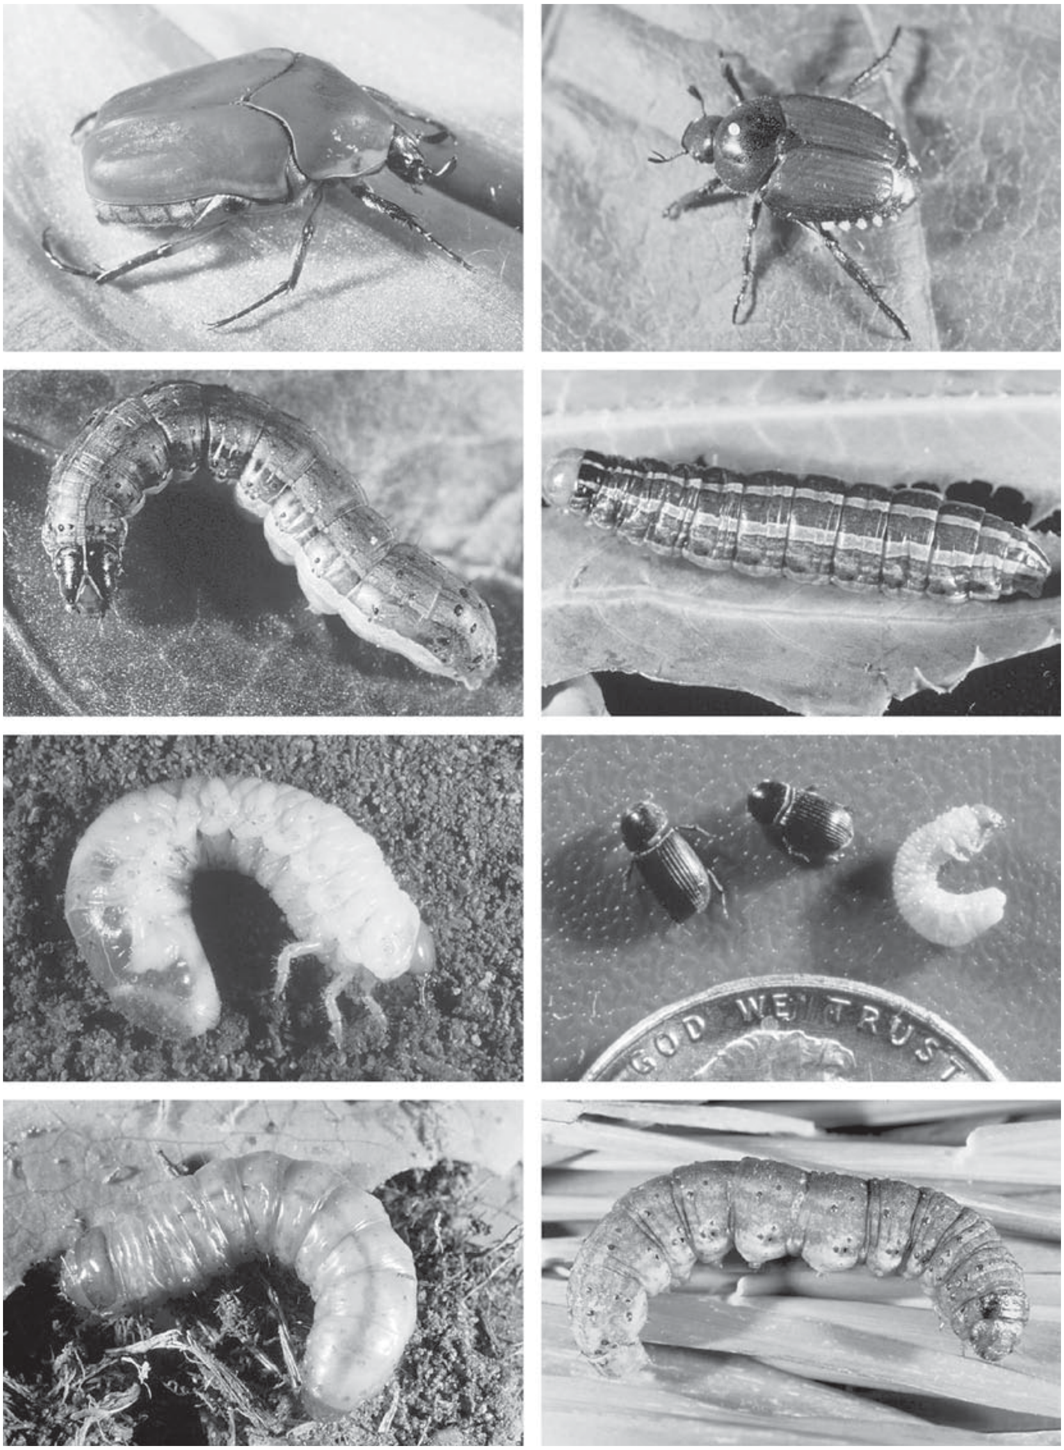
Armyworms (Lepidoptera: Noctuidae)

Armyworms get their name because of their gregarious nature of crawling in large numbers from one field or feeding site to another after they have exhausted their food supply. Although these pests are often sporadic, they do have the potential for outbreaks. Most armyworm larvae are thick-bodied, hairless, striped caterpillars that chew on the foliage of turfgrass. There is one armyworm species that frequently attacks turfgrasses in both the northern and southern United States, the “common” or “true” armyworm.

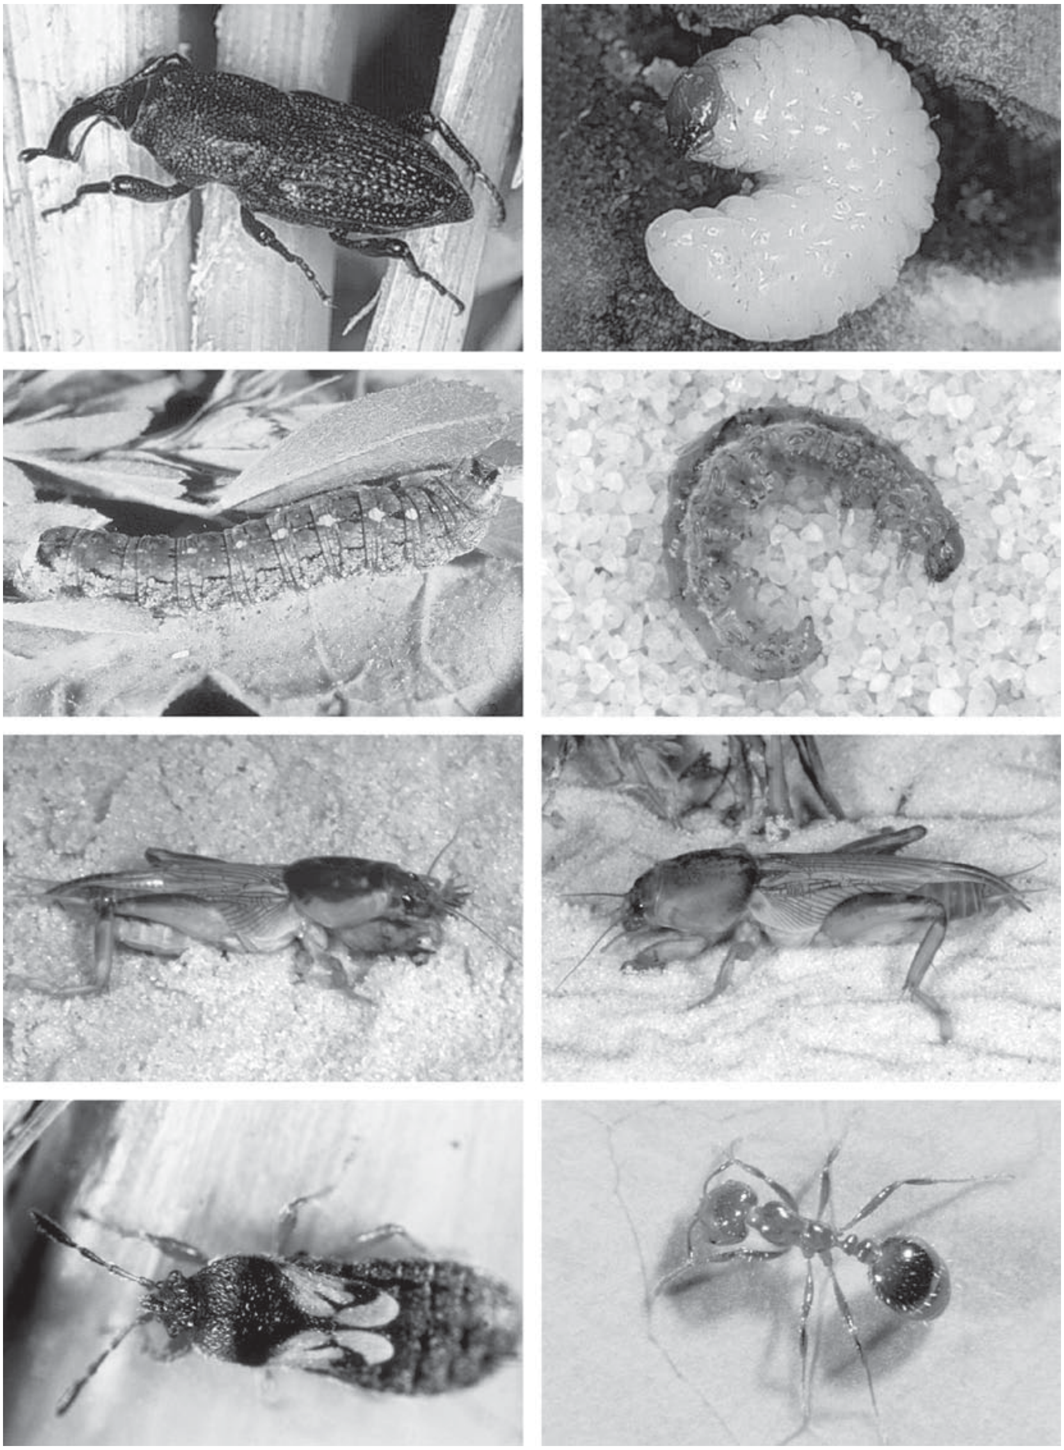
Armyworm, *Pseudaletia unipuncta* (Hawthorn)

Frequently referred to as the “common” or “true” armyworm in order to differentiate it from other armyworm species, the armyworm is a native species that is distributed throughout the United States and southern Canada east of the Rockies.

Armyworm adults are evenly pale-brown to grayish-brown moths with a wingspan of approximately 38–40 mm. The distinct white spot in the center of their front wings readily identifies them. The hind wing is dirty white. The female adult moths lay pearly white eggs, 0.5 mm diameter, in masses containing 20 to several hundreds of eggs. Young larvae, more than 2 mm long, are pale green. Mature larvae range from 35 to 50 mm in length, grayish to greenish-brown, with two pale-orange stripes along each side of the body and another pale-colored, broken stripe down the middle of the back. The head capsule is honeycombed with dark lines. Pupae are reddish-brown, about 16–19 mm long and shaped like a football.



Turfgrass Insects of the United States: Biology and Management, Figure 114 **Some important turfgrass pests: *top left*, green June beetle; *top right*, Japanese beetle; *second row left*, fall armyworm; *second row right*, bronzed cutworm; *third row left*, a June beetle larva (white grub); *third row right*, black turfgrass ataenius adults and larva; *bottom row left*, glassy cutworm; *bottom row right*, black cutworm.**



Turfgrass Insects of the United States: Biology and Management, Figure 115 **Additional important turfgrass pests: *top row left*, billbug adult; *top row right*, billbug larva; *second row left*, variegated cutworm; *second row right*, tropical sod webworm; *third row left*, tawny mole cricket adult; *third row right*, southern mole cricket adult; *bottom row left*, immature chinch bug; *bottom row right*, red imported fire ant.**

Armyworm caterpillars feed on a wide range of grasses. They especially like barley, corn, millet, oats, rice, rye and wheat. When such food supplies are depleted, they will attack nearby turfgrass. Young larvae initially feed on tender foliage resulting in a skeletonized appearance. Third instar and older larvae are primarily nocturnal and consume all or part of the leaf.

Armyworms overwinter as partially grown larvae or pupae in the southern half of the U.S. and possibly as partially grown larvae in the northern half. Infestation in the North may also be the result of spring migration flights of adults. In the temperate United States, there are typically two generations (broods) per year. The number of annual broods depends primarily on latitude. The first generation is a result of annual moth migration in the spring (i.e., late April through May). Once the eggs are laid, they typically hatch in as few as 3 days. Larvae usually go through six instars over a period ranging from 20 to 48 days. Pupation occurs in the soil and the duration of the pupal stage averages 15 days. Adult armyworm moths are nocturnal, with most flight activity occurring within 2 hours after sunset. A second generation occurs during June and July. In the southern regions, four to five generations may occur. Infestations in turfgrass are often most severe following drought conditions. Populations have a tendency to fluctuate widely from generation to generation and year to year.

Fall Armyworm, *Spodoptera frugiperda* (J. E. Smith)

The fall armyworm is found throughout much of the South and is a frequent problem in turfgrass, especially in the Southeast westward into Texas, New Mexico, Arizona and southern California. It does not overwinter outside of Florida and the immediate Gulf Coast area, and must disperse to reinfest areas each year. Populations usually do not reach the more northern areas until very late summer or fall.

Fall armyworm moths have a wingspan of about 38 mm and the forewings are generally a dark gray and mottled in appearance. There is a white spot near the tip of the forewing and a light diagonal mark in the middle of each wing. The back wings are white. The eggs are laid in clusters of 50–100 and are initially greenish white, but soon turn dark. The egg clusters often look gray and fuzzy from the scales of the female's wings. The caterpillars are green to brown, to almost black. The head is marked by a typical inverted "Y" on the "face" or front. There is a longitudinal dark stripe that runs the length of the body and a fainter, pale mid-dorsal stripe. Each abdominal segment has four small black dots. The fully grown larvae are 35–50 mm long. The pupa is 13 mm long and is found in the soil. It is reddish-brown, somewhat football shaped, and becomes black prior to emergence of the moth.

Fall armyworms feed on a wide range of plants, but prefer grasses of all types. However, this pest is most commonly associated with bermudagrasses in the southern U.S. They can and do feed on both cool and warm season turfgrasses and are often most likely to attack lush, green, dense areas of turf. Fall armyworms are very common problems in areas that have recently been sodded or sprigged. The small larvae skeletonize the leaf blades while larger larvae may consume all above-ground plant parts. The turf also may turn brown and look dead from drought stress. The larvae often move from heavily damaged areas into new food sources. Warm season turf usually recovers from such feeding, but if it occurs late in the season, the turfgrass may be stressed going into the winter.

Fall armyworm moths are active at night and may be attracted to lights. They lay eggs on a wide range of objects, usually light-colored, that are adjacent to turf areas. These sites may include fence posts, metal buildings, flagpoles, the underside of leaves of various landscape plants, gutters, etc. Eggs hatch quickly in warm temperatures and the small larvae spin down on silken thread to the turf surface and begin feeding. Small caterpillars feed at any time of the day, but larger ones feed more at night to avoid predation by birds. The fall armyworms will feed for 2–3 weeks and then burrow into the soil to pupate. New moths emerge 2 weeks later and the cycle starts again. Multiple infestations can occur in the same location and population as high as 100 per square meter have been observed. The number of generations per year depends upon location and migration of the moths. Migration varies each year depending upon weather conditions, which are responsible for enhancing the migration of the moths. In the extreme South, four or more generations may occur and the damage from the larvae may begin in the spring. In locations further north, only one generation will occur and it may not be seen until August or September. Wet springs sometimes increase the likelihood of fall armyworm outbreaks.

Chinch Bugs (Hemiptera: Lygaeidae)

Chinch bugs damage turfgrass by sucking plant juices from stems (i.e., leaf sheaths) and crowns, causing gradual yellowing and eventual dead patches of turf. Damage occurs predominantly during hot, dry periods of time in mid- to late summer. Sunny areas are often most heavily infested. There are four chinch bug species that are important turfgrass pests in the United States (i) the hairy chinch bug, (ii) the common chinch bug, (iii) the "buffalograss" chinch bug, and (iv) the southern chinch bug.

Hairy Chinch Bug, *Blissus leucopterus hirtus* Montandon

The hairy chinch bug occurs across the eastern Canadian provinces and from the northeastern United States to the Middle Atlantic states south to Virginia and west to Minnesota.

Chinch bugs have gradual metamorphosis, thus the immature (nymph) life stage is similar in physical appearance and feeding habits to the adult, however, there is variation in size, color and wing development. There are five nymphal stages; the first instar nymphs are tiny, approximately 2.5 mm long, bright red with a white band across the abdomen. As the nymphs develop and mature, their color changes from bright red to orangish-brown and ultimately black once they reach the fifth instar. Hairy chinch bug adults are approximately 6.0–6.4 mm long and 1.0 mm wide, and females typically are slightly larger than males. Adults range in color from grayish-black to black and white and often are covered with fine hairs and the legs are typically a dark, burnt-orange tint. There is a triangular-shaped marking in the middle of the outer edge of each wing. Populations of hairy chinch bugs may consist of mostly long-winged (macropterous) or short-winged (brachypterous) individuals, or contain both wing forms. The long-winged chinch bugs have wings that extend to the tip of the abdomen, and short-winged chinch bugs have wings that extend only halfway to the tip. The adults lay eggs that are tiny, elongate, and bean-shaped; initially they are white, but become orange-red within a few days prior to hatching.

The hairy chinch bug is one of the most important insect pests of northern turfgrasses, especially home lawns. It prefers cool-season turfgrasses including creeping bentgrass, fine fescues, Kentucky bluegrass, and perennial ryegrass. However, hairy chinch bugs will feed also on zoysiagrass, a warm-season turfgrass species that occasionally occurs where cool-season turfgrasses dominate. Both the adults and nymphs cause damage to turfgrass plants by inserting their piercing-sucking mouthparts into stems and crowns, extracting plant juices while pumping toxic salivary fluids into the plant. Subsequently, turfgrass plants are damaged by the loss of plant fluids as well as the clogging of the conducting tissues within the stems. Generally, hairy chinch bug occurs sporadically in scattered aggregations rather than uniformly distributed across the turf. Damage typically occurs during hot, dry periods in mid- to late summer when turf is commonly experiencing drought stress symptomology. Additionally, hairy chinch bug prefers open, sunny areas of turf that have heavy thatch accumulation as well as high percentages of perennial ryegrass and fine-leaf fescue. Initial damage often appears as irregular patches of wilted, yellowish-brown turf that frequently is mistaken for drought stress. As populations grow, often reaching 200–300 bugs per 0.1 m^2, feeding damage intensifies and damaged patches of turf begin to coalesce into large areas of dead or dying turf that does not recover regardless of irrigation or rainfall.

Typically there are two generations per year in the temperate United States; however, in the most northern portion, as well as Canada, there is only one generation per year. The adults overwinter in the turfgrass thatch, leaf litter, and similar sites. They become active in the early spring as temperatures reach 10°C. Thereafter, the adults feed and mate for approximately 2 weeks before females begin laying eggs in mid-April to May. In areas where there is only one generation per year, egg-laying may be delayed by several weeks and occurs over an extended period. Females lay as many as 20 eggs per day for a period of about 2–3 weeks. Eggs typically are laid in leaf sheaths or in the thatch. Because insects are cold-blooded animals, they are dependent on temperature, thus the developmental rate of eggs and nymphs varies within species and geographic range. Eggs that are laid during April may require as long as a month to hatch, and eggs laid in midsummer may hatch in as few as 7–10 days. Where two generations occur, the first generation typically matures in 4–6 weeks, usually by mid-July. The second-generation adults then begin laying eggs from mid-July through late August. These eggs hatch soon thereafter, and the nymphs complete development by September or October. As cooler temperatures prevail, the adults seek out protected sites to overwinter. The most extensive damage to turf commonly occurs during periods of heat and drought stress, typically in late July and August when the first generation adults are actively feeding and laying eggs.

Common Chinch Bug, *Blissus leucopterus leucopterus* (Say)

The common chinch bug is an occasional pest of turf, especially in the Great Plains region. It feeds primarily on small grains and other field crops, however, sometimes it damages turfgrass, especially when located in close proximity to maturing small grain fields. Several turfgrass species that are likely to be attacked by the common chinch bug include creeping bentgrass, fescues, Kentucky bluegrass, perennial ryegrass, and zoysiagrass. This species closely resembles the hairy and the buffalograss chinch bugs both in appearance and damage.

Buffalograss Chinch Bug, *Blissus occiduus*

The buffalograss chinch bug was first identified in Nebraska feeding and causing damage on buffalograss. Upon its discovery, it was understood that the buffalograss chinch bug was limited to buffalograss as a host. However, it has recently been reported damaging zoysiagrass, and may have the potential also to feed on and damage several other turfgrasses and small grain crops. This species closely resembles other chinch bugs species in appearance and damage.

Southern Chinch Bug, *Blissus insularis* Barber

The southern chinch bug is a major pest throughout the range of its primary host, St. Augustinegrass.

Distribution is generally from the Carolinas down through all of Florida and west to Texas. They also can be found in California, Mexico and throughout the Caribbean. Like other chinch bugs, they damage the turfgrass by sucking out plant juices.

Southern chinch bugs are similar to other chinch bugs, but slightly smaller than the hairy chinch bug. The adults are about 1 mm wide and 3–3.5 mm long and are black with shiny white wings. Most characteristics are similar to other chinch bugs including the presence of long- and short-winged adults.

The southern chinch bug is one of the most important insect pests of home lawns in the deep South. Virtually all St. Augustinegrass will be infested with southern chinch bugs, but not necessarily at damaging population levels. Southern chinch bugs will feed also on bermudagrass, centipedegrass, bahiagrass, and zoysiagrass. As with the other species of chinch bugs, their feeding on stems, crowns, and stolons removes plant juices, but also injects a toxin. This causes the grass to turn yellow and often die. Populations often are aggregated and damage appears in patches. Drought or heat-stressed areas of lawns are areas that usually are attacked first and most severely.

There are probably two to three generations in the most northern areas of the southern chinch bug range. Further south in northern Florida and the Gulf Coast area, three to four generations are common. In south Florida, seven or more generations can occur. Overwintering in the most northern areas is primarily as adults while all stages are present in the more southern areas.

Cutworms (Lepidoptera*:* Noctuidae)

Cutworms are plump, smooth, dull-colored caterpillars that hide in the turf profile in burrows or aerification holes during the day, emerging at night to feed on the foliage and leaf sheaths of turfgrass plants.

Black Cutworm, *Agrotis ipsilon* (Hufnagel)

The black cutworm is considered the most destructive cutworm that attacks turfgrasses. It is a major pest of creeping bentgrass putting greens, tees, and occasionally fairways throughout the United States and worldwide. Black cutworm larval feeding damage typically results in small, irregular sunken patches or pockmarks that often are mistaken for golf ball marks. Subsequently, black cutworm damage reduces the smoothness and uniformity of the putting green surface. Because aesthetics and playability are high priorities for golf course superintendents, multiple insecticide applications are done each growing season to control this important turfgrass insect pest.

Adult black cutworm are robust, hairy (scaly) moths with a wingspan of approximately 35–45 mm. The forewings are dull-brown to grayish-black, and slightly lighter in color or pale toward the tip of the wings. A distinctive, black, dagger-shaped marking is located in the center of each forewing, approximately 6 mm from the tip. The hindwings are considerably lighter, uniformly cream to dirty white, with darker veins. Black cutworm adult moths typically hold their wings flat over the back in a triangular position when resting. Males can be differentiated easily from females by their comb or feather-like antennae, whereby female moth antennae are filiform or slender and thread-like.

Black cutworm females lay eggs predominantly singly near the tip of grass blades. Eggs are approximately 0.5 mm in diameter. They are cream colored initially, later becoming darker as the embryo develops. Larvae are hairless with the exception of a few scattered bristles. The dorsal side, above the spiracles, ranges in color from gray to black, and the ventral side is typically lighter gray. Spiracles are typically black and extend from the prothorax to the terminal abdominal segment. As a whole, the body of a black cutworm larva is without distinct stripes or marking except for an indistinct, pale stripe down the middle of the dorsal side. Under magnification, the cuticle (skin) has a pebble-like surface, and is generally greasy in appearance. Like many other caterpillars, there are three pairs of true legs on the thorax and five pairs of fleshy prolegs on the abdomen. Neonate larvae, less than 24 h old, are approximately 3.5 mm long whereas mature larvae range from 30 to 45 mm long and are approximately 7 mm wide. Black cutworm larvae typically have six instars, however, they sometimes have seven. Upon maturity, black cutworm larvae pupate in the turf profile predominantly in the soil, and occasionally in the thatch associated with the turf. Pupae are reddish-brown to dark brown in color and are about 19 mm long.

The black cutworm is distributed throughout most of North America, as well as in Europe, Asia, Africa and elsewhere. Depending on geographic location, latitude and temperature, there can be two to six generations per year. In the southern U.S., in states such as Louisiana and Alabama, there are five to six overlapping generations, whereas in the northern U.S., in states such as Minnesota and Wisconsin, there may be only one or two generations per year. The black cutworm has difficulty surviving subfreezing soil temperatures, thus, it may be unable to overwinter in some years north of the transition zone (a narrow range between the cool-season temperate region and warm-season zone, extending from southern Illinois, Missouri and Ohio to Tennessee and North Carolina). As a result, spring infestations in northern areas begin with the arrival of migratory adults from southern states. Black cutworm moths can be carried several hundred miles in a few days by strong southerly winds. In Wisconsin, the first spring migrants typically arrive in late April to early May; damage from their offspring begins appearing in early to mid-June. Damage from the second generation (brood) starts appearing late July through early August. Occasionally a third generation will appear in late summer or early fall if temperatures are conducive, otherwise it is understood that third generation adults will migrate south as temperatures are less favorable. Multiple larval sizes (instars) may be present at a given time because black cutworm populations tend to spread out their emergence and egg-laying as the season progresses. In addition, the first generation appearance of black cutworm in states located in the northernmost temperate U.S. may have a later arrival of migrating adults than states in the southernmost location of the temperate U.S. In the southernmost states (e.g., Alabama, Louisiana, Mississippi and Georgia), first generation larvae may be present as early as February and March and cutworm problems may persist into November and December. In North Carolina, adults have been captured in pheromone traps every month of the year except January. Turfgrass in Florida and Gulf Coast areas may experience problems with cutworms all year. Areas with warm season turfgrass that are closer to the transition zone may experience cutworms as early as March and April through late October.

Both black cutworm moths and larvae are nocturnal. Adults do not cause any turf damage, however, they do feed by sucking nectar from flowers. Soon after emergence, adult females call (attract) males by releasing a sex pheromone (chemical sex attractant). Once fertilized, female moths begin laying eggs. Individual females can lay as many as 1,200–1,600 eggs over a 5- to 10-day period. Eggs are predominantly attached to the tips of grass blades singly. Eggs typically hatch in 3–6 days depending on temperature. Once hatched, the young larvae (first and second instars) begin feeding on leaf blades, both day and night. Young larvae feed on both the top and bottom sides of the of leaf blades in a skeletonizing manner. As larvae develop and mature, older larvae (third to sixth instars), they become nocturnal (feeding only during the scotophase) as well as developing a subterranean habit, forming silk-lined burrows in the turf thatch or soil. On golf course turf, the larvae will commonly occupy aerification holes, spike marks, or golf ball injury sites. Black cutworm larvae hide in the aforementioned burrows during the daylight, and venture out to feed at night. The larvae typically pass through six molts, maturing in 20–40 days. Young larvae do not cause measurable damage, however, large larvae are highly destructive, consuming relatively large amounts of turfgrass foliage in a single night. Once black cutworm larvae reach maturity, pupation occurs within the larval burrow or the turfgrass profile. After approximately 14–21 days, the adult moth emerges.

Most black cutworm larvae feeding occurs from around midnight until just before dawn. On golf course putting greens, wandering larvae can move approximately 20 m or more in a single night. This ability to move helps explain why golf course putting greens and tees are sometimes reinfested soon after being treated with a short-residual insecticide. It is likely that black cutworm larvae are moving onto putting greens from the surrounding area.

Bronzed Cutworm, *Nephelodes mimians* Guenée

The bronzed cutworm is only an occasional pest of home lawns and golf course turf, and unlike the black cutworm, they rarely damage golf course putting greens and tees. Bronzed cutworm is distributed across the northern half of the U.S. east of the Rocky Mountains, as far south as Tennessee.

Adult bronzed cutworms are similar in size to black cutworm, however, they lack the black dagger-shaped mark on the wings. The forewings are highly variable in color ranging from brown to purplish-gray to maroon, and there is a wide, darker-brown band across the middle of each forewing. The hindwings are buff-colored similar to the black cutworm. Bronzed cutworm eggs resemble black cutworm eggs. Larvae are fat-bodied, light to dark brown dorsally and lighter ventrally, and they have a distinctive bronze sheen. Larvae also have a light-yellow stripe that extends longitudinally the entire length of the body on the center of the dorsal side, with another pale longitudinal stripe on each side of the body. Spiracles are black and are located on each thoracic and abdominal segment. Fully developed, mature larvae are 35–45 mm long. Bronzed cutworm and black cutworm pupae look similar in color and size.

Although the bronzed cutworm has been well studied in field crops, little is understood about its biology in turf. Unlike most turf-infesting cutworm species, the bronzed cutworm has only one generation per year. Adult moths emerge, mate, and lay eggs in late summer or early fall. The eggs, however, do not hatch until the following spring. After eggs hatch in April, larvae begin feeding and developing until fully developed in mid- to late May, when most damage occurs. As bronzed cutworm larvae reach maturity, they burrow into the soil and form pupal cells where they remain until pupation in mid-August. Thereafter, new adult moths emerge in approximately 30 days.

Variegated Cutworm, *Peridroma saucia* (Hübner)

The variegated cutworm is an occasional pest in lawns and golf course roughs, especially in rural areas where turfgrass areas are bordered by field crops where infestations may originate. It occurs throughout both North and South America.

Variegated cutworm moths have yellowish to brownish forewings that frequently have a row of small black dashes on the leading edge of the wing. Similar to the bronzed cutworm, they lack the black dagger-shaped marking present on black cutworm moths. Variegated cutworm moth hindwings are whitish, with dark-shaded veins. Variegated cutworm eggs are similar in size and color to black cutworm eggs. However, variegated cutworm eggs are laid in groups of several hundred eggs in a single layer on foliage. Mature larvae are approximately 35–46 mm long and vary in color from pale gray to dark brownish-gray. A row of pale yellow dots and dashes extend longitudinally on the dorsal side of the body, and a distinct brownish W-shaped marking is apparent on the eighth abdominal segment, as well as a yellowish or orange area near the terminal abdominal segment. The larvae also have a rather indistinct, black, yellowish or orange marking that extends longitudinally on both sides. Pupae are similar to both bronzed and black cutworm.

The variegated cutworm has from three to six generations per year depending on geographic location. Adult moths emerge from overwintered pupae in March and April. Larvae from eggs deposited by the first generation moths are typically fully developed by late May. The subsequent generations occur from June to November, with the last generation producing overwintering pupae. A complete generation, egg to adult, typically requires 8–9 weeks. Compared to other cutworm species, the variegated cutworm is less subterranean and nocturnal, thus is sometimes feeds fully exposed during daylight, especially on cloudy days.

Sod Webworms

There are more than 20 species of sod webworms that feed on turfgrasses in North America, however, only about three or four species are pests in specific geographical regions. Among the more common sod webworm species that attack turfgrasses in the northern U.S. are the bluegrass webworm, *Parapediasia teterrella* (Zincken); the larger sod webworm, *Pediasia trisecta* (Walker); and the western lawn moth, *Tehama bonifatella* (Hulst). All of the aforementioned sod webworms species at one time were grouped together in the genus *Crambus*. Because their biology is similar, they can be discussed together. The tropical sod webworm, *Hertopetogramma phaeopteralis* (Guenée), has a wide distribution only in the southeastern U.S. and will be discussed separately.

In general, sod webworms are relatively small larvae that live in silk-lined tunnels in the turf canopy, specifically in the thatch and soil, hence the name "webworms."

Adult sod webworms are small, buff-colored moths that have wingspans that range in size from 19 to 25 mm. The forewings are primarily whitish, dull gray to tan, with longitudinal stripes as well as other indistinct markings of brown, black, gold, silver, and even yellow. Such markings are used to identify individual species. Hindwings are typically lighter, whitish to light-gray, with delicate fringes on the outer margins of the wing. When resting, the wings are usually folded over the body. Possibly the most distinguishing characteristic of sod webworm moths is the presence of two small, snout-like projections that extend forward from the front of the head. These snout-like projections are merely mouthparts, but are the reason why sod webworm moths are frequently referred to as "snout moths." Moreover, the combination of folded wings and the snout enable sod webworm adults to be distinguished from other turfgrass moths. Sod webworm eggs are extremely tiny, oval to barrel-shaped, with fine, longitudinal ribbing on the surface. Ribbing is distinctive for each species. Sod webworm larvae range in color from beige to gray to brown to greenish, depending on species. Nearly all sod webworm species have characteristic dark, circular spots and coarse hairs scattered randomly over the body. Fully developed larvae are typically 16–25 mm long. Pupae are "torpedo-shaped," approximately 10–13 mm long, and vary in color from tan to dark brown.

Several species of sod webworms are distributed throughout the temperate U.S., however, damage appears to be greatest in the Midwest and the eastern U.S. Sod webworms attack and damage several turfgrass species including creeping bentgrass, Kentucky bluegrass, perennial ryegrass, as well as fine-leaf and tall fescues, however, they will also feed and cause damage on other grasses that are considered weeds. Certain turfgrasses, such as perennial ryegrass and fescues that contain endophytes, are relatively resistant to sod webworms. Sod webworm larvae hide in silk-lined burrows in the turf canopy, emerging at night to feed on turfgrass foliage. Feeding damage results in leaves and stems being chewed off just above the crown; thereafter, the plant material is pulled into the burrow where it is consumed. Initial signs of sod webworm feeding damage typically appears as general thinning of the turf, followed by small irregular patches of brown, closely cropped grass. Close inspection of the damaged area reveals silk-lined tunnels and clumps of green insect frass (fecal pellets) near or around the burrow. When infestations are high and damage escalates, the small irregular patches begin coalescing into large irregular patches of brown, closely cropped grass. Early symptoms of sod webworm damage are typically masked, especially when the turf is dormant from drought stress, and as a result the damage rapidly becomes apparent after the turf recovers from the environmental stress and the sod webworm damaged area fails to recover. Moreover, sod webworm damage frequently is mistaken for several fungal diseases, golf ball damage, golf shoe (spikes) damage, as well as black cutworm damage.

Sod webworms in the northern U.S. overwinter as partially grown larvae in silk-lined chambers in the turf canopy. In the early spring when soil temperatures become conducive, sod webworm larvae resume feeding and growing, eventually pupating. Thereafter, adults typically emerge in 10–20 days, depending on species and temperature. Immediately after adult emergence, mating occurs, and females typically begin laying eggs by the following night. The adults are nocturnal, active at dusk or after dark. Adult females are rather unique in their oviposition behavior. They fly rather close to the turf surface (30–60 cm above), erratically for short distances, fluttering or hovering over the turf dropping approximately 60 eggs like bombs from a military aircraft. Each female lives for about 2 weeks or less, laying several hundred eggs during her lifetime. The dropped eggs do not contain any sticky substrate for adhesion, therefore, they tend to settle into the turf canopy where they are rarely seen. Eggs typically hatch in about seven days, and there are usually six to eight instars. Newly hatched and early instar larvae feed by scraping surface tissues from leaf blades. Soon thereafter, larvae drop to the ground to form the silk-lined burrows or tunnels. As larvae develop and mature, they feed predominately at night. A complete life cycle, egg to adult, requires 6–10 weeks, and depending on geographic location, most temperate region sod webworm species have two to three generations per year.

Adult tropical sod webworms do not roll their wings around their bodies when they are at rest. Instead they hold them in more of a delta-winged fighter plane configuration. The dingy brown moths have a wingspread of about 20 mm. The larvae is a dingy cream color, but will take on a green appearance when the larvae are feeding. They develop through seven or eight instars, reaching a maximum length of 19 mm. The head is yellowish brown. The larvae feed only at night and require about 25–45 days to complete development. Tropical sod webworms attack and damage all species of warm season turfgrass. Highly maintained bermudagrass is attacked most often and damaged most severely. The larvae give the turf a ragged, notch appearance from their feeding and eventually the turf will take on a close-cropped appearance and turn yellow. Damage is often first noticed near flower beds and shrubs. Damage is common in southern Florida in the spring and throughout the rest of its range in the Southeast by late summer. Generations may continue well into the fall and damage often is mistaken for fall armyworm feeding.

Crown and Thatch Inhabitants: Burrowing Insects

The larval stage of numerous types of billbugs and weevils damage turfgrasses by burrowing into the stems (leaf sheath) or by damaging the crowns (apical meristems). The apical meristem is the most vulnerable part of the plant because it is the source that contains the growing points whereby roots, shoots, and leaves originate. Subsequently, when burrowing insects attack turfgrasses, plant death often results.

Annual Bluegrass Weevil, *Listronotus maculicollis* (Dietz)

The annual bluegrass weevil, formerly called the hyperodes weevil, is a serious pest of closely cut annual bluegrass (*Poa annua*) on golf courses, bowling greens, and tennis courts in the northeastern U.S. Although both the adults and larvae cause damage to turfgrasses, adult damage is minor compared to larval damage.

Annual bluegrass weevil adults are small, 3.5–4.0 mm long, generally black or dark charcoal-gray beetles. The body is covered with fine, yellowish hairs and scales that typically wear off as the beetle ages. Thus, older adults often appear shiny black. Newly emerged adults are light reddish-brown, and often do not darken for several days. The thorax is approximately one-third as long as the abdomen, and the head is prolonged into a blunt (broad and short) snout. As a result, the annual bluegrass weevil is regularly confused with other turf-infesting billbugs that are similar in morphological characteristics. However, annual bluegrass weevil can be accurately differentiated by its shorter and broader snout; billbugs have a longer, narrower snout. Annual bluegrass weevil antennae are attached at the tip of the snout and can be folded back along the side of the snout in a compact groove. Annual bluegrass weevil eggs are rice-shaped, approximately 1 mm long, rounded at both ends, yellow initially but eventually becoming smoky gray to black before hatching. Eggs are laid between leaf sheaths of annual bluegrass. Females typically lay two to three eggs end to end within the leaf sheath. Larvae are creamy white, legless, with a distinct sclerotized brown head capsule. Larvae are approximately 1 mm long when newly hatched, and about 5 mm long when fully grown. There are five instars, and all are similar in appearance, differing only in size. Pupae are approximately 3.5 mm long, whitish at first, but later become reddish brown before the adults emerge. The snout, legs and wing pads are visible on the pupa, but are folded close to the body.

The only host that annual bluegrass weevil attacks is closely cut annual bluegrass. Although damage is only minor, the adults chew notches or holes in grass blades. The larva is the primary damaging life stage. Young larvae feed and tunnel within the plant stems. As larvae develop and become too large to feed within plant stems, they burrow out and feed externally on the crown of the plant. One larva can kill several plants during its lifetime. Damage typically begins along the edges of golf course fairways, especially those bordering wooded areas or other overwintering sites, as well as around the edges of putting greens and tees. Damage first appears as yellowish-brown, wilting or scattered dead patches of turf that eventually coalesce into larger dead areas as larvae develop and mature. The tunneled stems easily break off near the crown of the plant. Large infestations have the potential to cause severe damage to golf course putting greens, tees and fairways, especially where annual bluegrass is prevalent.

The annual bluegrass weevil has one to two generations per year depending on geographical locations; in more northern areas of its range it has only one generation per year. Adults overwinter in refuges such as leaf litter under trees, tufts of tall fescue, or other sheltered sites including golf course roughs where the turf is typically higher. Adults become active in the spring (mid-April), when they begin to crawl or fly to closely cut annual bluegrass hosts to begin feeding. Adult annual bluegrass weevil typically hide in the foliage during daylight, and later climb up turfgrass plants to feed at night. In early May, adults begin laying eggs. The eggs typically hatch in 4–5 days, depending on temperature. Immediately thereafter, the newly hatched larvae begin burrowing within the grass stems until they reach the third instar. Older larvae, third to fifth instars, burrow out of the plant to feed along the exterior, primarily on the plant crown. Upon maturation, annual bluegrass weevil larvae pupate sometime in mid- to late June in earthen cells just under the soil surface. The second generation adults emerge in late June or early July to feed, mate, and lay eggs.

In areas where there are two generations per year, most populations pupate by late August and adults emerge sometime in September, and migrate back to overwintering sites.

Billbugs (Coleoptera: Curculionidae)

Billbugs are one of the most misdiagnosed pests of turfgrass. Turfgrass managers often confuse billbug damage with symptoms of drought stress, disease or other insect damage such as chinch bugs and white grubs. There are four species of billbugs that are considered major insect pests within their range in the U.S. These species include the bluegrass billbug, Denver billbug, Phoenician billbug, and the hunting billbug. Billbug damage is similar to that of weevil damage. Both the adults and larvae feed and cause damage to turf, however, adult damage is minor compared to larval damage.

Bluegrass Billbug, *Sphenophorus parvulus* Gyllenhal

The bluegrass billbug is among the most serious pests of Kentucky bluegrass and perennial ryegrass in the temperate U.S. It is distributed throughout most of the U.S. and southern Canada where cool-season turfgrasses are grown. Damage frequently results in areas of brown, dead turf.

Adult bluegrass billbugs are characteristic billbugs that have a long, slender, beak-like snout. They are approximately 7–8 mm long, excluding the length of the snout. Adults are hard-bodied, sclerotized, usually slate gray to black in color, and may sometimes appear brownish from dried soil adhering to their body. Newly emerged adults are initially reddish-brown, but eventually become dark after a few days. Bluegrass billbug eggs are elongate, bean-shaped, translucent white eggs approximately 1.6 mm long. Larvae are plump, legless, creamy white grubs with a sclerotized brown head capsule. All larval instars are similar except for size; early instars (first and second) range in size from 1.3 to 2.4 mm long and mature larvae (fifth instar) are approximately 6–10 mm long. Pupae are approximately 8.5 mm long, creamy colored, gradually changing to reddish brown prior to adult emergence. The pupa has several morphological characteristics of the adult, the snout and legs are tucked under the thorax, and the wings are folded along the side of the abdomen.

Kentucky bluegrass is the preferred host of the bluegrass billbug, but it also will feed on and cause damage to perennial ryegrass as well as occasionally fine-leaf and tall fescues, especially when they are near heavily infested Kentucky bluegrass sites. Damage is usually worst from late June to early August, especially when turf is undergoing heat and drought stress. Although damage is only minor, the adults chew notches or holes in grass blades. The larva is the primary damaging life stage. Young larvae feed and tunnel within the plant stems. As larvae develop and become too large to feed within plant stems, they burrow out and feed externally on the crown of the plant. One larva can kill several plants during its lifetime. Damage first appears as yellowish-brown, wilting or scattered dead patches of turf that eventually coalesce into larger dead areas as larvae develop and mature. The tunneled stems easily break off near the crown of the plant. Lower populations of bluegrass billbugs typically produce scattered brown patches of turf, whereas heavier infestations can completely destroy areas of turf.

Adult bluegrass billbugs overwinter practically everywhere, in areas including thatch, soil crevices, under bark mulch or leaf litter, as well as other sheltered locations. However, it has been reported that crevices between the sidewalks and lawns is a preferred winter refuge. Adults become active in late April to mid-May when soil temperatures reach approximately 18°C. Once active, they are frequently seen crawling over sidewalks, curbs and driveways on warm spring days as they are seeking out suitable turfgrass in which to feed and lay eggs. After mating, adult female bluegrass billbugs begin laying eggs into small crevices created by adult feeding, chewed in grass stems just above plant crowns. Eggs typically are laid singly, and occasionally in groups of two or three. Each female can lay up to 2–5 eggs per day, and as many as 200 in her lifetime. Nearly all eggs are laid by early July, however, some females may continue laying eggs as late as August. Eggs usually hatch in approximately 6 days, and young larvae begin feeding within the grass stems, later burrowing down to feed on the plant crown as they mature. Infested turfgrass plants are hollowed out and packed with a powdery frass. As the bluegrass billbug larvae become too large (second or third instar) to feed within the turfgrass stems, they burrow out and move to the soil to feed externally on both the crowns and roots. An accurate indicator of bluegrass billbug activity is the presence of fine, whitish, sawdust-like frass near the feeding site. Larvae are most abundant in the soil from early June to early August, and they typically require 35–55 days to mature, depending on temperature. Thereafter, they pupate in small earthen cells in the soil. The adults emerge in approximately 8–10 days. Thus, adults are abundant in late summer and fall, briefly feeding before seeking out overwintering sites as cooler temperatures prevail. Occasionally, some early emerging adults may begin to lay eggs for a second generation, however, resulting larvae do not develop fast enough to mature before the onset of winter.

Denver Billbug, *Sphenophorus cicatristriatus* Fahraeus

Compared to other billbug species, little is known about the biology and life history of the Denver billbug. However, damage from this insect pest has been reported in Colorado, Kansas, and central and western Nebraska. It is considered the most serious pests of Kentucky bluegrass in Colorado. Damage frequently results in areas of brown, dead turf.

Adult Denver billbugs are considerably larger than either the bluegrass or hunting billbug, reaching 8–12.5 mm long. The Denver billbug adult is differentiated from the other two species by its larger size and the presence of distinctive, double-lobed markings on the wing covers. The Denver billbug may overwinter as an adult, but is more likely to spend the winter as a mid-to-late stage larva. After a spring feeding period by the larvae, eggs are laid by adults, and subsequent larvae develop over the summer. Larvae are plump, legless, creamy white grubs with a sclerotized brown head capsule. All larval instars are similar except for size, early instars (first and second) range in size from 1.3 to 2.4 mm long and mature larvae (fifth instar) are approximately 6–10 mm long. Pupae are approximately 9.0 mm long, creamy colored, gradually changing to reddish brown prior to adult emergence. The pupa has several morphological characteristics of the adult, the snout and legs are tucked under the thorax, and the wings are folded along the side of the abdomen.

Kentucky bluegrass is the preferred host of the Denver billbug, but it will also feed on and cause damage to perennial ryegrass. Damage typically occurs in the fall and early spring. Damage symptoms of the Denver billbug are comparable to that of the bluegrass and hunting billbug. The larva is the primary damaging life stage. Young larvae feed and tunnel within the plant stems. As larvae develop and become too large to feed within plant stems, they burrow out and feed externally on the crown of the plant. One larva can kill several plants during its lifetime. Damage first appears as yellowish-brown, wilting or scattered dead patches of turf that eventually coalesce into larger dead areas as larvae develop and mature. The tunneled stems easily break off near the crown of the plant. Lower populations of bluegrass billbugs typically produce scattered brown patches of turf, whereas heavier infestations can completely destroy areas of turf.

Phoenician Billbug, *Sphenophorus phoeniciensis* Chittenden

The Phoenician (or Phoenix) billbug occurs primarily in southern California and Arizona. The adults and larvae have a typical billbug appearance. The adult Phoenician billbug has an M-shaped raised area on the pronotum. It is primarily a pest of bermudagrass and zoysiagrass, particularly in those areas that are stressed or poorly maintained.

The injury from Phoenician billbug feeding is greatest during the summer months, at times of maximum temperatures and drought stress. The larval stage is the principal stage that causes damage. The small larvae usually feed inside the plant stems. The larvae continue to feed and once they become larger, they feed outside the stem around the crown and stolons of the plant. Larvae can kill a plant (or several plants) but usually the bermudagrass is growing quite rapidly during the summer and damage goes unnoticed until fall. Damage usually appears as stressed turf that turns yellowish-brown and wilts, which is easily mistaken for drought stress. Scattered dead patches may occur later in the season or be observed the following spring as the bermudagrass fails to grow. The damaged stems break off easily at the crown of the plant. Populations often are highest and damage most severe in sunny, drought-prone locations.

Hunting Billbug, *Sphenophorus venatus vestitus* Chittenden

The hunting billbug closely resembles the bluegrass billbug but is slightly larger and has parenthesis-like markings on the back of the thorax. This billbug species prefers warm season turfgrass species including but not limited to bermudagrass and zoysiagrass. On occasion, hunting billbug will damage Kentucky bluegrass. The hunting billbug is primarily a pest of the southeastern U.S., however, it is also found in the mid-Atlantic states as well as further west and north into Missouri, Kansas and southeast Nebraska.

Adult hunting billbugs are characteristic billbugs that have a long, slender, beak-like snout. They are approximately 6–11 mm long, excluding the length of the snout. Adults are hard-bodied, sclerotized, usually slate gray to black in color, and may sometimes appear brownish from dried soil adhering to their body. Hunting billbug eggs are elongate, bean-shaped, translucent white eggs approximately 1.6 mm long. Larvae are plump, legless, creamy white grubs with a sclerotized brown head capsule. All instars are similar except for size; early instars (first and second) range in size from 1.3 to 2.4 mm long and mature larvae (fifth instar) are approximately 7–10 mm long. Pupae are approximately 8.5 mm long, creamy colored, gradually changing to reddish brown prior to adult emergence. The pupa has several morphological characteristics of the adult; the snout and legs are tucked under the thorax, and the wings are folded along the side of the abdomen.

Damage is usually greatest from mid-June through early August during the period of maximum heat and drought stress. The larva is the principal damaging life stage. Young larvae feed and tunnel within the plant stems. As larvae develop and become too large to feed within plant stems, they burrow out and feed externally on the crown of the plant. One larva can kill several plants during its lifetime. Damage first appears as yellowish-brown, wilting or scattered dead patches of turf that eventually coalesce into larger dead areas as larvae develop and mature. The tunneled stems easily break off near the crown of the plant. Lower populations of hunting billbugs typically produce scattered brown patches of turf, whereas heavier infestations can completely destroy areas of turf.

As is the case with the Denver billbug, little is known about the biology of this pest. The hunting billbug has been reported to overwinter as dormant adults in the soil. Adults become active in late April to mid-May when soil temperatures reach approximately 18°C. Once active, they are seen frequently crawling over sidewalks, curbs, and driveways on warm spring day as they are seeking out suitable turfgrass in which to feed and lay eggs. After mating, adult female bluegrass billbugs begin laying eggs into small crevices created by adult feeding, chewed in grass stems just above plant crowns. Eggs typically are laid singly, and occasionally in groups of two or three. Each female can lay up to 2–5 eggs per day, and as many as 200 in her lifetime. Nearly all eggs are laid by early July, however, some females may continue laying eggs as late as August. Eggs usually hatch in approximately 3–10 days, and young larvae begin feeding within the grass stems, later burrowing down to feed on the plant crown as they mature. Infested turfgrass plants are hollowed out and packed with a powdery frass. As the bluegrass billbug larvae become too large (second or third instar) to feed within the turfgrass stems, they burrow out and move to the soil to feed externally on both the crowns and roots. An accurate indicator of bluegrass billbug activity is the presence of fine, whitish, sawdust-like frass near the feeding site. Larvae are most abundant in the soil from early June to early August, and they typically require 35–55 days to mature, depending on temperature. Thereafter, they pupate in small earthen cells in the soil. The adults emerge in approximately 8–10 days, thus adults are abundant in late summer and fall, briefly feeding before seeking out overwintering sites as cooler temperatures prevail.

Soil Inhabitants: Root-Infesting Insects

White Grubs (Coleoptera: Scarabaeidae)

White grubs are the most widespread, and considered the most destructive, insect pests of turfgrasses in the continental U.S. Most species of white grubs damage turfgrass by chewing off the roots near the soil surface. Most often, white grub damage occurs during periods of hot and dry weather. Subsequently, turf loss can be relatively abrupt and severe. To compound this problem, vertebrate predators such as armadillos, badgers, birds, moles, raccoons, skunks and various other animals may dig up infested areas of turf in search of grubs. In many cases these animals cause more damage than the grubs themselves.

Because white grubs feed on the roots below ground, they often go undetected until measurable loss to the root system has occurred. Moreover, grubs can be relatively difficult to control because soil insecticides must penetrate the turf canopy and thatch layer in order to effectively make contact with the grubs located in the soil. To achieve maximum control, turfgrass managers, through appropriate application equipment, adjuvants or surfactants, gravity, and irrigation or natural rainfall, must effectively place respective insecticides into the target zone where the grubs are located.

The larval stage (grub) typically is the damaging life stage to turfgrass, however, some species of beetles cause damage to ornamental plant materials as adults. White grubs are stout-bodied beetle larvae. About 15 species are pests of turfgrasses in North America, with about 10 species considered to be important: Aphodius grubs, Asiatic garden beetle, black turfgrass ataenius, European chafer, green June beetle, Japanese beetle, May beetles, northern and southern masked chafers, and Oriental beetle. These species of white grubs are generally similar in appearance, habits, and the damage they cause. An overview of the biology of individual species follows.

Aphodius Grubs, *Aphodius granaries* (L.) and *Aphodius paradalis* Le Conte

Two species that belong to the genus *Aphodius* are occasional pests of turfgrass, especially golf course fairways. *Aphodius* grubs are relatively small grubs compared to most other white grubs. They closely resemble black turfgrass ataenius grubs, and because they are frequently found in association with black turfgrass ataenius, often they are confused or misidentified. Although they seem to be less frequently associated with turf than black turfgrass ataenius, they are capable of causing serious damage to turf.

Adults are typically black with a reddish tinge, reddish-brown legs, and pale antennae. The adults have two triangular projections on the outer edge of the tibia and hind leg, whereas black turfgrass ataenius lack these projections. *Aphodius* eggs are tiny (less than 0.7 mm when fully hydrated), and pearly white. Larvae are typically white grubs, however, they are considerably smaller than most other common turf-infesting species. Newly hatched first instars are approximately 2.4 mm long, and are difficult to see. Second instar larvae are about 5 mm long and third instars are approximately 7.0 mm long. Fully mature third instars often are mistaken for young grubs of other species such as European chafers, Japanese beetles, and masked chafers. A distinguishing morphological characteristic that differentiates the two species of Aphodius larvae, as well as black turfgrass ataenius and other white grubs, is the raster pattern. The raster pattern is a distinctive pattern of hairs, spines, and bare spaces on the raster located on the ventral side of the last abdominal segment, anterior of the anus. The raster of Aphodius grubs has two rows of short spines forming a distinctive V-shaped pattern, whereas black turfgrass ataenius grubs have a random arrangement of spines as well as two distinctive, pad-like structures at the tip of the abdomen, anterior of the anal slit.

Both the adults and larvae of *Aphodius* feed primarily on decaying organic matter, especially animal manure. However, occasionally they will feed on living roots of cool-season turfgrasses such as annual bluegrass, creeping bentgrass, and Kentucky bluegrass. *Aphodius* grubs cause sporadic, severe damage predominantly to golf courses in the temperate U.S. Damage to home lawns is uncommon. The initial symptoms of *Aphodius* larval damage are patches of thin or wilted turfgrass that resemble drought stress, however, the turf does not respond or recover with the application of irrigation. As turfgrass root loss continues, the turf typically dies in irregular patches that eventually coalesce into larger dead areas. Heavily infested areas of turf can be rolled up similar to a loose piece of carpet. Upon close inspection or sampling, the grubs, pupae, and adults can be found under the dead patches of turf in the soil. Irrigated turfgrass with a high proportion of annual bluegrass are especially susceptible. Populations of as many as 200–300 m^{-2} are not uncommon. In addition, vertebrate predators frequently forage for grubs, resulting in additional turf damage.

The life history of *Aphodius* is poorly understood. Observations from Ohio, Michigan and Ontario, Canada suggest that there is only one generation per year with adults becoming active during the first warm days of spring; egg-laying apparently begins 2–3 weeks earlier than that of black turfgrass ataenius. However, other published reports indicate the possibility that two annual generations may be possible, especially in the more southern parts of the species range. Nonetheless, because *Aphodius* species are frequently associated with black turfgrass ataenius, similar biological attributes may be extrapolated to effectively manage *Aphodius*.

Asiatic Garden Beetle, *Maladera castanea* (Arrow)

The Asiatic garden beetle is a relatively minor pest of turfgrass, however, it can be locally abundant and damaging, especially in the temperate northeastern U.S.

Asiatic garden beetle adults are dull chestnut-brown, with a velvety appearance and a slight iridescent sheen. The beetles range in size from 8 to 11 mm long and 5–6.4 mm wide. The elytra (wing covers) do not quite reach the tip of the abdomen, leaving the terminal two segments of the abdomen exposed. The ventral side of the Asiatic garden beetle adult is partially covered with yellow hairs, and each visible segment of the abdomen has a row of backward-pointing yellow hairs that extend across the width of the body. The dorsal side of the elytra is bald with the exception of a row of fine hairs on the outer margins. Another distinctive morphological characteristic is the presence of scattered, small hairs on the dorsal (top) side of the head. Asiatic garden beetle eggs are pearly white, oval and are approximately 1 mm in diameter. After becoming hydrated from soil moisture, they become almost spherical. The eggs are typically laid in clusters of 3–19 eggs that are loosely held together by a gelatinous secretion. Newly hatched first instars are approximately 1.4 mm long and reach 19 mm long when fully mature. They are like most other white grubs, having a C-shaped body, a brown head capsule, and six jointed legs. However, the body color of Asiatic garden beetle larvae typically remains somewhat lighter than in other white grub species. The important distinguishing feature is the single, transverse curved row of spines on the raster, together with a Y-shaped anal opening. The hind legs have tufts of hairs, and extremely small claws relative to those on the pro- and meso-legs (front and middle legs, respectively). The presence of a whitish, enlarged, bulbous morphological structure (the stipes) on each maxilla beside the jaws is another distinctive feature of Asiatic garden beetle grubs. The pupa is approximately 7–10 mm long, and appears white initially but turns tan as it matures. Initially the pupa is enclosed in the final instar skin, which soon splits and is pushed back over the terminal portion of the abdomen; thus, it lies exposed in an earthen cell created by the larva. This characteristic is common also in the European chafer and May beetles.

Asiatic garden beetle grubs feed on the roots of all cool-season turfgrasses as well as weeds, woody ornamentals, herbaceous perennials, and vegetables. Adult Asiatic garden beetles prefer box elder, butterfly bush, cherry, Devil's walkingstick, Japanese barberry, oriental cherry, peach, rose, strawberry, sumac, and viburnum. Asiatic garden beetle larvae feed on the roots of various turfgrass species, causing typical white grub injury resulting in thinning, wilting, irregular dead patches of turf. Well or highly maintained turf that is irrigated regularly and is located near weedy areas containing adult Asiatic garden beetles' preferred food sources is more likely to be infested. Compared to other white grub species such as Japanese beetles, an equal number of Asiatic garden beetle grubs is typically less destructive. It is likely that this is a result of the fact that Asiatic garden beetle grubs typically feed deeper in the soil profile, thus leaving more of the turfgrass root system intact. Where Asiatic garden beetle infestations are heavy, it is not uncommon to observe more than 100 grubs/m^2, resulting in severe damage. Not only do Asiatic garden beetle grubs cause damage, but the adults feed on more than 100 species of woody and herbaceous ornamental plant material. When beetles are abundant, preferred plants can be stripped of foliage and flowers.

Asiatic garden beetle has a univoltine (one life cycle per year) life cycle similar to the Japanese beetle. Adults are most abundant from mid-July to mid-August. Adult females burrow into the turf canopy to lay eggs in the soil at about 2.5–5 cm in depth. Each female is capable of laying up to 60 eggs in her approximately 30-day lifetime. Once laid, eggs typically hatch in about 10 days; immediately thereafter the young larvae commence feeding on the tender, succulent roots of turfgrass and decaying organic matter until sometime in the fall when the first measurable frost occurs. The majority of Asiatic garden beetle grubs will have attained the final instar (third) by the first frost, however, approximately 25% will overwinter as second instars. As the soil temperatures continue to decline, the grubs will continue to burrow deeper into the soil profile, ultimately overwintering approximately 20–43 cm below the turf surface in a semi-dormant, nonfeeding state. Sometime in mid- to late April, the grubs will move slowly back up to the root zone where they will begin feeding until mid-June. Thereafter, mature grubs will begin preparing earthen cells or cavities 4–10 cm below the turf surface where they will pupate. Pupation occurs mainly from mid-June through mid-July, and typically lasts for approximately 10 days. New adults remain in the pupal cell for a few days until they become fully sclerotized (hardened) and their color changes from whitish to chestnut-brown. Soon after, the adults burrow upward and emerge from the soil to feed, mate, and lay eggs in susceptible areas of turf.

Black Turfgrass Ataenius, *Ataenius spretulus* Haldeman

Although sporadic in occurrence, the black turfgrass ataenius causes severe damage to golf courses in the temperate U.S., especially where cool-season turfgrasses are grown. They are also occasional pests where bentgrass greens are utilized in warm season turfgrass areas of the U.S. Black turfgrass ataenius has many of the same biological characteristics as several other white grub species, however, its season life cycle differs in that there are typically two generations per year throughout much of its range. In the more southern areas of the U.S., its life cycle is poorly understood, but more than two generations may occur in some areas.

Adult black turfgrass ataenius are relatively small, shiny black beetles ranging in size from 3.6 to 5.5 mm long and approximately half as wide. There are distinct longitudinal grooves on the elytra. Newly emerged adults are reddish-brown initially, and darken in a few days. Eggs are minute, less than 0.7 mm in diameter after absorbing water from the soil, and pearly white. Larvae are typical white grubs in appearance, however, they are considerably smaller than other turfgrass-infesting species. Newly hatched larvae are quite small, approximately 2.4 mm long, thus they are relatively difficult to see. Second and third instars are about 5 mm and 7.0 mm long, respectively. Fully mature black turfgrass ataenius grubs are mistaken frequently for young grubs (first instars) of several other white grub species such as European chafer, Japanese beetle, and both northern and southern masked chafers. However, black turfgrass ataenius larvae can be distinguished easily by the two distinctive, pad-like structures located at the terminal end on the ventral side of the abdomen anterior to the anal slit. Upon maturation, black turfgrass ataenius grubs pupate into small, approximately 4.2–5.7 mm long, pupae that are initially cream colored, but eventually become reddish-brown before the adult beetle emerges. A distinctive characteristic of black turfgrass ataenius pupae is that the wings and legs are folded close to the body.

Black turfgrass ataenius larvae typically attack and cause damage to the roots of annual bluegrass, creeping bentgrass, and Kentucky bluegrass on golf courses. They also feed on decaying organic matter, and the adults feed on manure and decaying organic matter. Because black turfgrass ataenius grubs feed on the roots of turfgrasses, the first symptoms appear as patches of thin or wilted turf that resembles drought stress, however, the turf does not recover with the application of irrigation or rainfall. As damage and subsequent root loss increases, the turf typically dies in irregular patches that eventually coalesce into larger dead areas. Heavily infested areas can be pulled or rolled up similar to loose carpet. Upon close inspection of the turf, large numbers of larvae, pupae and adults can be observed in the soil under the turf. Black turfgrass ataenius seems to prefer, and are most common in, areas of turf that are close-cut, with a moist, compacted layer of thatch. Additionally, golf course fairways that have a high proportion of annual bluegrass composition are especially susceptible. Because black turfgrass ataenius grubs are relatively small, they typically are found in higher densities than most other white grub species, with populations of 215–325 m^{-2} not uncommon. Accenting the damage associated with black turfgrass ataenius grubs, vertebrate predators frequently forage for grubs, resulting in additional turf damage.

Depending on geographic location, black turfgrass ataenius has one to two generations per year. There is typically only one generation per year in the Great Lakes states, New York, northern New England, Ontario, and other parts of its range. Adults reportedly overwinter along the edges of wooded areas along the perimeter of golf courses.

The adult beetles seek refuge in leaves, pine needles, grass clippings, and other debris in the upper 2.5–5 mm of the soil. Most of the overwintering black turfgrass ataenius adults have mated. Subsequently, in the early spring, from late March to early April, the adults become active and can be observed in swarms flying over golf course putting greens and fairways on warm afternoons as well as around lights at night. Soon thereafter, black turfgrass ataenius adults begin laying eggs in early May continuing until mid-June. Black turfgrass ataenius eggs are laid in clusters of approximately 11–12 eggs within cavities formed by the female near the soil-thatch interface. Eggs typically hatch within 7 days, and the larvae immediately begin feeding on fine, succulent roots and organic matter. This first generation of grubs typically is present from late May until early July, with damage commonly appearing in late June. Larvae require approximately 4 weeks to mature; thereafter, they burrow down into the soil profile to pupate and emerge as adults sometime in late June through early July. Upon emergence, these beetles mate and begin laying eggs in July through early August, producing a second generation of grubs which typically causes damage in August and early September. These grubs develop, mature, and pupate by late August or early September, producing adults that mate and emigrate to overwintering sites in the late fall. Generations appear to overlap and more than one life stage is common at a given time since the adults lay eggs over a period of several weeks. In geographic areas where there is not enough time to complete development of a second generation, these beetles mate but will not lay eggs. In areas of southern California, there is great variation from year to year in the occurrence of black turfgrass ataenius. Damaging populations of grubs do not occur until late in the summer in most years, but occasionally early summer damage may occur. Frequent insecticide applications for cutworms as well as high temperatures in the summer may reduce the likelihood of black turfgrass ataenius infestation on putting greens in the southern areas of the U.S.

European Chafer, *Rhizotrogus majalis* (Razoumowsky)

The European chafer is a native of Europe, where it is a serious turfgrass pest. In the U.S. as well, it is a turfgrass insect pest, primarily in the northeast. Where European chafer occurs, often it is considered the most damaging grub species. European chafer grubs are considerably larger than most other white grub species, especially Japanese beetle larvae. Thus, they commonly are more destructive than equal numbers of other species. In addition, they typically feed later into the fall and resume feeding earlier in the spring than other grub species.

European chafer adults are medium-sized, light-reddish beetles measuring approximately 13–15 mm long, with a slightly darker head and pronotum. The posterior edge of the dorsal side of the pronotum has a narrow band of light-yellow hairs, and the ventral side of the thorax is covered with pale yellow hairs. The terminal portion of the abdomen protrudes beyond the elytra, and they have distinct longitudinal grooves and minute punctuations. Both European chafers and May beetles resemble one another, however, European chafers are slightly smaller and they lack a tooth on the tarsal claws of the mesothoracic legs. Additionally, the European chafer has more distinct grooves on the elytra. Newly laid eggs are oval, shiny, milky white initially, but become dull gray after a few days. As they absorb water from the soil, the eggs become spherical, swelling to approximately 2.3–2.7 mm in diameter prior to hatching. European chafer larvae are typical C-shaped white grubs, with a yellowish-brown head and six distinct, jointed legs. The larvae can be differentiated easily from other white grub species by the raster pattern. It has two distinct, nearly parallel rows of small spines that diverge outward at the tip of the abdomen, similar to a slightly open zipper. The raster pattern, in combination with a Y-shaped anal slit, readily distinguishes European chafer larvae from other turfgrass-infesting white grub species in the temperate U.S. First instar European chafer grubs are initially translucent white, though the terminal portion of the abdomen becomes dark after feeding. Fully mature larvae are approximately 23 mm long. Both the prepupa and pupa resemble most other white grub species. They are approximately 16 mm long, smaller than May beetle pupae, yet larger than Japanese beetle pupae. European chafer pupae shed the larval exoskeleton, whereas Japanese beetle and Oriental beetle pupae lie within the shed larval skin.

European chafer larvae feed on the roots of all cool-season turfgrasses, as well as numerous grassy and broadleaf weed species in pastures and nurseries. The grubs cause thinning, wilting, and subsequent irregular patches of turf that can be readily pulled back or rolled up from the soil like a roll of carpet. Population densities of 18–28 grubs/m^2 are not uncommon in lawns and golf course turf. Damage by European chafer grubs typically appears in September, especially when the turf is already stressed by both heat and drought. Moreover, damage also can be observed in the spring when the grubs resume feeding on the previously weakened turf. Although European chafer adults occasionally will sample the margins of tree leaves, they rarely cause any measurable damage.

The European chafer has a life cycle that closely resembles those of other white grub species such as Japanese beetle and May beetle. In northern portions of Michigan and New York, adult European chafers begin emerging in mid-June and are most abundant from late June until mid-July, and terminate by late July. In areas further south, such as New Jersey, Ohio and Pennsylvania, adult activity typically occurs about 2 weeks earlier. Adults are most active on warm, clear nights when the temperature is above 19°C, and on favorable nights large numbers of adults begin emerging from the turf canopy near sunset. The adults fly to nearby trees, swarming about by the thousands. After a courtship period of approximately one hour, mating pairs begin to make their way to the turf canopy, ultimately returning into the soil before sunrise. Female European chafer adults continue to return to trees several times to re-mate during their 1- to 2-week lifetime. Each female lays 20–40 eggs in her life. Eggs are typically laid singly at 5–10 cm depth in the moist soil. Eggs hatch in approximately 2 weeks, and most hatch by late July. There are three instars of European chafer grubs; first instars are predominant until mid-August, second instars are present in early September, and third instars continue to feed and develop into November. Similar to other white grubs species, European chafers move down into the soil profile just below the frost line to overwinter. In the spring, when soil temperatures become conducive, the grubs return to the upper 2.5–5 cm near the soil-thatch interface to vigorously feed until late May. In early June the European chafer larvae begin moving down into the soil profile, to a 5–25 cm depth, to form earthen cells to pupate. The prepupal life stage requires approximately 2–4 days, while the pupal stages typically takes about 2 weeks. Thereafter, adults begin emerging in mid-June.

Green June Beetle, *Cotinus nitida* L

The green June beetle is a native of the eastern U.S., and is widely distributed east of the Mississippi river, north to St. Louis, Missouri, and south to Texas. They are most common in the southernmost edge of the temperate region where cool-season turfgrasses are grown. Because of their relatively large size, both the green June beetle adults and grubs regularly attract attention where they are abundant. Adult green June beetles are rather prolific fliers that are mistaken often for wasps as they swarm in a “buzzing” manner over the turf in mid-summer. Green June beetle grubs are relatively large compared to other turfgrass-infesting white grub species.

Adult green June beetles are considerably larger than Japanese beetles. They are approximately 19–25 mm long and 12.5 mm wide. They vary in color on the dorsal side of the body and elytra from dull brown with longitudinal stripes of green, to uniform, velvety forest green. The outer margins of the elytra range in color from tan to orange-yellow. The ventral side of the body is shiny metallic green or gold. Newly laid eggs are dull white, approximately 1.5 mm in diameter. As the eggs absorb water from the soil, they become larger, 3 mm in diameter, and more spherical in shape. First instar grubs are approximately 6–7 mm long, second instars are 15–17 mm long, and fully mature larvae are relatively large (45–48 mm long), robust, and more parallel-sided compared to other white grub species. Green June beetle grubs have short, stubby legs and mouthparts in relation to their overall body size. Upon maturation, the green June beetle forms a cocoon-like cell composed of soil particles held together by a sticky secretion, within which pupation occurs. Green June beetle pupae are large, approximately 25 mm long and 12.5 mm wide. The pupae are initially whitish, but gradually darken over time and eventually exhibit tints of the adult coloration before the adults emerge. They can be identified readily by their distinct locomotion; essentially, they scurry along on their backs, upside-down.

Green June beetle grubs primarily feed on decomposing organic matter, including compost, thatch, and grass clippings. There are indications that poorly managed turfgrass with excessive thatch may be at greater risk, and that the use of organic fertilizers just prior to the adult flights may make a turfgrass area more attractive for egg-laying. Green June beetle grubs do not feed on the roots like many other scarabs, however, they do cause considerable damage by their burrowing and tunneling behavior. The grubs make distinct, open vertical burrows with a surface hole approximately the size of a human's thumb. The burrowing and tunneling action of green June beetle larvae causes loose soil to be excavated out at the mouth of the burrow at night, forming a small mound approximately 50–75 mm across. The aforementioned mounds are frequently mistaken for ant mounds except that the soil particles are considerably coarser. This action disrupts the roots system, dislodging the turfgrass, and loosens the surface topsoil, permitting the turf to desiccate. As a result, the turf typically wilts and thins, allowing the invasion of broadleaf and grassy weeds. Adult green June beetles occasionally damage tree leaves, though they mostly feed on ripening fruits, tree sap and other sugary food sources. Similar to the grubs, the adults create little piles of soil as they burrow into and out of the turf canopy for egg-laying and resting.

Like many other scarabs, the green June beetle has a 1-year life cycle. Adults typically emerge in late June with peak activity occurring over a 2–3 week period, usually in mid-July in Kentucky; this event may be 2–3 weeks earlier in the south and 1–2 weeks later in areas further north. Green June beetle adults are active during the daytime, and rest on vegetation as well as under the thatch during the night. After mating, green June beetle female adults seek out turf areas with moist soils containing high levels of organic matter. The females burrow down into the turf approximately 5–13 cm, excavating a small cavity where she lays a cluster of 10–30 eggs. The cluster of eggs is enclosed in a small-sized sphere of soil held together by a sticky secretion. Each green June beetle female makes numerous egg chambers, laying as many as 60–75 eggs over a 2-week period of time. Eggs hatch in approximately 2 weeks. Subsequently, the young larvae begin feeding at the soil/thatch interface by early August. After continuing to feed and grow for several weeks, green June beetle larvae attain the third instar in late October or early November in the northern regions of their distribution. Third instars can be seen as early as the end of August in some Mid-Atlantic states, but also will remain active until November. As the soil temperatures continue to decline, the grubs will continue to burrow deeper into the soil profile, ultimately overwintering approximately 20–76 cm below the turf surface in a semi-dormant, non-feeding state. In some of the southern states, where soil temperatures do not drop significantly, green June beetle grubs can remain active throughout the winter on warm nights. Sometime in mid- to late April, the grubs will move slowly back up to the soil/thatch interface to feed until late May. Thereafter, mature grubs will begin preparing earthen cells or cavities, 20–40 cm below the turf surface, where they will pupate. Pupation occurs mainly in early June, and typically lasts for approximately 10–20 days. After about 3 weeks, adult green June beetles burrow upward and emerge from the soil to feed, mate, and lay eggs in susceptible areas of turf.

Japanese Beetle, *Popillia japonica* Newman

The Japanese beetle is a native to the main islands of Japan, where it is not considered a pest. However, in the eastern U.S. it is considered by many to be the worst insect pest of turfgrasses and ornamental landscapes. As a result, countless dollars and resources are aimed at controlling Japanese beetle adults and larvae. Japanese beetle larvae are white grubs that cause typical root-feeding damage. As for the adults, unlike most scarab adults, Japanese beetles attack and cause serious damage to over 300 ornamental plant species.

Japanese beetle adults are attractive, broadly oval insects that are approximately 8–11 mm long and 5–7 mm wide. The head, thorax, and abdomen are shiny, metallic green. With the exception of the head, much of the dorsal side of the body is covered with hard, coppery-brown elytra that do not fully extend to the tip of the abdomen. Another distinguishing character is the presence of five patches of white hairs that are located on each side of the abdomen, as well as another pair of white tufts on the dorsal side of the terminal abdominal segment posterior to the elytra. These tufts of hairs differentiate Japanese beetles from all other beetles that they closely resemble. Like many other insect species, the females are typically slightly larger than their male counterparts. Newly laid eggs are pearly white and oblong, approximately 1.5 mm long. Upon absorption of water from soil moisture, the eggs become spherical, almost doubling in size within a few days. The larvae are typical white grubs with three pairs of distinct, jointed legs, and a yellowish-brown head capsule; they too assume the C-shaped position in the soil and when handled. Newly hatched grubs are translucent white, becoming darker once they have fed. Like all white grub species, there are three larval instars. First instars are approximately 1.5 mm long, and fully mature third instars are 25–30 mm long. When compared to European chafers, masked chafers, and May beetles, they are considerably smaller. Japanese beetle larvae can be identified easily by their distinctive raster pattern that exhibits two rows of short spines that are arranged in the shape of a truncated V pattern. Pupae are typically scarab-like, and are cream colored initially, but gradually become tan to light brown. They measure about 14 mm long and 7 mm wide. Within a few days of adult emergence, the pupa appears metallic green.

Japanese beetle adults feed on over 300 species of herbaceous and woody ornamental plant species, including numerous popular shade trees. Initial feeding damage usually occurs in the upper canopy of preferred trees, on the upper leaf surface, leaving only a lace-like skeleton of the leaf veins. The grubs feed on the roots of equally as many plants, including all cool-season turfgrasses, weed species and ornamental plants. Damage to turfgrass by grubs results in thinning, wilting, and subsequent irregular patches of turf that can be readily pulled back or rolled up from the soil like a roll of carpet. Feeding damage by larvae to ornamental plant material frequently results in poor plant health and in some cases eventual death of the plant material.

Much like many other scarab species, the Japanese beetle has a 1-year life cycle throughout most of its range in the U.S. Depending on geographic location, adult emergence is most common in mid- to late June with peak activity occurring in early July. Emergence may occur about 2 weeks earlier in the Carolinas and 2–3 weeks later in the more northern states. Within days of emergence, mating and egg-laying occurs. Virgin female adults call males with a chemical sex attractant (pheromone). As many as 20–100 males may aggregate around a single female attempting to mate with her. After mating, the female will seek out suitable turfgrass sites in which to lay eggs. Such sites include areas with moist, loamy soil covered with well-maintained, lush, closely cut turf. Throughout this mating and egg-laying process, both male and female adults continue to feed gregariously on ornamental plants, usually beginning in the upper canopy of the tree. Females remate after each egg-laying episode, laying eggs in clutches of 1–4 eggs in the upper 7.5 cm of soil. This process is repeated every few days during the normal lifespan of a female, 30–45 days, during which she may lay as many as 40–60 eggs. After about a 2-week incubation period, the first instar grubs begin feeding on fine, succulent roots and organic matter, usually sometime in late July or early August. In approximately 2–3 weeks, the grubs will molt, becoming second instars, and eventually reaching mature grubs (third instars) after another 3–4 weeks. Throughout this time, as periods of dry soil moisture or drought exist, the grubs may burrow deeper in the soil profile. As cooler temperatures prevail in the late fall, and the first measurable frost occurs, the grubs will begin to burrow deeper into the soil to depths of about 5–20 cm below the soil surface where they will overwinter in a semi-dormant, non-feeding state. As soil temperatures warm to above 10°C in the spring (late March or early April), the grubs will begin to move back up into the root zone to resume vigorously feeding for approximately 4–6 weeks before going back down into the soil profile to form an earthen cell in which to pupate, normally in late May or early June. Pupation typically requires approximately 2–3 weeks; thereafter, adult Japanese beetles emerge. At a latitude of Kentucky, Virginia and Maryland, adults and eggs will be present in July, first and second instars present by mid-August, and third instars from late September, and overwintering until May. Prepupae and pupae are seen at this latitude in May and early June. Timing of these developmental stages will be 2–3 weeks later in northern regions and about 1–2 weeks earlier in southern regions.

May Beetles, *Phyllophaga* spp.

There are approximately 25 species of May beetles that may infest and feed on the roots of turfgrasses in North America. They are rather destructive as a result of their large size, and because they destroy the roots relatively close to the soil surface. Compared to most other white grub species, May beetles typically occur at considerably lower densities than other turf-infesting grub species.

May beetle adults are brownish, reddish-brown to almost black, medium- to large-sized, heavy-bodied beetles ranging in size from 11 to 24 cm long. Depending on species, body pubescence varies greatly; some species are almost hairless, while other are quite fuzzy. It is very difficulty to differentiate among the various species. Egg are pearly white and oval when first laid, but become more spherical after absorbing water from the soil. When fully mature and hydrated, eggs are nearly 2.5–3 mm wide. In most species, fully mature or third instar grubs are approximately 25–38 mm long. May beetle grubs have a V- or Y-shaped anal slit with the stem of the Y shorter than the arms. The most distinguishing characteristic is the raster pattern that exhibits two parallel rows of short spines, and resembles a zipper. The pupa is about 7–10 mm long, and appears white initially but turns tan as it matures. The pupa is initially enclosed in the final larval instar skin, which soon splits and is pushed back over the terminal portion of the abdomen. Thus, it lies exposed in an earthen cell created by the larva. This characteristic is common with the Asiatic garden beetle and European chafer.

May beetle grubs attack the roots of nearly all common turfgrasses. They cause extensive damage to turfgrass much like many of the other turf-infesting scarab species. The adults feed on tree leaves, chewing on the tissue between the veins, similar to Japanese beetles. Preferred hosts include birch, elm, hickory, oak, persimmon, poplar and walnut. In extreme situations, whole trees are sometimes defoliated in the spring.

Depending on the species, May beetles have 1- to 4-year life cycles. Nearly all the May beetle species that occur in the temperate U.S. have a 3-year life cycle, however, certain species have a 2-year life cycle in the transition zone and father south where warm-season turfgrasses are grown. There are a select few species that have only 1-year cycles. All *Phyllophaga* species have a life cycle that includes the developmental stages of an egg, three larval instars, a pupa, and an adult. The adults of most species are active from April to June depending on geographic location. In some southern regions, though, flight activity may be seen during any month of the year. May beetle adults emerge and are active just after sunset, when they fly to the tops of trees to feed and mate before returning to the turf before sunrise. Subsequently, they are highly attracted to lights, and often are observed bouncing off screen doors. After mating, females fly to the turf to burrow down approximately 8–10 cm to lay eggs singly in moist soil. An individual female typically lays approximately 20–50 eggs in her lifespan. After an incubation period of about 3–4 weeks, the eggs hatch and first instar grubs begin feeding on the succulent roots of turfgrass and organic matter. The larvae then quickly develop, growing and molting into fully developed second instars by early fall (September). Thereafter, they continue feeding into the late fall before the first measurable frost occurs, when they migrate downward to lower depths for overwintering. In the early spring, the following April, the second instars migrate upward to resume feeding on the roots of turfgrass, eventually molting into third instars by mid-June. The third instars continue to feed and grow, causing most of their damage in July and August. For May beetle species with a 2-year life cycle, they will reach their full size and pupate by the end of the second summer. Most of these 2-year species reach full maturity as adults by late fall of the second year, but remain in the soil throughout the winter, emerging the following spring. For species with a 3-year life cycle, as cooler temperatures prevail during the fall of the second year, the nearly fully mature larvae slowly migrate downward again in late September and early October to overwinter. Finally, in the third year of the life cycle, in the early spring during late March and early April, the third instars again migrate upward to feed throughout April and May before they complete their larval development. In June, the larvae migrate slightly downward to a depth of approximately 15–25 cm where they form an earthen cell in which to pupate. By late June, the third instars become prepupae, transform into pupae in July and August, becoming adults sometime in late August or early September. The young adults remain in the aforementioned earthen cell until the following spring, when they emerge in May or June. Regardless of whether the species has a 2- or 3-year life cycle, most of the damage is occurs during the second year.

Northern and Southern Masked Chafers, *Cyclocephala borealis* (Arrow) and *Cyclocephala lurida* (Bland)

Both northern and southern masked chafers are native to North America, and are widely distributed from the Atlantic seaboard westward to the Rocky Mountains and into the southwestern U.S., and from southern New York to as far south as South Carolina. Northern and southern masked chafers are among the most destructive insect pests of turfgrass in the Midwest and Central U.S., causing typical white grub damage. In addition, there is often significant indirect injury due to the feeding of vertebrate predators on these grubs. Distribution of both species overlaps throughout much of the Midwest. However, southern masked chafers are more common in the southern extent of their range.

Northern and southern masked chafers are quite similar in appearance and size in all life stages. Northern masked chafer adults are dull yellow-brown beetles, approximately 11–12 mm long and 6–7 mm wide. The only distinction from the southern masked chafer is that southern masked chafer is more shiny, and reddish-brown. Males and females of both species have distinguishable darker, chocolate brown color across the head and eyes that enables one to differentiate them from most other scarab species that are similar in size and color. Other important morphological characteristics that help to identify northern masked chafer beetles are the dense hair on the ventral side of the thorax, and the scattered arrangement of erect hairs on the wing covers. The adults of southern masked chafer lack such hairs. Newly laid eggs of both the northern and southern masked chafers are pearly white, oval, approximately 1.3–1.7 long, that like other white grub species, become considerably larger and more spherical after absorbing water from the soil. The larvae of northern and southern masked chafers are typical white grubs with a C-shaped body and six jointed legs. It is practically impossible to differentiate the two species. Newly hatched grubs are translucent white, becoming grayish after feeding, and they are about 4–5 mm long. Fully mature northern and southern masked chafer grubs are considerably larger and more robust than Japanese beetle larvae, ranging in size from 23 to 25 mm in length. They also have a reddish-brown head capsule compared to a more yellowish-brown head capsule in Japanese beetles. Their raster pattern exhibits an evenly spaced, non-uniform arrangement of approximately 20–30 stout hairs. Pupae are approximately 17 mm long and are creamy initially, later becoming reddish-brown as they mature.

Although northern and southern masked chafer grubs eat the roots of all turfgrasses, including endophytic cool-season species, they also feed on decaying organic matter and frequently are found in mulched plant beds, heavier organic soils and compost heaps. When damage does occur to turf, typical white grub feeding damage is common. The adults do not feed or cause damage to turf or other plant material.

The northern and southern masked chafers both have a 1-year life cycle like many other scarab species. The adults are active in June and July, with peak activity occurring in late June through early July in areas such as southern Ohio. They may be observed up to a month earlier in more southern locations. There is a distinct difference in adult behavior between northern and southern masked chafers. Southern masked chafer is predominantly active from just after sunset until around 11:00 p.m., whereas northern masked chafer is mostly active after midnight. Otherwise, their behavior is quite similar in that they swarm over the turf surface on warm, humid nights, especially after a heavy rain, in search of mates. As soon as mating occurs, the female will burrow into the turf canopy to lay her eggs in the soil. The eggs are laid singly or in small clusters in the upper 2.5–5 cm of the soil. The incubation period is approximately 14–18 days depending on temperature, and most eggs hatch by late July to mid-August. When soil moisture is adequate, the larvae will grow and develop relatively quickly, molting into second instars in approximately 3 weeks. By early September, the grubs develop into third instars, continuing to feed and grow until about mid- to late October when cooler soil temperatures force them to go deeper into the soil profile to overwinter. Similar to other white grub species, they overwinter in a earthen cell just below the frost line. In the spring, when temperatures become conducive, they migrate back up into the root zone to resume feeding until fully mature in mid- to late May. Thereafter, the fully mature larvae begin moving down into the soil profile to form earthen cells to pupate. The prepupal life stage proceeds, requiring approximately 4–6 days, while the pupal stage typically takes about 14–20 days to complete. Thereafter, adult beetles begin emerging in mid- to late June.

Oriental Beetle, *Exomala orientalis* (Waterhouse)

The Oriental beetle is native to the Philippines, but was accidentally introduced into the U.S. in Connecticut sometime before 1920. It was initially called the "Asiatic beetle" when it was first discovered in the U.S. The Oriental beetle is primarily a pest of regional importance in the northeastern temperate U.S. However, in recent years it has caused extensive damage to turfgrass (both warm- and cool-season turfgrass) as far south as northern Georgia. It is present throughout the Appalachian mountains and even the foothills in North Carolina. Like most turf-infesting scarabs, it causes typical grub damage.

Adult Oriental beetles are broadly rounded beetles approximately 9–10 mm long with relatively spiny legs. The adult beetles range in color from predominantly straw-colored to nearly entirely brownish-black. Their head is typically solid dark brown and the elytra have distinct longitudinal grooves. The eggs are somewhat milky-white, oblong, approximately 1.5 mm long, becoming slightly larger and more spherical after absorption of water. Oriental beetle larvae closely resemble Japanese beetle grubs. Both species have a transverse anal slit, though they can be differentiated easily by their raster patterns. Oriental beetle grubs have two parallel rows of 10–16 short, stout inward-pointing spines. Fully mature (third instar) Oriental beetle grubs are approximately 20–25 cm long. The prepupa resembles that of the Japanese beetle. Pupae are approximately 10 cm long, cream colored at first, but eventually become light brown as they age. The pupa also has as distinct thick fringe of hairs at the terminal segment of the abdomen.

Oriental larvae feed and destroy the roots of all cool-season turfgrasses as well as nursery stock and strawberry. The resulting damage is typical of most turf-infesting white grub species. The adults cause very little damage to plant material.

Like most scarab species that infest turf, the Oriental beetle has a 1-year life cycle. Its life cycle is similar to that of the Asiatic garden beetle and the Japanese beetle, with adults emerging in late June to early July. In many areas, the adults emerge a week or two earlier than the Japanese beetles. Because they are relatively weak fliers as compared to the Japanese beetle, they often are found crawling around, especially on flowers. Adult females lay their eggs singly 2.5–23 cm deep in moist soils. Each female lays about 25 eggs in her lifetime, throughout July and into early August. The eggs typically hatch after an incubation period of about 3 weeks. The larvae immediately begin feeding on the succulent roots of turfgrass, growing and developing into second instars by early September, and third instars by early October. Grub damage is most apparent in early September, especially when the turf is experiencing heat and drought stress. As cooler soil temperatures prevail, the nearly mature grubs burrow down into the soil to hibernate in earthen cells. In the spring, when soil temperatures are conducive in April and early May, they migrate back to the root zone to feed until early June. Thereafter, the grubs again burrow down slightly into the soil profile to pupate in earthen cells. The prepupal and pupal periods last for approximately 1–2 weeks, respectively. Nearly all of the grubs pupate by mid- to late June, and the adult beetles subsequently begin emerging in late June. Timing of these developmental changes may be approximately 1–2 week earlier in the southern region of its distribution (North Carolina) than in the more northern states.

Mole Crickets (*Scapteriscus* spp.) (Orthoptera: Gryllotalpidae)

Mole crickets are undeniably some of the most destructive insect pests of turfgrass in the southeastern United States. Four species of mole crickets can be found in the U.S., although only two of the four cause considerable damage to golf courses, lawns and sod farms. The tawny mole cricket, *Scapteriscus vicinus* Scudder, and the southern mole cricket, *Scapteriscus borellii* Giglio-Tos (formerly *S. acletus* Rehn and Hebard) are believed to have been introduced through ports in the early 1900s from South America, and are the two most prominent pest species. Both tawny and southern mole crickets can be found in the coastal region of the Southeast, from the southern portion of North Carolina over to eastern Texas. Two other species of mole crickets, the short-winged mole cricket

(*S. abbreviatus* Scudder) and the northern mole cricket (*Neocurtilla hexadactyla* Perty) can be found in the U.S. as well. The northern mole cricket is a native species that rarely, if ever, reaches pest status. It can be found from southern New England south to Florida and west to the Central Plains. The short-winged mole cricket is incapable of dispersing through flight due to its shortened wings, and thus, is typically found in coastal areas near ports of entry. When present in abundant numbers, the short-winged mole cricket can cause significant damage to turfgrass. At this time, its distribution is limited to Georgia, Florida, and some areas of the Caribbean, including Haiti, Nassau, Puerto Rico, Cuba and the Virgin Islands.

Tawny mole crickets are a more significant pest than southern mole crickets due to the fact that their diet consists mostly of plant material, including both the above-ground and below-ground parts of the turfgrass, while the southern mole crickets are primarily predaceous. The tunneling nature of both species makes them very damaging to turfgrass. As the crickets tunnel in their underground burrows, mechanical damage of the root system occurs, resulting in desiccation and susceptibility to other types of damage from foot traffic or golf carts.

Mole crickets are difficult to mistake for other turfgrass pests due to their unique appearance. Adults are relatively large, ranging from 3.2 to 3.5 cm long, and have characteristic shovel-like front legs. The pronotum of mole crickets is heavily sclerotized and their bodies are covered with a dense coat of fine hairs. The nymphs resemble the adults, but are smaller in size, and lack fully grown wings. At maturation, the front wings of the southern mole crickets and tawny mole crickets are folded back and almost reach the tip of the abdomen. To differentiate between the two species, one can look at the coloration or the tibial dactyls. Tawny mole crickets are typically golden brown with a mottled coloration on the pronotum and more robust, while southern mole crickets are grayish with four pale-colored dots on the pronotum. The most reliable distinguishing characteristic between the two pest species is the arrangement of the tibial dactyls. Both species have two dactyls, with the separation between the two for the tawny mole crickets being V-shaped and narrower than the width of one dactyl, while the southern mole crickets have a larger U-shaped space that is about the size of the width of one dactyl.

There are three distinct developmental stages of mole crickets: eggs, nymphs and adults. Both species produce one generation in most areas of their distribution, although southern mole crickets may have two generations per year in south Florida. Adults of both species have significant dispersal flights in the spring and minor flights in the fall. Tawny mole crickets typically fly from February to May in Florida, while southern mole crickets fly from March to June, and it is not uncommon to have flights of both species occurring on the same night. Flights for both species generally occur up to a month later in their northern range in the Carolinas. Tawny mole crickets will complete most flight activity before oviposition, while southern mole crickets will fly between clutches. The tendency of southern mole crickets to fly between egg-layings may have contributed to their quick spread after introduction into the U.S. Flights begin soon after sunset and continue for approximately 60–90 min in response to the calls of the males. Although the majority of flying mole crickets appear to be females, it is not uncommon for males to comprise a percentage of the flying crickets. Some of the flights are performed in an attempt to find a suitable mate, but many of the females that fly have already mated and use the intensity of the males' calls to indicate good oviposition sites. The moisture levels present in the soil influence the intensity of the calls, and because desiccation is a major factor in egg mortality, it is necessary for the females to find adequate soil moisture for successful oviposition.

Once the female finds a suitable site, she will spend about 2 weeks feeding and tunneling before laying a clutch of 25–60 eggs. Once the eggs have been laid, the female seals the tunnel and leaves the eggs to develop and hatch in 3–4 weeks, depending on the temperature. Females of both species can lay as many as 10 clutches of eggs. Oviposition begins as early as March for tawny mole crickets in northern Florida, and may continue well into April and June. Some southern mole crickets begin laying eggs as early as April in northern Florida, with peak egg-laying occurring in May and June. Timing for egg-laying and hatch is usually delayed by a month in the northern regions. Typically all tawny eggs have been laid by the beginning of July, while it is not unusual to see newly hatched southern mole cricket nymphs into September. After hatching, new nymphs will tunnel closer to the surface and begin feeding. As the nymphs continue to grow and go through 7–10 instars, damage will become more evident. By December, approximately 85% of tawny mole crickets have molted to adults, while only 25% of the slower-developing southern mole crickets reach maturity before winter. Those nymphs that do not reach adulthood by winter will complete development in the spring. Even though there are adults of both species present by fall, no mating or egg-laying appears to occur after fall flights. Crickets of both species overwinter as large nymphs or adults and do not become active again until the spring when temperatures rise. Mole cricket activity is most significant at night following heavy rains or irrigation when the crickets come to the surface to forage for food.

Effective management of mole crickets involves scouting, mapping, sampling and treatment. In the spring when adults are present, mating and flying, considerable damage may appear. Due to the large size of the crickets, unpredictable weather and large dispersal flights, it is difficult to effectively control crickets in the spring. At this time, spot treatment is advised for sensitive or critical areas. It is also very important to map those areas that appear to have significant adult activity for treatment of nymphs later. The time period after egg hatch when nymphs are small and nearer the surface is the best time to treat, usually in mid-June or early July. It is best to concentrate on those areas where adult activity was seen in the spring. Soapy water flushes can be used to confirm the presence of small nymphs in areas where adult activity was seen earlier in the year. An important aspect of control is to get the insecticide treatment to come into contact with the crickets. Therefore, areas of mole cricket activity should be allowed to dry for several days and then pre-irrigated the night before treatment, thus bringing the nymphs closer to the surface and making control easier. As crickets continue to grow and increase in feeding, damage may reappear in the fall, but effective control of small nymphs is the best way to minimize their impact.

Ground Pearls (*Margarodes* spp.) (Hemiptera: Coccidae)

Ground pearls are a common name for several species of unique scale insects that spend most of their life in the soil and feed on the roots of various species of warm-season turfgrass. The two most common species in turf are *Margarodes meridionalis* Morrill and *Eumargarodes laingi* Jakubski. These pests are present almost everywhere in the U.S. that warm season turfgrass is most common, from North Carolina across to California.

Ground pearls are subterranean, and the female spends most of its life in the soil. The pinkish-white eggs are laid in clusters in the soil and covered with a white waxy substance. The first instar nymphs that hatch are only 0.2 mm long and this crawler stage attaches itself to a root. Once attached it covers itself with a waxy substance and begins formation of the “pearl.” As the pearl grows it may appear to have a purple to yellowish globular covering. The pearls range in size from 0.5 mm to 2 mm in size. Adult females may appear in the late spring and throughout the summer. They are pinkish sac-like creatures with well-developed forelegs and are about 1.6 mm in length. The male is rarely seen and has a gnat-like appearance.

Ground pearls attack a range of warm-season turfgrasses, but appear to be most common on bermudagrass, centipede, zoysiagrass, and St. Augustinegrass. Centipede often appears to be the most severely damaged. The distribution is sporadic, but where infestation does occur, the damage can be quite serious. The nymphs (pearls) feed on the roots by extracting plant juices (and possibly injecting toxic substances), which results in an initial appearance of unhealthy, yellow turfgrass. This appearance usually worsens during hot, dry summers and the plant often will turn brown and then die. This rapid death would indicate toxin may be involved. The damaged areas vary from a few centimeters to several meters in diameter. The turfgrass usually does not regrow in these areas even the next summer. Weeds often grow in these irregular, but somewhat circular areas. Through time, the damaged areas may eventually coalesce and a significant portion of the turf may die.

The life history of this pest is not well understood across its range, but one generation per year probably occurs throughout its range. Under unfavorable conditions, the ground pearls may take longer than a year to complete their life cycle. The nymphs overwinter in the soil, and some nymphs will mature in the spring and summer, emerge from the cyst and move toward the soil surface as adults. The adults may be seen moving on the soil surface in late spring and all summer. After moving for a short period of time, they reenter the soil and move down only about 5–8 mm to secrete the waxy coat in which the eggs will be laid a few days later. The females lay eggs without mating, as they reproduce parthenogenically. They lay about 100 eggs over a 2-week period and the eggs hatch in about 10 days to 2 weeks. The new crawlers move to the roots, attach and begin to encyst once feeding is initiated. Ground pearls have been found as deep as 25–30 cm in the soil. A fungal disease of ground pearls has been reported, and ants probably play a significant role as predators.

Red Imported Fire Ant (*Solenopsis invicta* Buren) (Hymenoptera: Formicidae)

The red imported fire ant has become a pest of great significance throughout the warm season turfgrass areas of the South, particularly the Southeast west to Texas. This introduced species of ant was accidentally introduced from South America into the Mobile, Alabama, area around 1930. This ant has spread rapidly throughout the South in all areas with mild winters and adequate moisture. States as far north as Virginia and Tennessee now battle this problem.

The mounds from fire ants are typically conical in shape and vary considerably in size, but large mounds are usually 25–40 cm in diameter and may be 20–30 cm in height. The mounds may penetrate more than a meter into the soil. In very sandy soils the mounds may be less well developed. They usually are found in open sunny areas and often appear following a disturbance of the soil (e.g., construction). Mounds commonly appear at the base of trees, structures, near rotting logs and stumps, power boxes, and along curbing and sidewalks. A mound contains three forms of adult ants as well as the brood (immature ants). Adult ants can be black reproductive males, queens or worker ants. The large egg-laying queens have no wings while the unmated queens and males are winged. The worker ants (which are the ants most commonly seen foraging near the mound) are wingless, sterile females and they vary in size from 1.5 to 4 mm in length. These workers have a shiny black abdomen and reddish-brown head and thorax.

Red imported fire ants forage and feed on a variety of materials, often on insects and related organisms, seeds, carrion and discarded food items. These ants can both sting and bite, but the venom from their sting is the biggest problem. They can sting repeatedly and are quite aggressive against anything that disturbs their mound. A relatively small percentage of people are hypersensitive to the venom in the imported fire ant sting and can become quite ill from even one sting. Fire ants also cause problems by creating unsightly mounds that may smother the turfgrass, create an uneven surface, and damage mowing equipment. They do not feed directly on the turfgrass, but they can be found infesting any turfgrass species that grows in a climate appropriate for fire ant survival.

Mating flights can occur any time of year, but are most common in the spring and early summer. Mating flights often occur after a rainy period. Reproductive males and unmated females (both winged) fly in the spring and after completion of the mating flight, the newly mated queen lays eggs in a small chamber in the soil. The males die soon after the flight, while the queen sheds her wings and begin the task of starting a new colony. Approximately 10–15 eggs are laid and once they hatch in a little over a week, the queen takes care of them until they are adults in about 3 weeks. These adults then begin taking care of the queen and egg production increases up to 200 eggs per day. These new fire ants mounds are inconspicuous, and often are not noticed until fall. During the summer, the colony increases in size and by late in the year, the above-ground portion of the mound may be quite prominent. Mature colonies may contain anywhere from 100,000 to more than 500,000 ants. The workers typically live 2 months, but a queen can survive for 5 years. Some colonies may contain more than one queen. Colonies with single queens are more territorial and areas with such colonies usually will have 40–150 mounds per acre. Multiple queen colonies are less protective and workers roam freely from one mound to another. There may be more than 200 mounds per acre in these situations.

Management of Turfgrass Insect Pests

Effective and environmentally responsible insect pest management begins with a planned, well-designed control strategy that considers a multitude of tactics including but not limited to biological, chemical, cultural, and plant resistance. This pest management strategy is referred to frequently as Integrated Pest Management (IPM). IPM relies on a combination of preventative and curative (i.e., corrective) measures to keep pest densities below levels that would cause unacceptable damage. The goal of IPM is to manage pests effectively, economically, and with nominal risk to people, animals and the environment. IPM is not a rigid pest management program that precludes the use of pesticides, nor is it a biological or organic pest control program. IPM is merely a decision making process that considers all control tactics that will provide acceptable control of a respective pest. When successful, IPM typically reduces dependence on pesticides.

The process of IPM involves the following seven principal steps:

Sampling and Monitoring

Regularly inspecting areas of turf throughout the growing season enables a turfgrass manager to detect pests early, before they reach damaging levels. Monitoring can aid in assessing the need for action, provide an evaluation of the success of previously implemented control tactic(s), and develop site history information that will provide invaluable insight for potential future problems.

Pest Identification

Accurate identification is essential. The biology of a pest cannot be understood if the pest is not correctly identified.

Decision-Making

Management decisions are guided by action thresholds (density of pests that will cause unacceptable damage). As decisions are made, factors such as likelihood of success, treatment cost and environmental consequences are considered.

Appropriate Intervention

All appropriate management tactics, including biological, chemical, cultural control and plant resistance, must be considered. Turfgrass managers first must attempt to determine the cause of the pest outbreak, and make the necessary cultural management practice adjustments to reduce the risk of future problems. Occasionally, insecticide treatments may be warranted, however, always consider less toxic products when practical.

Follow-up

Through consistent and disciplined sampling and monitoring, turfgrass managers can effectively evaluate the success of a control tactic as well as determine the need for further action.

Record-Keeping

Accurate and detailed record-keeping enables a turfgrass manager to recall when and where specific pest problems have occurred and to plan to deal with them in the future. Such information can help managers to evaluate previous management practices and may provide insight in developing and/or modifying future pest management programs. Record-keeping also provides managers with a document that may circumvent potential litigation.

Employee and Client Information

Another crucial component of a successful IPM program is communication. This involves educating employees, clients and the public. Education of employees can be accomplished by developing ongoing training programs that focus on pest recognition, and biology and agronomic factors that affect pest management decisions. Other educational opportunities, such as field days, workshops and short-courses, also provide valuable training that helps induce employees to work more safely and effectively as well as helping to increase professionalism and environmental stewardship. As for effective client communication, information vehicles such as newsletters, fact sheets, bulletins, fliers, personal communication, electronic mailings, etc., all provide excellent opportunities to convey valuable information. Finally, communication to the public sector can be accomplished through newspaper articles, bulletins, open houses, town meetings, television promotions, etc.

IPM considers all appropriate management options, including biological, chemical, cultural and plant resistance.

Biological Control

Biological control is the use of predators, parasitoids, and disease-causing microbes or pathogens to suppress pest populations (Table 17). Compared to chemical control research, to date there has been very little research on the impact and use of predators and parasitoids in the turfgrass system. Most biological control research efforts have been directed at microbial control (i.e., bacterial, fungal, viral, and entomopathogenic nematodes). Moreover, of this work, much has focused on entomopathogenic nematodes (i.e., insect parasitic nematodes). Entomopathogenic nematodes are microscopic roundworms that attack and kill insect larvae, and reproduce within the dead host. They are beneficial organisms that naturally occur in most soils, and they are practically harmless to humans, plants and animals. There are numerous species of insect parasitic nematodes; different species and strains of nematodes vary in their activity against different species of insects. As with many biological control agents, specific environmental conditions must be met in order for nematodes to be effective: they are sensitive to direct sunlight and high temperatures, and they require thin films of water that enable them to move over soil particles.

Despite the potential that biological control agents possess, only a limited number of companies currently market biological control agents. As a result, product availability and cost often discourage turfgrass managers from integrating them into their integrated pest management program. To further confound the reluctance of the use of biological control agents, they are frequently directly compared to conventional insecticides, and because they do not consistently perform at the same level, they are often discounted or not considered as a viable control option. Nonetheless, more consideration should be given to biological control agents.

Chemical Control

When used judiciously, selectively and responsibly, insecticides are tremendously important tools in an overall IPM program. To date, chemical control continues to be the most common control strategy. This is likely due to numerous factors such as convenience, economics, effectiveness, familiarity and/or confidence of turfgrass managers with this strategy. Nonetheless, chemical control should not be the primary line of defense in managing turfgrass insect pests. When effective, alternative control strategies are available, always consider tactic(s) that have the least risk to people and the environment. Conversely, in some instances alternative, non-chemical control strategies may not be available. Thus, insecticide treatments may be the only control option. Subsequently, when selecting an insecticide, always consider products that are least hazardous to people and

Turfgrass Insects of the United States: Biology and Management, Table 17 Beneficial invertebrates: predators and parasitoids

Organism	Taxonomy	Type	Host(s)
Ant	Hymenoptera: Formicidae	Predator	Eggs and larvae of numerous insects
Big-eyed bug	Hemiptera: Geocoridae	Predator	Chinch bug, greenbug, mites, eggs and larvae of small arthropods
Entomopathogenic nematodes	Secernentea: Rhabditida	Predator/Pathogen	Numerous insect larvae
Green lacewings	Neuroptera: Chrysopidae	Predator	Aphids, mealybugs, and other soft-bodied arthropods
Ground beetles	Coleoptera: Carabidae	Predator	Eggs and larvae of numerous arthropods
Tiger beetles	Coleoptera: Carabidae	Predator	Eggs and larvae of numerous arthropods
Lady beetles	Coleoptera: Coccinellidae	Predator	Aphids and mealybugs
Rove beetles	Coleoptera: Staphylinidae	Predator	Eggs and larvae of arthropods
Scoliid wasps	Hymenoptera: Scoliidae	Parasitoid	Green June beetle larvae and other white grubs
Spiders	Arachnida: Araneida	Predator	Most insects
Tiphiid wasps	Hymenoptera: Tiphiidae	Parasitoid	Most white grub species

the environment, and that will provide the most effective control in an economical manner.

As previously mentioned, turfgrass insects can be categorized into three primary groups (i) leaf and stem, (ii) thatch, and (iii) root zone/soil. Subsequently, chemical control of insect pests in respective groups require specific considerations and application procedures.

Leaf and Stem Insect Pests

The turf area should be mowed and the clippings removed prior to the insecticide application to enhance the insecticide penetration into the turf canopy. A thorough irrigation before an insecticide application will help move insects out of the turf canopy (i.e., thatch and soil) and bring them to the surface. For night feeding insects such as black cutworm or sod webworm larvae, insecticide applications should be made in the late afternoon or early evening to maximize potential for exposure to the target pest and minimize the likelihood of photodegradation (i.e., sunlight decomposition) and volatilization of the insecticide, as well as reduce pesticide exposure to humans and animals. When liquid (i.e., sprayable) insecticides are used, avoid irrigation for at least 12 h to maximize contact and subsequent control. Regardless of insecticide formulation, avoid mowing turf after application for at least 24 h. When granular products are used, a moderate application (i.e., one-quarter inch or 6 mm) of irrigation is recommended to help dissolve and activate insecticide granules. Liquid and granular applications have their respective advantages and disadvantages. Liquids typically provide greater mortality from initial contact and they frequently leave a residue that results in some residual control. In contrast, granules have little initial contact activity, and because they have a tendency to bounce off the foliage, they are not effective against foliage dwelling insects such as mites and greenbugs. However, they provide somewhat longer residual control of thatch dwelling insect pests.

Thatch Inhabiting Insect Pests

Turfgrass insects that inhabit thatch can be difficult pests to control depending on the quantity of thatch accumulation, as well as the active ingredient and formulation of the insecticide. When thatch accumulation is one-half inch (12 mm) or greater, the effectiveness of insecticide applications is greatly impeded. Consequently, reducing the thatch layer by de-thatching or aerification prior to an insecticide application will increase insecticide efficacy. Another important tactic for effective management of thatch inhabiting insect pests is to apply a moderate (i.e., one-quarter inch or 6 mm) amount of irrigation prior to the insecticide application to maximize the likelihood of the treatment reaching the target pest. Overall, granular insecticides tend to perform better than liquid formulations, however, the active ingredient of the product is the overriding factor that influences the effectiveness.

Root Zone/Soil Inhabiting Insect Pests

Soil dwelling or root feeding insect pests are often the most difficult to control. Pests such as white grubs and mole crickets can be controlled with either liquid or granular insecticides. The two primary strategies for controlling soil inhabiting or root feeding insects are (i) preventative and (ii) curative (i.e., corrective) control.

Preventative control is a strategy in which an insecticide is applied before a possible insect problem and subsequent damage develops. This approach can be compared to an insurance policy; potential damage is avoided or minimized. This approach to insect pest management can be quite attractive to turfgrass managers since it is relatively easy to implement and it requires dramatically less time and effort in monitoring, sampling and decision-making. Preventative control requires the use of insecticides that have a relatively long residual activity (i.e., more than 100 days). Nonetheless, turfgrass managers must still understand the biology of the pest in order to accurately time the treatment to ensure maximum control of the target pest.

Curative control is the complete opposite of preventative control; this approach is essentially a reactionary or corrective strategy. This approach heavily relies on monitoring and sampling of turf areas. When populations of a turfgrass insect pest are determined to be above an unacceptable level (i.e., threshold), an insecticide application is made to control the pest. Curative control applications typically are applied after damage is evident, though ideally before severe damage results. Regardless of the formulation or active ingredient of the insecticide, the application must be watered in thoroughly with a minimum of one-half to three-quarters of an inch (12–18 mm) of post treatment (i.e., after the application) irrigation to move the residue through the thatch to the target zone where the pest is located. If an irrigation system is not available, simply rely on anticipated rainfall. Another effective strategy for optimal control of soil inhabiting and root feeding insects is the application of pretreatment irrigation. The application of one-half inch (12 mm) of water 24–48 h before insecticide treatment will encourage the target insects to move closer to the surface and to decrease the absorbency of the thatch. This approach is especially important if conditions have been hot and dry and insects are deeper in the soil.

When using any chemical control agent or product, always read and follow the label directions. Be conscientious of the potential impact on humans, animals and the environment. Consider using products that are the least toxic and hazardous. Ultimately, remember that there are no "silver bullets" that will eliminate all pests.

Cultural Control

Cultural control is described as suppressing pest populations or reducing their damage by normal or slightly modified management practices. These measures must be implemented before the insect reaches pest status or damage occurs. Essentially, cultural control is a proactive approach to pest management. Such management practices include, but are not limited to, (i) mowing, (ii) irrigation and drainage, (iii) fertility, and (iv) thatch management. Ultimately, healthy turfgrass is more tolerant to potentially damaging insect populations.

Mowing

Generally, proper mowing practices such as sharp mower blades and removing no more that one-third of the grass blade at each mowing will make the turf healthier and subsequently more tolerant to insect damage. Excessively close mowing and/or scalping greatly reduces plant vigor, thus decreasing tolerance to environmental stresses. As a result, close-cut turf tends to have greater susceptibility to damage from certain turfgrass insect pests. Close and consistent mowing may remove the eggs of some insect pests such as the black cutworm.

Irrigation and Drainage

Irrigation and drainage can have both a positive and negative impact on the potential for insect damage. Certain insect pests prefer hot and dry conditions while other prefer irrigated turf where soils have adequate moisture. For example, Japanese beetle adults will seek out moist areas of turf to lay their eggs. This is likely due to the fact that moist soils are required for egg and young larval survival. Thus, withholding irrigation during adult egg-laying may reduce the potential for survival of eggs and subsequent grub damage. Unfortunately, this cultural management strategy is not practical for a golf course manager since adult activity occurs in late June through August. Conversely, turfgrass insect pests such as chinch bugs prefer hot and dry conditions for survival and optimal reproduction. Therefore, irrigating or watering when chinch bugs are present will help to minimize damage and subsequent survival and reproduction. Overall, sound irrigation contributes to healthy, vigorous turf, thus, the turf is able to withstand higher pest populations and recover more rapidly from insect damage.

Fertility

Similar to the effects of irrigation and drainage, fertility also can have both a positive and negative impact on the potential for insect damage. For example, high levels of nitrogen fertility often result in rapid, succulent growth, subsequently increasing the likelihood of insect damage. Excessive nitrogen fertilization coupled with improper irrigation and mowing also can result in a thatch accumulation which provides a hospitable environment for insects such as billbugs, cutworms, chinch bugs, and sod webworms. Additionally, heavy fertilization of cool-season turfgrasses in the spring stimulates rapid shoot growth at the expense of a deep, healthy root system. These weak, shallow-rooted turfgrass plants are less likely to recover from insect damage. A proper, well balanced fertility program can result in health, vigorous turf that has a greater potential to recover from insect damage. Moreover, in some instances, fertilization coupled with appropriate irrigation can aid in the ability of turf to recuperate from insect injury such as white grub damage. For specific fertility and irrigation recommendations, consult your local cooperative extension agent or state specialist.

Thatch Management

Thatch is described as a tightly intermingled layer of living and dead roots, crowns, rhizomes, stolons and organic debris that accumulates between the zone of green vegetation and the soil surface. Certain levels of thatch (i.e., less than one-half inch or 12 mm) accumulation are beneficial, however, this layer in the turf canopy also provides a prime habitat for insect pests. In addition, thatch also acts as a barrier to the penetration of soil insecticides targeted at soil dwelling and root feeding insects. As a result, turfgrass managers frequently spend valuable time and resources attempting to reduce thatch to an acceptable level. Thatch accumulation can be managed effectively through proper irrigation, fertility, aerification and verticutting (i.e., vertical mowing or de-thatching).

Plant Resistance

Establishing insect-resistant turfgrasses is another valuable IPM tool. Resistance to insects has been discovered in numerous plants, though the degree of resistance may vary considerably from one plant species to another. Even within a species, one cultivar or variety can have varying levels of resistance to particular insect pests. When it comes to plant genetics, there are often trade-offs associated with plant resistance. While a plant may be developed for a characteristic such as color, other beneficial traits may be sacrificed or lost to attain this trait (e.g., insect resistance). Unfortunately, plant resistance to insects is a relatively low priority of both managers and plant breeders. There is higher priority or value in developing a plant material that exhibits improved color, texture, growth, cold-hardiness, disease resistance, etc. Subsequently, only a few insect resistant turfgrasses exist. Nonetheless, of the insect resistant turfgrasses that are available, most are quite effective in managing pests. One mechanism by which plant resistance is expressed is via endophyte-infected turfgrasses. Endophytes are fungi that live within healthy grass plants, but have no adverse effect on the turfgrass plants. To date, they are known to occur only in perennial ryegrass, and tall and fine-leaf fescues. Endophytes produce alkaloids that are toxins that do not harm the plant, but are either deterrents or toxicants to the insects that feed on the above-ground plant parts, including stems, leaf sheaths and leaves. Only nominal levels of the alkaloids are present in root tissues, thus, endophyte-infected turfgrasses do not provide meaningful control of root feeding insects. In addition to the insect resistance attributes that endophytes have, they also may improve stress tolerance and enhance resistance of turfgrass to some diseases. Unfortunately, there are no endophytic cultivars of Kentucky bluegrass or creeping bentgrass, nor do they occur in warm-season turfgrasses.

Turnip Aphid, *Lipaphis erysimi* (Kaltenbach) (Hemiptera: Aphididae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Turnip aphid is found in both tropical and temperate areas throughout the world. It is often confused with cabbage aphid, however, so distributional records and economic impact of both species are sometimes incorrectly reported.

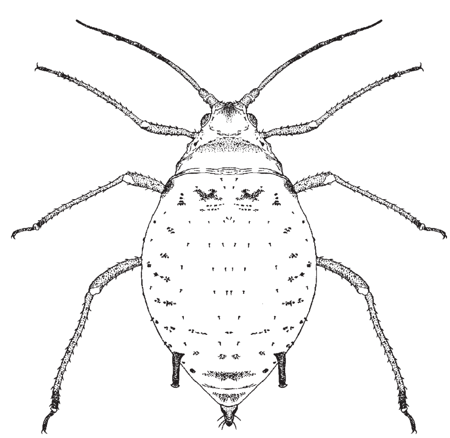
Life History

The turnip aphid is very prolific. Under temperate conditions, 11–25 generations are reported annually. Under the warmer conditions, up to 35 generations have been observed annually. Aphid longevity is usually 20–40 days, and reproduction begins about 6 days after aphids reach maturity. Wingless parthenogenetic females typically produce 80–100 young, often at a rate of 4–6 per day. Winged parthenogenetic females produce fewer offspring.

An egg-producing (oviparous) female form is known. Egg deposition rarely occurs, however, with nymph-producing (viviparous) forms occurring on crops and weeds throughout the year, even in cold climates. Oviparous females have been observed on several continents, however. Therefore eggs, although rarely observed, may occur on crops.

There are four instars. Nymphs are pale greenish yellow in color, and average about 0.6, 0.9, 1.0, and 3.3 mm in length during the four instars, respectively.

The wingless (apterous) adult females are whitish green or green in color, and measure about 1.4–2.4 mm in length. The dorsal surface of the thorax and abdomen of wingless adult females is marked with two rows of dark bands, which coalesce into a single band on the distal abdominal segments. The legs are pale with dusky joints. The antennae are dark and the cornicles pale with dusky tips. The entire body is lightly covered with a white secretion (Fig. 116).



Turnip Aphid, *Lipaphis erysimi* (Kaltenbach) (Hemiptera: Aphididae), Figure 116 **Wingless adult female of turnip aphid, *Lipaphis erysimi* (Kaltenbach).**

The winged (alate) adult females are pale green in color, with a black head and thorax. The last three abdominal segments are marked dorsally by narrow black bands. The sides of the abdomen also bear black patches. The legs are brownish to blackish, and the antennae black. The cornicles are dusky yellowish, with a small black area around the base. The wings are transparent, but marked with conspicuous black veins. Winged females measure about 1.4–2.2 mm in length.

Males have also been observed occasionally, but are too infrequent for their biology to be known. The wingless male is quite small, measuring 1.2–1.3 mm in length. It is olive-green to brown in color.

Turnip aphid generally can be differentiated from cabbage aphid by the very sparse occurrence of waxy exudate on the body, and by the slightly longer cornicles, 0.23 mm, of the former. In humid climates, however, there tends to be greater accumulation of waxy secretions on the aphid body. Therefore, it is probably better to use the shape of the cauda, a structure found at the tip of the abdomen, to differentiate these two species. When viewed from above, the cauda of cabbage aphid is triangular, about as wide as long. In contrast, the cauda of turnip aphid is slender, about twice as long as wide.

This aphid has been found associated with all *Brassica* crops, including such vegetables as broccoli, Brussels sprouts, cabbage, cauliflower, collards, kale, kohlrabi, mustard, radish, rape, turnip, and watercress. Cruciferous weeds also are known to be suitable hosts.

Turnip aphid is host to many parasitoids and predators. *Diaeretiella rapae* (MacIntosh) (Hymenoptera: Braconidae) is frequently reported to be an important biological suppressant, but in rapidly maturing crops such as radish apparently there is insufficient time for the parasitoids to attain high levels of abundance. Various ladybird beetles (Coleoptera: Coccinellidae), flower flies (Diptera: Syrphidae), lacewings (Neuroptera: Chrysopidae), and the fly *Aphidoletes aphidimyza* Rondani (Diptera: Cecidomyiidae) prey on the aphids. Fungus epizootics sometimes occur when aphid population densities are high, especially during the autumn months.

Damage

Turnip aphids feed principally on the undersides of leaves, but under high aphid densities or during the winter months the aphids may move to the center of the plant and feed on both the upper and lower surfaces of tender young foliage. They also feed readily on the stem tissue of the flowers. Heavy infestations will kill plants, and even light infestations will cause the leaves to cup, with yellowing of the foliage occurring where aphids are concentrated. Stunting of the plants is common, but contamination of foliage with aphid bodies, cast skins, and honeydew is the principal type of direct damage.

Turnip aphid may also serve as a vector of stylet-borne plant viruses. At least 10 viruses are transmitted, including cabbage black ring spot, cauliflower mosaic, radish mosaic, and turnip mosaic virus.

Management

Aphid water pan or sticky traps capture winged turnip aphids, but trap catches do not correlate well with overall aphid populations on plants. However, these techniques are useful to detect when winged aphids enter fields. This information is critical for the prevention of population establishment and the transmission of viruses.

Although sanitation is perhaps the most important factor in turnip aphid management, insecticides are used extensively. Systemic and nonsystemic insecticides are commonly applied in liquid or granular formulations, often at short intervals.

Turnip Root Maggot, *Delia floralis* (Fallen) (Diptera: Anthomyiidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Turnip root maggot is found in northern regions of Asia, Europe, and North America. Turnip root maggot greatly resembles seedcorn maggot, *Delia platura* (Meigen), and many records probably represent mixed populations.

Life History

Throughout its range, there is but one generation per year. Turnip root maggots overwinter as pupae, and flies from the overwintering population emerge throughout the summer months. Late July and early August are peak emergence times.

Eggs of turnip root maggot are white, elongate, and one side is concave while the opposite side is convex. Eggs are marked with longitudinal ridges, and measure about 1.1–1.2 mm long and 0.28–0.38 mm wide. Eggs are laid in July and August, and are usually deposited in clumps in the soil around the base of plants. Females normally deposit about 200 eggs during their adult life of about 40 days. Eggs hatch 8–9 days after being deposited.

Larvae also are whitish in color, undergo three instars, and attain a length of 9–10 mm before pupating. Duration of the larval stage is 5–8 weeks. The anterior larval spiracles have 14–16 lobes, a character that is useful for distinguishing this maggot from most related species. Larvae are found feeding on the host plant from August to October. At maturity they move in the soil a short distance from the feeding site and pupate.

The puparium is oval, and bluntly rounded at each end, and brown in color. The average length is about 6.5–7.5 mm. Pupae are the overwintering stage, and therefore are present from August until the following spring, a period of 8–10 months.

Flies generally resemble cabbage maggot adults, but are slightly larger, measuring 7–9 mm long. They also lack the tuft of bristles at the base of the hind femora that is distinctive in cabbage flies, and their color tends to be a lighter gray. Adults live 1–2 months, and usually begin to deposit eggs when they are about 9–10 days old.

The host range of turnip root maggot is quite similar to that of cabbage maggot, *Delia radicum* (Linneaus), but turnip maggot is more abundant in northern latitudes and where soils are light. Turnip maggot is known principally for its damage to rutabaga and turnip, which explains the common name. However, it damages most crucifers, including weed species. It is generally considered to be a truly phytophagous insect, like cabbage maggot, rather than being attracted to stressed or plant disease-infected plants, like seedcorn maggot.

Biology of this insect is not well known, and the natural enemies are particularly poorly studied. It appears that predators and fungi that are associated with other *Delia* spp. also affect turnip root maggot. Studies in Norway showed that over 40% of turnip root maggot eggs were consumed by predators in only 2–3 days. Plots with greater numbers of carabids and staphylinids (both Coleoptera) had greater egg mortality, and insecticides interfered with predation.

Damage

Turnip root maggot can be quite damaging. In Canada's Prairie Provinces, up to 40% of commercial turnips and 80–90% of rutabagas have been made unsuitable for consumption due to feeding damage by this insect. Larvae generally confine their feeding to roots, but sometimes work their way up into petioles of the lower leaves. They normally scarify the surface of the root, rarely penetrating very deeply. For crops where the root is not harvested, such as cauliflower, the damage is much less, due to both the indirect nature of the injury and the fact that larvae tend to occur so late in the season that the plants are fairly mature.

Management

Yellow sticky traps can be used to monitor abundance of adults. Flies are more likely to land on horizontal surfaces than vertical surfaces, however, so water pan traps might be more suitable. Allyl isothiocyanate is an important element in host acceptance, functions as an oviposition stimulant, and may be useful in monitoring. Management of turnip root maggot often depends on use of insecticides, usually applied as a granular formulation at planting, to protect against larval injury.

In general, fast maturing varieties seem especially prone to damage. Chinese cabbage, mustard, and some cauliflower cultivars were especially susceptible to injury, whereas kale and radish were quite resistant, and broccoli was intermediate. In an evaluation of 22 cauliflower selections, significant differences in susceptibility to injury were identified. There was a positive correlation between plant damage and number of eggs deposited by flies.

Weather and soil conditions affect damage potential. As is the case with seedcorn maggot, damage is worse in cool, wet years. Also, in the Prairie Provinces of Canada, damage by turnip root maggot occurs principally on farms that are irrigated. In Norway, turnip root maggot is the principal crucifer pest on light soils, whereas cabbage maggot is the major pest on heavy soils.

Tussock Moths (Lepidoptera: Lymantriidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Tussock moths, family Lymantriidae, total 2,490 species worldwide; actual fauna likely exceeds 3,000 species. Most of the fauna is Old World

Tussock Moths (Lepidoptera: Lymantriidae), Figure 117 Example of tussock moths (Lymantriidae), *Lymantria dispar* (Linnaeus) from Germany.

tropical (ca. 2,090 sp.). Two subfamilies are used, Orgyiinae and Lymantriinae, but this classification is uncertain. The family is in the superfamily Noctuoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults small to very large (16–135 mm wingspan); some with brachypterous females (some are apterous). Maculation mostly somber browns and grays, but some mostly yellow or white, or more colorful; a few species even with hyaline wings. Adults mostly nocturnal but some are diurnal or crepuscular. Larvae are leaf feeders, sometimes gregariously. Host plants include many different plant families. Many species are serious defoliators of forest trees (Fig. 117).

Twig Borer

An insect that enters the shoot tip of a growing woody plant, causing the twig to wilt and die.

Twirler Moths (Lepidoptera: Gelechiidae)

JOHN B. HEPPNER

Florida State Collection of Arthropods, Gainesville, FL, USA

Twirler moths, family Gelechiidae, are a very large family, with over 4,830 species described, however, possibly with a fauna exceeding 10,000 species worldwide. Subfamily arrangements have varied but now include four subfamilies, plus many tribes: Physoptilinae, Gelechiinae, Pexicopiinae, and Dichomeridinae. The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (4–35 mm wingspan), with head smooth-scaled and labial palpi recurved; haustellum scaled; maxillary palpi 4-segmented. Hindwings usually with distinctive falcate apical point and with long fringes (Fig. 118). Maculation varied, but mostly somber colors, but some can be colorful and with metallic-iridescent markings. Adults mostly nocturnal but some are diurnal or crepuscular. Many adults tend to twirl in circles on leaves when disturbed. Larvae have a range of feeding habits but most are leaf skeletonizers, using a

Twirler Moths (Lepidoptera: Gelechiidae), Figure 118 **Example of twirler moths (Gelechiidae), *Filatima albilorella* (Zeller) from Florida, USA.**

leaf fold or leaf tie as protection. A large variety of plants are used as hosts. Some species are economically important.

Twospotted Spider Mite, *Tetranychus urticae* Koch (Acari: Tetranychidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

The most widespread and important of the spider mites is twospotted spider mite, *Tetranychus urticae* Koch, which is found throughout the world in temperate and subtropical locations. Though most damaging in warmer regions, twospotted spider mite survives temperate climates better than most other species of spider mites. Also, this species can become very troublesome in greenhouses everywhere.

Life History

With a life cycle of only 8–12 days at 30°C and about 17 days at 20°C, over 20 generations may develop annually, though conditions rarely allow this rate of population cycling. Overwintering may occur on many hosts in warm-winter climates, and in cold winter areas forage legumes and greenhouses often shelter these pests, but adult twospotted spider mite females also pass the winter under leaves or other organic debris in a state of diapause. The development time of the immature stages is 4–5 days at 30–32°C, but is extended to about 16–17 days when the temperature is 15°C at night and 28°C during the day.

The eggs are whitish and spherical. They measure about 0.10–0.15 mm in diameter. Eggs are often deposited singly on the lower surface of foliage, but sometimes on the upper surface, usually under dense strands of silk. Females oviposit at a rate of 5–6 eggs per day, for a total of 60–120 eggs. Duration of the egg stage is about 3 days at 30°C and 6–7 days at 20°C.

The first instar is called the larva, and is colorless initially but yellowish or pinkish in color after feeding. The body is nearly spherical in shape, and bears three pairs of legs. The terminal portion of the larval stage is a nonfeeding period called the nymphochrysalis or protochrysalis. Duration of the first instar is 1–2 days at 30°C and 2–3 days at 20°C.

There are two nymphal instars, the protonymph and the deutonymph. These stages are easily separated from the larva because they bear four pairs of legs. They tend to be green or red in color.

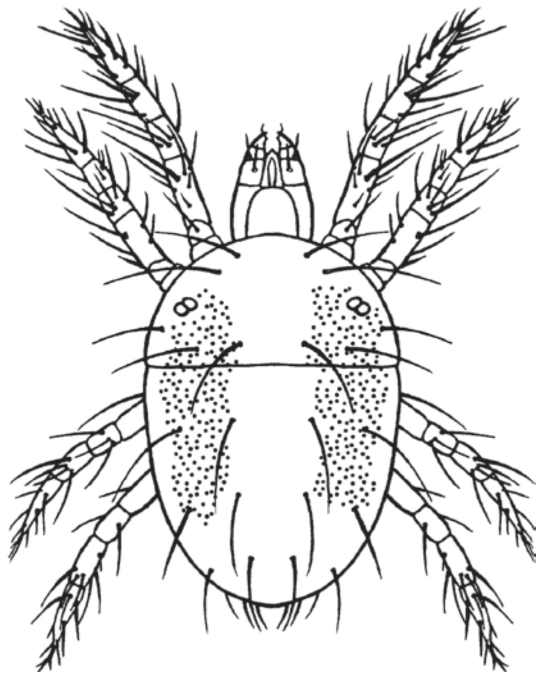
As in the larval stage, the terminal portion of each nymphal period is a nonfeeding period called the deutochrysalis and teliochrysalis, respectively. Duration of each instar is 1–2 days at 30°C and about 3 days at 20°C.

Adults are 0.4–0.5 mm long. Males are slightly smaller than females, and are usually less abundant than females. Like the nymphs, adults bear four pairs of relatively long legs. They also have numerous long hairs on their legs, and long but sparse hairs on their body. Females tend to be oval in body shape, males elongate-oval or diamond-shaped. The actively feeding female is usually greenish, with dorsolateral dark spots. Overwintering females of twospotted spider mite become orangeish red. Color is not a very reliable character with tetranychid mites; accurate determination depends on examination of tarsal characteristics and genitalia of males.

Males are attracted to immature females by a sex pheromone, perform extensive mating rituals and may mate repeatedly. The preoviposition period of females is 1–2 days. Fertilized females produce both male and female offspring; unfertilized females produce only males. Duration of the adult stage is normally about 30 days except when overwintering. The preoviposition period of adults is less than a day at 30°C, and 1–2 days at 20°C. Adults disperse by crawling and by wind-borne dispersal (Fig. 119).

These mites affect a large number of vegetable crops, though tomato, bean, and cucurbit crops are affected most often. They also damage cotton, soybean, strawberry, tree fruit crops and many ornamental plants.

The natural enemies of spider mites are numerous and diverse. Among the most important are predatory mites, particularly *Phytoseiulus persimilis* Athias-Henriot (Acari: Phytoseiidae); ladybird beetles, particularly *Stethorus* spp. (Coleoptera: Coccinellidae); dusty-wings (Neuroptera: Coniopterygidae); pirate bugs, particularly *Orius* spp. (Hemiptera: Anthocoridae); some plant bugs (Hemiptera: Miridae); and thrips, particularly *Scolothrips sexmaculatus* (Pergande) (Thysanoptera: Thripidae). Also, fungi sometimes cause epizootics.



Twospotted Spider Mite, *Tetranychus urticae* Koch (Acari: Tetranychidae), Figure 119 **Adult female twospotted spider mite, *Tetranychus urticae* Koch.**

Damage

Twospotted spider mites generally feed on the lower leaf surface. They pierce individual cells with their stylets, withdrawing the cell contents. Twospotted spider mite can feed on 18–22 cells/min, resulting in many dead cells, and often a speckled appearance. Leaf transpiration is accelerated, and affected leaves may dry and drop from the plant. Yellowing and speckling are the most common early plant responses to feeding, though reddening may also occur. Injection of plant growth regulators or interference with growth regulators during feeding is also reported. Wilting, tissue death, and leaf deformity and abcission are characteristics of prolonged and high density infestations. Disruption of photosynthesis results in stunting of plant growth and reduced fruit yields. Mite products such as webbing, eggs, cast skins, and fecal material also detract from the cosmetic quality of plants.

Prior to the 1940s spider mites were infrequently considered to be serious pests, but since then they have assumed major pest status in some crops. Apparently mite problems are induced by crop management practices, particularly the use of broad-spectrum insecticides. Also, the suitability of crops for mites is greatly enhanced when mites develop on plants that receive excessive nitrogen fertilization, grow in a dusty environment, or are stressed by inadequate moisture and high temperatures. These environmental factors can convert plants that might be only poor hosts into very good hosts, resulting in mite population increase and crop damage.

Management

Visual examination of foliage for leaf stippling on the upper surface, and mites and webbing on the lower surface, is the usual method of sampling. Older, or lower, leaves are usually examined. Infestations tend to be clumped initially, with clumping decreasing as the crop matures and females disperse to younger foliage.

Chemical insecticides (acaricides) are commonly used in greenhouses to prevent injury by mites, though natural enemies usually are capable of maintaining spider mite densities at low levels on crops grown under field conditions. In the field, insecticides directed at other pests can induce mortality among natural enemies of mites, causing spider mite population increases. Therefore, considerable effort is now directed at managing pests without disrupting natural control of mites, often by use of selective insecticides. Avoidance of early-season applications of insecticides is also recommended. Certain classes of insecticides, particularly pyrethroids, are especially disruptive. If chemicals must be applied for mite suppression, thorough coverage of the plants is essential. Frequent application of insecticides has led to many cases of resistance among spider mites. Resistance has not developed to oils, but oils are effective mostly against eggs, and frequent application leads to phytotoxicity among vegetable crops. Insecticidal soaps are similarly useful, though eggs are not entirely susceptible. Neither oil nor soap should be used at temperatures above 32°C. Sulfur is applied to some crops, but not to cucurbits, and not if temperatures exceed 32°C.

Cultural practices can have considerable influence on mite damage. Water stress disrupts the physiology of the host plant, making it more suitable for mite survival and population increase. Dry, dusty conditions also favor mite survival because blowing dust interferes with the predators of mites more than it does the mites; the latter are partially protected beneath their silk webbing. Thus, overhead sprinkler irrigation may alleviate mite problems. Excessive nitrogen fertilization of crops also favors mite population increase. Weeds and senescent crops can be important sources of mites, as can winter legume forage crops. Plant cultivars vary considerably in resistance to mites, and in some crops this offers excellent opportunity to manage mites whereas in others there seems to be little inherent resistance.

Biological suppression of mites through supplemental release of predators has been well developed for greenhouse crops. This approach is not often implemented for annual crops grown outdoors, though the successful use of the predatory mite *Phytoseilus persimilis* Athia-Henriot (Acari: Phytoseiidae) for twospotted spider mite suppression in strawberry fields shows that the approach is applicable if allowed by crop economics. This predatory mite is commonly used to suppress twospotted spider mite in greenhouses. Effective use of *P. persimilis* involves maintenance of a low level of pest mites so that the predators do not starve, and the distribution of pests (prey) uniformly in the greenhouse so that the predatory mites also will become widely distributed. Supplemental release of predatory mites may be needed to maintain a favorable ratio of predators to prey, often between 1:6 and 1:25. The maintenance of stable predator–prey–host plant relations is not a simple task, and even seemingly benign environmental changes such as variation in light intensity within the greenhouse affect stability.

Twostriped Grasshopper, *Melanoplus bivittatus* (Say), (Orthoptera: Acrididae)

This grasshopper is widely distributed in northern North America. In the United States it extends from the Atlantic to the Pacific Ocean, and is absent only from the Gulf Coast region. In southern Canada it occurs from Nova Scotia to British Columbia.

Life History

Over most of its range, twostriped grasshopper displays one generation annually, with the egg stage overwintering. In Colorado, eggs begin to hatch in June, though hatching can occur over a 4–6 week period. Nymphs may be present until September, but adults appear beginning in July. Oviposition commences in August and continues until adults are killed by cold weather. At higher elevations in British Columbia, a 2-year life cycle is reported.

The egg is elongate-cylindrical, with the ends tapering to blunt points. The eggs are olive in color and measure about 5.0 mm in length and 1.2 mm in diameter. The reported values of number of eggs per pod and total fecundity vary considerably among studies. One study reported 69.7 eggs per pod and a mean total of 129 eggs per female, whereas another reported 43.3 eggs per pod and a total of 355 eggs. The number of pods produced per female ranges from 4 to 15, with a mean interval between oviposition of 4 days, but this assumes good weather. Eggs are arranged in columns of four within a frothy secretion; the egg structure is called an egg pod. The pods are curved, measure 30–38 mm in length and 6–7 mm in diameter. They are inserted into the soil at a depth of 2–5 cm, and topped with a frothy plug. Favorite oviposition sites are along fence rows, ditch banks, and pastures with compact, undisturbed soil. Pods are often inserted among the roots of plants, and a soil moisture content of 10–20% is preferred. The act of oviposition requires about 2 h. The egg is the overwintering stage, and typically persists in the soil for 7–8 months. Embryonic development begins in the summer and autumn after oviposition, and is 60–80% complete before embryos enter diapause for the winter. However, they can be induced to hatch if exposed to about 5°C for 90 days.

Nymphal development normally requires 30–50 days. Most nymphs display 5–6 instars, but 7 instars occurs occasionally. Nymphal development time when fed lettuce or alfalfa and cultured at 21°C is about 10, 8.5, 10, 11, and 14 days, respectively for, instars 1–5. The young nymphs initially are dark brown or greenish, but gain a distinct dark stripe along the pronotum behind each eye at the third instar. The wing development is poor until instar 3, and the developing wings point downward. At instar 4, the wing orientation is reversed, with the wings oriented upward, but also pointing posteriorly. In the fifth instar, the wings are quite evident and extend out to at least the second abdominal segment. The number of antennal segments is 12–13, 17–18, 19–22, 23–25, and 24–26 for instars 1–5, respectively. Corresponding body lengths are 5–6.6, 7.4–10.4, 9–14, 15–21, and 20–17 mm. Nymphs are on the soil and seeking food each morning, but may ascend plants to escape the heat of the soil by noon. Like the adult stage, nymphs will perch on elevated roosts at night, and will sun themselves in the morning and in cool weather to attain optimal body temperature.

This is a fairly large and robust species. Males measure 23–29 mm in length, females 29–40 mm. The general body coloration is olive or brownish green dorsally and yellowish or yellowish green ventrally. The head and pronotum tend to be darker, usually olive green. A narrow but distinct yellow stripe passes from behind each eye along the pronotum and forewings, extending nearly to the wing tips. The stripes are often bordered below with black, especially on the anterior portions of the body. The stripes come together posteriorly in the forewings, forming a "V." It is this pair of yellow stripes that is the basis for the common name of this grasshopper. The forewings are usually uniform in color except for the stripes, and the hind wings colorless. The hind femora are yellow with a dark stripe along the outer face. The hind tibiae are variable, usually reddish but also greenish, yellowish, and purplish, and equipped with black spines. The male cerci are short, broad, and boot-shaped.

Adults seek crop borders and roadsides for reproduction. Mated females have a 7- to 14-day preoviposition period, after which they oviposit within the roots of grasses and weeds. Duration of oviposition is about 30 days (range 15–55 days) (Fig. 120).

Damage

This species is adaptable, and is found in a variety of habitats. However, it is most abundant in moist meadows, dense vegetation along water courses, and in disturbed, weedy areas. In the Great Plains region it is abundant in moist tallgrass regions, but uncommon in the drier shortgrass prairie. Twostriped grasshopper feeds on both grasses and broadleaf plants, but prefers the latter and fares poorly in habitats lacking broadleaf plants. Plants in the families Compositae and Cruciferae seem to be preferred. Among the uncultivated vegetation consumed is arrowleaved colt's foot, *Petasites sagittatus*; burdock, *Arctium lappa*; dandelion, *Taraxacum officinale*; dog mustard, *Eruscastrum gallicum*; flixweed, *Descurainia sophia*; needleleaf sedge, *Carex eleocharis*; leadplant, *Amorpha canescens*; oxeye daisy, *Chrysanthemum leucanthemum*; pepperweed, *Lepidium densiflorum*; plantain, *Plantago major*; redtop, *Agrostis alba*; sand dropseed, *Sporobolus cryptandrus*; Canada thistle, *Cirsium arvense*; sunflower, *Helianthus* spp.; wavyleaf thistle, *Cirsium undulatum*; mustard, *Brassica* spp.; and others. In North Dakota alfalfa fields, the plants most often consumed, after alfalfa, were kochia, *Kochia scoparia*; wild oat, *Avena fatua*; awnless bromegrass, *Bromus inermis*; tansymustard, *Descurainia sophia*; marsh elder, *Iva xanthifolia*; and quackgrass, *Agropyron repens*. On prairie, however, the plants most often consumed were Kentucky bluegrass, *Poa pratensis*; leadplant, A*morpha canescens*; and western ragweed, *Ambrosia psilostachya*. Survival rates and body weights are higher, and development times shorter, on mixed diets than on single hosts.

Twostriped grasshopper commonly infests vegetable and field crops, though most injury is limited to field margins. Among vegetable crops injured are beet, cabbage, chicory, corn, lettuce, onion, potato and likely others. Field crops such as alfalfa, birdsfoot trefoil, clover, young barley and oat, timothy, vetch and the immature seedheads of wheat also are fed upon. Flowers and ornamental plants are not immune to attack.

The natural enemies of the crop-feeding *Melanoplus* spp. are quite similar. For information on natural enemies of twostriped grasshopper, see the section on natural enemies of migratory grasshopper, *Melanoplus sanguinipes* (Fabricius).

Survival and population increase in grasshoppers are favored by hot weather. High numbers tend to occur after a period of years with abnormally hot and dry weather during the spring and summer months. This is especially true in northern areas, where it tends to be cooler. Enough precipitation is required to provide adequate food for grasshoppers, of course, but protracted periods of rainfall during egg hatch, especially if accompanied by cool weather, disrupt feeding by young grasshoppers and induce high mortality. The late onset of winter can favor grasshopper population increase because it allows adults additional time to produce eggs.

Twostriped grasshopper consumes the leaves of numerous plants. Damage is greatest in areas adjacent to weeds, and along fence rows, irrigation ditches, roadsides, and fallow fields. Damage is exacerbated by drought, which apparently increases nymphal survival rates and decreases the amount of weed vegetation available to the grasshoppers. Although the grasshoppers will feed at night if it is sufficiently warm, where nights are cool these grasshoppers tend to perch on elevated objects at night. This behavior allows them to be warmed by the light from the setting and rising sun, maximizing their period of activity. This also results in nibbling on the resting substrate by the grasshoppers; these grasshoppers will feed on the bark of bushes and young trees, and even damage shingles on buildings and eat holes in vinyl window screens while perching. The nymphs and adults are fairly dispersive, walking tens or even hundreds of meters in the search for food. At high densities they show propensity to swarm, which is expressed by band formation in the nymphal stage and flight by adults. The temperature threshold for flight is 30–32°C. Ascending to heights of 200–500 m, and flying with the wind, swarming adults can disperse long distances.

Management

Grasshopper populations are usually assessed by visual observation. A sweepnet is a useful tool to aid in collection, and its use a prerequisite to identification of the species complex. It is important to determine if grasshoppers collected from noncrop areas are crop-feeding species because there are many nonpest grasshoppers that restrict their feeding to grasses or weeds. It is advisable to monitor nearby uncultivated land, particularly weedy areas, in addition to crop plants, due to the tendency of the pest species to invade crops later in the season.

Liquid formulations of insecticides are commonly applied to foliage to protect against damage. Because grasshoppers rarely develop in crops, but instead invade from weedy areas, it is often the edges of crop fields that are most injured. Therefore, application of insecticide to the borders of crop fields is often adequate to protect an entire field. It is even better to apply insecticides to the developing grasshopper populations in weedy areas before they move to crops. This not only minimizes damage to crop plants, but often results in younger grasshoppers being targeted for elimination. Younger grasshoppers are more susceptible to insecticides, with large nymphs and adults sometimes difficult to kill.

Application of insecticide-treated bait is an effective alternative to foliar treatments for *Melanoplus* spp. because these grasshoppers spend considerable time on the soil where they come into contact with baits. Bait formulations are bulky and more difficult to apply than liquid products, so they are less often used, but have the advantage of limiting exposure of crops to insecticide residue and of minimizing mortality of beneficial insects such as predators and parasitoids due to insecticide exposure. Also, the total amount of insecticide active ingredient necessary to obtain control is usually considerably less when applied by bait because the grasshoppers actively seek out and ingest the toxin. Finally, for relatively expensive products that must be ingested to be effective, such as microbial insecticides, baits are the most effective delivery system.

The attractant used most commonly for grasshopper bait is flaky wheat bran, though other products such as rolled oats are sometimes suggested. No additives, other than insecticide (usually 5% active ingredient), are necessary because the wheat bran is quite attractive to *Melanoplus* grasshoppers. Other additives such as sawdust, water, vegetable or mineral oil, molasses, amyl acetate, salt, or sugar have been suggested, but provide little or no additional benefit over dry bran. The bait should be broadcast widely to maximize the likelihood of grasshopper contact, and should be applied while grasshoppers are in the late instars because adults ingest less bait.

Elimination of weeds within, and adjacent to, crops is the most important cultural practice, and can have material benefit in preventing damage to crop borders. However, during periods of weather when grasshoppers become numerous they may move long distances and invade crops.

Tillage is an effective practice for destruction of eggs. Deep tillage and burial are required, shallow tillage having little effect. All the crop-feeding *Melanoplus* species deposit some eggs in crop fields, especially during periods of abundance, but it is fence row, irrigation ditch, field edge, and roadside areas that tend to be the favorite oviposition sites, so tillage is not entirely satisfactory unless other steps are taken to eliminate grasshopper egg pods from these areas that cannot be tilled. Though providing suppressive effects, deep tillage is not consistent with the soil and water management practices in many areas, so may not be a good option.

Row covers, netting, and similar physical barriers can provide protection against grasshoppers. This approach obviously is limited to small plantings, and can interfere with pollination. Also, grasshoppers are capable of chewing through all except metal screening, so this approach does not guarantee complete protection.

The opportunities for biological control are limited. Historically, poultry were found to consume large numbers of grasshoppers and could provide considerable relief if the grasshopper-infested garden was small or moderate in size and the birds were plentiful. This remains a viable option for some people, and turkeys are usually considered most suitable among poultry. The birds may also inflict some direct damage to plants, however, so introduction of poultry is probably most viable when grasshoppers are plentiful and threatening.

The microsporidian pathogen *Nosema locustae* is well studied as a microbial control agent of *Melanoplus* spp. and is available commercially. It is fairly stable, and easily disseminated to grasshoppers on bait. However, its usefulness is severely limited by the long period of time that is required to induce mortality and reduction in feeding and fecundity. Also, the level of mortality induced by consumption of *Nosema* is quite low, often imperceptible. It is best used over very large areas, not just on individual farms, and should be applied at least one year in advance of the development of potentially damaging populations.

Fungi have also been investigated for grasshopper suppression. A grasshopper strain of

Beauveria bassiana has been effective in some trials, and *Metarhizium anisopliae* var. *acridum* has worked well for grasshopper and locust suppression in Africa and Australia, so it may prove useful for *Melanoplus* spp. Behavioral thermoregulation by grasshoppers, wherein they bask in the sun and raise their body temperatures, is potentially a limiting factor for use of fungi. Basking grasshoppers easily attain temperatures in excess of 35°C; such high temperatures decrease or even prevent disease development in infected grasshoppers. Inconsistent quality control in production of fungi also limits use of these organisms for grasshopper control.

Two-Spotted Stink Bug, *Perillus bioculatus* (Fabricius) (Hemiptera: Pentatomidae, Asopinae)

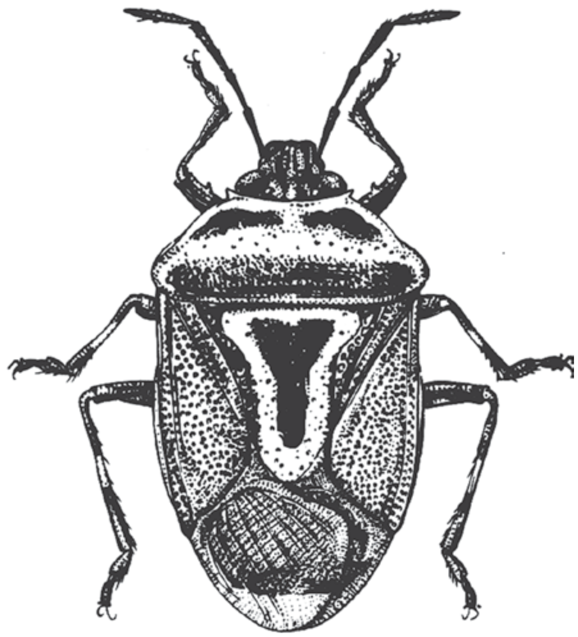
PATRICK DE CLERCQ
Ghent University, Ghent, Belgium

The two-spotted stink bug or double-eyed soldier bug, *Perillus bioculatus*, is a predatory bug belonging to the pentatomid subfamily Asopinae. It is believed to have originated somewhere from the southeastern Rocky Mountains to the Plains region and to have followed the eastward migration of the Colorado potato beetle, which appears to be its primary prey, at least in agricultural settings. The insect is presently found from Mexico into Canada.

Like those of other asopines, adults of *Perillus bioculatus* are broadly oval and more or less shield-shaped. Adult males are 8.5–10 mm long and the females are 10.5–11.5 mm long. Basically, there are three color forms: in the white form, the background is white with black and brown markings; in the yellow form, there are less pale areas, which are yellow rather than white, and all markings are black; in the red form, the background is red, and markings are black. The adults (Fig. 121) may gradually change from white or yellow to red, but not vice versa. The adults live for 1–2 months and are capable of laying 100–300 eggs. The bug has two to three generations per year and overwinters as an adult from September to October to April to May; adults usually hibernate in litter, but have also been found to enter buildings.

The eggs are blackish and barrel-shaped to somewhat elongate; the operculum is encircled by a row of about 15 micropylar processes, which are much smaller than in the spined soldier bug, *Podisus maculiventris*. The egg is on average 1.2 mm long and is 0.9 mm at its widest diameter. The eggs are laid in clutches consisting of 10–25 eggs, often arranged in a double row. There is no embryonic development below 15°C. At temperatures between 20°C and 25°C, eggs hatch within 5–8 days.

The nymphs are round to oval in shape. There are five nymphal instars. The body length of the five instars averages 1.5, 3, 4–5, 6–7, and 7–9 mm, respectively. First and second instars have a black head and thorax and a tomato red abdomen with dark patches. In third and fourth instars, the red background color may vary from tomato red to orange red or reddish yellow; the black color of the thorax often shows a greenish luster. In the fifth instar, there are two distinct forms; the dark



Two-Spotted Stink Bug, *Perillus bioculatus* (Fabricius) (Hemiptera: Pentatomidae, Asopinae), Figure 121 Adult of two-spotted stink bug, *Perillus bioculatus*.

form is greenish black and red, whereas in the pale form, the thorax and abdomen are mainly white to yellowish with dark markings. In the fifth instar, distinct wing pads are developed. During the last three instars, the red color may gradually change to yellow and white; on the other hand, nymphs with a yellowish background color may also become red. The carotinoid pigment responsible for the red coloration in the nymphs and the adults is believed to originate from their food. At high temperatures, the red pigment of the nymphs is quickly oxidized, yielding paler individuals.

The first instars hardly move about and form close groups. The gregariousness of the nymphs is more pronounced than in *Podisus maculiventris*, and even in later instars, the nymphs tend to form clusters, especially when they are preparing for the next molt and when temperatures are low. The first instars usually do not feed on prey and only require moisture, mainly in the form of plant juices. The nymphs start to attack prey from the second instar on. The nymphs and adults have a thickened rostrum or beak which they use to kill their prey and to suck up the liquefied prey tissues. Smaller nymphs in particular are often observed to attack prey collectively; on the other hand, gregariousness can also enhance the development of smaller nymphs by their opportunistic feeding on prey killed by larger, conspecific nymphs. Like other asopines, all predatory stages regularly feed on plant sap. Development of the nymphal stage requires about 3 weeks at 20–25°C, partly depending on food availability and quality.

Perillus bioculatus appears to be more of a specialist pentatomid predator compared to the spined soldier bug, *Podisus maculiventris*. In the field, the predator is usually found in association with the eggs and larvae of coleopterans, mainly from the Chrysomelidae family. It has been reported to feed on other insects, including the larvae of several lepidopterans. The bug appears to be, however, a rather timid predator with a dislike for highly mobile or aggressive prey. The two-spotted stink bug is best known for its predation on the Colorado potato beetle, *Leptinotarsa decemlineata*. The predator attacks all life stages of the beetle, but some scientists found that it has a preference for the eggs. Interestingly, the bugs usually suck out every egg in a mass, unlike some of the pest's predators with chewing mouthparts. It has been estimated that *Perillus bioculatus* can consume over 300 eggs during its nymphal period. This suggests a great potential for eliminating Colorado potato beetle populations provided that the pentatomid is present early enough in the season. Because natural populations of the predator in potato fields are usually too low early in the season, augmentative releases of laboratory-reared individuals may help in suppressing outbreaks of the pest in early spring. However, some workers have questioned the predator's dispersal and predation capacities, particularly under cool climates. Nonetheless, in small scale field plots, significant reductions of high density populations of Colorado potato beetle larvae have been achieved by releasing one to three second- or third-instars per plant. Like the spined soldier bug, *Perillus bioculatus* has been introduced in different parts of Europe for biological control of the Colorado potato beetle, but none of these introductions were successful. However, there are reports of established populations in the European part of Turkey since 2003, probably as a result of an accidental introduction.

High numbers of predators needed for augmentative field releases necessitate an economically viable mass production. The two-spotted stink bug can be reared on larvae of several noctuids (including *Trichoplusia* and *Spodoptera* spp.), a method that is cheaper than rearing it on the Colorado potato beetle, because the noctuids are easily mass-reared on artificial diets. The availability of an artificial diet for the predator itself may further reduce costs of mass propagation. Artificial diets have been developed that can support consecutive generations of the predator, but development and survival rates are reduced and fecundity is only one tenth of that raised on live prey.

Tympanum

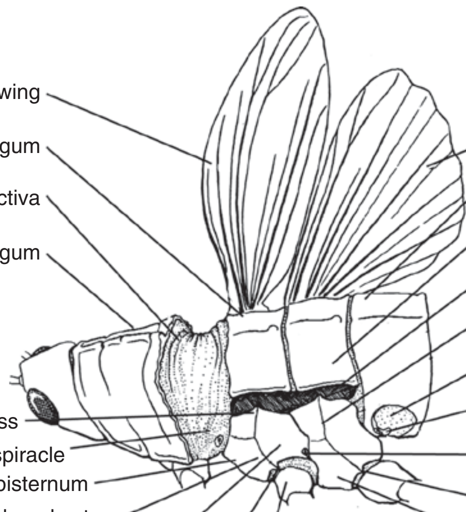
A membrane-covered cavity on the thorax, abdomen, leg or other part of the body that functions like an ear to perceive sound. These chordotonal organs are optimized to perceive high frequency sound (Fig. 122).

Typhus

There are several types of typhus, all of which are associated with arthropods. The most common are epidemic and endemic typhus. Epidemic typhus (also known as Brill disease) is associated with poor hygiene, and often is associated with cold temperatures. It is spread by lice. Historically, it is associated with periods of warfare and human disaster. Endemic typhus (also known as murine typhus) is associated with rat fleas and rat feces. It is most common during the warm weather when rats and fleas are most abundant. These forms of typhus are caused by rickettsia, either *Rickettsia prowazekii* (epidemic tphus) or *Rickettsia typhi* (endemic typhus).

Symptoms include high fever, severe headache, nausea and vomiting, abdominal pain and a transient rash. It is a severe illness, and may result in death if it is not treated, particularly in the case of epidemic typhus. Symptoms occur within 14 days of exposure, and the disease is treated with antibiotics. Sanitation and avoidance of flea-infested rats and rat feces is recommended.

Other forms of typhus include tick typhus and scrub typhus. Tick typhus, transmitted by ticks, is a form of spotted fever and is found in Africa and the Indian subcontinent. Scrub typhus is transmitted by mites, and is found in Southeast Asia and the Pacific islands. Avoidance of wild



Tympanum, Figure 122 **Head and thorax of a grasshopper (Orthoptera).**

animals and animal habitats is recommended for avoidance of these diseases.

Uhler, Philip Reese

Philip Uhler was born at Baltimore, Maryland, USA, on June 3, 1835. He is known as America's greatest hemipterist. Uhler was born into a prominent merchant family but was not interested in his father's business, preferring natural history. In 1864 he was placed in charge of the insects at the Museum of Comparative Zoology at Harvard University, and the library at Cambridge, Massachusetts. He resigned in 1867 to return to Baltimore where he became assistant librarian at the Peabody Institute. In his spare time he studied entomology, economic entomology at first but then on Hemiptera. A book-buying trip to Europe in 1888 allowed him to examine many of Europe's insect collections, and he soon became a leading authority in this field. However, failing eyesight caused him to give up these pursuits in 1890. Uhler named many of Hemiptera collected on the early explorations of western North America. Notable publications include "List of Hemiptera of the region west of the Mississippi River, including those collected during the Hayden explorations of 1873," and "Hemiptera, Standard Natural History, Vol. 2." Uhler died at Baltimore, Maryland, on October 21, 1913.

Ultrastructure of Insect Sensilla

VONNIE D.C. SHIELDS

Towson University, Towson, MD, USA

The cuticle of insects is largely responsible for the success of these terrestrial arthropods. It is rigid and hard in areas requiring support and protection and flexible in regions associated with locomotion and the detection of mechanical stimuli. It is highly impermeable and restricts water loss from the body surface. Cuticle does not expand, thereby limiting growth, making it necessary for growing insects to periodically shed the existing cuticle (a process called molting) and to replace it with another, larger one. The insensitivity of insect integument also limits the reception of stimuli. This insensitivity is remedied by the presence of transcuticular sensory mechanisms, each specifically designed to detect one of a wide range of stimulus types.

Sensory perception for taste, smell, touch, sound, vision, proprioception, and geo-, thermo-, and hygroreception involves a three-stage process consisting of coupling, transduction, and encoding. Coupling connects the stimulus to the sensory neuron. Transduction converts the stimulus energy to electrical energy (receptor current). Encoding is the process that generates action potentials from the receptor current.

All type I sensilla (see below, Classification of sensilla), with the exception of certain scolopidial sensilla, consist of a specialized sensory cuticle innervated by the dendrites of one or more sensory neurons and usually three or four accessory cells that enwrap the neurons and associated sinuses. The exoskeleton and small size of insects impose certain restrictions on the nervous system, which are reflected in their behavior. Small size and short transmission fibers reduce the distance for impulse conduction and decrease reaction time. This allows them to respond very rapidly to stimuli. Size limitation also implies a decrease in neuronal number and a consequent reduction in informational capacity. The insect nervous system is organized in such a way that stimulation of a single sense cell may trigger a series of responses. Insects possess primary sense cells, which not only receive the stimulus, but initiate and transmit information by means of a direct connection with the central nervous system.

Cuticular Parts

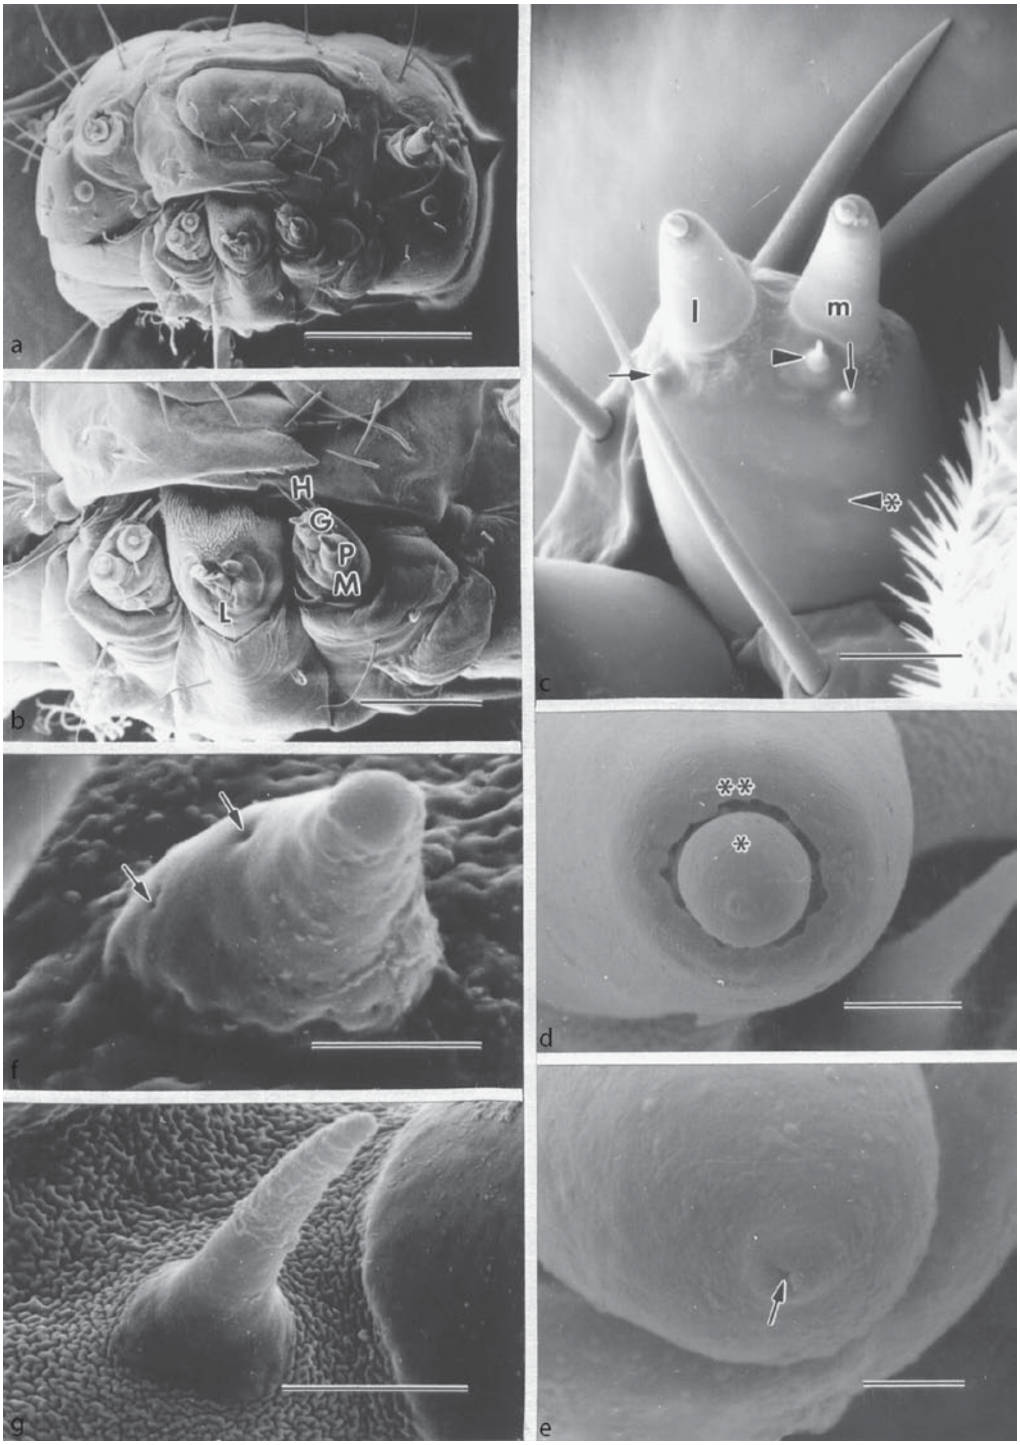
The components of an insect sensillum, that are considered to be cuticular, are those that are shed with the exuvium at a molt. These include the sensory cuticle and intracuticular structures (pore canals and pore tubules or filaments), the socket or insertion in the surrounding insensitive cuticle, and the sleeves or sheaths that extend inward around the distal part of the dendrite (Figs. 1–6).

Lipoidal pore canals are found in the body cuticle, as well as in the walls of the sensory cuticle, but are modified to varying extents. The canals usually contain pore filaments or tubules possessing an osmiophilic, lipoidal wall and a non-osmiophilic, non-lipoidal core. In most sensilla, pore canals open into the sensillar sinus liquor of the lumen within the sensory cuticle and in some sensilla, pore canals extend the length of the cuticular wall and open into the liquor of the sensillar sinus, under the sensory cuticle.

The dendritic sheath is cuticular in origin and is shed at a molt. Examination by transmission electron microscopy (TEM) reveals that the dendritic sheath is an invagination of the surface layer of epicuticle and resembles the superficial cuticulin layer in composition and density. The dendritic sheath is thought to possibly play a significant role in the stimulus transfer mechanism between the outer sensory cuticle and the enclosed dendrite in sensilla that are mechanosensitive (see below, Mechanosensilla).

Classification of Sensilla

The sensory neurons of insect sensilla are classified into two types: type I and type II. Type I neurons are bipolar, contain a ciliary structure in the distal dendrite, and innervate the sensory cuticle. The distal dendrite can be simple, branched, or lamellated in different types of sense organs. These neurons originate de novo within the epidermis. The neuronal perikaryon (cell body) remains peripheral in location, while the axon grows inward toward the central nervous system (CNS). A Type I sensillum is derived from an epidermal



Ultrastructure of Insect Sensilla, Figure 1 **SEM micrographs. (a, b) *Spodoptera frugiperda*. (c–e) *Mamestra configurata*. (f, g) *Choristoneura fumiferana*. (a) Frontal view of whole head. Scale bar = 1 mm. (b) Frontal view of ventral mouthparts. G, galea; H, dorsal guard hair on the galea; L, labium; M, maxilla; P, maxillary palp. Scale bar = 400 μm. (c) Fronto-ventral view of a right galea showing lateral (l) and medial (m) uniporous styloconic sensilla and three aporous basiconic sensilla: spire-shaped (arrowhead),** mother cell, which divides to form the nerve and sheath cells.

Type II neurons are bipolar or multipolar, lack a ciliary structure, and are never associated with cuticular processes. These neurons innervate the body wall, alimentary canal, muscles, epidermis, connective tissues, and sheath cells. They may have originated within the central nervous system and then migrated outwards to innervate mesodermal and epidermal tissues.

A type I sensillum can be defined as a sense organ that has one or more Type I bipolar neurons whose dendrites are enveloped by at least two sheath cells. All type I insect sensilla presumably evolved from an epidermal hair (seta) and all their component parts are believed to be homologous.

Traditionally, sensillar types have been classified on the basis of the morphology of their cuticular parts and their position on, within, or under the cuticle.

Sensilla Trichodea

These are hairs innervated by one to several neurons. They can vary greatly in length and are freely moveable on a basal membrane. They can be solely mechanosensitive, dually mechano- and contact chemosensitive, olfactory, or thermosensitive.

Sensilla Chaetica

These are bristles or spines innervated by one or more neurons. They are similar to the sensilla trichodea, but have thicker walls. They are typically set in a socket and can be mechano- or contact chemosensitive.

Sensilla Basiconica

These are pegs, cones, or papillae innervated by one to several neurons. They are similar in function to trichoid sensilla, as well as being hygrosensitive.

Sensilla Coeloconica

These are basiconic pegs or cones set in shallow pits innervated by two to several neurons. They are most often chemo-, thermo-, or hygrosensitive.

Sensilla Ampullacea

These are basiconic pegs set in deep pits innervated by two to several neurons. The surface opening is often much narrower (flask-shaped) than that of coeloconic sensilla. They have sensory characteristics similar to the sensilla coeloconica.

Sensilla Squamiformia

These are sensory scales innervated by one or more neurons and may be mechano- or chemosensitive. They have not been identified in immature insects.

lateral (horizontal arrow) and medial (vertical arrow). An aporous campaniform sensillum (arrowhead with asterisk) is located approximately midventrally on the galeal wall. Scale bar = 25 µm. (d) Higher magnification of the tip of a styloconic sensillum. Each sensillum consists of a small terminal cone or peg (asterisk) inserted into a socket (double asterisk) on a large style. Scale bar = 4 µm. (e) Apical view of the cone of a styloconic sensillum with a terminal pore (arrow). Scale bar = 1 µm. (f) Aporous basiconic sensillum. Beneath the pores (arrows), are longitudinal pore canals filled with pore tubules that extend to the surface of the cuticle. Scale bar = 2 µm. (g) Aporous spire-shaped basiconic sensillum. Scale bar = 5 µm. Both types of sensilla in (f, g) are inserted into inflexible sockets.

Scale bar = 250 μm. (b) Adult male antennal flagellum showing long multiporous pheromonal trichoid sensilla (arrows). Scale bar = 250 μm. (c) Higher magnification of an annulus from (a) showing many long, multiporous trichoid sensilla (arrows). The majority of these sensilla have ultrastructural characteristics typical of olfactory sensilla. Each arrowhead indicates an aporous styliform complex sensillum. Scale bar = 100 μm. (d) Higher magnification of a region from (c), showing long multiporous trichoid (arrow) and shorter

Sensilla Campaniformia

These are dome, bell, or cupola-shaped structures positioned at or below the surface of the cuticle. They are characteristically innervated by one neuron and are solely mechanosensitive.

Sensilla Placodea

These are plate-like sensilla innervated by several to many neurons. They are positioned level with, slightly raised above, or depressed below the surface cuticle, and are olfactory.

Sensilla Scolopophora

Also called chordotonal organs, these are subcuticular and are not associated with an external modification of the cuticle, though they maintain an attachment to it. Each sensilla unit is innervated by one to three neurons. There are two types of scolopidial sensilla: amphinematic and mononematic. Amphinematic scolopidia are drawn into a distal thread or tube and may be either integumental (direct attachment with the cuticle) or subintegumental. Mononematic scolopidia lack such a thread or tube and are subintegumental (without any direct attachment to the cuticle). Some chordotonal sensilla are propriceptive in function and respond to stretch during movements of body parts, while others respond to air-borne vibration.

Sensilla Styloconica

These are cones, pegs, or squat hairs, inserted at the tip of a conical or cylindrical projection (style) of insensitive cuticle. They are innervated by one or a few neurons and are mechano- and/or chemosensitive.

Other uniquely-shaped sensory structures have been described in insects as large conical sensory appendices, domes, knobs, partitioned plates, knobbed rods, flower-shaped domes, ear-like sensilla auricularis, clubbed hairs, and coniform or styliform complexes.

There are three main sensillar categories: AP (aporous) or NP (no-pore) sensilla, which are either mechanosensitive or hygro- and thermosensitive; UP (uniporous) or TP (terminal-pore) sensilla, containing gustatory neurons alone, or in combination with a mechanosensitive cell, and MP (multiporous) or WP (wall pore) sensilla, occurring as two main types: single-walled (SW) sensilla, with pore tubules, and double-walled (DW) sensilla, with spoke canals and the sensillar liquor as stimulus conducting systems. SW sensilla contain olfactory neurons, whereas DW sensilla contain olfactory and/or thermohygrosensitive neurons.

basiconic (arrowhead) olfactory sensilla. Scale bar = 10 μm. (e) Higher magnification of a multiporous trichoid (asterisk) and two multiporous basiconic sensilla (double asterisks) sensilla. The shaft of the trichoid sensillum bears circumferential cuticular ridges (arrows), more apparent at a higher magnification in (f). The cuticular shafts of both trichoid and basiconic sensilla bear numerous pores, more apparent at a higher magnification in (f) and (a–c). The pores of the basiconic sensillum are distributed in oblique linear rows (arrowheads) along the long axis of the sensillum. Scale bar = 1 μm. (f) Higher magnification of the middle portion of the cuticular shaft of a trichoid multiporous sensillum showing that the shaft of the sensillum bears circumferential cuticular ridges (arrows). These ridges form a helical pattern over the basal quarter of the length of the sensillum and a more circular pattern over the remaining length. The cuticular shaft is also perforated by pores (arrowheads) in cuticular depressions that are arranged in a single row along the midline of the ridges. Scale bar = 1 μm.

(a) Cross section near the base of the peg of a uniporous styloconic sensillum showing four chemosensory distal dendrites and the tubular body of the mechanosensory dendrite (asterisk). These dendrites all contain longitudinally oriented microtubules. The tubular body of the mechanosensory dendrite is composed of an accumulation of microtubules lying parallel to one another within an electron-dense matrix. The mechanosensory dendrite is closely apposed to the cuticular wall (cu) of the cone. At this level, the dendritic sheath (arrowhead) is thin on the side adjacent to the cone cuticle, prior to**

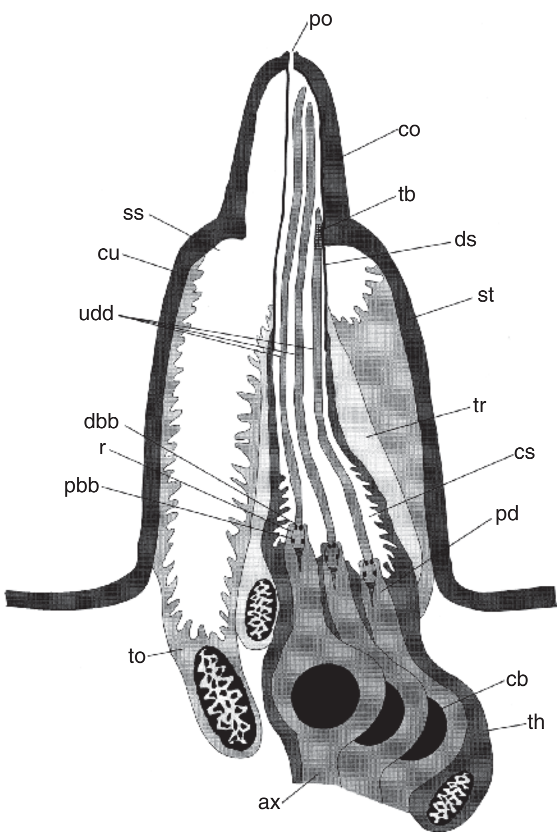
Aporous (AP) Sensilla

Mechanosensilla

AP sensilla lack a permeable pore in their sensory cuticle, but may have a typical cuticular pore canal system with pore tubules extending to the surface cuticle. During a molt, the exuvial dendritic sheath is pulled through the new cuticle at its point of cuticular insertion. When the exuvium is cast, this sheath is broken off, often resulting in a molting scar or pore. This pore can easily be misinterpreted as one that is permeable and belonging to UP sensilla.

AP sensilla are mainly mechanosensitive and are innervated by a single, unbranched neuron that is enclosed by a relatively thick dendritic sheath. The characteristic feature of these mechanosensilla is an accumulation of microtubules, called a "tubular body," usually located in the distal region of the distal dendrite. The tubular body generally consists of 50–100 tubules lying parallel to one another in an electron-dense material, although considerable variation in complexity and structure has been noted in numerous insect species. It is thought to be the site of sensory transduction.

becoming thicker, proximally. The dendrites are surrounded by the dendritic channel (double asterisk). Scale bar = 0.1 μm. (b) Multiporous auriculate sensillum. Note the numerous distal dendritic branches (asterisks) and extremely thin cuticular wall bearing numerous pores (arrowheads) and underlying pore tubules (arrows). The pore tubules, associated with each pore, extend from the base of a small circular pore kettle toward the dendrites through the surrounding sensillar sinus (ss). Some of the pore tubules appear to contact a few of the dendritic branches. Scale bar = 0.4 μm. (c) Cross section cut near the base of an aporous spire-shaped sensillum. At this level, two distal dendrites, one of which is lamellated (asterisk), are enclosed by a thick dendritic sheath (arrowhead) and surrounded by the dendritic channel (double asterisks). ss, sensillar sinus. Scale bar = 0.2 μm. (d) Cross section showing five proximal dendrites (asterisks) from a uniporous styloconic sensillum. One of the dendrites (arrow) is cut at the apex of the distal basal body of the proximal dendrite. The basal body bears a 9 × 3 + 0 microtubular configuration and nine radiating alar spokes of electron-dense material. One alar spoke arises from each of the nine triplet microtubules. At this level, the inner sheath cell (i) projects longitudinal folds with discrete complexes of microfibrils and microtubules (arrowheads with asterisks) around the proximal dendrites and encloses a ciliary sinus (double asterisks). The cytoskeletal elements are located along the inner border of the highly infolded inner sheath cell and adjacent to the ciliary sinus. Arrowhead, mitochondrion. Scale bar = 0.1 μm. (e) Cross section of a distal dendrite enclosed by a highly convoluted dendritic sheath (arrowhead) from an aporous basiconic sensillum. The microtubules within the dendrite are arranged in a single row along the periphery of the dendritic membrane (arrow). This membrane is in close apposition to the dendritic sheath. The inner sheath cell (i) enwraps the sensory neuron from its origin, near the proximal end of the dendritic sheath, to the level of the neuronal cell bodies. Scale bar = 0.2 μm. (f) Longitudinal section showing a distal dendritic segment (arrowhead) inserting into a proximal dendritic segment (arrowhead with asterisk) from a uniporous sensillum. Distal (upper arrow) and proximal (lower arrow) basal bodies are located in the distal end of the proximal dendrite. From the distal basal body, nine ciliary rootlets (r with arrowhead) extend proximally in a ring around the proximal basal body to which they attach. Scale bar = 0.5 μm. (g) Cross section showing four similar contiguous sensilla (asterisks) housed in an aporous styliform complex sensillum. Each sensillum unit is innervated by three bipolar sensory cells. Two of the distal dendrites are cylindrical and one is lamellate in shape. At this level, each of the distal dendritic bundles is individually ency a thick dendritic sheath (arrowhead). Scale bar = 1 μm.



Ultrastructure of Insect Sensilla, Figure 5
Diagrammatic reconstruction of a uniporous sensillum. This sensillum has a single pore positioned at the apex of the cone. Only three sensory cells are shown. ax, axon; cb, cell body; co, cone; cs, ciliary sinus; cu, cuticle; dbb, distal basal body; ds, dendritic sheath; pbb, proximal basal body; pd, proximal dendrite; po, pore; r, rootlets; ss, sensillar sinus; st, style; th, thecogen cell; to, tormogen cell; tb, tubular body of mechanosensitive neuron; tr, trichogen cell; udd, unbranched distal dendrites.

Thermo-Hygro Sensilla

AP sensilla may also serve a thermo-hygrosensitive function. Essential features regarded as adaptations to hygro- and thermoreception are the lack of pores; an inflexible socket; the occurrence of dendritic outer segments which fill the lumen of the peg (type 1, moist/dry receptors), or the occurrence of one or two dendritic outer segments which terminate below the peg (type 2, cold receptors or type 3, with unknown function). Typically, AP thermo-hygrosensilla are innervated by three bipolar neurons referred to as a "triad," consisting of two type-1 and one type-2 neurons.

Uniporous (UP) Sensilla

UP chemosensilla are usually termed contact chemosensitive, gustatory, or taste sensilla. Their chemosensitivity is generally predicated on contact with chemicals in solution. They are typically innervated by three to five or six unbranched distal dendrites and have one permeable apical or subapical pore, through which chemical communication between the dendrites and the external environment occurs. This pore also serves as the molting pore remaining open after the exuvial dendritic sheath is shed.

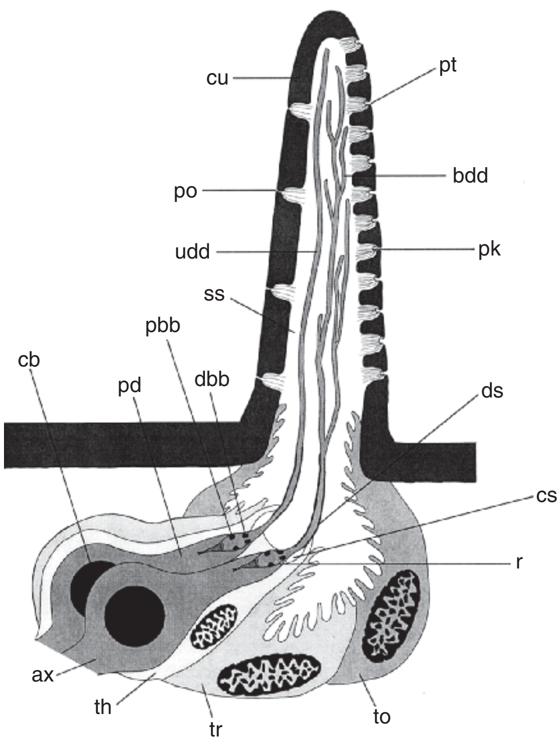
Pores of UP sensilla may have either a simple pit pore (UPP) or a sculptured porous point (UPS). The latter may vary from simple grooves leading to the pore to finger-like cuticular projections surrounding the opening. Pores vary in shape and size, ranging in diameter from 10 to 200 nm. They may contain a viscous mucoid extrusion from the dendritic channel that can cover the external opening. It is thought that this extrusion continuously fills the pore and may serve to conduct chemical stimulants within the dendritic channel to the dendrites below. Pores contain pore tubules or plugs of fenestrated fibrils of cuticular or other origin, in addition to the dendritic channel liquor. Such plugs may function by conferring selectivity to the conduction mechanism and a specificity of response to the sensillum.

Differences in the permeability of the galeal lateral and medial styloconic pegs (cones) to heavy metal ions, such as cobalt, mercury, and lead, have been shown to occur in several larval lepidopteran species, including *Mamestra configurata*, *Trichoplusia ni*, *Spodoptera frugiperda*, *Choristoneura fumiferana*, *Lymantria dispar*, and *Malacosoma lutescens*. The differences in permeability to these ion markers are of significance in interpreting the varying electrophysiological response to certain stimulants or deterrents applied to the terminal pore.

Some or all of the dendrites from UP sensory neurons extend through the dendritic channel towards the tip. Many UP sensilla contain a mechanosensitive neuron, whose dendrite terminates in a tubular body at the base of the sensory cuticle. Such sensilla are dually contact chemo- and mechanosensitive.

The dendritic sheath in UP sensilla is fused to the inner wall of sensory cuticle at the base of the pore and the liquor in the terminal dendritic channel is continuous with the liquor in the ciliary sinus. The dendritic sheath physically separates the dendritic chamber or channel from the sensillar sinus. The sheath is thought to be permeable to some small ions, but impervious to larger molecules. A permeable dendritic sheath would enable the sensillar sinus to act as a reservoir for ions, required by dendrites in producing the receptor potential and maintaining a resting potential. The dendritic channel is often appressed to the sensory cuticle along one side of the sensillum along much of its length.

In UP sensilla, pore tubules, comprising the cuticular sidewall lipoidal pore canal system, extend from the sensillar sinus through the sensory cuticle to the surface of the sensillum and selectively transport materials. The sidewall pore canal system around the terminal pore and distal portion of the dendritic sheath has been shown to be permeable to cobalt and mercury ions in some lepidopterous larvae, but not in others. The functional significance of the permeability of the sidewall pore canal system into the sensillar sinus is not known.



Ultrastructure of Insect Sensilla, Figure 6

Diagrammatic reconstruction of a multiporous sensillum showing the features of both a thick- and thin-walled sensillum in the same drawing for comparative purposes. Only two sensory cells are shown. The unbranched distal dendrite, thick cuticular wall, and pores with underlying pore tubules (left half of drawing) show features typically found in a thick-walled trichoid sensillum. The branched distal dendrite (bdd), thin cuticular wall, pore kettles, and pores with underlying pore tubules (right half of drawing) show features typically found in a thin-walled basiconic sensillum. Basiconic sensilla are typically shorter in height, have a cuticular wall that is generally thinner and pierced by a higher density of pores, have a greater number of pore tubules associated with each pore; and have many dendritic branches that fill the lumen of the sensillum, in comparison to trichoid sensilla. ax, axon; bdd, branched distal dendrite; cb, cell body; cs, ciliary sinus; cu, cuticle; dbb, distal basal body; ds, dendritic sheath; pbb, proximal basal body; pd, proximal dendrite; po, pore; pk, pore kettle; pt, pore tubule; r, rootlets; ss, sensillar sinus; th, thecogen cell; to, tormogen cell; tr, trichogen cell; udd, unbranched distal dendrite (modified from Shields and Hidebrand 1999a with permission from publisher).

Multiporous (MP) Sensilla

MP sensilla all possess an abundance of pores in their sensory cuticle. A mechanosensitive dendrite is not typically associated with these sensilla. There are two basic types of MP chemosensilla: single-walled sensilla with pore tubules and double-walled sensilla with spoke canals. MP sensilla are commonly referred to in the literature as MPP and MPG, since examination by scanning electron microscopy and TEM revealed a pitted and grooved surface, respectively.

Multiporous Pitted (MPP) Sensilla

MPP sensilla can be subdivided into two types based on thickness of the sensory cuticle and the conduction mechanism beneath the effective pore. Typically, thin- and thick-walled MPP sensilla have cuticles ~100–300 nm and 200–1000 nm, respectively. Pore density and diameter varies in thin and thick-walled sensilla, from 15–60/μm^2 to 2–20/μm^2, and 20–25 nm to 6–15 nm, respectively. The pores in both thin- and thick-walled types are funnel-shaped and flare outward from a narrowed opening just below the cuticular surface. In thin-walled MPP, each pore usually opens into a small circular chamber (pore kettle), 100–200 μm^2 in diameter, which abuts the sensillar sinus. Generally, more than 15 (sometimes as high as 50–60) pore tubules (averaging 15 nm in diameter) per pore kettle extend from its base toward the dendrites through the sensillar sinus.

Pore tubules are considered to be component parts of the sensory cuticle. The sensory pore tubule system of sensory cuticle is likely homologous with that of the pore canal and pore tubule system of the body integument. It is thought that sensory pore tubules are maintained either through the sensillar sinus or via the dendritic terminations. The cuticular pore canal system may function to transport lipoidal material from the epidermis to the surface for cuticular maintenance, in addition to the formation of a superficial lipoidal layer. This layer may act as a barrier against moisture loss through the cuticular pores and may contain proteinaceous components. It may also trap specific stimulant molecules that diffuse to the nearest pore along the pore tubules directly to a dendrite or, indirectly through the sensillar liquor.

In MPP sensilla, the dendrites emerge from the open end of the dendritic sheath, which terminates at or near the base of the sensory cuticle, into the sensillar channel. This channel is continuous with the sensillar sinus. A molting scar may be visible on the cuticular surface near the point of dendritic sheath termination.

Thin-walled MPP sensilla are typically innervated by two or three dendrites. The dendrites emerge beyond the open, distal end of the dendritic sheath and branch (about 7–150 branches). Generally, 10–12 pore tubules extend from the base of large pore kettles, which lie in close proximity to the sensillar sinus. These sensilla have a wider range of chemosensitivity than thick-walled MPP sensilla and are referred to as "generalist" sensilla.

In thick-walled MPP, the pore-kettles are reduced and cylindrical pockets often extend from the sensillar sinus toward the pore. Generally, three to eight pore tubules extend from the base of the pore funnel into the sinus either through the cuticular wall or pocket, where present. Thick-walled MPP sensilla are typically innervated by two to five unbranched neurons. These sensilla generally have a more selective range of chemosensitivity than thin-walled MPP sensilla and are referred to as "specialist" sensilla.

MPP sensilla are considered to be primarily olfactory. The transduction process is thought to involve six "steps": (i) adsorption of the molecule into a superficial lipoidal and/or proteinaceous layer at the outer surface of the sensillar wall to the nearest pore; (ii) diffusion along the pore tubules directly to the dendritic membrane or into the sensillar fluid; (iii) binding to a receptor molecule on the dendritic membrane; (iv) possible configurational change of the receptor protein; (v) resulting increase in conductance generating a receptor potential, and (vi) rapid inactivation of the odorant molecule.

Multiporous Grooved (MPG) Sensilla

MPG sensilla possess double concentric walls; the inner wall is smooth and surrounds the distal dendrites, and the outer wall is scalloped or fluted with longitudinal groves. The inner wall extends from the tip of the sensillum to near its base. The two walls are connected by cuticular spokes. Each spoke contains a radial spoke channel that is continuous with the sensillar sinus liquor. These channels, usually 20–30 nm in diameter, extend inward towards the distal dendrites. The sensillar sinus liquor bathes the dendrites. Small pores (10–20 nm in diameter) are found at the bottom of each longitudinal groove and are connected with the inside of the sensillum via the spoke channels. Material from the sensillar sinus appears to flow along the spoke channels over the grooved surface of the sensillum, presumably representing the trapping and conduction mechanism for chemical stimulant molecules.

MPG sensilla are typically innervated by two to five neurons with branched distal dendrites. In some species, the dendritic sheath may extend from near the base of the sensillum and fuse radially with the cuticle. In others, it may continue to near the ciliary region of the dendrites. The dendritic sheath is molted through an apical pore and pore tubules are absent. Wall thickness in MPG sensilla ranges from 300 to 400 nm and pore density is estimated at just over 200/μm^2. These sensilla are considered to be primarily olfactory.

Sensory Neurons

Insect sensory neurons are typically bipolar, with an enlarged perikaryon that is usually located in or below the epidermis. The dendrite extends distally from the distal pole of the cell body toward the dendritic sheath and sensory cuticle. The axon extends proximally from the perikaryon towards the central nervous system. The dendrite is abruptly constricted about midway along its length at the ciliary region (see also, below). This point demarcates the thin, distal dendritic segment from the thicker, proximal dendritic segment. The distal segment is also referred to as the ciliary segment or cilium. Typically, there is only one ciliary process per neuron.

Distal dendritic segments contain evenly dispersed longitudinal microtubules as the sole organelle. Vesicular inclusions and multivesicular bodies may also be present between the microtubules or just above the ciliary region. The distal dendritic segments are enclosed in a dendritic sheath from near their base to a variable point distally. Invaginations of the dendritic sheath produce longitudinal folds that partially or completely separate the dendrites along a portion of their length. In UP sensilla, the tip of the mechanosensitive dendrite often becomes completely separated from the other dendrites. Tight or gap junctions may also occur between the dendrites within the dendritic sheath.

The ciliary region is usually short and may be distinctly funnel-shaped, assuming a $9 \times 2 + 0$ microtubular arrangement near its point of origin. This microtubular arrangement is maintained distally in most scolopophorous and some aporous thermohygrosensilla. The ciliary region dilates into the distal dendritic segment, at its point of entry into the dendritic sheath, and the doublet microtubules separate and increase in number. Vesicular inclusions and multivesicular bodies may be present within the ciliary region.

The narrow distal dendritic segment inserts centrally into the wider tip of the thicker proximal segment. The distal and proximal, centriole-like basal bodies lie directly below the ciliary segment and are arranged in tandem. Each basal body has a $9 \times 3 + 0$ microtubular configuration. The distal basal body is located at the apex of the proximal dendritic segment, whereas the proximal basal body lies in tandem and slightly below it. The nine tubule doublets extend distally into the ciliary segment, presumably originating from the distal basal body. A circle of doublet tubules is embedded in a thin, dense "collar" or "necklace" of electron-dense material, just above the distal basal body. Rootlets with periodic cross-striations extend proximally from within the distal basal body. They pass around and attach to the proximal basal body and proceed toward the perikaryon. In scolopophorous sensilla, the rootlets are well developed and usually fuse to form a solid striated rod or ciliary root that extends toward the perikaryon. Vesicles, multivesicular bodies, and mitochondria typically surround the distal and proximal basal bodies. The vesicular contents are presumably used in the development and maintenance of the sensillar cuticular components. The cytoplasm of the proximal dendrite and perikaryon contains an abundance of rough and smooth endoplasmic reticulum, longitudinal microtubules, vesicles, Golgi bodies, free ribosomes, and mitochondria. The nuclei of the neuronal cells bodies are typically large, rounded, centrally located, and contain finely dispersed chromatin, indicative of high metabolic activity.

Axons from the sensory cells project to the CNS. The axons merge along common tracts to form nerves. Typical organelles found in the axon are mitochondria and evenly distributed longitudinal microtubules. Several wraps of glial cells individually enwrap the basal portions of each of the neuronal cell bodies and axons, typically inserting under the wrap of the inner sheath cell. In larger nerves, collections of axons are enclosed by a perineurial cell layer, which is further enclosed by a basement membrane in the hemocoel.

Sheath Cells

Accessory or sheath cells are specialized epidermal cells that envelop the neurons of insect chemosensilla. Typically, there are four sheath cells: a thecogen (inner), trichogen (intermediate), tormogen (outer), and a basal or glial cell. The inner, intermediate, and outer sheath cells enwrap the dendrites and the distal part of the nerve cell body. A basal glial cell enwraps the basal part of the cell bodies and axons. The number of sheath cells varies from 2 to 4 depending on the sensillar type. Each sheath cell forms at least one complete wrap around the neuron along most of its length and often overlaps.

The inner sheath cell typically wraps once around the sensory neuron(s), from the base of the dendritic sheath to some part of the cell body. The proximal dendrite and perikaryon of each sensory neuron are each individually wrapped by the inner sheath cell. This sheath cell usually terminates to one side of the neuronal perikaryon in an expansion containing its nucleus. The dendritic sheath is secreted by the inner sheath cell. The inner sheath cell may also be involved in the formation of the sensory cuticle if only two sheath cells are present in the sensillum.

In the ciliary region, the inner sheath cell encloses a small, ciliary sinus and also extends small microvilli into it. Microvillation indicates a possible secretory activity. The dendritic sheath and inner sheath cell form a continuous tube enclosing the contents of the ciliary sinus. A sinus liquor (fluid secreted into the ciliary sinus by the inner sheath cell) bathes the proximal and distal ends of the distal and proximal dendritic segments, respectively. This liquor is usually finely granular and electron-lucent. It is thought to contain nutrients secreted by the inner sheath cell.

The inner sheath cell also forms well-developed longitudinal desmosomal junctions with the distal termination of the proximal dendritic segments. Bundles of longitudinally-oriented microtubules and microfibrils, located along the inner border of the inner sheath cell, are associated with these junctions. The microfibrils are about 6 nm in diameter and resemble actin fibers. The microtubule and actin cytoskeletal elements may provide cellular rigidity and serve as mechanically stabilizing elements, respectively. The dendrites presumably grow through the inner sheath cell during development.

Both intermediate and outer sheath cells are very similar to each other in structure and function. The intermediate sheath cell enwraps the inner sheath cell along most of its length. The intermediate sheath cell also lines part of the sensillar sinus and extends microvilli, from its outer surface, into this sinus. This cell may secrete the sensory cuticle. The outer sheath cell envelops the intermediate sheath cell, from near the neuronal cell body to the sensory cuticle. This cell is thought to secrete the base or socket of the seta. The outer sheath cell encloses the sensillar sinus and similarly, extends microvilli from its outer surface into this sinus. Both intermediate and outer sheath cells presumably sequester nutrients from the underlying hemolymph and actively transport and secrete them into the sensillar sinus.

Since the dendritic sheath is thought to be selectively permeable to ions, the sensillar sinus, located adjacent to the dendritic channel, may function as an ion reservoir to replenish ions lost during dendritic activity. The intermediate and outer sheath cells are also thought to maintain a chemical environment appropriate for the stimulus conduction and transduction processes of the dendrites. These cells may be involved in cuticular maintenance and the provision of nutrients for the inner sheath cell. The sensillar sinus is usually larger than the ciliary sinus, however, its size is variable depending upon the type of sensillum. Similar to the inner sheath cell, the intermediate and outer sheath cells successively draw to one side near the level of the neuronal cell bodies and each terminates in an expansion containing the nucleus. The proximal extremities of the intermediate and outer sheath cells usually terminate in close proximity to the hemocoel, from which they are separated by a basement membrane. The inner, intermediate, and outer sheath cells are all rich in mitochondria, vesicles, multivesicular bodies, rough endoplasmic reticulum, free ribosomes, longitudinal microtubules, and Golgi bodies.

The glial sheath cell individually enwraps the basal portions of each of the neuronal cell bodies, always inserting under the wrap of the inner sheath cell. The glial cell also individually enwraps the axons. The cell body of the glial cell is small, as is its nucleus. Within its nucleus, the chromatin is condensed into large granules. The cytoplasm contains abundant rough endoplasmic reticulum and few mitochondria. A cytoplasmic layer of either the inner or glial sheath cell, proximally, separates all parts of every neuron from one another, from the base of the cilium. The axons within the nerve are individually enwrapped by the glial cells. The axon presumably grows through the glial cell in development.

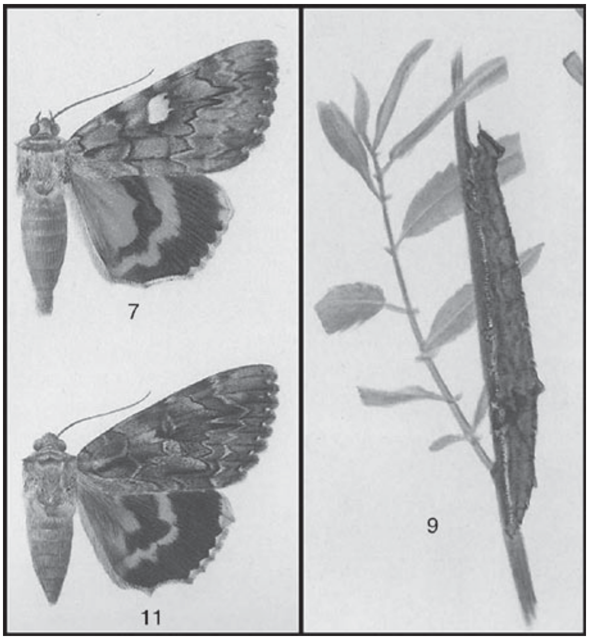
Unapparent Resources

Food resources (either insect or plant) that are "hard to locate" or unapparent to potential predators or herbivores. Unapparent resources often are protected against consumption by generalist predators or herbivores by possessing a toxin that deters consumption (contrast with apparent resources).

Underwing Moths – The Genus *Catocala* (Lepidoptera: Noctuidae)

LAWRENCE F. GALL
Yale University, New Haven, CT, USA

The genus *Catocala* Schrank (Fig. 7) is a speciose group of colorful and large moths in the family Noctuidae. The adults range from 4 to nearly 14 cm in wingspan. *Catocala* are commonly known as "underwings," in reference to the contrast between their drab, bark-colored forewings and their racily patterned hindwings, which are usually jet black with prominent yellow, orange, or red bands, and white fringes.



Underwing Moths – The Genus *Catocala* (Lepidoptera: Noctuidae), Figure 7 Details of adult and larval Catocala species, from Plates VI and XIII, in the monograph of North American species in the genus published by Barnes & McDunnough (1918).

Distribution

On a worldwide basis, *Catocala* is the second most speciose genus in the Noctuidae, exceeded in number of species only by cutworm moths in the genus *Euxoa* Hübner. *Catocala* occur throughout the northern hemisphere, though most frequently in deciduous forests, and the slightly more than 200 described species are split nearly evenly between the Nearctic and Palearctic regions. The *Catocala* faunas of the eastern and southern United States are among the most diverse, with 40–50 species occurring sympatrically in many areas. Interestingly, in contrast to most other Holarctic noctuid genera, there is no single species of *Catocala* whose geographic range includes both the Nearctic and Palearctic.

Phylogeny

Catocala contains several monophyletic species groups, comprising species with similar larval foodplant use. However, the relationships among these groups and of *Catocala* to other catocaline noctuids remain unclear, mirroring the incomplete understanding of phyletic relationships within the expansive subfamily as a whole. The species-level taxonomy of the Nearctic taxa has been examined in detail, but the corresponding Palearctic literature is less comprehensive, and no monographic treatment of the world fauna has been published. Most *Catocala* species were described during the nineteenth century, and the early workers in the genus, who were male, followed a tradition of coining specific epithets reflecting themes of romance, sorrow, and/or notable women. Thus, for example, *Catocala amatrix* Hübner (sweetheart), *C. lacrymosa* Guenee (tearful), *C. insolabilis* Guenée (inconsolable), *C. titania* Dodge and *C. cordelia* Hy. Edwards (from Shakespeare).

Biology

All species of *Catocala* whose life histories are known are single brooded. The adults are nocturnal and on the wing in mid to late summer in most localities. When at rest during the daytime on tree trunks and branches, adult *Catocala* conceal their brightly colored hindwings under the forewings, and are highly cryptic. However, adult *Catocala* are also wary when at rest, and will fly off suddenly and rapidly if disturbed. They usually settle again instantly upon reaching another perch, often vanishing from plain view. *Catocala* species have characteristic escape flights and resting habits: for example, some species circle the trunk and land again on the same tree, whereas others invariably fly to another tree. In studies with avian predators, the hindwings of *Catocala* have been shown to serve both as an initial startle mechanism and as a subsequent deflective device that focuses attacks away from the body. Many patterns of lepidopteran wing damage have been categorized quantitatively using *Catocala* as test subjects, and particular damage patterns have been correlated with behavioral responses on the part of predators. Field-collected *Catocala* regularly bear such wing damage patterns that can be traced to attacks by birds, bats and lizards.

Winter diapause in *Catocala* takes place in the egg stage. The eggs are laid singly or in rows or clumps on the larval foodplants. The eggs of most species are strongly dorsolaterally flattened, and the female moths have elongate, modified ovipositors which they use to secrete the eggs under exfoliating bark, or in crevices on branches and tree trunks. The larvae of most species hatch in spring and commence feeding on young foliage in April and May. Considering the genus as a whole, hatching from individual egg clutches varies from synchronous (2–3 days) to staggered (7–8 weeks), but each *Catocala* species exhibits a characteristic spread in its egg hatch that mirrors the foliating schedule of its larval foodplants.

Catocala larvae are active, semi-loopers that feed nocturnally. Most have cryptic bark-like coloration and morphologies, especially in the later instars. Mature larvae often have variously developed projections on the dorsal surface of the fifth abdominal segment that closely match leaf scars, buds, or broken branch tips; as well as a dense row of fine, sublateral filaments that are pressed against the substrate. Both of these characteristics break up the outline of the resting larva and enhance its crypsis. The young larvae rest preferentially on the midribs of leaves and on petioles, and shift to resting on branches and tree trunks as they mature. Most *Catocala* species pass through five larval instars, with some species having six or seven instars. Larval development is usually completed within 5–7 weeks of egg hatch. Pupation occurs in a loose silken cocoon of leaf litter and debris, with adults hatching in 3–4 weeks.

Unlike most other noctuid genera, the high species diversity in *Catocala* is coupled to a quite limited larval foodplant diet. In total, the genus is known to use only nine dicotyledonous families as larval hosts. However, even that liberally estimates foodplant breadth, because the overwhelming majority of *Catocala* species feed on plants in the families Fagacaeae, Salicaceae, Rosaceae, and Juglandaceae. No *Catocala* species is known to feed on plants from more than one of these plant families, and the foodplants of a given *Catocala* species are normally limited to one or more closely related plant genera. *Catocala* that use Fagacaeae, Salicaceae, and Rosaceae are found throughout the northern hemisphere, but Juglandaceae-feeding is essentially limited to North America, to a complex of two dozen closely related species apparently representing a single phyletic radiation. Although the larvae of many *Catocala* species can be collected commonly, the genus is not known to cause significant economic effect (at least in North America; possible exceptions include *C. maestosa Hulst* and *C. agrippina* Strecker, which sometimes occur in high density on pecan trees).

Collection

Because of their size and beauty, *Catocala* moths have been favorites with collectors for centuries. The adults are readily captured at both mercury vapor and ultraviolet light traps, and many species can be attracted to artificial bait sources. The term "sugaring" for moths refers to collecting using sweetened artificial bait, and *Catocala* have always figured prominently in the sugaring lore (the technique also goes by many other synonyms, such as "wine roping"). A functional artificial bait mixture requires a source of sugar as well as alcohol, but the lepidopterological literature is richly punctuated with collectors' idiosyncratic additions to lure *Catocala* and other prizes, like treacle, pureed banana, and expensive Barbados rum. Sugaring is a notoriously fickle and as yet poorly quantified collecting technique, producing divergent results in certain geographic regions, at some seasons, and under particular climatic conditions; sultry and unsettled weather immediately preceding electrical storms generally seems to be the most productive. Another time-honored, and sporting, collecting method that focuses specifically on *Catocala* is "tree tapping," in which one attempts to locate and creep up on adults without startling them as they rest during the day on tree trunks and branches.

Urban Entomology

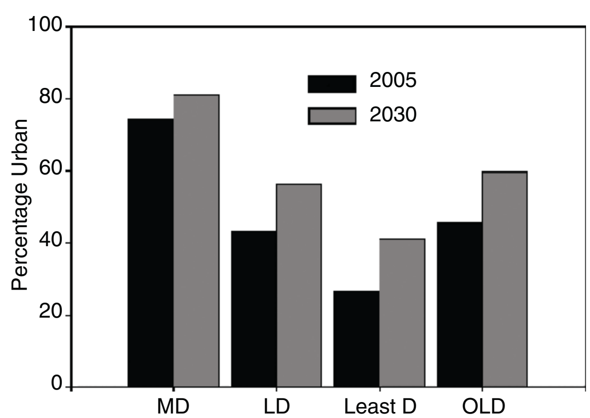
MICHAEL K. RUST
University of California, Riverside, CA, USA

Insects and related arthropods of importance in the urban environment are broadly covered under the auspices of urban entomology. Most arthropods in human environments go unnoticed. However, some species pose significant problems because they directly affect the health of humans or their domesticated animals, attack human structures, foods, goods, materials, or plants that adorn urban settings.

A relatively small number of insect species have been intentionally introduced into the urban environment. Examples include the gypsy moth, *Lymantria dispar*, that was intentionally introduced into Massachusetts in 1868. It is highly probable also that the Asian lady beetle, *Harmonia axyridis*, was intentionally introduced in the 1980s. Many pest species have been accidentally introduced with human commerce and travel. Some invasive species have adapted themselves to disturbed human habitats and have rapidly spread worldwide via commerce and human travel. The German cockroach, *Blattella germanica*, is an excellent example of such a species. It is rarely found outdoors, preferring heated and controlled environments typically associated with human food preparation. Probably native to eastern Asia, it spread throughout the eastern Mediterranean region by Greek or Phoenician vessels. It remained in southern Russia until after the Thirty Years War (1618–1648) spreading into Europe and finally becoming established in England in the mid 1800s. It is now cosmopolitan. Interestingly, it is even becoming established in restaurants and other food handling establishments in the rapid modernization of China.

With the increasing rate of global urbanization, problems associated with arthropod pests in urban centers will continue to grow. In 1950, about 731 million people (29.0%) lived in urban areas. At the turn of the twenty-first century, this had increased to greater than 2.8 billion people (46.7%). By the year 2030, it is estimated that there will be greater than 4.9 billion people (59.9%) living in urban areas. The most dramatic increases in urbanization and challenges will occur in developing countries (Fig. 8). As these countries attain greater development, the complex of urban invasive species will likely spread to these urban centers, or attain the problem status now associated with more developed countries. Many of these countries and developing urban centers exist in areas endemic to arthropod vector borne diseases such as malaria, dengue, encephalitis, yellow fever, and plague. The importance of urban and medical entomology in tropical urban centers will increase in the future.

The urban environment can be separated into those plant and animal communities that surround dwellings and buildings and reside within the domestic environment of structures. Plant communities of urban settings can be categorized



Urban Entomology, Figure 8 **Anticipated changes in urbanization from 2005 to 2030 in various countries throughout the world: MD – more developed countries include Europe, Northern America, Australia/New Zealand and Japan; LD – less developed countries include all regions of Africa, Asia, Latin America and the Caribbean, Melanesia, Micronesia and Polynesia; Least D – least developed are defined by 34 countries in Africa, 10 in Asia, 1 in Latin America; OLD – other less developed countries (http://esa.un.org/unup).**

as areas with remnant native plants, disturbed lands populated by volunteer plants, and actively cultivated landscapes. For example, it is estimated that there are some 300 million trees in the United States. In addition, the ornamental and nursery industry continues to grow; in the United States, the estimated value of the nursery and ornamental industry was $13.4 billion in 2001. Consequently, urbanization can result in more species-diverse landscapes, however, it is typically at the expense of native plants. This may be especially true along the urban-rural interfaces, and certainly increases the likelihood of problems with invasive insect pests.

In urban animal communities, the percentage of urban specialists such as the German cockroach or house fly dramatically increases as the overall species diversity decreases. Within human dwellings, the degree to which structures are sealed and indoor environments are maintained greatly affects the diversity of insects and arthropods. Highly regulated indoor environments favor species such as the German cockroach, Indian meal moth, cat flea, flour beetles, dermestid beetles, and Pharaoh ant. Because modified indoor habitats are similar in urban centers throughout the world, these pests are readily establish in developing urban centers. The list of indoor pests in Singapore, Tokyo, Los Angeles, New York City, London, Paris, and New Delhi are remarkably similar.

Insects, arthropods, and plants can be categorized into three broad groups in regard to urbanization (see Table 1). First, "Urban Avoiders" are species that are sensitive to human disturbances, including those species adapted to old growth forests, wetlands, and grasslands. These species are displaced in the course of urbanization. Second, the "Urban Adapters" are those species that are able to survive in human disturbed environments, as well as native environments. For example, many of the wood-destroying pests such as termites are native to the region and exploit both naturally occurring wood sources and human structures. Many of the species found in urban settings belong to this group, especially the native herbivorous species found along the urban-rural interface. Finally, the "Urban Exploiters" are commensal species that are dependent on human activities. Many of the grasses, weeds, and ornamentals in urban environments are, in fact, considered to be Urban Exploiters. Consequently, the turfgrass pests such as sod webworms and chinch bugs, or ornamental plant pests such as Japanese beetle, are also considered to be exploiters. This distinction may change in different geographical regions. For example, the American cockroach, *Periplaneta americana*, lives outdoors around structures in subtropical areas such as Florida and Hawaii and is clearly an Urban Adapter. However, in more desert, semi-arid areas of Arizona and California, it is an Urban Exploiter, being restricted to sewers, greenhouses, and animal rearing facilities. Similarly, the German yellowjacket in the western United States exploits urban dwellings, however, it is widely adapted to rural habitats in Chile. Other species, such as the German cockroach, brownbanded cockroach, and cat flea, are only found inside structures throughout most of their current range.

In the process of urbanization, the diversity of native plants and animals can be dramatically altered. In core urban areas, 80% of the land may be covered with pavement or buildings. Studies of rural-to-urban gradients suggest that the species richness of butterflies, herbivorous insects, ants, and other native species decreases towards the urban centers. The number of Urban Exploiters typically increases towards the center. The urban climate and increased temperatures can result in increased floral diversity. The species richness and diversity of butterflies may even peak at moderately disturbed sites. Some species such as aphids, leafminers, cockroaches, and flies can successfully colonize even in urban centers. However, urbanization can lead to a loss of specialists such as parasitoids, leaving certain herbivorous species in abundance.

The impact of many of the urban adapters and exploiters necessitates their control in urban settings. An increased awareness of the urban community over the last 10 years of the potential harm of insecticides and herbicides has resulted in

Urban Entomology, Table 1 List of some of the most important species that are Urban Adapters and Urban Exploiters of the urban environment. The list excludes those arthropods of medical and veterinary importance

	Order	Family	Common names[a] (genus species)
Urban adapters[b]			
	Araneae	Sicariidae	Brown recluse spider (*Loxosceles reclusa*)
		Theridiidae	Black widow spider (*Latrodectus mactans*)

[a]Common names adopted from the Entomological Society of America "Common names of insects & related organisms"
[b]Urban adapters are species that occur in broad human land uses found in suburban landscapes. Many so-called edge species, which are adapted to the forest edge and open areas, live here. These species exploit both foods derived from human activity as well as naturally occurring foods
[c]Urban exploiters or synanthropes are dependent on human activity. Urban cities often have more in common with other urban centers than the surrounding environment. Consequently, these are often invasive and exotic species

a growing effort to incorporate Integrated Pest Management (IPM) in urban environments. For these efforts to be successful, education and outreach programs within the urban community are essential. Unlike the agricultural community, the urban community has not been actively involved in IPM processes. Baits have been extremely successful in controlling cockroaches, subterranean termites and certain species of ants. Biological control efforts have been successful in controlling a variety of ornamental pests, such as the ash whitefly, the winter moth *Operophtera brumata*, acacia psyllid, and eucalyptus borer.

Uric Acid

The principal form of waste product elimination by insects. Uric acid, a purine, is synthesized by fat bodies from protein nitrogen and nucleic acid nitrogen. It is excreted from the Malpighian tubules. Though uric acid is energetically costly to produce, it is very conservative of water, and so aids greatly in water conservation.

Urodidae

A family of moths (order Lepidoptera). They commonly are known as false burnet moths.

► False Burnet Moths
► Butterflies and Moths

Urogenital Myiasis

Invasion of the urinary tract or bladder by fly larvae, resulting in bleeding, pain, and frequent urination. The insects associated with this ailment include latrine fly, *Fannia scalaris* (Fabricius) (Fanniidae); false stable fly, *Muscina stabulans* (Fallen) (Muscidae); house fly, *Musca domestica* L. (Muscidae); and lesser house fly, *Fannia canicularis* (L.) (Fanniidae).

► Myiasis

Urogomphus (pl., urogomphi)

Paired processes located dorsally on the ninth abdominal segment.

Urostylidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Urticaria

Itchy, and often elevated or discolored spots on the skin; wheals or hives.

Urticating Hairs

Hairs that cause a stinging or burning sensation in humans or other animals upon contact because they contain poison glands, or simply because the barbed hairs are irritating.

Usinger, Robert Leslie

Robert Usinger was born at Ft. Bragg, California, USA, on October 24, 1912. He attended the University of California-Berkeley where he received both his B.S. in 1935 and his Ph.D. in 1939. At that time he accepted a faculty position at University of California-Davis, where he worked until World War II. Following military service, he transferred to Berkeley, where he taught and conducted research. Usinger was a systematist, with expertise in Hemiptera. He traveled the world in pursuit of insects. He published several important books and monographs on systematics and Hemiptera, including "Methods and principles of systematic zoology" (with Mayr and Linsley, 1953), "Aquatic insects of California" (1956), "General zoology" (with Storer, 1965), and "Monograph of the Cimicidae" (1966). He was an active member of the International Commission on Zoological Nomenclature, and the Entomological Society of America, including service as president of the latter organization. Usinger died prematurely on October 1, 1968, in San Francisco.

Uvarov, (SIR) Boris Petrovich

Boris Uvarov was born on November 5, 1888, in Ural'sk Province, Russia. He was interested in insects from an early age, and attended Petersburg (Leningrad) University from 1906 to 1910. He studied Orthoptera, and was already publishing on the importance of habitats as early as 1910 (though this was not his first paper, having already published three botanical papers). After graduating, Uvarov immediately obtained an appointment as an entomologist in southern Russia in a cotton-growing district, where he had the opportunity to work on biology and control of migratory locust and Moroccan locust. In 1915 he transferred to another office that had responsibility for Georgia and Armenia. He also lectured at Tbilisi University, and published numerous papers on local grasshoppers/locusts. This was an important period in Uvarov's formation of phase theory, in that he gained an appreciation of the importance of local conditions in insect biology. With the collapse of the Russian Empire, Uvarov relocated to London, where he worked for the Imperial Bureau of Entomology. Here he published "Locusts and grasshoppers" in English (1928), as well as taxonomic work and important reviews on nutrition and climate. Here he also began to publish profound insight into locust phases and polymorphism, and the importance of solitary versus gregarious mode of life. This was an entirely unprecedented insight into insect biology, a variation that is matched only by sociality in terms of behavior, and equivalent to climate and parasitism in terms of importance in population regulation. In England, Uvarov implemented data collection that produced important information on several locusts, including range of several species and the important concept of locust management by preventing the locusts from reaching the gregarious stage. Starting in 1945 Uvarov and a small team of acridologists received official designation as the "Anti-locust Research Centre" and conducted important studies on African and Asian locusts until his official retirement in 1959. This did not stop his entomological contributions, however, and he then published "Grasshoppers and locusts" Volume 1 in 1966, and Volume II in

1977. Uvarov's contributions totaled over 400 publications; about half were taxonomic and about half were population biology and suppression. His insight into phase biology serves as a unique and long-lasting tribute to his creativity and analytical abilities. His influence has been profound, perhaps unprecedented among grasshopper and locust workers, and for this reason he has been called the "father of acridology." He was knighted in 1961. He died in London on March 18, 1970.

Valdivian Archaic Moths (Lepidoptera: Heterobathmiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Valdivian archaic moths, family Heterobathmiidae, include about nine species, with three named thus far. The family is the single member of the superfamily Heterobathmioidea and the sole member of the suborder Heterobathmiina. Adults small (10–11 mm wingspan), with head rough-scaled, with small mandibles; labial palpi are 3-segmented and short; maxillary palpi are 5-segented and folded. Maculation is usually iridescent purple with fine spots. All are diurnally active as adults, feeding at Nothofagus (Fagaceae) flowers. Larvae are leafminers of Nothofagus trees in southern South America.

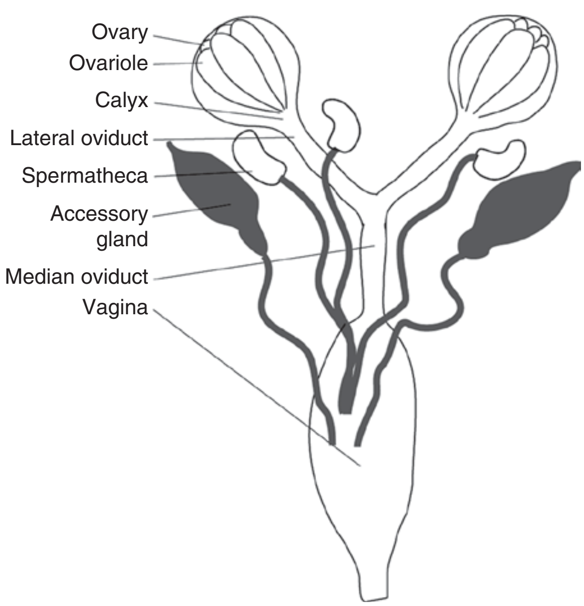
Valdivian forest moths, family Andesianidae, total only 3 known species from southern Andean forest



Vagina, Figure 1 Diagram of the female reproductive system, as found in *Rhagoletis* (Diptera) (adapted from Chapman, The insects: structure and function).

zones of Argentina and Chile. The family is the most primitive of the Monotrysian moths, in its own monobasic superfamily Andesianoidea, and in the section Nepticulina. Adults are robust and of medium size (27 to 61mm wingspan), with head scaling roughened; haustellum very short (with vestigial mandibles present); labial palpi elongated (with elongated 2nd segment); maxillary palpi 5-segmented (unfolded); and antennae bipectinate in males (filiform in females). Wing maculation is lustrous gray with numerous darker vertical striations, plus some dark spotting. Wing venation is heteroneurous but somewhat primitive with added veins. Adults apparently are nocturnal (possibly crepuscular), mainly in *Nothofagus* forests. Biologies are unknown, but larvae are likely to be stem borers.

Van Den Bosch, Robert

Robert van den Bosch was born on March 31, 1922, in Martinez, California, USA. He was educated at the University of California, Berkeley, where he received a degree in physical education before shifting his emphasis to entomology. He received his Ph.D. in 1950. He worked at the University of Hawaii from 1949 to 1951, the University of California-Riverside from 1951–1963, and the University of California-Berkeley from 1963 to 1978. van den Bosch had great influence in the fields of integrated pest management and biological control. Along with colleagues V.M Stern, R.F. Smith and others at the University of California, van den Bosch espoused an integrated approach to pest management that used chemical insecticides as only one element of pest suppression, relying on biological and cultural control for much mortality among pest populations. More specifically, chemical pesticides were viewed as a necessary but undesirable tactic that would be used only when absolutely necessary. The deleterious effects of pesticides including pesticide resistance among the target pests, inadvertent mortality to nontarget organisms such as beneficial insects and wildlife, and hazards to pesticide applicators were noted as reasons to avoid pesticide use. Though many have now come to accept this view, this was a radical viewpoint in the 1950s and 1960s when insecticides seemed to many to be miracle products. van den Bosch published more than 150 technical articles and several landmark books including "Biological control" (with P.S. Messenger, 1973), "Introduction to integrated pest management" (with M.L. Flint, 1981), and "The pesticide conspiracy" (1978). The latter was particularly provocative and served to sensitize both the research community and public to the lack of sound policy with regard to pesticide use in the United States. van den Bosch also served as chair of the Division of Biological Control at the University of California-Berkeley, from 1969 until his premature death at age 56, on November 19, 1978.

Van Duzee, Edward Payson

Edward Van Duzee was born at New York, New York, USA, on April 6, 1861. The son of a scientist, Edward was encouraged to work in the sciences, and he did so quite successfully, eventually becoming known as the greatest hemipterist in the United States. He became assistant librarian of the Grosvenor Library, a research library, in Buffalo, New York, in 1885, and then head librarian 10 years later. This environment allowed him to devote his attentions to the Hemiptera, and the bibliography of Hemiptera. Van Duzee collected throughout the United States. About 1900 he began a great monograph of the Hemiptera, a project that took 10 years to complete. It proved to be an outstanding compilation and serves as a model of completeness. Van Duzee left the Grosvenor Library after 27 years of employment, and before the catalogue was completed, due to ill health. He accepted employment as an instructor at the University of California, Berkeley, and the catalogue "Hemiptera of America north of Mexico, excepting the Aphididae, Coccidae, and Aleyrodidae" was printed by the University. Van Duzee did not enjoy teaching, and in 1916 accepted a position as assistant librarian and curator of entomology at the California Academy of Sciences. He spent the next 24 years building the insect collection, and also served as editor of the journal "The Pan-Pacific Entomologist" for the first 14 years of its existence. In all, Van Duzee published more than 250 articles over the course of his career. He died on June 2, 1940.

Variegated

Describes structures that are varied in color or have an irregular pattern.

Variegated Cutworm, *Peridroma saucia* (Hübner) (Lepidoptera: Noctuidae)

John L. Capinera
University of Florida, Gainesville, FL, USA

Variegated cutworm is found in many areas of the world. It occurs in North and South America, the Hawaiian Islands, and also portions of Europe, Asia, and North Africa. The origin of this insect is uncertain, but is thought to be Europe, where it was described in 1790. First observed in North America in 1841, it is now abundant in southern Canada and the northern United States, where it is often considered to be the most damaging cutworm pest of vegetables.

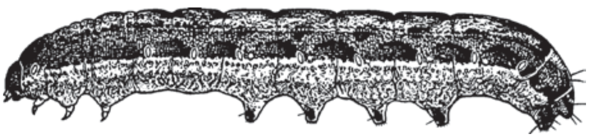
Life History

There are 2–4 generations annually, with two generations common in colder regions such as Canada, and 3–4 in warmer areas. Flights of moths are protracted, and generations are difficult to discern based on adult populations. Overwintering may occur in the pupal stage, or perhaps the larval stage, but there also is evidence that moths migrate into cooler areas from warmer latitudes each spring, and return to warmer regions in the autumn. For example, in a study conducted in Iowa, USA, 3–9% of moths collected during the spring flight were considered to have emerged from overwintering pupae, with the balance migrating from southern latitudes. The April-May spring flight in Iowa tends to be followed by generations and adult flights in June-July, August-September, and October-November. Total duration of the life stages is usually 35–70 days. Overwintering in colder areas such as Canada is unlikely except in relatively warm areas such as along the seacoast.

The egg of variegated cutworm is hemispherical in shape; the egg is flattened at the point of attachment to a leaf or plant stem. The surface of the egg is marked with ridges, about 42 in number, radiating from the center. The egg is 0.55–0.58 mm in diameter and 0.40–0.45 mm in height. Initially, eggs are white in color, but soon turn brownish. The developmental threshold for the egg stage is estimated at 3.0–6.0°C. Duration of the egg stage is 4–6 days in warm weather (20–30°C), but 10 days when held at 15°C. Eggs are deposited in clusters, often numbering several hundred per egg mass. Females may deposit 1200–1400 eggs during their life span.

There normally are six instars. The developmental threshold for the larval stage is estimated at 2.6–6.7°C. Duration of the instars is reported to be 6.5, 4.6, 4.8, 4.7, 6.7, and 16.8 days for instars 1–6, respectively, at 15°C. When reared at 25°C, instar durations are reduced to 3.1, 1.9, 2.2, 2.2, 2.9, and 8.4 days, respectively. Head capsule widths are 0.30–0.35, 0.46–0.62, 0.80–1.00, 1.20–1.65, 1.9–2.6, and about 3.0–3.2 mm, respectively. Body lengths are estimated at 2.0–3.0, 3.6–6.5, 5.3–9.0, 12–16, 25–28, and 35–46 mm for instars 1–6, respectively. Body color is (Fig. 3, Fig. 4) brownish gray to grayish black. The most distinctive character is a dorsal yellow or whitish spot, present on each of the first 4 abdominal segments, often the first six segments, although this character may be absent in early instars. Less distinctive is the black W-shaped mark on the eighth abdominal segment of the last

Variegated Cutworm, *Peridroma saucia* (Hübner) (Lepidoptera: Noctuidae), Figure 3 **Adult of variegated cutworm, *Peridroma saucia* (Hübner).**



Variegated Cutworm, *Peridroma saucia* (Hübner) (Lepidoptera: Noctuidae), Figure 4 **Larva of variegated cutworm, *Peridroma saucia* (Hübner).**

instar, and light brown or tan on the posterior end of the body. An inconspicuous black line is often present laterally above the spiracles. An orange-brown line may connect the spiracles, and below the spiracles there usually is some irregular yellowish or orange coloration. The head is orange-brown and marked with darker spots.

The larva forms a cell in the soil and pupates near the soil surface. The pupa is mahogany brown, and measures 15–23 mm long and 5–6 mm wide. The developmental threshold of the pupal stage is estimated at 4.3–8.5°C by various authors. Duration of the pupal stage is about 33 and 13 days at 15 and 25°C, respectively.

The adult is fairly large in size, the wing span measuring 43–50 mm. The front wings normally are grayish brown, tinged with reddish and shaded centrally and distally with darker brown. The background color varies, however, from dark brown to yellowish brown. A bean-shaped spot and a smaller round spot are usually evident centrally. The hind wings are iridescent or pearly white with brown veins and brown shading marginally. The head and thorax are dark brown, whereas the abdomen is lighter brown. Females produce a sex pheromone to attract males. Oviposition commences 7–14 days after emergence of the adults.

This cutworm has an extremely wide host range. Unlike some cutworms that expand their dietary range only when confronted with overpopulation and starvation, variegated cutworm feeds readily on numerous plants. Based on frequency of reports, variegated cutworm is likely to be found damaging beet, cabbage, lettuce, potato, and tomato, but nearly all vegetable crops are attacked. Variegated cutworm also is known to damage fruit trees, including apple, apricot, avocado, cherry, currant, gooseberry, grape, lemon, mulberry, orange, plum, raspberry, and strawberry. Other crops injured include alfalfa, barley, clover, corn, cotton, flax, hops, mint, sunflower, sugarbeet, sweet clover, tobacco, wheat, and many flower crops. Weeds are occasionally consumed, but seem not to be preferred. Some of the weeds eaten are jimsonweed, *Datura* sp.; dock, *Rumex* sp.; dogfennel, *Eupatorium capillifolium*; plantain, *Plantago* sp.; ragweed, *Ambrosia* sp.; and shepherdspurse, *Capsella bursa-pastoris*.

Numerous natural enemies are known from variegated cutworm; 20–75% mortality is not uncommon, with wasp and fly parasitoids accounting for most of the deaths among larvae. In a study of variegated cutworms in Oklahoma, USA, six species of Braconidae, three species of Ichneumonidae, and one species of Eulophidae were associated with this cutworm, but among the Hymenoptera only *Ophion* sp. (Ichneumonidae) accounted for more than 5% mortality. In the same study, 12 species of Tachinidae were observed, but among the Diptera only *Archytas apicifer* (Walker) and *Peleteria texensis* Curran (both Tachinidae) accounted for more that 5% mortality. In Oregon, USA, eight species of Hymenoptera were round attacking variegated cutworm larvae. The parasitoid *Meteorus communis* (Cresson) (Braconidae) was recovered from about 35% of the intermediate age larvae. Not only did the parasitism affect abundance of cutworm in subsequent generations, but caused a 93% reduction in foliage consumption by parasitized larvae. A study of variegated cutworm in Hawaii demonstrated 33–80% parasitism, with most of the parasitism due to *Hyposoter exiguae* (Viereck) (Ichneumonidae), *Cotesia marginiventris* (Cresson) and *Meteorus laphygmae* Viereck (both Braconidae) (all Hymenoptera).

Other Hymenoptera known to parasitize variegated cutworm include *Apanteles xylinus* (Say), *Chelonus insularis* Cresson, *C. militaris* (Walsh), *Meteorus autographae* Muesebeck, *M. leviventris* (Wesmael), *Microplitis feltiae* Muesebeck, *Rogas perplexus* Gahan, and *R. rufocoxalis* Gahan (all Braconidae); *Campoletis sonorensis* (Cameron), *Enicospilus merdarius* (Gravenhorst), *Nepiera fuscifemora* Graf, and *Ophion flavidus* Brulle (all Ichneumonidae); and *Dibrachys canus* (Walker) (Pteromalidae). Other Diptera parasitizing this cutworm are *Archytas aterrimus* (Robineau-Desvoidy), *A. cirphis* Curran, *Bonnetia comta* (Fallen), *Carcelia* spp., *Chaetogaedia monticola* (Bigot), *Clausicela opaca* (Coquillett), *Eucelatoria armigera* (Coquillett), *Euphorocera claripennis* (Macquart), *E. omissa* (Reinhard), *Gonia longipulvilli* Tothill, *G. porca* Williston, *G. sequax* Williston, *Lespesia archippivora* (Riley), *Madremyia saundersii* (Williston), *Peleteria texensis* (Curran), *Periscepsia helymus* (Walker), *P. laevigata* (Wulp), *Voria ruralis* (Fallen), *Winthemia leucanae* (Kirkpatrick), *W. quadripustulata* (Fabricius), and *W. rufopicta* (Bigot) (all Tachinidae). It is likely that many other wasps and flies attack this insect.

The fungus *Metarhizium anisopliae* and viruses can inflict mortality, but incidence is often low. Both a granulosis and a nuclear polyhedrosis virus are known to affect this cutworm.

Damage

Larvae cause considerable mortality to seedlings by cutting off the plant at the soil surface. Larvae also are defoliators, and although they commonly frequent low-growing herbage, they readily climb trees to feed on buds and foliage. Young larvae may remain on the foliage during the daylight hours, but feed principally during the evening hours. Large larvae often hide in the soil or other sheltered locations during the daytime hours, moving to exposed areas of foliage in the evening to feed. Larvae may burrow into tomato fruit and the heads of cabbage and cauliflower. At high densities, larvae may assume a gregarious, dispersive "armyworm" habit, but this is uncommon. This species also invades greenhouses frequently.

Larvae consume about 125 sq cm of sugarbeet or 160 sq cm of potato foliage during their larval development. Potato and many other plants can tolerate some defoliation without significant yield decrease. Late in the season, after tuber formation is nearly complete, potato can withstand up to 75% leaf loss without yield decrease. At this time up to 40 variegated cutworms per plant can be tolerated. However, at an earlier period in the season such as at full bloom, plants may be able to tolerate only three cutworms per plant.

Management

Adult populations can be monitored with blacklight traps and pheromone traps. Captures by the two types of traps are correlated, but pheromone traps capture larger numbers from the spring generation whereas blacklight traps capture larger numbers at other times of the year. Pheromone traps, although not completely species specific, provide considerable selectivity relative to blacklight traps, thereby reducing labor requirements associated with population monitoring.

Larval populations are difficult to sample. Young larvae may be found clustered on foliage, but older larvae tend to hide in sheltered locations or burrow beneath the soil surface during the daylight hours. If plants are severed at the soil surface, or have disappeared, it is important to rake the soil surface and search for cutworm larvae.

Insecticides are commonly recommended to protect young plants from cutting damage, and older plants from defoliation and fruit injury. Insecticide applications are directed at the foliage or soil, the latter because the larvae often seek shelter there. Insecticides differ greatly in their effectiveness, and larger larvae are considerably more difficult to kill. Insecticide-treated bran baits are effective against variegated cutworm. *Bacillus thuringiensis* is not recommended.

Cutworm problems often develop in weedy fields or portions of fields infested with weeds. It is advisable to till, or otherwise destroy weeds, 10–14 days in advance of planting, as this should cause small larvae to starve. If seedlings are to be transplanted into a field or garden, larger plants are preferred because they are less likely to be irreparably damaged by cutworms. Transplanted plants derive considerable protection if surrounded by a barrier such as a can or waxed paper container with the bottom removed. Aluminum foil wrapped around the base of the seedling also deters cutting by larvae.

Variegated cutworm is susceptible to infection by entomopathogenic nematodes (Nematoda: Steinernematidae and Heterorhabditidae) but demonstration of practical use under field conditions is lacking.

Varley, George C

George Varley was born in 1910 and educated at Cambridge University, Cambridge, England. As a student, he became interested in mathematical models relating to population dynamics, a subject that would fascinate him for his entire career. He completed his Ph.D. in 1935 and then held a series of positions at University of California at Riverside, Cambridge University, King's College at Newcastle, and finally he was appointed Hope Professor at Oxford. He served in this latter capacity for 30 years, retiring in 1978. At Oxford, Varley worked on winter moth for 20 years, producing an unusually complete understanding of its biology, and developing key factor analysis as a method of analyzing life tables. It was a technique that would become a basic ecological method for analyzing animal populations. Varley's work proved to be very influential in population ecology. He died in 1983.

Varroa Mite, *Varroa destructor* Anderson and Trueman (Acari: Varroidae)

JAMIE ELLIS
University of Florida, Gainesville, FL, USA

The varroa mite, *Varroa destructor* Anderson and Trueman, is the world's most devastating pest of western honey bees (*Apis mellifera*, Hymenoptera: Apidae). Although the varroa complex includes multiple species, *V. destructor* is the species responsible for the vast majority of the damage attributed to mites from this genus. Until 2000, it was believed that *Varroa jacobsoni* Oudemans was the mite responsible for widespread honey bee colony losses. However, taxonomic work published in 2000 indicated that a previously unidentified species of varroa (*V. destructor*) was responsible for the damage; *V. jacobsoni* was shown to be only moderately harmful to western honey bees. This discussion is limited to *Varroa destructor*.

Varroa mites are ectoparasites that feed on the hemolymph of immature and adult honey bees. *Apis mellifera* is not the mite's natural host. In fact, the mite is native to Asia where it parasitizes another cavity-dwelling honey bee, *Apis cerana* (the eastern or Asian honey bee). *Apis cerana* is believed to have some natural defenses against the mite and consequently rarely is affected negatively by the mite. Only when the mite shifted hosts did people begin to realize how devastating it could be, and this occurred when colonies of *Apis mellifera* were moved to and propagated in Asia. Varroa's host shift did not occur instantly; evidence suggests that it may have taken 50–100 years. Since that time, the mite has spread around the world and has become nearly cosmopolitan in distribution (Fig. 5). Those countries not hosting varroa mites maintain strict quarantine procedures to lessen the chance of an accidental importation of the mite.

Varroa Mite Biology

Although the varroa mite is a natural parasite of *A. cerana*, most of its biology has been determined using *A. mellifera* due to the mite's importance as an economic pest on this honey bee species. With that in mind, most of the following discussion will relate to varroa's presence on *A. mellifera* rather than on *A. cerana*.

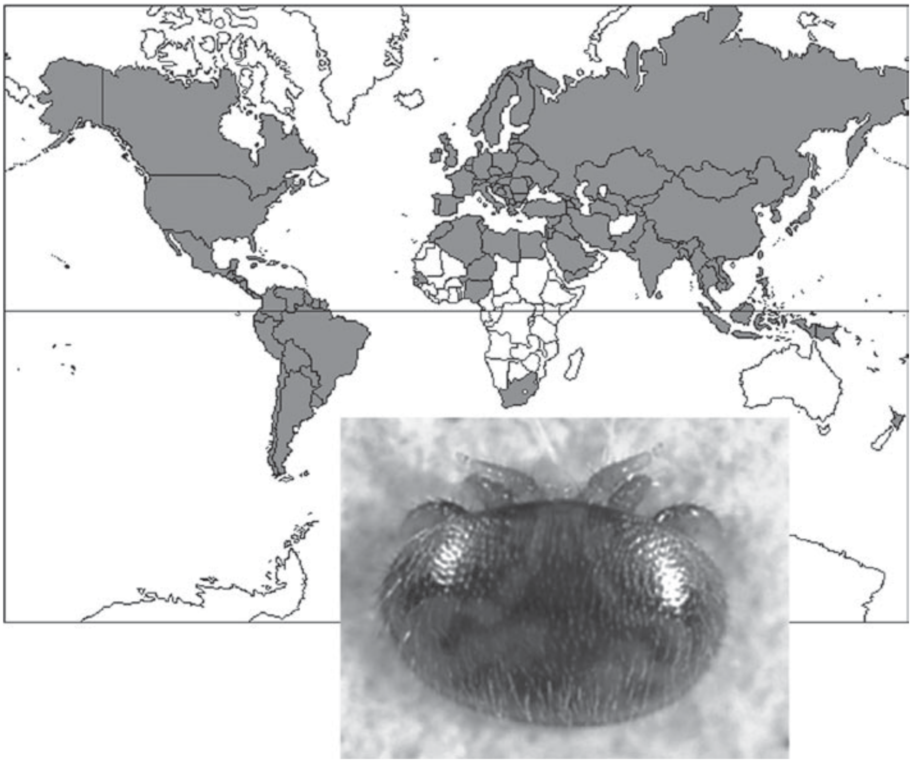
Adult female varroa mites (about 1.1 mm long and 1.6 mm wide) can be found either on adult or immature honey bees. They must, however, reproduce on honey bee brood. Immature varroa can be found only on capped brood and male varroa (about 0.8 mm long and 0.7 mm wide) will never leave these brood cells.

The adult females are brownish-red in color and oval in shape (Fig. 5) while the males are soft bodied and white. Although small according to human standards, a varroa female is one of the largest ectoparasites known when considered in relation to its host. Because varroa-associated damage is always caused by female mites, the rest of this discussion will proceed from the female varroa mite's perspective.

Adult females undergo two phases in their life cycle, the phoretic and reproductive phases. During the phoretic phase, female varroa feed on adult bees and are passed from bee to bee as bees walk past one another in the colony. During phoresy, the female varroa live on adult bees and usually can be found between the abdominal segments of the bee. Varroa puncture the soft tissue between the segments and feed on the bee's hemolymph through the puncture.

Anatomically, female varroa mites are well-adapted bee parasites. Their flattened shape allows them to fit between the abdominal segments. Furthermore, they have claws that allow them to grasp the bee and ventral setae that allow them to remain attached to the bee. The mite's cuticle has a chemical pattern similar to that of the bee's, possibly allowing it to escape notice while on the bee. Additionally, the cuticle is highly sclerotized, thus occasionally protecting it from bee aggression.

Phoretic varroa mites also can be passed between colonies of bees when infested bees drift into another colony. This happens frequently in managed honey bee situations where individual bee colonies are located within meters of one another. It is common for bees in this situation to return (drift) to the wrong colony. Interestingly, it has been shown that bees from colonies heavily infested with varroa drift more than bees from uninfested colonies. Varroa passing within a colony from bee-to-bee and between colonies by



Varroa Mite, *Varroa destructor* Anderson and Trueman (Acari: Varroidae), Figure 5 **An adult female *Varroa destructor* (photo by Michael O'Malley, University of Florida), and the worldwide distribution of *Varroa destructor* (from Ellis and Munn. 2005. Bee World 86:88–101).**

drifting demonstrate that the mites can be transmitted naturally both horizontally and vertically.

Varroa mites also may pass between colonies other ways. First, beekeepers often aid weak colonies by adding bees or brood from a healthier colony; this practice spreads the mite. Second, beekeepers may transport colonies from one area to another, facilitating the spread of varroa regionally. Third, individual colonies may swarm, moving to a new location and spreading varroa simultaneously. Finally, mites may spread between colonies as bees from the colonies rob (or steal honey from) each other. It is common for strong colonies to rob weaker colonies in periods of nectar dearth. Mites pass easily from bee to bee in these instances. All of these methods have contributed to varroa's global distribution as a honey bee pest.

The phoretic period of the mite appears to contribute to the mite's reproductive ability. Although mites artificially transferred to brood cells immediately after they mature are able to reproduce, their reproductive rate is lower than that of mites undergoing a phoretic period. The phoretic period may last 4.5–11 days when brood is present in the hive or as long as 5–6 months during the winter when no brood is present in the hive. Consequently, female mites living when brood is present in the colony have an average life expectancy of 27 days, yet in the absence of brood, they may live for many months.

In order to reproduce, phoretic mites must enter bee brood cells. Honey bees construct a waxy matrix in which they form hexagonal compartments or cells. Queen bees oviposit in these cells, and three days later, a bee larva emerges from the egg and begins to develop. Once the larva reaches a certain age, worker bees in the colony construct a waxy capping over the entrance to the cell. The larva develops into a prepupa and then a pupa under the capping. Twenty-one, twenty-four, or sixteen days after an egg is oviposited, an adult worker, drone (male), or queen bee emerges from the cell (aged respectively).

Varroa mite females must enter a brood cell before the bees seal it. In *Apis mellifera*, they may enter either a worker or drone cell, but the mites are more attracted to drone brood. A mite that is ready to reproduce will leave the adult bee on which it is feeding and crawl down the wall of the cell to the honey bee larva at the bottom of the cell. At this point, the female mite is referred to as a foundress mite. Only larvae of a certain age are attractive to the mite, that age being larvae just about to be capped or in the process of being capped. After crawling under the larva, the female mite will submerge itself in the brood food under the larva where it will remain until the cell is capped by other worker bees. While submerged, the mite erects its peretrimes which serve as breathing tubes, allowing the mite to breathe while it is submerged.

Once other worker bees have capped the cell, the larva consumes the remaining brood food, thus freeing the mite. The freed mite climbs onto the larva and begins feeding. The mite defecates on the upper part of the cell wall while feeding on the bee. Shortly thereafter, the mite lays its first egg on the surface of the cell wall. The egg is unfertilized and will develop into a male mite. Subsequent fertilized eggs are oviposited by the female mite toward the back of the cell approximately every 25–30 h. These hatch into female mites.

The newly emerged protonymphs join their mother on the ventral side of the developing bee pupa around the bee's fifth abdominal segment. Here, the mother and offspring alternate between periods of feeding on the bee and defecation on the base of the cell. The developing protonymphs molt into deutonymphs and then into adult mites. The entire process from egg to adult mite takes 6–7 days for both sexes of the mite.

Unless more than one foundress enters the cell prior to capping, mite offspring are forced to mate with their siblings. When male varroa undergo their final molt, their piercing mouthparts change into hollow tubes. The male mite uses this structure to transfer packets of sperm to openings in the female, at the base of her third pair of legs. Although the adult female varroa can infest and reproduce in more than one cell, it mates only in the cell in which it was born. Shortly after mating, the sperm transport system of the female varroa degenerates, thus prohibiting future matings.

Considering mortality in brood cells and improper matings, the average foundress mite produces about 1 offspring per worker cell she enters and about 2 offspring per drone cell (drones take longer to develop so more mites are produced in drone cells). Therefore, in the average temperate climate, mite populations can increase 12-fold in colonies having brood half of the year and 800-fold in colonies having brood year-round. This makes the mite very difficult to control, especially in warmer climates where colonies maintain brood year-round.

Effects of Varroa Mite

The varroa mite has affected the apiculture industry negatively in every country into which it has been introduced. In fact, in some areas varroa mite has all but domesticated the western honey bee. Individuals reporting the effects of varroa mite after they arrived in the USA stated that honey bee colonies could not survive unless beekeepers intervened with a chemical treatment.

Accurate estimates of the effect of varroa mite on the apiculture industry are hard to find, but it is safe to assume that the mites have killed hundreds of thousands of colonies worldwide, resulting in billions of dollars of economic loss. Varroa mites have caused beekeeper production costs to rise, thus lowering the profit margin in beekeeping.

Varroa mites also have affected the feral (wild) population of bees in many areas. Since feral colonies were not managed for varroa mites and the colonies were left unprotected, the loss of feral colonies quickly resulted as varroa continued to spread. On the other hand, feral colonies that survived varroa mites have slowly developed resistance mechanisms that have allowed them to persist in the presence of the mite. This did not happen with managed colonies because beekeepers started treating chemically for varroa mites almost instantly, thus keeping alive susceptible populations of bees. This practice is changing.

Varroa mites weaken and ultimately kill colonies by out-reproducing their host. Typically, bee populations peak in late spring to mid-summer with a steady decline in population occurring in mid- to late summer. Varroa mite population increase is similar to that of the bees but is offset by a number of weeks. Therefore, varroa mite populations are just beginning to peak when bee colony populations typically begin to decline. This is usually the start of significant varroa mite problems.

Varroa mites rarely kill adult bees, but they do shorten bee lifespan and may even alter bee behavior. Varroa mites can kill immature bees, and their ability to do so is correlated with the number of varroa mite foundresses that enter a brood cell prior to it being capped. The more mite foundresses in a cell, the less likely the immature bee will develop successfully and emerge as an adult.

Other effects of varroa mites on bees are just beginning to be understood. For some time, scientists have known that honey bees host a number of viruses. There is evidence that some of these viruses are associated with varroa mite presence and levels in a colony. It now is believed that varroa mites can transmit multiple viruses to their hosts and that these viruses, not the varroa mites themselves, may cause the majority of the damage that bees experience while hosting the mites.

To illustrate this point, one of the most telling signs of a varroa presence in a colony is the occurrence of newly emerged adult bees with misshapen (Fig. 6) wings. A virus, named deformed wing virus and present in immature bees, is responsible for this symptom. Bees with this virus are unable to use their wings; therefore, the bees will never be able to contribute to the colony's foraging efforts since they never will be able to fly. Deformed wing virus can be so prevalent in maturing bees that they can emerge without any wings at all. Researchers suspect that other viruses play an important role in the varroa mite/honey bee relationship, but the roles of these viruses are not well understood.

Varroa Mite, *Varroa destructor* Anderson and Trueman (Acari: Varroidae), Figure 6 A newly emerged worker bee with misshapen wings. A virus, transmitted to the developing bee by varroa, is responsible for this symptom (photo by Sean McCann, University of Florida).

Detection and Treatment of Varroa Mite

The detection and treatment of varroa mites is an ever-changing science. Since varroa mite's spread around the world, methods to accomplish both have been investigated and refined. Because detection and treatment are dynamic topics, this treatise will focus only on general methods rather than specific techniques.

Although small, varroa mites can be seen on adult bees with the naked eye. They often are found feeding between segments on the bees' abdomens or crawling quickly elsewhere on the bees' bodies. Varroa mites look very similar to another bee commensal, the bee louse (*Braula coeca*, Diptera: Braulidae), and this has led to mistaken identifications. Despite this, the identification can be made simple when one remembers that the bee louse is a wingless fly with six legs while the varroa is a mite with eight legs.

A much better way to look for varroa in a colony is to examine bee brood. It is easier to find mites on drone brood (although finding them on worker brood is possible) because (i) varroa mites are attracted to drone brood more strongly than they are to worker brood, and (ii) drone brood is easier to remove from the cells. Immature bee brood is white, making it very easy to see the reddish-brown varroa mite.

Even though varroa mites can be detected visually on adult and immature bees, the number of mites on each only gives one an index rather than an accurate measurement of varroa mite populations in the hive. Measurements have become more accurate with the advent of sampling tools, the most popular of which are varroa sticky screens and ether rolls.

Varroa sticky screens are pieces of cardboard coated in a sticky substance. The cardboard is then covered with a wire mesh that prohibits bees from touching the sticky substance but allows varroa to fall through the mesh. These screens can be inserted under the honey bee nest and used to trap falling varroa. Varroa, both live and dead, regularly fall off their host bees. This may be facilitated by the grooming activity of the bees, but it probably occurs naturally as well. When a sticky cardboard insert and screen are present underneath the nest, the falling varroa will pass through the screen and get trapped on the sticky surface of the cardboard. Researchers have been able to correlate varroa mite fall in 24-, 48-, and 72-hour periods with actual varroa mite populations in the colony. Sticky boards are useful because they sample the entire colony for the presence of varroa mites, rather than any subset of bees within the colony.

Ether rolls yield quicker results than sticky traps but can be less accurate because only a subset of the entire colony is sampled. In an ether roll, about 300 adult bees are collected in a glass jar, after which they are sprayed with ether. After the ether is added to the jar, the jar is lightly shaken for 30 s, during which time varroa mites present on the adult bees will adhere to the inside walls of the jar, facilitating their quantification. A newer version of this sampling protocol has been developed using powdered sugar rather than ether. Once the dusted bees are shaken, the bees can be released (they are alive) and the sugar can be dumped into water. After contacting the water, the sugar dissolves, thus facilitating varroa quantification.

Traditionally, these sampling methods were not used very often because treatment for varroa mites was recommended twice yearly, regardless of the number of mites in a colony. Recently, investigators around the world have tried to employ an integrated pest management (IPM) approach to varroa mite control. Sampling devices are paramount in this management scheme where treatment is recommended after varroa populations in a colony reach an economic threshold. A sampling device is needed in order to determine when an economic threshold is reached.

Many studies have been conducted in an effort to determine the economic threshold for varroa in a colony but results have varied. Factors affecting the economic threshold include temperature, colony strength, geographic location, the presence of other pests/pathogens, level of colony resistance to varroa, etc. As such, an economic threshold for varroa probably will not be universal and will have to be determined regionally. In the USA, independent studies have suggested that the economic threshold for varroa mite is around 3,000 mites/colony. Again, this number will vary depending on a number of factors, including those listed above. With the establishment of economic thresholds and sampling devices, varroa mite management has become easier, although IPM is not as widely practiced by beekeepers as one would hope.

Traditionally, varroa mites have been controlled chemically. In fact, chemical-based, in-hive treatments have followed varroa everywhere the mite has been introduced. Pyrethroids, organophosphates, essential oils, and organic acids have been used by many countries to control varroa. Initially, the pyrethroid fluvalinate showed high levels of efficacy (>90%) against varroa mites. However, varroa mites have a demonstrated ability to become quickly resistant to this and other synthetic acaricides. This has made many acaricides useless in areas where varroa resistance to chemicals has developed. Further exacerbating this is the issue that many of the synthetic chemicals used inside bee colonies to control varroa double as insecticides in other pest-management schemes. So, varroa mites have made it necessary for beekeepers to put insecticides into insect colonies, the results of which are only just beginning to be understood. The effects of chemical varroa treatments on honey bees include reduced longevity of queen bees, reduced sperm loads in and longevity of drones, brood death, and reduced queen laying patterns. Many more effects are believed to exist.

Because of the reduced efficacy of chemicals used to control varroa mites, attention has turned to the application of non-chemical methods for limiting varroa populations. For example, varroa are attracted disproportionately to drone brood. This has led some beekeepers to practice selective removal of drone brood from bee colonies after it has been capped. This practice eliminates a cohort of varroa mites from colonies. Also popular is the use of screened bottom boards to lower varroa mite populations. Although its level of efficacy is debated, replacing solid bottom boards of a bee colony with screen mesh can reduce varroa populations as much as 14%.

A number of other non-chemical methods purported to lower varroa mite populations are used by beekeepers, with varying degrees of success. These include placing colonies in full sunlight, dusting the adult bees in the colony (often with powdered sugar), fogging mineral oil and other liquids into the colony, using small-cell comb, etc. It is important to note that although concrete data supporting the efficacy of these methods is lacking, future research may establish a benefit from these and similar practices.

Without question, the most significant advancement toward controlling varroa non-chemically has come in the realm of bee breeding. A number of bee defensive responses to varroa have been identified and selected for in natural and artificial breeding programs; the most notable of these are hygienic behavior and grooming behavior. Bees that exhibit grooming behavior use their legs to comb themselves. They do this both to themselves and to other bees in the colony. This behavior can increase the number of varroa that fall off the bees, thus lowering the number of varroa in a colony.

Hygienic behavior is the most studied of all the natural defenses against varroa. Although it is not a behavior specifically targeted toward varroa mite, its manifestation can lower varroa mite populations within a colony. Bees that are hygienic can detect many problems that affect brood (American foulbrood, varroa, chalkbrood, etc.), even if it is capped, and remove the affected brood. Because varroa mites go into cells immediately prior to the cell being capped, hygienic bees are given little time to "find" varroa mites before the cell is capped. As a result, hygienic bees have a refined ability to detect varroa mites in capped cells, remove the capping, and abort the brood. Often, this behavior can lead to the death of the mite, thus lowering varroa populations. It is interesting to note that a heightened form of hygienic behavior called "varroa sensitive hygiene" (VSH) has been found in some bees. VSH bees are able to detect varroa in capped cells and remove only those varroa that are reproducing.

Effort also has been concentrated in finding races of bees that are generally resistant to varroa mites. This includes bees that do not have a single defensive behavior targeting varroa mite yet maintain a very low varroa mite population in the colony. The most successful of these programs includes the Russian honey bee program headed by the United States Department of Agriculture honey bee genetics lab in Baton Rouge, Louisiana, USA. Russian bees are a European subspecies of bee introduced into eastern Russia 100 + years ago. Because varroa mites are native to the area, Russian bees have developed a general resistance or tolerance to the mite. Russian bee queens were introduced into the US in 1997 and are gaining popularity among beekeepers.

Many feel that varroa control is maturing holistically even though this approach is slow to be adopted by beekeepers. Ample research has shown that an IPM-based approach to varroa mite control is more economical than the conventional methods heavily relying on chemical pesticides. For example, using any combination of the non-chemical varroa controls mentioned above can lower varroa populations in a colony >40%. Despite this, holistic varroa mite control will continue to mature and can be improved.

In conclusion, varroa remain a vexing problem for bees, beekeepers, and bee scientists alike. It generally is believed that finding a "cure" for varroa will prove one of the most significant advancements in modern-day apiculture. Varroa mite's presence in bee colonies already has led to substantial research funds being invested in studies investigating honey bee biology, ecology, and pathology. Until a cure for varroa mites is found, this parasitic mite will remain a key player in the loss of honey bee colonies globally.

Vector Capability of Blood-Sucking Arthropods: A Forecasting Matrix

ANDREY N. ALEKSEEV
Russian Parasitological Society, St. Petersburg, Russia

The ability to predict the potential for hematophagous arthropods to become vectors of pathogens is important in assessing their potential hazard to human or livestock health. The question of why one or another pathogen can be transmitted by a particular blood-feeding arthropod (hematophage), but not vectored by others, was first posed by Russian scientist Evgeny Pavlovsky, who formulated a theory of natural focality of infections and parasitic diseases.

Vladimir Beklemishev, a specialist in invertebrate evolution, comparative anatomy and systematic, was apparently the first who attempted to answer this question. He proposed a matrix based on the taxonomy of the vectors and the pathogens. According to this matrix, the ability to transmit a certain pathogen is limited to certain taxa. For example, this matrix forecasted that *Ixodes* ticks can transmit spirochetes, rickettsiae, and rickettsia-like microorganisms. However, the forecasting methodology was disregarded by the scientific community so Berlemishev's paper was never translated into English. As a result, the discovery of the vectors of Lyme disease and ehrlichiosis agents was made as late as the 1980s. Had the matrix received greater attention, the search for vectors might have progressed more rapidly.

A new, updated, prognostic matrix is presented (see Forecasting Matrix, Table 1) that takes into account food consumption of vectors. Most of the vector groups are insects, and more than half are Diptera.

According to the type of pre-adult feeding, all hematophagous arthropods can be divided into two large groups. In one group (Forecasting Matrix, Nos. 9–15), only blood (or lymph, as in bush mites) serves as a source of food, or at least part of food components must contain blood (as in flea larvae). Preimaginal (pre-adult) stages using many different sources of food, but not blood, compose the second group (Forecasting Matrix, Nos. 1–8). Only representatives of the first group (blood consumers on all stages) appear to serve as relevant or potential vectors of rickettsiae or rickettsia-like (*Ehrlichia*, *Cowdria*) microorganisms, with a single exception. The exception is triatomid bugs known as vectors of only one pathogen, *Trypanosoma cruzi*, which is the Chagas disease agent in South and Central America. This representative of the insect order Heteroptera shows a very specific type of quasi-peritrophic, chitin-like membrane in its midgut, allowing for no other parasites but pure-blood-consumers to develop. The infective form of *T. cruzi* is excreted with bug feces. These vectors might be called specific contaminators if the pathogen would not develop in the bug gut to achieve the infectious stage.

Rickettsiae develop either in digestive tract epithelium of lice and fleas (Forecasting Matrix – *dte*) or both there and in other cells, including salivary glands and ovarial cells in infected ticks and mites. This peculiar capability of rickettsiae for development and "conservation" in the gut epithelium of hematophagous arthropods allows them to survive during the vector' s molting periods (Forecasting Matrix, Nos. 9–10; 11–14) and thus to be transferred to the next stage of arthropod development, and even into the next generation. The phenomenon of transstadial transmission leads to understand how tsutsugamushi (or river, or bush) fever agent survives inside the free-living predaceous (entomophagous) nymphs and adults of trombiculid mites. Why rickettsiae are able to develop only in the vectors whose larval stage is hematophagous is not yet clear. Worm-like flea larvae are mainly detrivorous and only get the necessary components of blood from the

Vector Capability of Blood-Sucking Arthropods: A Forecasting Matrix, Table 1 Potential vector capacity forecasting matrix. Variants of transmission ability: ⊕ = proved for man; + = proved for animal; – = absent; P = potential

blood-containing excreta of adults. Nonetheless, clearly this kind of diet is necessary to make the adult flea gut epithelium an available medium for pathogenic rickettsial penetration and proliferation.

Arboviruses are represented by numerous families with very different core and envelope structures. Arboviruses can reproduce only intracellularly. The ability of an arthropod to serve as a virus vector seems to be based less on a potential vector's properties and more on arbovirus specificity. Ticks and gamasid mites, however, are known not only as vectors of many arboviruses but also reservoirs, being capable of transmitting them both transstadially and transovarially.

The majority of true, or potential, vectors are polyphagous, polyxenous ectoparasites, which are able to obtain blood from various vertebrate species. There is only one exception that confirms the rule, i.e., the louse *Pediculus humanus corporis* (Anoplura), an obligate hematophage at all stages and, according to the matrix, a monoxenous human parasite that can be a vector of rickettsiae. Indeed, these lice provide a very good environment for the accumulation and multiplication of the specific human typhus agent, *Rickettsia provazeki*. Being obligate hematophages, lice serve as a very good reservoir for still another specific human pathogen belonging to the spirochete (*Borrelia*) group. Both these pathogens are specific human disease agents and are transmitted from man to man. Rickettsiae in lice only develop in the gut epithelium and the pathogen's transmission by lice as well as fleas is a result of an infectious insect being crushed and rickettsia-infected feces penetrating into skin scratches. Yet *Borrelia*, the above obligate blood-consuming pathogen, is only capable of development in the arthropods whose ontogenetic stages are strictly hematophagous, i.e., lice, ticks, and gamasid mites. Trombiculid mites as lymph consumers must be excluded from this group as well as fleas, whose larvae feed not only on blood containing "parental excreta" but also detritus.

Borreliae develop in the gut content of lice, ticks and mites. In lice, however, they are capable of neither invading the louse body cavity nor being transmitted specifically through the bite of an infected insect. In contrast, borreliae in infected ticks are able to migrate through the body cavity into salivary glands. Infected ticks transmit this pathogen specifically (e.g., Lyme disease pathogen by nymphs or adults of *Ixodes* ticks attached to the host skin). The peculiarities of *Borrelia* biology suggest that other blood-sucking insects are unable to transmit these pathogens.

Bacilli, e.g., the plague agent *Yersenia pestis* as a natural focal disease of man, develop successfully in the flea gut and are transmitted through flea regurgitation during attempts to suck blood from their host. This pathogen can develop and even be transmitted by ticks as well, but these acari fail to play any part in plague transmission. All other arthropods must be excluded as potential vectors of bacilli.

Protozoan agents have a much wider range of potential and real vectors. Only pyroplasmids from the genera *Theileria* and *Babesia* that show a specific mode of sporogonia in the salivary gland cells of ticks are vectored by hard and soft ticks. As no other blood-sucking arthropod has the necessary type of cells in their salivary glands, this means that it is useless to search for vectors of these specific pathogens other than ticks.

Trypanosomatids are capable of development in all blood-sucking arthropods, irrespective of preimaginal food consumption, exclusive of lymphophagous trombiculid mites and obligate human ectoparasites like body lice. Only insects, not ticks or mites, can serve as hemosporid vectors. Most of them transmit these pathogens to birds. Of special note are the *Anopheles* (Culicidae) mosquitoes, vectors of human malaria agents (i.e., *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium ovale*). Interestingly, inclusion of the *Pseudomonas* group of microorganisms in the larval diet is essential for the successful development of these haemosporids in the potential vector organism.

Helminths, predominantly Filarioidea nematodes, are transmitted by a very wide range of vectors, mainly insects. Among these helminths, some are very dangerous parasites (e.g., loaosis by Tabanid flies and *Onchocerca* species by black flies) which cause blindness in humans. Mosquitoes also are vectors of dangerous filarial diseases such as brugiosis and elephantiasis.

The forecasting matrix (Table 1), though gaining little attention in the past, contains important patterns that help predict likely disease-vector relationships. For example, new species of rickettsial, spirochetal and pyroplasmid pathogens might be discovered among ticks and gamasid mites. New arboviruses might be revealed among tabanids and black flies, but not likely from lice or kissing bugs. This matrix virtually precludes a successful search for hemosporid protozoans among lice and other purely hematophagous arthropods at all ontogenetic stages.

Vector Competence

The ability of a potential vector to actually vector a disease. Many arthropods are capable of vectoring disease in an ideal (e.g., laboratory) environment, but fail to be effective vectors in the field. Some factors influencing vector competence include age of the vector and host, synchrony of vector and host, availability of alternate hosts, behavior/host preference of the vector, ability of the disease organism to maintain or increase titer in the vector, environmental conditions, prior exposure and host resistance.

Vectors of Phytoplasmas

PHYLLIS G. WEINTRAUB
Agricultural Research Organization Gilat Research Station, Negev, Israel

Phytoplasmas are phytopathogenic Mollicutes. These minute wall-less bacteria are found exclusively in phloem and primarily on sieve elements and cannot be cultured artificially. They were first associated with "yellows" diseases in 1926, although at the time they were thought to be viruses. Since then, phytoplasmas have been found in hundreds of plant species. Over 300 plant diseases are known worldwide, including economically important flowers, vegetables and orchards.

Phytoplasmas are vectored from plant to plant by a select group of Hemipterans feeding in the phloem. Of these insects, the leafhoppers and planthoppers have been shown to vector phytoplasmas, and more recently, a psylla (*Bactericera trigonica*) has been shown to vector phytoplasmas in carrots.

Once an insect has fed in the phloem of a phytoplasma-infected plant, a number of events must take place for it to be a successful vector. There are a number of anatomical and physiological barriers that the phytoplasma must overcome: it must successfully survive salivary and digestive enzymes; penetrate and replicate in the midgut cells; penetrate out of the midgut cells into the hemolymph; survive any phagocytes or encapsulation by hemocytes while in the hemolymph; travel to, penetrate and replicate in the salivary glands; and finally be released into the phloem of a plant as the insect feeds. The period of time from when the insect first acquires the phytoplasma until the time it can vector it to a new plant is the latent period. While a minimum amount of time is required for the physiological processes, it is also affected by temperature. Furthermore, vectors can acquire more than one type of phytoplasma.

There are a number of techniques available to detect and identify specific phytoplasmas in insects; however, all molecular (i.e., DNA probes, PCR/RFLP, and chromosome sequencing) and immunological (i.e., ELISA, dot hybridization and southern hybridization) tests cannot distinguish a vector species from an insect that has simply fed on an infected plant and thus has phytoplasma in its alimentary canal. To determine if an insect is a vector, it must be allowed to feed and transmit the pathogen. A relatively new technique combines molecular techniques with insect feeding. The potential vector, contained in a small tube, is allowed to feed through Parafilm on a sucrose solution. If the insect is an infective vector, PCR analysis of the sucrose will yield positive results. This technique allows rapid determination of the type of phytoplasma and the percent of infective vectors in any population.

To date, there are no efficient methods to control the spread of phytoplasma diseases, only to reduce its impact. Efforts to develop such control measures focus either on the plant or the insect vector. Phytoplasmas are not seed-transmitted but can be transmitted by grafting. Planting resistant varieties of plants or grafting to resistant rootstock is the best option to reduce spread of the disease, but resistant rootstock varieties do not exist for all plants. Tetracycline solutions have been variously applied to control infections in orchards. Such methods are usually effective only for the duration of the treatment; once stopped, symptoms return. However, currently there is research on genetically engineering plants to express antibodies, which may be a solution in the future. In cases where there are no resistant source plants, clean plants must be protected from insects with physical (nets or screening) or chemical (insecticides) means. Thorough knowledge of the biology of the vector and epidemiology of the disease will eliminate unnecessary insecticide treatments when the vector is either not present or is in a non-infective phase. If the vector is monophagous, using clean source plants and eliminating wild reservoir plants can achieve control of the disease. If the vector is polyphagous, border rows of a plant more "desirable" to the insect could be planted and heavily treated to protect the crop.

Phytoplasmas offer a great challenge to the researcher because they cannot be cultured and because there is no effective control. New molecular biological techniques are aiding in the quest for more understanding about the pathogen, pathogen-vector interaction, and pathogen-plant interaction.

Vegetable Leafminer, *Liriomyza sativae* Blanchard (Diptera: Agromyzidae)

Vegetable leafminer is found commonly in southern North America, and in most of Central and South America. Occasionally it is reported in more northern areas because it is transported with plant material. It cannot survive cold areas except in greenhouses.

Host Plants

Vegetable leafminer attacks a large number of plants, but seems to favor those in the plant families Cucurbitaceae, Leguminosae, and Solanaceae. Nearly 40 hosts from 10 plant families are known in Florida. Among the numerous weeds infested, the nightshade, *Solanum americanum*; and Spanishneedles, *Bidens alba*; are especially suitable hosts in Florida. Vegetable crops known as hosts include bean, celery, eggplant, onions, pepper, potato, squash, tomato, watermelon, cucumber, beet, pea, lettuce and many other composites. Vegetable leafminer was formerly considered to be the most important agromyzid pest in North America, but this distinction is now held by American leafminer, *L. trifolii*.

Natural Enemies

Vegetable leafminer is attacked by a number of parasitoids, with the relative importance of species varying geographically and temporally. In Hawaii, *Chrysonotomyia punctiventris* (Crawford) (Hymenoptera: Eulophidae), *Halicoptera circulis* (Walker) (Hymenoptera: Pteromalidae), and *Ganaspidium hunteri* (Crawford) (Hymenoptera: Eucoilidae) are considered important in watermelon. In California and Florida, the same genera or species were found attacking vegetable leafminer on tomato or bean, but *Opius dimidiatus* (Ashmead) (Hymenoptera: Braconidae) also occurred commonly in Florida. Levels of parasitism are often reported to be proportional to leafminer density, but parasitoid effectiveness can be disrupted when insecticides are applied. Steinernematid nematodes can infect *L. trifolii* larvae when the nematodes are applied in aqueous suspension and the plants are held under high humidity conditions.

Life Cycle and Description

The developmental thresholds for eggs, larvae, and pupae are estimated at 9° to 12°C. The combined development time required by the egg and larval stages is about 7–9 days at warm temperatures (25° to 30°C). Another 7–9 days is required for pupal development at these temperatures. Both egg-larval and pupal development times lengthen to about 25 days at 15°C. At optimal temperatures (30°C), vegetable leaf miner completes development from the egg to adult stage in about 15 days.

Egg

The white, elliptical eggs measure about 0.23 mm in length and 0.13 mm in width. Eggs are inserted into plant tissue just beneath the leaf surface and hatch in about three days. Flies feed on the plant secretions caused by oviposition, and also on natural exudates. Females often make feeding punctures, particularly along the margins or tips of leaves, without depositing eggs. Females can produce 600–700 eggs over their life span, although some estimates of egg production suggest that 200–300 is more typical. Initially, females may deposit eggs at a rate of 30–40 per day, but egg deposition decreases as flies grow older.

Larva

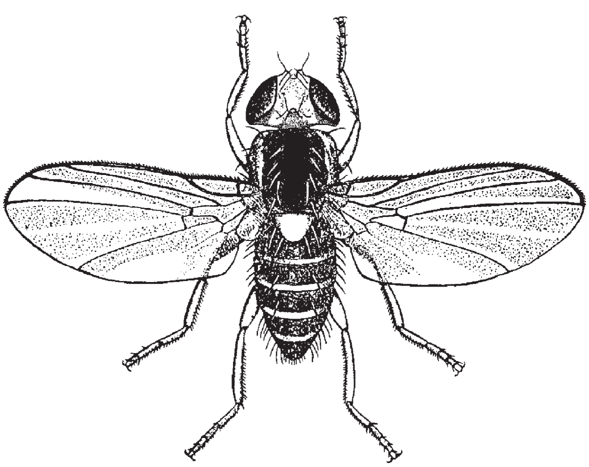
There are three active instars, and larvae attain a length of about 2.25mm. Initially the larvae are nearly colorless, becoming greenish and then yellowish as they mature. Black mouthparts are apparent in all instars, and can be used to differentiate the larvae. The average length and range of the mouthparts (cephalopharyngeal skeleton) in the three larval feeding instars is 0.09 (0.6–0.11), 0.15 (0.12– 0.17), and 0.23 (0.19–0.25) mm, respectively. The mature larva cuts a semicircular slit in the mined leaf just prior to formation of the puparium. The larva usually emerges from the mine, drops from the leaf, and burrows into the soil to a depth of only a few cm to form a puparium. A fourth larval instar occurs between puparium formation and pupation, but this is generally ignored by authors.

Pupa

The reddish brown puparium measures about 1.5 mm in length and 0.75 mm in width. After about nine days the adult emerges from the puparium. Mating initially occurs the day following adult emergence.

Adult

The adults (Fig. 8) are principally yellow and black in color. The shiny black mesonotum of *L. sativae* is used to distinguish this fly from the closely related American serpentine leafminer, *Liriomyza trifolii* which has a grayish black mesonotum. Females are larger and more robust than males, and have an elongated abdomen. The wing length of this species is 1.25–1.7 mm, with the males averaging about 1.3 mm and the females about 1.5 mm. The small size of these flies serves to distinguish them from pea leafminer, *Liriomyza huidobrensis* (Blanchard), which has a wing length of 1.7–2.25 mm. The yellow femora of vegetable leafminer also help to distinguish these species, as the femora of pea leafminer are dark. Flies normally live only about a month. Flies are uncommon during the cool months of the year, but often attain high, damaging levels by mid-summer. In warm climates they may breed continuously, with many overlapping generations per year.



Vegetable Leafminer, *Liriomyza sativae* Blanchard (Diptera: Agromyzidae), Figure 8 Vegetable leafminer adult, *Liriomyza sativae*.

Damage

Foliage punctures caused by females during the acts of oviposition or feeding may cause a stippled appearance on foliage, but this damage is slight compared to the leaf mining activity of larvae. The irregular mine increases in width from about 0.25 mm to about 1.5 mm as the larva matures, and is virtually identical in appearance and impact with the mines of *L. trifolii*. Larvae are often easily visible within the mine where they remove the mesophyll between the surfaces of the leaf. Their fecal deposits are also evident in the mines. Researchers have found that 30–60% yield increases are possible when effective insecticides were applied.

Management

Sampling

Several methods for population assessment have been studied, and collecting puparia in trays placed beneath plants and placement of yellow sticky traps to capture adults are most popular. Yellow sticky traps, however, have the advantage of being able to quickly detect invasion of a field by adults from surrounding areas.

Insecticides

Foliar application of insecticides is often frequent in susceptible crops. Insecticide susceptibility varies greatly both spatially and temporally. Many organophosphate and carbamate insecticides are no longer effective. Insecticides are disruptive to naturally occurring biological control agents, and leafminer outbreaks are sometimes reported to follow chemical insecticide treatment for other insects.

Cultural Practices

Some crops vary in susceptibility to leaf mining. This has been noted, for example, in cultivars of tomato, cucumber, cantaloupe, and beans. However, the differences tend to be moderate, and not adequate for reliable protection. Placement of row covers over cantaloupe has been reported to prevent damage by leafminer. Sometimes crops are invaded when adjacent crops are especially suitable. Weeds are a source of flies, but also a source of parasitoids.

Vegetable Pests and their Management

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Throughout the world, vegetables are an important element of the human diet, providing a vital source of carbohydrates, vitamins, and minerals. Some vegetables remain unique to specific cultures, whereas others have gained wide acceptance and have been transported to several continents where they are grown extensively. In many cases, insect pests have been transported to new continents as well (Figs. 9 and 10). In some cases, the insects apparently were transported along with the initial plant material. In other cases, the insects were introduced as “hitch-hikers” on other products, but once gaining entrance to their new home found it quite suitable because their host plants had preceded them. Another important source of pests is host adaptation or host switching, wherein insects adapted to feeding on a particular plant (often a weed or other non-crop plant) begin feeding on introduced crops. Such insects usually adapt to crop plants in the same plant family as their original host, or inherently have a broad host range.

The major groups of vegetable crops and some key pests follow. A more complete list of pests, their hosts and geographic ranges, and the plant tissues damaged are listed in Table 2.

Artichoke (Family Compositae)

Artichoke, more correctly known as globe artichoke, is a thistle-like plant grown for the edible blossom bud. It is a perennial, with new growth arising annually from the roots. Like some other perennials, it can be grown with some success as an annual crop by planting roots, but this is not a common practice. Although artichoke can be grown over a broad geographic area, it is not cold-hardy. Commercial production is generally limited to Mediterranean climates, where the cool, moist environment favors its growth. It is not a popular vegetable, and is considered by many to be a “luxury” vegetable. The origin of artichoke appears to be the western Mediterranean region of Europe. A similar plant grown for the leaf stalks is cardoon, but this plant is not grown extensively. The key pest of artichoke is the artichoke plume moth, *Platyptilia carduidactyla* (Riley) (Lepidoptera: Pterophoridae), though such aphids as the artichoke aphid, *Capitophorus elaeagni* (del Guercio), and the bean aphid, *Aphis fabae* Scopoli (both Hemiptera: Aphididae), can be quite damaging at times.

Polyphagotarsonemus latus (Banks), broad mite	AF, AS, AU, EU, NA, SA	numerous cops	foliage
Tetranychus urticae Koch, twospotted spider mite	AF, AU, AS, EU, NA, SA	numerous but principally cucurbit, legume, and solanaceous crops	foliage

[a]Regions are AF, Africa; AU, Australia/New Zealand; AS, Asia; EU, Europe; NA, North America; SA, South America
[b]Crops are artichoke, family Compositae; asparagus, family Liliaceae; chenopods, family Chenopodiaceae; crucifers, family Cruciferae; cucurbits, family Cucurbitaceae; legumes, family Leguminosae; lettuce, family Compositae; okra, family Malvaceae; onion, family Amaryllidaceae; pepper, family Solanaceae; solanaceous, family Solanaceae; sweet corn, family Graminae; sweet potato, family Convolvulaceae; umbellifers, family Umbelliferae

Asparagus (Family Liliaceae)

Asparagus is a hardy perennial plant, and once established, remains productive for 15 to 20 years. It is grown in many temperate climates, and is winter-hardy in most climates. It is usually grown from crowns (roots), but seeds may be used. Seeds are spread freely by birds, and it is common to find asparagus growing wild along roadsides, fences and irrigation ditches. Asparagus is popular in home gardens grown in northern areas, probably because it is one of the first crops available for harvest in the spring. It has been a popular vegetable since ancient times, and originated in the Mediterranean region. The spears or stems are harvested as they first push up from the soil; once they begin to branch, they become tough and inedible. The most serious pests are the asparagus aphid, *Brachycorynella asparagi* (Mordvilko) (Hemiptera: Aphididae), and the asparagus beetles, *Crioceris* spp. (Coleoptera: Chrysomelidae).

Bean and Related Crops (Family Leguminosae) (Bush Bean, Chickpea, Cowpea, Dry Bean, English Pea, Faba Bean, Lentil, Lima Bean, Mung Bean, Pigeon Pea, Snap Bean, etc.)

Legumes are known for their ability to harbor nitrifying bacteria; nitrogen enhances soil productivity. The cultivated legume vegetable crops are not particularly efficient as a source of nitrogen for plant growth, however, so fertilization is still required. They are, however, a relatively good source of vegetable protein, so they are an important dietary component in areas where animal protein is limited. Most of the leguminous vegetable crops are warm-weather crops and are killed by light frosts. English pea is a notable exception, thriving under early season and cool weather conditions, but killed by heavy frost. The legume vegetables are annual crops. The *Phaseolus* bean crops, such as snap bean and lima bean, are native to Central America. English pea and cowpea likely originated in Asia. The legumes are cultivated for their seeds or seed pods, and are eaten fresh or dried.

There are many important pests of legumes, and they vary among crops and geographically. The seed-attacking maggots, *Delia* spp. (Diptera: Anthomyiidae), can be important pests under cool weather conditions. The Mexican bean beetle, *Epilachna varivestris* Mulsant (Coleoptera: Coccinellidae) is important in North America. The Old World bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae), affects pigeon pea crops in Africa and Asia. English pea is quite susceptible to infestation by the pea aphid, *Acyrthosiphon pisum* Shinji (Hemiptera: Aphididae), the pea leaf weevil, *Sitona lineatus* (L.) (Coleoptera: Curculionidae), and the pea midge, *Contarinia pisi* (Winnertz) (Diptera: Cecidomyiidae); they are most damaging in northern areas. Cowpea is plagued by cowpea weevils, *Callosobruchus* spp. (Coleoptera: Bruchidae). Locally, a number of other pests can be important, particularly thrips, leaf miners, leafhoppers, and flea beetles.

Beet and Related Crops (Family Chenopodiaceae) (Beet, Chard, Spinach, Swiss Chard)

Beet apparently originated in the Mediterranean region, and spinach originated in Iran. The beet and its relatives are biennial crops, requiring more than one year, but less than two, to complete their natural life cycle. They are grown as annuals when cultivated as vegetables. Though originally grown entirely for its foliage, cultivars of beets with edible below-ground portions (the edible "root" is mostly thickened stem material) became popular in Europe beginning about 1800. Beet and chard are not important crops except in cool-weather climates. Spinach is more popular as a commercial crop relative to other chenopods, but is relatively unpopular compared to many warm-weather vegetables. In home gardens, these crops thrive nearly everywhere. The principal pests are the green peach aphid, *Myzus persicae* (Sulzer) (Hemiptera: Aphididae), and the beet and spinach leafminer, *Pegomya* spp. (Diptera: Anthomyiidae). In western North America and in Europe, the beet leafhoppers, *Circulifer tenellus* (Baker) and *C. opacipenis* (Leth.) (both Hemiptera: Cicadellidae), can be very damaging.

Cabbage and Related Crops (Family Cruciferae) (Broccoli, Brussels Sprouts, Cabbage, Cauliflower, Chinese Cabbage, Collards, Kale, Kohlrabi, Mustard, Radish, Rutabaga, Turnip, Etc.)

Cruciferous vegetables, often called "cole" crops, are grown for their leaves. These are cool-season crops, and tolerate light freezes and even brief heavy freezes, but prolonged deep freezes are fatal. Though naturally biennials, they are grown as annuals. Cabbage and its many forms originated along the shores of Europe; mustard and radish are from Asia. Some are popular foods throughout the world, others are of regional significance. Perhaps the most interesting vegetable in this group is broccoli, which has become popular only since the 1950s. Cauliflower is a moderately important crop. Cabbage and turnip have declined in importance, though cabbage remains a significant crop. Rutabaga is an important dietary element in northern climates, and collards are important in southern areas. The principal pests of cabbage and its closest relatives include the root maggots, *Delia* spp. (Diptera Anthomyiidae); the cabbage aphid, *Brevicoryne brassicae* (Linnaeus), and the turnip aphid, *Lipaphis erysimi* (Kaltenbach) (both Hemiptera: Aphididae); the diamondback moth, *Plutella xylostella* (Linnaeus) (Lepidoptera: Pyralidae); the cabbage looper, *Trichoplusia ni* (Hübner) and the cabbage moth, *Mamestra brassicae* (L.) (both Lepidoptera: Noctuidae); and the imported cabbageworm, *Pieris rapae* (Linnaeus) (Lepidoptera: Pieridae). Mustard and radish tend to be plagued more by the green peach aphid, *Myzus persicae* (Sulzer) (Hemiptera: Apididae).

Carrot and Related Crops (Family Umbelliferae) (Carrot, Celery, Celeriac, Chervil, Coriander, Fennel, Parsley, Parsnip)

The umbelliferous vegetables are biennial, but are grown as annuals. They require cool weather to develop properly. Most survive heavy frost, but are killed by prolonged freezing weather. The major crops of this group, carrot and celery, originated in the Mediterranean region. Carrot and parsnip are grown for their roots; celery, celeriac and fennel for the swollen stem bases; and parsley and coriander (cilantro) for their foliage. Carrot and celery, and to a lesser degree parsley and coriander, are popular vegetables. Parsnip is an important crop in northern climates because it stores well during the winter months, and can even be left in the soil during freezing weather. Fennel is growing in popularity, but as yet, is a minor crop awaiting discovery by some cultures. Chervil is grown in Europe, and different types are grown for their roots and foliage. In some areas, the carrot weevil, *Listronotus oregonensis* (LeConte) (Coleoptera: Curculionidae), the willow-carrot aphid, *Cavariella aegopodii* (Scopoli) (Hemiptera: Aphididae), and the carrot rust fly, *Psila rosae* (Fabricius) (Diptera: Psilidae), are important pests. Leafhoppers (Hemiptera: Cicadellidae) sometimes transmit aster yellows disease. The American serpentine leafminer, *Liriomyza trifolii* (Burgess), and the serpentine leaf miner, *L. sativae* Blanchard (both Diptera: Agromyzidae), are often a serious threat to commercially grown celery.

Lettuce and Related Crops (Family Compositae) (Celtuce, Chicory, Endive, Escarole, Lettuce, Radicchio)

Lettuce is a popular salad vegetable. Lettuce apparently originated in Europe or Asia, and has been grown for over 2,000 years. Lettuce and most related crops are grown for their leaves, though, in the case of celtuce, the stem is eaten. Lettuce and related crops are cool-season annuals. Although killed by heavy frost, these crops are also susceptible to disruption by excessive heat. Hot weather causes lettuce to flower and become bitter tasting. Several insects are important pests of lettuce. The aster leafhopper, *Macrosteles quadrilineatus* Forbes, (Hemiptera: Cicadellidae), is an important vector of aster yellows in some production areas. Several species of aphids (Hemiptera: Aphididae), including the lettuce aphid, *Nasonovia ribisnigri* (Mosley), and the lettuce root aphid, *Pemphigus bursarius* (L.), may be damaging, though the green peach aphid, *Myzus persicae* (Sulzer), generally is the most important pest. Numerous caterpillars such as the corn earworm, *Helicoverpa zea* (Boddie), and the cabbage looper, *Trichoplusia ni* (Hübner) (both Lepidoptera: Noctuidae), also threaten lettuce crops.

Okra (Family Malvaceae)

Okra is thought to be native to Africa and is an important crop in tropical countries. It is an annual plant and is killed by light frost. Okra is grown for the seed pods which, like snap beans, are harvested before they mature. Okra is unusually tall for a vegetable crop, often attaining a height of 2 m. The pods are subject to attack by several pests. Some of the most damaging are: the red imported fire ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae); the cotton aphid, *Aphis gossypii* Glover (Hemiptera: Aphididae); the Old World bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctudae); the southern green stink bug, *Nezara viridula* (Linnaeus) (Hemiptera: Pentatomidae); cotton stainers, *Dysdercus* spp. (Hemiptera: Pyrrhocoridae); and leaffooted bugs, *Leptoglossus* spp. (Hemiptera: Coreidae).

Onion and Related Plants (Family Alliaceae) (Chive, Garlic, Leek, Onion, Shallot)

The onion and its relatives are biennial or perennial plants, but cultivated as annuals. These have long been important crops, with the use of onions documented for nearly 5,000 years. Their origin is thought to be Asia. Onion is grown principally for the below-ground leaf bases, which form a bulb, but the tops are also edible. They are tolerant of cool weather, but also thrive under hot conditions. Onion and garlic are cultivated widely. The key pests of onion are onion thrips, *Thrips tabaci* Lindeman (Thysanoptera: Thripidae), and the onion maggot, *Delia antiqua* (Meigen) (Diptera: Anthomyiidae).

Rhubarb (Family Polygonaceae)

Rhubarb is cultivated as a perennial. Its origin is northern Asia, and its use can be traced back about 5,000 years. Rhubarb thrives where summers are cool. The stalks, or leaf petioles, are used as food, though this vegetable is infrequently consumed. Most commercial production occurs in northern regions, but it remains principally a home garden crop. There are few important pests of rhubarb, with the bean aphid, *Aphis fabae* Scopoli (Hemiptera; Aphididae), and the rhubarb curculio, *Lixus concavus* Say (Coleoptera: Curculionidae), perhaps the most serious.

Squash and Related Crops (Family Cucurbitaceae) (Cucumber, Melons, Pumpkin, Squash, Watermelon, Etc.)

The cucurbit crops are important vegetables, though they vary in economic importance. They are annual plants, and are warmth-loving crops. Light frost will kill cucurbits, and even cool weather will permanently disrupt growth. All are cultivated for their fruit. Squash and pumpkin originated in Central and South America; cucumber, melons and watermelon are from Africa, or perhaps Asia. Cucurbit crops have some serious insect pests, including the squash vine borer, *Melittia cucurbitae* (Harris) (Lepidoptera: Sesiidae); the squash bug, *Anasa tristis* (De Geer) (Hemiptera:

Coreidae); the melonworm, *Diaphania hyalinata* (L.), the pumpkin caterpillar, *Diaphania indica* (Saunders), and the pickleworm, *Diaphania nitidalis* (Stoll) (all Lepidoptera: Pyralidae); the red pumpkin beetle, *Aulacophora* spp., and cucumber beetles, *Acalymma* sp. (all Coleoptera: Chrysomelidae). Whiteflies (Hemiptera: Aleyrodidae) and aphids (Hemiptera: Aphididae) are plant virus vectors.

Sweet Corn (Family Graminae)

Corn, which is usually known as maize outside of North America, apparently was domesticated in Mexico, and perhaps is descended from a similar grain, teosinte. Corn originally was cultured because it was productive, a good source of carbohydrates and other nutrients, and the grain stored well. Sweet corn is a recent innovation that was first developed in the mid 1700s, and lacks the storage characteristics of the older types, or grain corn. Corn is grown for the seeds, which are clustered in a structure called the "ear." Sweet corn is a popular vegetable, and the development of fresh corn that does not quickly lose its sweetness (supersweet cultivars) has increased demand for whole-ear corn. Many pests feed on corn, including the corn earworm, *Helicoverpa zea* (Boddie), the fall armyworm, *Spodoptera frugiperda* (J.E. Smith), and several cutworms (all Lepidoptera: Noctuidae); the *Diabrotica* rootworms (Coleoptera: Chrysomelidae); the European corn borer, *Ostrinia nubilalis* (Hübner) (Lepidoptera: Pyralidae); the Japanese beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae); and the corn leaf aphid, *Rhopalosiphum maidis* (Fitch) (Hemiptera: Aphididae).

Sweet Potato (Family Convolvulaceae)

Sweet potato is an immensely important crop in some parts of the world, principally in tropical areas. The sweet potato probably originated in Mexico and is well adapted to tropical growing conditions. Some moist-fleshed sweet potatoes are called yams, but yams are a separate species normally found in Polynesia. A perennial crop, sweet potato is normally grown as an annual. It is cultivated for its tuber. The sweet potato cannot tolerate prolonged cool weather and perishes if exposed to light frost. The sweetpotato weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Curculionidae), is the most damaging pest of this crop, but the sweetpotato vine borer, *Omphisa anastomasalis* (Guenée) (Lepidoptera: Pyralidae), wireworms (Coleoptera: Elateridae), whiteflies (Hemiptera: Alyrodidae), and the flea beetle and the cucumber beetle larvae (both Coleoptera: Chrysomelidae) are economically threatening.

Tomato and Related Plants (Family Solanaceae) (Eggplant, Pepper, Potato, Tomatillo, Tomato)

The solanaceous crops are among the most important vegetable crops. Both the crops and the pests are quite diverse. Potato ranks as the most valuable, but tomato and pepper also rank among the most highly valued crops. The potato is grown for its tuber, and the other crops for their fruit. The origins of the solanaceous crops are diverse; eggplant originated in India, potato and tomato in Peru, and tomatillo and pepper in Mexico or Guatemala. Tomato, tomatillo, pepper and eggplant are warm-season perennials that are cultivated as annuals. The potato is a cool-season perennial cultured as an annual. Potato crops are at risk from the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae), but several aphids (Hemiptera: Aphididae) also are commonly damaging, particularly the green peach aphid, *Myzus persicae* (Sulzer) and the potato aphid, *Macrosiphum euphorbiae* (Thomas) (both Hemiptera: Aphididae). Beet leafhoppers *Circulifer tenellus* (Baker) and *Circulifer opacipennis* (Leth.) (Hemiptera: Cicadellidae), can be damaging to potatoes and tomatoes. Tomato is affected by the silverleaf whitefly, *Bemisia argentifolii* Bellows and Perring (Hemiptera: Aleyrodidae); the corn earworm, *Helicoverpa zea* (Boddie) (Lepidoptera: Noctuidae), and many other pests. The pepper weevil, *Anthonomus eugenii* Cano (Coleoptera: Curculionidae), is the key pest of pepper in warm-weather areas of North America.

The Characteristics of Pests

Pests vary from place to place, and from time to time. In some cases, pests are consistently abundant or damaging (so-called key pests), but in other cases, many years may pass before a particular species attains pest status. Most vegetable producers plan for the regular, or key, pests (many of them are mentioned above or are listed in the table) and take preventative actions to keep the pests from inflicting injury. It also is wise to monitor crops and to be alert for the less regular pests that come along periodically and may also require some corrective action.

The Pest Complex

Irrespective of the crop, there usually is a diversity of pests attacking, often including one or more aphids, flea beetles, leaf beetles, weevils, and cutworms or leaf-feeding caterpillars. The pest complex is often quite similar within related crops (members of the same plant family), and so it is not surprising to see the potato aphid (Hemiptera: Aphididae) on tomato, or the Colorado potato beetle (Coleoptera: Chrysomelidae) on tomato and eggplant, because they are all members of the family Solanceae and have similar plant chemistry. Some pest species distinguish among related plants, however, and so specialists, such as the pepper weevil (Coleoptera: Curculionidae), are limited to a single host, in this case, pepper.

In contrast, the pest complex often is quite different among crops from different plant families. Thus, the squash bug (Hemiptera: Coreidae) and the pickleworm (Lepidoptera: Pyralidae), are limited to Cucurbitaceae; the tuber flea beetle and the Colorado potato beetle (both Coleoptera: Chrysomelidae), are limited to Solanaceae; and the asparagus beetle (Coleoptera: Chrysomelidae), and the asparagus aphid (Hemiptera: Aphididae), are limited to asparagus.

Polyphagous species, insects with a very wide host range, display different behavior. Insects, such as the melon aphid, the green peach aphid (both Hemiptera: Aphididae), the silverleaf whitefly (Hemiptera: Aleyrodidae), and the Japanese beetle (Coleoptera: Scarabaeidae), seem to feed on almost everything. This is not true, of course, as they have preferred, or more suitable, hosts, but their host range includes hundreds of species. Thus, they can be expected to appear on, and perhaps be damaging to, many crops.

Crops are not the only factor determining the presence of pests. Weather and climate are quite important because some pests are adapted for warm climates and others for cool climates. Thus, their tolerance of weather and climate determines the extent of their geographic range as surely as an ocean or a mountain range. For instance, silverleaf whitefly (Hemiptera: Aleyrodidae), melon thrips (Thysanoptera), or broad mite (Acarina) are not seen in cool climates; nor are pea leaf weevil (Coloptera: Curculionidae), Japanese beetle (Coleoptera: Scarabaeidae), or European crane fly (Diptera: Tipulidae) found in subtropical and tropical environments. They are adapted to certain environments and cannot live outside their preadapted geographic range. Over time, they may evolve a broader tolerance and expand their geographic range, but this is a slow process. Interestingly, plants tend to be more tolerant of weather conditions than do their insect parasites. Therefore, the extremes of the host plant's geographic range often lack the "normal" complement of insect herbivores.

Weather also influences the dispersal of vegetable insects. Some species overwinter only in warm climates, dispersing northward annually.

Their ability to disperse varies from year to year depending on weather patterns, though, in many areas, it is not a question of whether or not they will disperse, but only when the dispersal will occur. Examples of annual long-range dispersal are common in North America, where species such as the black cutworm, the fall armyworm (both Lepidoptera: Noctuidae), the pickleworm (Lepidoptera: Pyralidae), the aster leafhopper, and the beet leafhopper (both Hemiptera: Cicadelidae) disperse northward annually.

Types of Damage

Insects usually affect vegetable crops by feeding directly on the harvested part of the plant (called direct pests), or on a part of the plant that is important to its productivity, such as the roots or the leaves. This latter group is known as indirect pests because they cause damage indirectly, by weakening the plant. Thus, caterpillars act as direct pests when they feed on the actual tomato fruit, but as indirect pests when they consume the tomato plant's foliage. Typically, species that function as direct pests are more damaging. Leaf feeding can be direct injury, however, when the foliage is harvested, as in lettuce or spinach. Foliage and fruit can be damaged above-ground, or plant tissues (roots, tubers, basal stem tissue) may be damaged below-ground. Damage can be manifested in leaf rolling or webbing, speckling, or growth deformities in addition to tissue removal.

A third important type of damage is plant disease transmission. Plant disease, particularly plant viruses, can be transmitted through the activities of insects. Some insects, such as aphids, may transmit diseases even to plants they do not normally feed upon. Disease transmission can occur while an aphid is sampling its environment, flying from plant to plant seeking an appropriate host. Even if the aphid alights on a plant that is unsuitable for its growth and reproduction, a short probe by the aphid with its mouthparts while it is testing the plant for suitability can be enough to transmit some viruses. Some insects also cause disease-like injury while feeding, even if they do not transmit a pathogen. This occurs when a component of the insect's saliva is toxic. Such insects are said to be toxicogenic and produce ailments such as hopperburn and psyllid yellows.

Approaches to Pest Management

Vegetable crops, like fruit crops, have high cosmetic standards. Thus, there is considerable economic pressure on vegetable producers to maintain their crops free of pests and pest-related injury. Vegetable crops, especially when marketed as fresh crops, also command a high price. The high cosmetic standards and prices cause producers to spare no effort to protect their crops from pest damage. This usually results in frequent insecticide applications. Even with the rapidly escalating costs of pesticides, insecticide costs usually are a minor component of the total costs of crop production. Thus, many growers do not hesitate to apply insecticides. It is not always necessary to apply insecticides, however, because there are times and places when insects are not sufficiently abundant to cause injury, or there are other alternative actions that can be taken to limit injury. There is adequate justification for careful monitoring of vegetable crops, and application of the economic injury level concept, which would eliminate unnecessary insecticide application.

Cultural practices, such as modifying the location or time of planting, tillage, weed control, level and type of irrigation and fertilization, and physical barriers, such as floating row covers, are techniques that can be used to reduce the ability of insects to infest and reproduce within crops. Such practices ideally will maximize environmental resistance, and eliminate the threat of pest damage. Sometimes these practices are completely adequate, and other times they are an important component of pest management that requires additional, complimentary intervention. In southern regions of the United States, for example, early-planted cucurbit crops usually escape infestation by the pickleworm (Lepidoptera: Pyralidae). Late-planted or autumn crops are routinely infested by this pest, necessitating the application of insecticides to prevent crop injury.

Host plant resistance involves the use of vegetable plant cultivars that inherently are less supportive of insect growth and development, or that are less injured by insect feeding. For example, the glossy varieties of crucifers that lack the waxy bloom and are, therefore, green rather than the normal grayish green color, are somewhat resistant to the diamondback moth (Lepidoptera: Pyralidae). Unfortunately, the genetic diversity in horticulturally acceptable vegetables (growth, shipping, appearance and taste characteristics affect "acceptability") is often quite limited, and cultivars with insect resistance often are unavailable. Also, plant breeders have not concentrated on producing pest-resistant vegetable crops to the degree that they have worked on field and forage crops. This lack of attention is due to the ready availability of insecticides and the high value of vegetables, which allows economic use of insecticides.

Biological control involves the use of biotic agents to suppress pest populations. In the case of invading pest species, this can be done by introducing natural enemies that have been "left behind" in the native land of the pest. Assuming successful introduction and establishment of an effective natural enemy, this approach sometimes results in adequate and continuous suppression, allowing cultivation of the crop without additional release of the natural enemy, and without insecticidal intervention. On the other hand, some pest problems require regular intervention. For example, many crops infested with caterpillars are treated several times during each cropping cycle with the bacterium *Bacillus thuringiensis*.

The most commonly used approach to pest suppression in vegetable crops is the use of chemical insecticides. Insecticides are used because there is almost always an effective product available; this is not true for cultural practices, host plant resistance, and biological control. Insecticides can be applied to the soil to prevent seed, seedling and young plant injury; to the foliage and fruit to protect against direct and indirect pests; and to baits or traps to reduce the number of pests available to injure crops. Insecticides can be very selective, or have a wide range of activity, depending on the need. Insecticides can be formulated to be systemic in action, to function as fumigants, and to have short or long residual activity. Thus, despite concern about the adverse effects of insecticides (primarily threats to humans and wildlife), they remain a commonly used tool for vegetable production.

Velvet Ants (Hymenoptera: Mutillidae)

DONALD G. MANLEY
Clemson University, Florence, SC, USA

Because of their generally bright colors and conspicuous appearance, velvet ants have long been favorite targets of insect collectors. Thus, it is with some degree of surprise that so little is known about them and their biology. Female mutillids, which are much more frequently observed than males, generally look very much like ants. They are wingless and can be seen scurrying about on the ground. They are, however, actually wasps. Their ant-like appearance, coupled with the fact that they are covered by a dense pubescence (hairs), has led to the common name of velvet ants.

Linnaeus included eight species of mutillids in his tenth edition of *Systema Naturae* in 1758. By the latter part of the nineteenth century, an estimated 3,500 to 4,000 species had been described, nearly all of which were included in the genus *Mutilla* Linnaeus. It was not until near the beginning of the twentieth century that many new genera were established.

The family Mutillidae is found worldwide but is predominantly tropical. As of 1975, there were approximately 8,000 described species. Brothers (1975) investigated the phylogeny of Mutillidae and recognized seven monophyletic subfamilies. That phylogeny is generally accepted. The family is now known worldwide from approximately 230 genera and subgenera, included in those seven subfamilies.

The higher-level classification is as follows:

Order: Hymenoptera
Superfamily: Vespoidea
  Subfamily: Myrmosinae
  Subfamily: Pseudophotopsidinae

Subfamily: Ticoplinae
Subfamily: Rhopalomutillinae
Subfamily: Sphaeropthalminae
Subfamily: Myrmillinae
Subfamily: Mutillinae

General Characteristics

Velvet ants can be divided into nocturnal and diurnal. The nocturnal mutillids are known almost exclusively from the males. They tend to be more wasp-like in appearance, brown or reddish-brown in color, and from 1 to 2 cm in length. Males almost always have two pairs of membranous wings.

Females of the diurnal velvet ants tend to be more ant-like in appearance. So far as known, all are wingless. Body color is most often black, brown, or reddish-brown. However, the body color is often not visible due to the dense pubescence. The hairs (more properly known as setae) are often brightly colored (red, orange, or yellow), or they may be a combination of one of the bright colors and black. Occasionally, the hairs may be entirely black or entirely white. The pattern of pubescence is usually species-specific. Males of even the diurnal velvet ants tend to be more wasp-like in appearance. Body color is most often black. Although some males may be brightly colored like the females, they are more frequently covered with black hairs over most of their body.

Sexual Dimorphism

As noted above, the males and females of velvet ants can look quite different (Figs. 12 and 13). Males generally have wings; females are wingless. Males tend to be more wasp-like in appearance; females tend to be more ant-like in appearance. Color of the hairs may be similar or quite different. Size may be the same or quite different. In some groups, males carry the females in flight during mating. Where this occurs, males are much larger. In other groups, females are generally much larger.

Taxonomy

The extreme sexual dimorphism in velvet ants has led to problems in taxonomy. Some genera are known from males only; others are known from females only. The same is frequently true for species within a genus. The genus *Dasymutilla* Ashmead is one of the most common genera in North America and includes all of the large, fuzzy velvet ants that most people readily recognize. The genus includes approximately 150 described species. Of those, approximately one third are known from males only, about one third from females only, and about one third are known from both sexes. In many cases, those species that exhibit a lesser degree of sexual dimorphism are known from both sexes, such as the large, red *Dasymutilla occidentalis* Linnaeus of the eastern United States commonly referred to as a “cowkiller”. In that species, males and females look almost identical except for the presence of wings in the males.

Biology

Relatively little is known about mutillid biology. It is known that mutillids are parasites (more correctly parasitoids) of other insects. Worldwide, the hosts are probably known for less than 10% of all described species. Of those that are known, most seem to be other ground-nesting bees and wasps, although there are some exceptions. A few species have been reported to parasitize tsetse flies in Africa.

Adults are generally active for only a few months out of the year, although specimens have been collected in every month of the year. Most observations have been of females, which are more limited in their mobility. Only a few observations have been recorded of mating behavior in this group. These have been almost entirely of diurnal species, as might be expected. There has been some consistency in those observations that have been made. Males usually fly a few centimeters above the ground into a slight breeze or wind, suggesting

Velvet Ants (Hymenoptera: Mutillidae), Figure 12 **A velvet ant female, *Dasymutilla occidentalis* (photo, L.J. Buss).**

Velvet Ants (Hymenoptera: Mutillidae), Figure 13 **A velvet ant male, *Dasymutilla* sp. (photo, L.J. Buss).**

that a pheromone (or sexual attractant) is involved. Courtship and mating are usually very brief with the entire process not lasting more than a couple of minutes.

Female mutillids apparently attack the larval stage of their host after the latter has spun its cocoon. Females enter the nests by digging through the soil or by breaking the walls of mud nests. Once they have gained entry, they chew a hole in the cocoon, turn around, and insert a single egg. They then plug the hole using salivary fluids and particles of soil or mud. After oviposition, about three days are required for the egg to hatch. The mutillid larva then proceeds to eat the host larva until the latter has been entirely consumed. This usually takes only a few days. The full-grown larva then spins a cocoon in the chamber prepared for the host, and pupates. Pupation is thought to take about twenty days.

In tropical and subtropical regions, there may be two to several generations a year. In the United States, mutillids apparently have only one generation a year. In colder regions, overwintering occurs in the pupal stage for most species. However, at least one species is known to overwinter in the adult stage.

Defense

One of the most interesting things about velvet ants is their vast array of defense mechanisms. First and foremost, they are wasps, and females are able to deliver a very painful sting. Interestingly, although males are not capable of stinging, they, too, have a very elaborate "stinging behavior." They do a very good acting job that will very frequently lead a potential predator to believe that they are being stung, thus affecting release of the male mutillid. Coupled with the sting, the often bright warning coloration will discourage many potential predators from attacking. Other defense mechanisms include a very tough exoskeleton, stridulation (the production of a squeaking sound that is used in mating as well as defense), quick zigzagging movements by females as they run on the ground, flight by males, and a good set of mandibles. It has been said that "an animal that discovers that the mutillid is hard-bodied and a powerful stinger is likely to remember its brilliant and unusual color pattern and to avoid it in the future" (Evans and Eberhard 1970:221).

Venezuelan Equine Encephalitis

Venezuelan equine encephalitis (VEE), or Venezuelan encephalitis, is principally a disease of rodents and horses, but does occur in humans. In South America, tens of thousands of human cases have been recorded, and hundreds of thousands of horse infections have been documented. It may pass undetected for decades and then erupts into significant epizootics, perhaps because it mutates easily. Strains of the virus differ considerably in their ability to infect mosquitoes and animal hosts. This viral disease is caused by an alpha virus of the Tongaviridae, and is transmitted by numerous mosquitoes, including *Aedes, Culex, Psorophora, Mansonia*, and *Deinocerites* spp. It is found in South and Central America, but occasionally occurs in southern areas of North America. In humans, it is characterized by fever, chills, headache, nausea, vomiting, and muscle and back pain. Generally, humans recover within a few weeks, with most of the time after the first few days consisting simply of lethargy or loss of energy. In severe cases, however, it progresses to encephalitis. The fatality rate in adults is less than 1%, but in children it may be 20%, and in horses it may be up to 10%.

Venoms and Toxins in Insects

JUSTIN O. SCHMIDT
Southwestern Biological Institute, Tucson, AZ, USA

When we think of insects, images of stings, venoms, toxins and bites often flash into mind. Perhaps this is a natural outcome of interactions among people and the insect world. Insects have been selected to avoid becoming dietary fare of humans and large predators; and our own evolutionary history has imbued us with an aversion to pain or damage. Insect venoms and toxins represent potential harm to us and fall into the category of nasty things to be avoided. Biologically, venoms and toxins are contrastingly different. Venoms are physically injected into us while toxins are applied or sprayed onto our bodies, or are active upon ingestion. Toxins are poisons. Venoms are liquid blends of biologically active substances, usually including toxins, that are injected into the body via a stinger, fang, hollow spine or other mechanical delivery system. A sting is a highly specialized device whose function is the delivery of venom. Bites are associated with feeding and their defensive roles are secondary or incidental to the primary role of obtaining a meal. For example, the strong mandibles of carpenter ants are primarily used for chewing wood, capturing prey, and feeding; but in times of danger, they are useful for delivering effective bites to whatever is perceived to be threatening.

Distribution in the Insect World

Venoms and toxins are widely distributed throughout the Insecta. Beetles (Coleoptera), moths and butterflies (Lepidoptera), and grasshoppers (Orthoptera) are especially good chemists at synthesizing or sequestering a dazzling array of toxins, with cockroaches (Blattodea), bugs (Hemiptera), lacewings and relatives (Neuroptera), and sawflies and ants (Hymenoptera), also having toxic species. Classical allomones, chemical defensive compounds that are primarily effective in repelling attackers, will not be covered here because toxic roles of allomones are usually secondary. Some exceptions do exist. Nasute termites laden with terpenes and formicine ants containing enormous quantities of formic acid are known to induce toxic effects when eaten in large quantities by some predators. The nature of toxic compounds virtually runs the gamut of imagination: from hydrogen cyanide in some chrysomelid beetles to steroids in dytiscid beetles, cantharidin (active ingredient of Spanish fly) in meloid beetles, leptinotarsin and Bushman arrow poisons in chrysomelid beetles, pyrrolizidine alkaloids in the cinnabar moth (Arctiidae), and heart-toxic cardenolides in monarch butterflies, lygaeid bugs, and a variety of other insects.

Insect venoms are more limited in taxonomic distribution than toxins; nevertheless, they are widespread. The hallmark groups of venomous insects are the wasps, ants and bees in the Hymenoptera. These groups possess a highly developed specialized sting apparatus called the aculeus that evolved into an exceptionally effective stinging device. Hymenoptera are the only order that possesses a true stinger; other taxa envenomate their targets either by biting mouthparts or venom-containing setae or hollow spines. Powerful venoms are injected into prey and sometimes defensively into predators by a variety of insects including Hemiptera-Heteroptera: belostomatids, naucorids, nepids, notonectids, hydrometrids, reduviids, nabids and enicocephalids; Neuroptera: osmylids, myrmeleontids, and ascalaphids; Diptera: asilids, sciomyzids, tabanids, mycetophilids, therevids, cecidoymiids and rhagionids; and Coleoptera: lampyrids, dytiscids, gyrinids, carabids, cicindelids, hydrophilids, and silphids. Weaker venoms are known from among a variety of other families within the same four orders.

Venomous spines can be an unpleasant signature of lepidopterous caterpillars. Caterpillars in five superfamilies, the Bombycoidea, Lasiocampoidea, Noctuoidea, Papilionoidea, and Zygaenoidea are known to possess venomous setae. Some of these can produce serious dermal and systemic medical reactions. Among the most notable of the urticating caterpillars are the gypsy and brown tail moths (Lymantriidae: *Lymantria* and *Euproctis*), the puss moths (Megalopygidae: *Megalopyge*), the slug moths, including the saddleback caterpillar in the Limacodidae, the processionary moths (Notodontidae: *Thaumetopoea*), *Premolis*, a caterpillar in the Arctiidae, that causes a chronically debilitating condition in rubber plantation workers, and the buck (*Hemileuca*), io (*Automeris*) and *Lonomia* moths in the Saturniidae. A few adult moths produce venomous barbed scales called flechettes that readily detach from the body and drift through the air. Episodes of especially serious reactions to this "airborne venom" coincide with outbreaks of hemileucid or processionary adult moths.

Sting and Venoms in the Hymenoptera

The hymenopteran sting apparatus is a marvel of biological engineering. It is Nature's miniature syringe, one that preceded medical syringes, and is finer and superior in precision and function to anything developed by physicians. This biological syringe has the same function as man-made syringes – to inject powerful biologically active fluids into the bodies of other organisms. A major difference between the two, however, is that man-made syringes are for injecting beneficial substances to help the organism, whereas hymenopteran "syringes" are for injecting substances that benefit the hymenopteran.

The stinger, like a medical syringe, consists of two major parts: a needle for piercing tissue, and a reservoir for holding the fluid to be delivered (Fig. 14). In the stinger, once the sting shaft (aculeus) penetrates the target, the venom is delivered by a combination of forces from muscles surrounding the reservoir (venom sac) and/or hemostatic pressure exerted on the reservoir, sometimes aided by a system of valves. Some sting systems, such as that of the honey bee, even possess an associated set of muscles (Fig. 14) and nerves to coordinate the sliding barbed lancets on the sting shaft to enable the stinger to pierce ever deeper completely independent of the rest of the insect. The process in which the sting apparatus is torn from the body of the hymenopteran is called sting autotomy and is limited to a few species of ants and social bees and wasps. All autotomous species live in large, populous colonies and autotomy is limited to the essentially sterile worker caste.

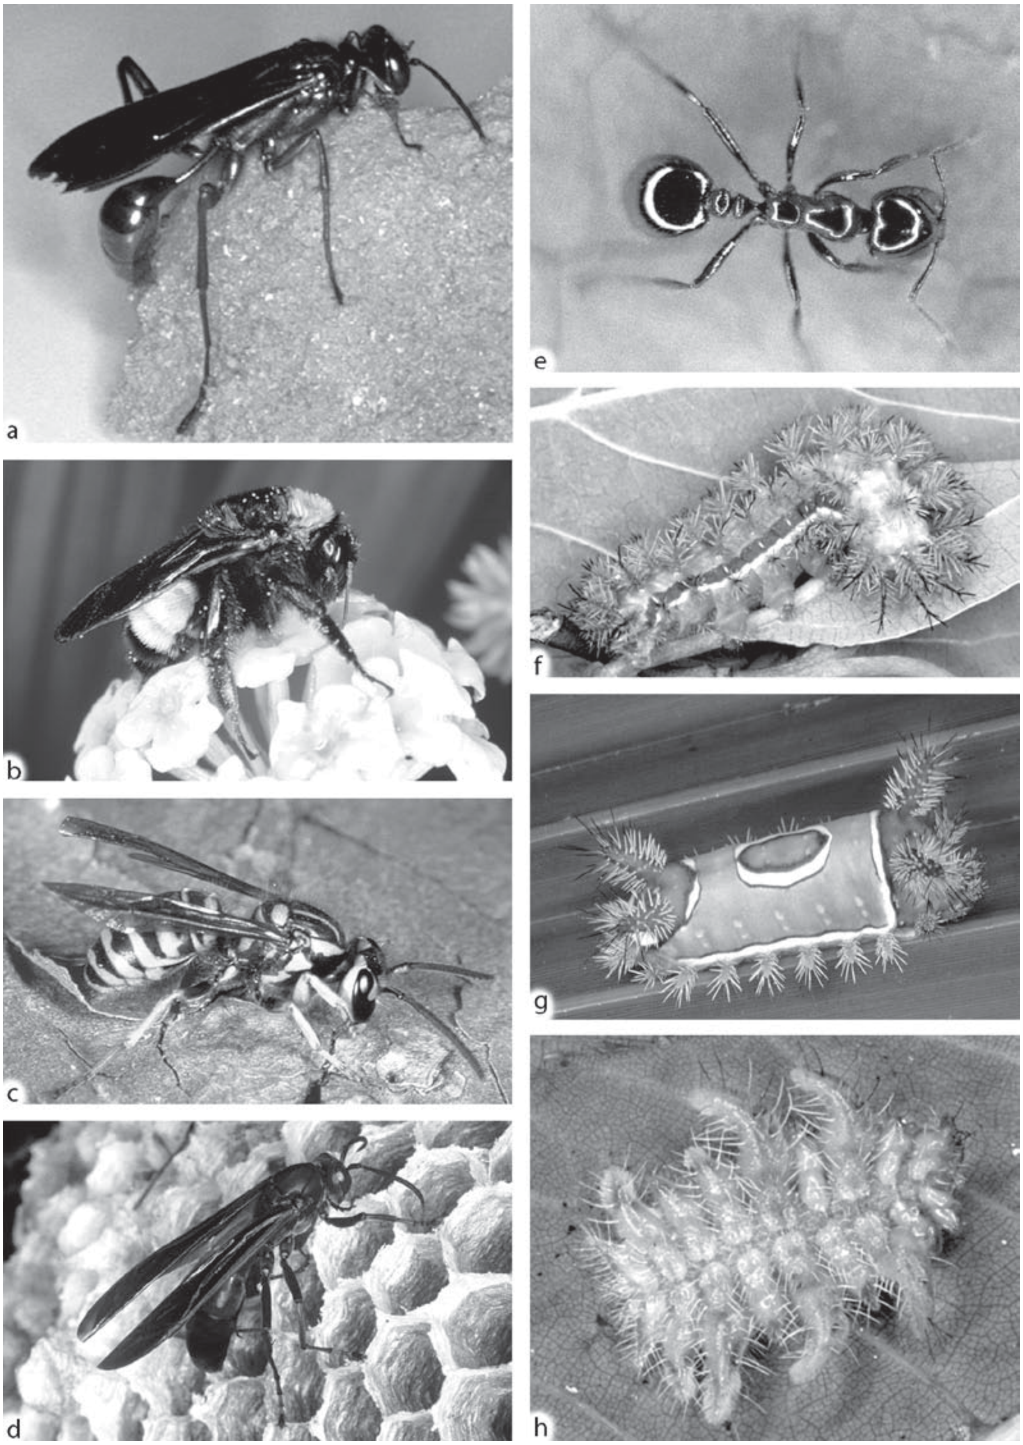
Venoms and Toxins in Insects, Figure 14 Honey bee autotomizing its sting apparatus. Note the glistening venom reservoir at the top of the sting base (photo by J.O. Schmidt).

Biological Function

Insect venom roles fundamentally relate to nutrition, either to help the venom producer in obtaining food or to help the venom producer from becoming food for something else (Fig. 15). In Hymenoptera, the ancestral use of venom is to paralyze prey as a food source for the hymenopteran's larvae. Parasitic wasps continue to use venom this way and their venoms will not be addressed further here. The more basal (Fig. 15a) lineages and the sphecid and many solitary vespid wasps of the aculeate wasps also maintain this primary use of their venoms. A major shift to defensive use of venom occurred in the bees, ants, and others in the Vespoidea. Bees shifted from the predatory lifestyle of their sphecid wasp ancestors to a vegetarian diet of pollen and nectar. No longer being needed for prey capture purposes, the venoms of bees were liberated from that constraint and evolved toward defensive uses. As a result, all bees use their stings only for personal defense or defense of their nest mates. Within the Vespoidea, sting and venom function exhibits a progression from use in prey capture to pure defense. Many groups, most notably the pompilid spider wasps and some ants, effectively use their venoms to paralyze or kill prey while concurrently being able to deliver painful stings to potential predators or adversaries, including humans. Velvet ants (Mutillidae), like the bees, evolved a lifestyle in which venom was no longer relevant to prey handling, and their venoms are strictly and effectively used for defense.

How Venoms Act Defensively: Pain

An immediate goal of an attacked hymenopteran is to stop the attack before serious damage occurs. A collateral goal is to prevent potentially harmful future attacks. The delivery of an instantaneously painful sting is an exceptionally effective means of achieving both goals. Pain (Table 3) is a organism's warning system that bodily damage is occurring, has occurred, or is about to occur. Thus, pain is ideal



Venoms and Toxins in Insects, Figure 15 **Some venom-producing insects: (a) mud dauber wasp, *Sceliphron* sp.; (b) bumble bee, *Bombus pennsylvanicus* (c) yellow jacket wasp, *Vespula squamosa;* (d) paper wasp, *Polistes metricus*; (e) red imported fire ant, *Solenopsis invicta*; (f) io moth caterpillar, *Automeris io*; (g) saddleback caterpillar, *Sabine stimulae*; (h) hag moth caterpillar, *Phobetron pithecium* (photos by James Castner, University of Florida).**

Venoms and Toxins in Insects, Table 3 **Pain levels produced by stings of representative Hymenoptera (scale 0 = lowest, 4 = highest pain)**

Taxon	Species (common name)	Acute sting pain	Duration of pain	Comments
Social Bees				
Apidae	*Apis mellifera* (honey bee)	2	4–10 min	
	Bombus sonorus (bumble bee)	2	2–5 min	
Social Wasps				
Vespidae	*Vespula* spp. (yellowjackets)	2	4–10 min	
	Dolichovespula maculata (baldfaced hornet)	2	3–4 min	
	Polistes spp. (paper wasps)	2	4–10 min	e.g., *P. fuscatus, P. exclamans, P. aurifer, dominulus*, etc.
	Polistes spp. (paper wasps)	3	5–15 min	e.g., *P. erythrocephalus, P. annularis, P. canadensis, P. infuscatus*, etc.
	Polybia occidentalis (common polybia wasp)	1	1–3 min	
	P. rejecta (a polybia wasp)	2	3–4 min	
	P. simillima (a polybia wasp)	3	5–15 min	initially 2, but burning pain of 3
	Belonogaster juncea colonialis (African fire tail wasp)	2	4–10 min	
	Agelaia myrmecophila (fire wasp)	2–3	5–15 min	
	Parachartergus fraternus (fierce wasp)	2	3–4 min	also can spray venom into eyes
	Brachygastra mellifica (honey wasp)	2	2–5 min	
	Ropalidia sp.	1	2–4 min	
	Synoeca septentrionalis (warrior wasp)	4	2 hr	initially 3, burn at 4 from 5 min to 2 hr
Ants				
Formicidae	*Myrmecia simillima, M. nigripes, M. gulosa* (bull ants)	1–2	2–5 min	sharp pain, no burning
	Odontomachus spp. (trap-jaw ants)	2	4–10 min	sharp pain, no burning
	Ectatomma spp.	2	1–4 min	*E. ruidum, E. quadridens, E. tuberculatum*
	Platythyrea lamellosa	1–2	4–10 min	itchy, burning, nettle-like, residual 20 min

Venoms and Toxins in Insects, Table 3 **Pain levels produced by stings of representative Hymenoptera (scale 0 = lowest, 4 = highest pain) (Continued)**

Taxon	Species (common name)	Acute sting pain	Duration of pain	Comments
	Streblognathus aethiopicus	2	5–10 min	burning pain, not sharp
	Pachycondyla villosa	2	4–10 min	sharp pain, not burning, same for *P. apicalis*
	Opthalmopone berthoudi	1	1–3 min	
	Megaponera foetens (Matabele ant)	1–2	2–3 min	sharp, but mild pain
	Paltothyreus tarsatus (giant African stink ant)	1–2	2–3 min	smell is worse than sting
	Termitopone crassinoda	2	4–10 min	sharp pain, not burning
	Dinoponera gigantea (giant ant)	2	4–10 min	sharp pain, not burning
	Paraponera clavata (bullet ant)	4	12–24 hr	excruciating waves of burning pain, undiminished for 12 hr; agile ants
	Eciton burchelli (army ant)	1	2–5 min	major worker
	Pseudomyrmex mexicanus	1	2–5 min	
	P. triplarinus (bull horn acacia ant)	2	4–6 min	amazingly intense for small ant
	Tetraponera sp.	1	2–4 min	
	Solenopsis invicta (red fire ant)	1	2–5 min	sharp, small ants, sting en masse
	Myrmica rubra (northern fire ant)	1	2–5 min	nettle-like, minor achy pain, lingers 20 min
	Pogonomyrmex (*Ephebomyrmex*) *cunicularius*	3	1–8 hr	slow, but intense, aching deep pain
	Pogonomyrmex (most of 20 spp.) (harvester ants)	3	1–8 hr	slow, but intense, piercing waves of aching deep pain, localized sweating, piloerection
Solitary Bees and Wasps				
Apidae	*Xylocopa* spp. (carpenter bees)	2	4–6 min	large genus, some variation in pain
	large bees in general	1	short	sharp, but minor, pain
Other bees	small bees in general	0–1	short	mostly trivial stings
Sphecidae	large *Sphex* sp.	1	short	slight pain
	Sphecius grandis (cicada killer)	1.5	2–5 min	sharp, immediate, not burning
	Chlorion aerarium	1	2–4 min	sharp, nettle-like

Venoms and Toxins in Insects, Table 3 Pain levels produced by stings of representative Hymenoptera (scale 0 = lowest, 4 = highest pain) (Continued)

Taxon	Species (common name)	Acute sting pain	Duration of pain	Comments
	Sceliphron caementarium (mud dauber wasp)	1	1–3 min	very minor
	sphecid wasps in general	0–1	short	trivial if they can penetrate skin
Scoliidae	various large species	0–1	short	sometimes residual hard spot in skin later
Mutillidae	*Dasymutilla klugii* (cow killer)	3	5–30 min	intense burning, variable reactions
	small-medium sized mutillids	1–2	2–10 min	more work needed on group
Pompilidae	*Pepsis grandis* (tarantula hawk)	4	3 min	debilitatingly intense, immediate, excruciating pain; usually vanishes 3 min
	smaller spider wasps	2–3	short	very sharp, immediate pain
Vespidae	Eumenid wasps	0–1.5	short	most minor; more work needed on group

for stopping an ongoing attack. Damage or impairment is a greater risk to a predator's survival and well being than the simple loss of a meal. An automatic reaction of predators receiving a painful sting is to abort the attack, usually by mouth gaping. Meanwhile, the future meal escapes. If the predator is a mammal, bird, lizard, or other long-lived intelligent animal, the painful experience and the insect responsible for that experience are likely to be remembered and avoided in the future. Is it any surprise that virtually all defensive venoms induce pain?

The painfulness of stings from various venomous species is not a constant. Not all stings hurt the same, and not all stings are equally effective in deterring predatory attack. Reason suggests that an extremely painful sting would be more effective in deterring attack than a mildly painful sting. But how can we scientifically distinguish between various degrees of algogenicity (the ability to produce pain) and the effectiveness of pain as a defense? Unlike action potentials in nervous networks that control muscles, electrical signals in sensory networks that transmit pain signals to the brain are not easy to measure. Modern medicine accesses pain by surveys completed by patients and clinical evaluations of facial and body expressions and signals. These are translated into numbers on a pain scale, typically a scale from 0 to 10. But pain levels produced in potential predators by an insect sting are not as easy to measure, nor as constant from one event to another. A solution to the problem is an insect sting pain scale having levels from 0 to 4. The number of levels (counting level 0) is 5 because of the inherent variability among stung people, differences in pain experienced based on body location stung, number of stings received, amount of venom delivered, etc. In the insect sting pain scale developed by the author and colleagues with the help of numerous friends and bystanders, a value for an "average" sting is determined. The sting pain of the common honey bee serves as the anchor point for the scale and is defined as pain level 2. Once anchored, a pain level of 1 represents pain clearly less than that produced by a honey bee; a pain level of 3 is more than that produced by a honey bee; and a pain level of 2 is roughly equivalent, maybe a little more, maybe a little less, than that of a honey bee. In my experience, differences between the levels are clearly evident to most people and leave little doubt. The extreme levels on the scale are 0, which represents an inability of the stinging insect to penetrate human skin or to produce pain, and 4, which represents immediate, excruciating and totally debilitating pain that completely shuts down one's ability to function normally – one simply does not walk away and act as if nothing happened after receiving a level 4 sting from an insect!

The average levels of pain induced by stings from representative stinging ants, wasps, and bees are listed in Table 3. Most ant and social bee and wasp stings are rated in the pain level range of 1–3, ample to gain the attention of a great majority of potential predators. For example, the most common insect stings, those from honey bees, yellowjacket wasps, baldfaced hornets, and paper wasps from the world's temperate regions, produce a pain level of 2. Stinging ants (ants that only bite do not qualify) are less frequently encountered in temperate climates, and those that are encountered usually produce less severe pain than their flying cousins. The one exception is the New World harvester ants in the genus *Pogonomyrmex* that live as far north as British Columbia and as far south as southern Argentina and Chile. Stings of these ants are famous for their piercing, throbbing deep pain that lasts for hours and has been described as feeling like the ripping of muscles and tendons. These stinging ants were also used in manhood rites by indigenous peoples in California because their painful and toxic stings facilitated life-guiding visions.

Solitary bee and wasp stings induce a wide range of pain intensities. The numbers in Table 3 somewhat belie the true biological situation wherein the vast majority of the more than 60,000 species are either incapable of penetrating human skin or produce a pain level, at most, of 1. Those species that command our attention are the exceptions: the spider wasps, velvet ants (Mutillidae), and the large carpenter bees. These insects are either colorful, or their striking black color contrasts with the environment surrounding them, thereby aposematically signaling predators to avoid them.

No treatment of insect sting pain would be complete without mention of the two most painfully stinging insects. The two, the bullet ant (*Paraponera clavata*) and the tarantula hawks (*Pepsis* spp.), though both producing the greatest human pain, do so in strikingly different ways. A tarantula hawk sting feels like a strike from a high voltage electric source that immediately takes over one's senses with an almost unimaginably excruciating and debilitating pain. The victim can do very little beyond releasing the wasp, then lying down and screaming. Fortunately, the pain usually abruptly subsides in 2–3 min, leaving the victim emotionally and physically exhausted, but no worse the wear in terms of long-term damage or impairment. The bullet ant impacts its victim with an immediate burning, throbbing pain that also blocks further effective functioning other than to release the ant. Even releasing the ant can be problematic, as the ant often tenaciously clings to its victim. Unlike the ephemeral pain from a tarantula hawk sting, the pain of a bullet ant sting only seems to increase over time coming in waves of intense pain followed by intervening periods of somewhat less pain. Uncontrolled trembling of the afflicted body part frequently occurs. The waves of pain continue unabated for at least 8 h, generally lasting more than 12 h, and sometimes continuing for a full day. No other insect species can meaningfully compete with the bullet ant for the title of being the most painfully stinging insect.

How Venoms Act Defensively: Damage

As effective as pain can be as a defense, it is not without its weaknesses. Pain is only a signal warning about damage, it is not damage itself. In a sense, pain alone is cheating, a form of Batesian mimicry. Unless some mechanical or physiological damage to the victim is produced by the sting, the sting is harmless. Natural selection pressure does not favor the loss of a meal because of a harmless signal; to the contrary, strong pressure would be exerted for learning to avoid or to ignore the signal and devour the cheating signaler. Intelligent and long-lived animals should adapt to stinging insects and readily exploit such, albeit spicy, morsels. In reinforcement of the effect of pain is another major activity of insect defensive stings – the ability to cause bodily damage. Damage is the "truth in advertising" of the insect sting; serious detrimental consequences can follow if stings are ignored. Consequences can include physical damage to a body part such that the part does not function well for a period of time, temporary to longer term sickness, or, though rarely, the attacker's death. Any of these effects will reduce an organism's ability to obtain food, avoid its own predators, seek a mate, or maximize reproduction. This translates into reduced fitness and exerts pressure on individuals and their genes to avoid future stings.

How is the damage potential of insect venoms measured? Unlike pain measurement, a variety of quantitative measures are available to determine damage (Table 4). The most robust and least equivocal measurement is lethality. Death is the ultimate defense, and dead predators do not attack again or produce descendants to attack the same insect or its own descendants. For insect venoms, the mouse was chosen as the model test organism because most defensive insect venoms are primarily directed against large vertebrate predators, and the mouse is a well characterized model for science and medicine. The lethalities to mice of representative insect venoms are listed in Table 4. Unlike many familiar measurements in which larger numbers indicate greater activity, lethality (LD_{50}) becomes greater as the quantity of venom needed to kill decreases; hence, the smaller the number, the more powerful the venom. Most social bees and wasps produce venoms having lethalities in the range of 2–6 mg venom/kg body weight. As a reference, rattlesnake venoms have average values around 4 mg/kg. By lethality measure, rattlesnakes and social bees and wasps produce about equally powerful venoms. The lethality values for ant venoms range widely from less than 0.1 mg/kg to somewhere over 100 mg/kg, and solitary bee and wasp venoms have low to nearly trivial lethalities.

Lethality is a strong, but indirect, measure of venom toxicity. Lethality measures the potency of the venom, but not its quantity, or the overall killing power of a sting. Lethal capacity (LC), or killing power, depends upon the potency of the venom and the amount of venom delivered. It is calculated by dividing the weight of venom per individual insect by the LD_{50} of its venom and is expressed as weight in grams of mouse that would receive a median lethal dose of venom from the sting of one average insect.

Virtually all social bee and wasp venoms pose grave potential threats of lethality to smaller vertebrate predators. With LC values from over 5 to 270 g, only one or a small number of stings from social bees and wasps are sufficient to kill a small attacking insectivore, and dozens to hundreds of stings can pose serious risks to large predators or humans. These venoms are truthful in the respect to both their advertising pain and their potential lethality.

Venomous ants present a more complex picture than social bees and wasps. LC values for the ants in Table 4 range from less than 1 g to over 1,000 g. Given that ants and social bees and wasps are highly social, with many individuals living in close-knit colonies, why the differences in their ranges of lethal capacity? Several factors might contribute to this difference. Many ants are much smaller than social wasps or bees and might not be worthy of much effort on the part of potential vertebrate predators. Also, most ant colonies are underground, or interspersed with inedible material, and are hard to consume as a unit, unlike social wasps and bees. Further, most ants produce noxious allomonal defensive chemicals and can bite viciously, qualities that social wasps and bees generally lack. These, plus the wide diversity of life styles exhibited by ants translates into great differences in selection pressures by large predators on various ant species.

Venoms and Toxins in Insects, Table 4 **Toxicity of stings of representative Hymenoptera measured by venom lethality and the lethal capacity of single stings**

Taxon	Species	LD_{50} (mg/kg)	venom per insect (µg)	Lethal capacity	Comments
Social Bees					
Apidae	*Apis mellifera* (honey bee)	2.8	160	57	
	Bombus sonorus (bumble bee)	12	760	63	
	Bombus impatiens (bumble bee)	11.5	290	25	
Social Wasps					
Vespidae	*Vespula germanica* (yellowjacket)	2.8	63	22	
	Dolichovespula maculata (baldfaced hornet)	6.1	140	23	
	Vespa mandarinia (giant hornet)	4.1	1,100	270	
	Polistes arizonensis (paper wasp)	2.0	170	85	
	P. erythrocephalus (paper wasp)	1.5	300	200	
	Polybia occidentalis (common polybia wasp)	5	28	5.6	
	P. simillima (a polybia wasp)	4.1	72	18	
	Belonogaster juncea colonialis (African fire tail wasp)	3.0	150*	50	*estimate
	Agelaia myrmecophila (fire wasp)	5.6	37	6.6	
	Parachartergus fraternus (fierce wasp)	5.3	200	38

Pompilidae	*Pepsis* spp. (tarantula hawks)	~60–150	1,400–2,500	10–40	3 species

Some of the extreme LC values among the ants can be explained by their individual situations. Bull ants (*Myrmecia*) and harvester ants (*Pogonomyrmex*) are conspicuous diurnally active ants whose lethal venoms are probably results of intense predatory pressure from lizards, birds, and perhaps amphibians. The intensely powerful venoms of these species suggest that the ants have mostly won the arms race with vertebrate predators. The bull horn acacia ants as represented by *Pseudomyrmex nigrocinctus* use their venoms effectively to repel both small and potentially large herbivores from their symbiotic host plants. Bullet ants (*Paraponera*) are large conspicuous ants that forage amongst a hotbed of insectivorous birds, lizards, amphibians, and monkeys in the canopy tops of tropical rainforests. *Paraponera* apparently also has won the arms race against their potential predators for they have no known vertebrate predators. Ants of low venom toxicity, including *Megaponera foetens, Paltothyreus tarsatus*, and *Opthalmopone berthoudi*, probably have little need for lethal venom. *Megaponera and Paltothyreus* both have powerful mandibles and, when disturbed, release some of the most noisome stenches known in the animal world. *Opthalmopone* has enormous eyes and is the swiftest and most agile of the ponerine ants. It can simply detect and evade most large predators. The reasons for the extreme lethality of venoms of *Ectatomma tuberculatum* and *Tetraponera* sp. are not known. Both species are behaviorally timid and neither acts aggressively when attacked.

Solitary bees and wasps all appear to possess venoms of low lethality. Those that have been analyzed are among the largest and most apparent or aposematic of the group, yet even these have venoms of low damage potential. Why? For the scoliid, pompilid and sphecid wasps, toxic or lethal venoms would work against the requirement of maintaining live, fresh prey as food for their young. This explanation would not apply for mutillid wasps and all bees because they do not sting prey. Perhaps for these groups of solitary Hymenoptera that have no large nests or colonies to defend, there simply is little need for toxic venom. In solitary Hymenoptera, any defensive need is fulfilled by the pain component, which provides the necessary one time escape opportunity. Overall venom lethality correlates with colony size and social complexity within the Hymenoptera.

Insect Venoms and Ecological Factors and Opportunities

Life is a juggling act balancing nutritional needs and opportunities on the one hand, and minimizing predation risks associated with foraging on the other. Predation risk limits times and places that organisms are able to feed, molds their physical characteristics, abilities and appearances, and even affects their life spans. Imagine how organisms could change their natural history and expand their ecological niches if released from predatory pressure. Insect venoms have achieved, in part, just that. By providing a powerful defense against many predators, the venomous sting relaxed constraints on the activities of sting bearers, enabling the evolution of secondary defenses including aposematic warning colors, sounds, odors, and behaviors. Common examples of aposematic colors are the brightly contrasting yellow and black, or black and white, patterns sported by wasps and bees, the red, yellow, orange, or white and black patterns abundantly observed on mutillid wasps, the iridescent blues or blue-blacks on many spider wasps, and the jet black colors, sometimes highlighted with red, of some bees and social wasps. Aposematic sounds are common in stridulating ants and mutillid wasps, many wasps and bees that increase their buzzing pitch when threatened, and mandible clicking in hornets. Aposematic odors are more common than generally recognized and abundant in mandibular gland secretions of a wide variety of ants, mutillid wasps, spider wasps, and other wasps and bees. A classic example of aposematic behavior is the wing flicking performed during foraging by many spider wasps. These aposemata alone, or in combination, serve as powerful signals to dissuade potential predators from attack.

With aposematism backed by a painful sting came further opportunities to enhance defense via evolution of Batesian and Müllerian mimicry. Müllerian mimicry among stinging bees and wasps is a textbook example illustrating the value of convergence in aposematic models to educate predators to avoid the whole mimetic guild after sampling only one member. Batesian mimicry occurs between powerfully stinging models and a variety of the more weakly stinging wasps, bees, and many flies and other insects. Sexual mimicry between female stinging models and their stingless conspecific males is another type of mimicry that helps protect potential mates and offspring. All of these defenses are possible because of venoms.

An effective sting liberates its bearer from constraints on other insects and opens otherwise unavailable ecological opportunities. Defended hunting and predatory wasps can openly forage during the day in visible locations, something more risky for parasitic wasps and flies. Bees can forage during the day on colorful flowers in conspicuous open areas. Ants can forage virtually any time of day or year within the physical restraints of their local environments. These sting-facilitated niche expansions enabled larger populations within individual species and speciation as previously unavailable niches are occupied.

The most profound evolutionary change associated with the sting was the evolution of sociality. To become highly social (eusocial) and live in massive colonies, a species must overcome the problem that their large numbers and mass presents a nutritional bonanza for large predators. Biting, scratching, kicking and other mechanical defenses are of little effect against predators hundreds to a million times larger than the individual insect. The sting functions as an "insect gun," a weapon that essentially neutralizes the size and strength differences between adversaries. It provides the one means of defense that is exquisitely effective against huge predators: by penetrating the predator's skin, the sting bypasses the external defensive barriers and delivers painful and toxic materials directly to the pain receptors and vulnerable systems within the body. Venoms and stings might not be the ultimate genetic forces that drove the evolution of sociality, but they certainly provided the proximal means enabling higher sociality. Of all the most complex and highly social groups of insects, only the termites evolved sociality in the absence of a sting mechanism. Two factors appear to have played crucial roles in allowing this. First, termites lived in wood or soil matrices that are hard and provide excellent defensive barriers to large predators. Second, they evolved sociality before the existence of ants and the majority of the other predaceous insects that could seriously threaten them. Thus, excluding the exceptional circumstances of termites, all highly social insects possessed a sting. The importance of venom in the evolution of sociality is further illustrated by other insect groups in early stages of social evolution including some aphids that have evolved individuals with sting-like mouthparts.

The biological significance of social insects can hardly be underestimated. Ants are omnipresent and dominant insect members in virtually all of the world's terrestrial ecosystems. Social wasps are major predatory driving forces in much of the warmer parts of the world. Social bees including bumble bees, stingless bees, and the honey bees (sometimes ecologically called "pollen pigs" for their ubiquity and effectiveness in exploiting flora resources), dominate the floral resources of many flowering plant communities. Without the evolution of the hymenopteran sting and sociality, the world would look dramatically different today.

Medical Aspects of Insect Venoms

When venomous insects are mentioned, the first thing that comes to mind in most insect aficionados and non-aficionados alike, is sting allergy. What professional entomologist is not familiar with hearing in informal settings, "I might die if I am stung again?" Such statements reveal two aspects of insect venoms – they have caught people's attention, and they can be a medical threat. The attention gaining part is a testament to how stinging insects have mostly won the game of educating our species to stay clear of them. The medical aspect is more complicated. About 40 people die per year in the US as a consequence of allergic reactions to insect stings, but more telling is the statistic that 4 million US individuals are at risk of experiencing a life threatening reaction upon the next sting. This 100,000-fold difference between the two figures indicates that insect stings are not nearly as dangerous as generally perceived – one might argue that they are medically trivial – and that, once again, insects are winning the game of intimidating us, a potential predator by their assessment.

Allergy to insect venoms can be a serious problem in a small minority of individuals. At the very least, an allergic reaction is a frightening and intimidating experience. More serious is the problem that allergic people might have to restrict their lifestyles, limiting outdoor exposure, and always being wary and ready to take emergency action if stung. A very few people, less than half the number that die from lightning strikes, and less than one third the number that die in off-road vehicle accidents, do actually succumb to insect stings. Fortunately, most medical problems associated with insect stings can be prevented or alleviated with immunotherapy using a series of tiny injections of insect venom and by carrying sting kits containing epinephrine to stop reactions. Given the available technology, no one should live in fear of stinging insects. The only excitement stinging insects should engender is an admiration for their beauty, amazing lives, and importance in the environment and enrichment of our lives.

Venoms of Ectoparasitic Wasps

DAVID B. RIVERS
Loyola College, Baltimore, MD, USA

The complex interactions that occur between ectoparasitic wasps and their hosts ultimately lead to altered host development, physiology, and behavior. Precisely how these host changes come about is poorly understood, but in most cases involving ectoparasitic wasps, a venom is injected into the host. Venoms of ectoparasitic non-aculeate Hymenoptera ("Parasitica") fall into two categories based on the impact on the host: those that evoke paralysis and those that are non-paralytic. The vast majority of ectoparasitic species studied produce paralyzing venoms. Such species are considered idiobionts and the venom confers an adaptive advantage in the relationship with the host: a mobile host can be permanently or temporarily paralyzed during egg laying by the female wasp. A still-mobile host is also a potential threat to developing parasitoids, consequently these venoms are more often permanent paralyzing agents. Paralyzing venoms are typically produced by the adult female wasp, however, for some ectoparasitic species (e.g., Chalcidoids), the wasp larvae produce salivary venoms/secretions that apparently can halt host development in a manner consistent with paralysis.

In contrast, non-paralyzing venoms do not render the host immobile. In fact, several species utilize non-mobile stages of the host (e.g., prepupae and pupae). These venoms seem to function by altering host physiology for the benefit of the developing parasites. In most cases, venom-induced host changes center around nutritional considerations of the immatures; female wasps must ensure that their progeny maximally use the host since for idiobiont species, the host does not feed following parasitism, and is thus a finite pool of nutrients. Venoms from ectoparasitic species belonging to the Pteromalidae and Eulophidae also are known to inhibit host molting, suppress immune responses, elevate lipid metabolism, slow or completely inhibit respiratory physiology, and alter protein expression in a variety of host tissues. Such host effects are consistent with parasitoids referred to as koinobionts, a condition more typical of endoparasitic species that depend on polydnaviruses.

Active venom proteins from ectoparasitoids, whether paralyzing agents or non-paralytic toxins, are much larger in molecular mass than those of the aculeate Hymenoptera, and perhaps this is related to the different usage of venoms among hymenopterans: aculeates use venom primarily in defense whereas venom is associated with reproductive strategies of non-aculeates. For example, low molecular weight proteins and peptides are typical of the venoms of social Hymenoptera (ants, bees, and wasps). The venoms of bees and social wasps are also abundant in neutral and basic amino acids. Comparatively few studies have examined the composition of ectoparasitic wasp venoms, but for those examined, the venom proteins are considerably larger than the aculeates. *Habrobracon hebetor* (Braconidae) produces a potent venom with at least two highly paralytic protein toxins (Brh-I and Brh-V, estimated molecular masses 71–73 kDa) and one smaller, less insectidical toxin (about 20–40 kDa). All three toxins appear to be glycosylated, a feature characteristic of mid- to high-molecular weight venom proteins of hymenopterans, but not of low molecular mass toxins. A 66-kDa venom protein has been isolated from *Euplectrus comstockii* (Eulophidae) that does not induce paralysis but does arrest host development by inhibiting larval-larval ecdysis. This arrestment protein is thought to be comprised of at least two subunits, suggesting that the native protein is possibly a dimer composed of two 33 kDa proteins. *Nasonia vitripennis* (Pteromalidae) produces a complex venom with over 9 major venom proteins visualized by denaturing electrophoresis (SDS-PAGE). A 69-kDa venom protein has been isolated from crude venom that retards host development and appears ultimately responsible for triggering death of the host.

The constituents of the venom are synthesized by venom glands, which are sometimes referred to as poison glands or acid glands. The venom glands of ectoparasitic wasps may connect to a large reservoir, or may attach directly to the distal portion of the vagina or common oviduct. Both the venom gland and reservoir are of ectodermal origin and are lined with chitin. The chitinous lining is derived from squamous epithelial cells and is an apparent necessity since many species store the venom in an active form as opposed to a precursor. Secretory cells are found throughout the venom apparatus (gland and reservoir), but localization of specific venom protein synthesis in any parasitic species has yet to occur. In at least *N. vitripennis*, the bulk of the venom is synthesized in the columnar epithelial cells lining the acid gland and is discharged directly into the lumen of the venom reservoir apparently packaged into small vesicles.

The precise tissues targeted by ectoparasitic wasp venoms have not been clearly identified, nor have the pathways activated/suppressed by these venoms been deciphered. Neuromuscular junctions most likely are targeted by paralytic venoms. For example, venom from *H. hebetor* is thought to evoke paralysis by binding to a receptor associated with the excitatory glutamatergic system on pre-synaptic membranes. Venom causes an accumulation of pre-synaptic neurotransmitter vesicles, thus blocking neurotransmitter release by inhibiting vesicle fusion with post-synaptic membranes. No other paralytic venoms from non-aculeate hymenopterans have been sufficiently studied for comparison with *H. hebetor* to determine if this is the norm or the exception among the parasitic Hymenoptera. Paralysis is, however, the norm for venoms of parasitic aculeate hymenopterans, but the mode of action of these venoms does differ from *H. hebetor*. The aculeate venoms trigger paralysis by blocking cation channels in pre- and post-synaptic membranes of host nervous and muscle tissues.

Non-paralytic venoms from ectoparasitic wasps seem to target a variety of tissues, most likely in a receptor-mediated fashion. Inhibition of larval and pupal ecdysis by *E. comstockii*, *E. plathypenae*, and *N. vitripennis*, respectively, suggests that these venoms disrupt tissue responsiveness to ecdysteroids, a condition that is not corrected by application of exogenous 20-hydroxyecdysone. This effect implies that some aspect of the receptor-hormone complex is disrupted or that the complex is not able to bind to and/or activate response elements within the cell nucleus. Venom from *N. vitripennis* also elevates *de novo* synthesis of host lipids in fat body and hemolymph, implicating an involvement of adipokinetic hormone activation and/or synthesis in response to envenomation. N. vitripennis venom also induces fly hosts to enter a developmental arrest that is characterized by a suppression of respiratory metabolism and altered protein expression, both of which show tremendous similarity to the diapause physiology of the host. The latter observation has led to speculation that the venom targets the host brain to redirect the cell-cycle control system. Consistent with this prediction is the observation that heat shock protein synthesis (hsp 23 and hsp 70) in host brains are highly upregulated following venom injection. The host response differs from a typical stress response in that all hsps are not uniformly upregulated due to envenomation by N. vitripennis, and the response persists for an extended duration.

Venom from at least two species, *Eulophus pennicornis* (Eulophidae) and *N. vitripennis*, alter hemocyte behavior in the host. In the case of *E. pennicornis*, venom is not thought to be directly associated with alterations in the numbers of circulating hemocytes, changes in phagocytic abilities, or loss of hemocyte membrane integrity, although it seems that the altered host immune response is only evident when both venom injection and oviposition occur. In contrast, venom from *N. vitripennis* specifically targets plasmatocytes and granulocytes independent of oviposition. Host plasmatocytes are destroyed within one hour of envenomation by a mechanism consistent with apoptosis. Granulocytes remain viable throughout parasitism, but lose the capacity to adhere to foreign objects and spread when cultured *in vitro*.

All ectoparasitic wasp venoms have the ability to ultimately kill the host. The most thoroughly investigated pathway eliciting host death involves the venom from *N. vitripennis*. Oncosis is the primary mechanism of host cell death. The venom apparently binds to a G-protein-sensitive receptor, activating one or more signal transduction pathways. The currently accepted mode of action for the venom involves the activation of phospholipase C, thereby elevating cAMP levels and eventually triggering release of free intracellular calcium from either mitochondria or smooth endoplasmic reticulum. Elevated intracellular calcium levels are thought to have a multiplicity of effects on target cells, including activation of cytosolic proteases that break down cytoskeletal proteins, and stimulation of endonuclease activity resulting in degradation of genomic DNA. Any of these effects can destroy the cell from within and contribute to the ultimate fate of the host, death. This mode of operation parallels the action of at least one toxin (mastoparan) isolated from several social wasps.

Venoms of Endoparasitic Wasps

DAVID RIVERS
Loyola College in Maryland, Baltimore, MD, USA

During oviposition by endoparasitic wasps, secretions of maternal origin are injected into the host insect along with the egg(s). For many of these endoparasitoids in the families Ichneumonidae and Braconidae, the secretions contain endosymbiotic viruses (e.g., polydnavirus, entomopoxvirus), virus-like particles (VLPs) or ovarian proteins that aid in the manipulation or alteration of the host. Host regulation includes behavioral, biochemical and physiological changes, such as immunosuppression, altered hormone titers, and/or changes in protein expression, which functionally aid in the development of the parasitoid's larvae. In most cases, the adult female also produces a proteinaceous venom that works synergistically or additively with the viral products. Some species also rely on embryonic factors such as teratocytes that may also contribute to host regulation and immune suppression by endoparasitoids. Typically, one or more of these maternally or egg-derived factors are necessary to ensure successful development of the feeding offspring. For example, venom or ovarian components may modulate expression and replication of viruses associated with the endoparasitoids, or may function to interfere with humoral and cellular immune components. Some species, however, rely exclusively on the action of venom to subdue the insect host. In fact, there is no evidence that these latter species contain any of the other factors (e.g., viruses, VLPs, teratocytes) commonly associated with endoparasitic wasps.

Venoms from endoparasitic wasps provide a rich and diverse array of bioactive components of both peptide and non-peptide origin. Endoparasitoid venoms are largely involved in regulation of host physiology and immune defense responses rather than paralysis/prey capture, which is more typical of ectoparasitic species. This is mainly related to the parasitism strategy in which the immature parasitoid larva develops internally while the host continues to grow. Venom is produced in a pair of specialized glands (= acid glands) and stored in a sac-like reservoir that is connected to the ovipositor through a duct. The opening of the reservoir to the duct contains a muscle-like sphincter that permits control over venom release. Striated muscles surround and attach to several points along the reservoir to facilitate rapid delivery of the venom fluid into the host. The amount of venom delivered to the host during envenomation is not known but likely varies depending on species of wasp and host, and whether the host has been previously parasitized.

Very little is known about the composition and biochemical properties of venom from endoparasitic wasps. From the few species that have been studied in detail, the composition of venom appears to be a complex mixture of proteins and peptides. This complexity might provide a means for a broader host range, although in nature endoparasitic species generally display narrow host specificity, or reflect various levels of interference with host physiology and immunity. It is also plausible that some of the venom constituents synergize or alter the function of other venom proteins inside the venom gland or reservoir (e.g., inhibit enzymatic activity) or inside the host. What is known about endoparasitic wasp venoms is that an array of small to high molecular weight proteins has been identified in most venoms studied. For example, the mass of venom proteins ranges from small peptides of less than 5 kilodaltons (kDa) to proteins of over 200 kDa. Earlier studies using electrophoretic (SDS-PAGE) protein profiles of venoms isolated from species belonging to the families Ichneumonidae and Braconidae revealed that most of the proteins were high molecular weight, and that nearly all proteins were glycosylated. However, recent analyses using more sensitive approaches such as two dimensional gel electrophoresis, reverse phase high performance liquid chromatography (rpHPLC) and mass spectrometry have demonstrated that smaller peptides are also present in venom, and that many lack a carbohydrate moiety. In addition, venom proteins from endoparasitoids are mostly acidic with pH ranging from 5.0–6.5, consistent with the venoms of ectoparasitic species.

Several constituents in the venom have been tentatively identified or a functional role for the proteins/peptides has been potentially uncovered. For example, based on analyses of primary structure of venom proteins, several are predicted to be signal peptides. Many of the proteins and peptides in the venoms show high homology to several known enzymes. These include trehalase, laccase, phenoloxidase, angiotensin-converting enzyme, serine protease and metalloprotease (reprolysin) in venom from *Pimpla hypochondriaca*, phenoloxidase and phospholipases B and A2 from *P. turionellae*, a putative chitinase from *Chelonus* sp. near *curvimaculatus*, and aspartylglucosaminidase-like from *Asobara tabida*. Additional studies have suggested the presence of various heat-sensitive hydrolases in the venom from *P. hypochondriaca*, more specifically acid phosphatase, β-glucosidase, esterase, β-galactodidase, esterase lipase and lipase.

Endoparasitoid venoms also appear to contain a number of putative enzyme inhibitors. These might be directly involved in host-parasitoid interactions (e.g., inhibition of phenoloxidase activation) or in stabilization and modification of venom proteins stored in the reservoir. The latter appears to be particularly critical to *P. hypochondriaca* since it is believed to produce a constitutively active phenoloxidase in the venom gland. In addition to enzymes and inhibitors, some species also contain several catecholamines (e.g., noradrenaline), apamine and mellitin, all of which are more commonly associated with the venoms of social Hymenoptera.

The mode of action of these venom proteins remains unclear. Obviously, putative enzyme inhibitors would be predicted to interact directly with the active site of targeted venom enzymes. However, with all other venom proteins, the precise mode of action has not been determined. In many species, venom proteins interact directly with polydnaviruses (PDVs), generating either complementary or synergistic effects. The mechanisms involved are unknown but it is generally believed that the venom proteins facilitate entry and stability of PDVs into host tissues. In other wasps, expression of viral genes does not occur in the absence of venom, clearly arguing for a regulatory role of venom proteins/peptides. Some venom proteins evoke a temporary paralysis or developmental arrest, the latter of which appears to be associated with disruption of endocrine tissue. In nearly all cases, venom triggers cell death, but the mechanism of death (i.e., oncosis vs. apoptosis) seems to be dependent on the host tissues involved. Whether the pathways leading to temporary paralysis and/or host arrestment are linked to cell death remains to be determined.

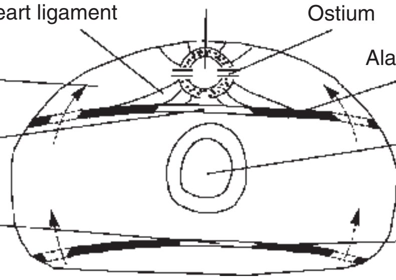
Ventral Diaphragm

A ventral layer of thin cells and muscle (Fig. 16) that assists in circulation of hemolymph around the nerve cord.



Ventral Diaphragm, Figure 16 **Cross section of an insect abdomen, showing components of the insect circulatory system and direction of hemolymph flow (adapted from Evans, Insect biology).**

Ventral Nerve Cord

The series of interconnected ganglia lying along the ventral surface of the insect, and providing nervous coordination.

Ventral

The lower surface.

Ventricle

A chamber of the insect heart (dorsal vessel).
► Dorsal Vessel: Heart and Aorta

Ventriculus

The true stomach of the insect; the midgut of the alimentary system.
► Alimentary Canal and Digestion

Vermiform

A body form that is worm-like, lacks a distinct head, and is legless. This term often is used to describe fly (Diptera) larvae, but also applies to newly hatched grasshoppers. Such newly hatched grasshoppers, called vermiform larvae, are enclosed in a membrane, so the legs are not functional. Vermiform larvae wiggle from the below-ground egg pod to the soil surface, where they free themselves from the membrane and possess functional appendages. Only after escaping from the membrane is the young hopper considered to be a first instar.

Vermileonidae

A family of flies (order Diptera). They commonly are known as worm lions.
► Flies

Vermileonidae

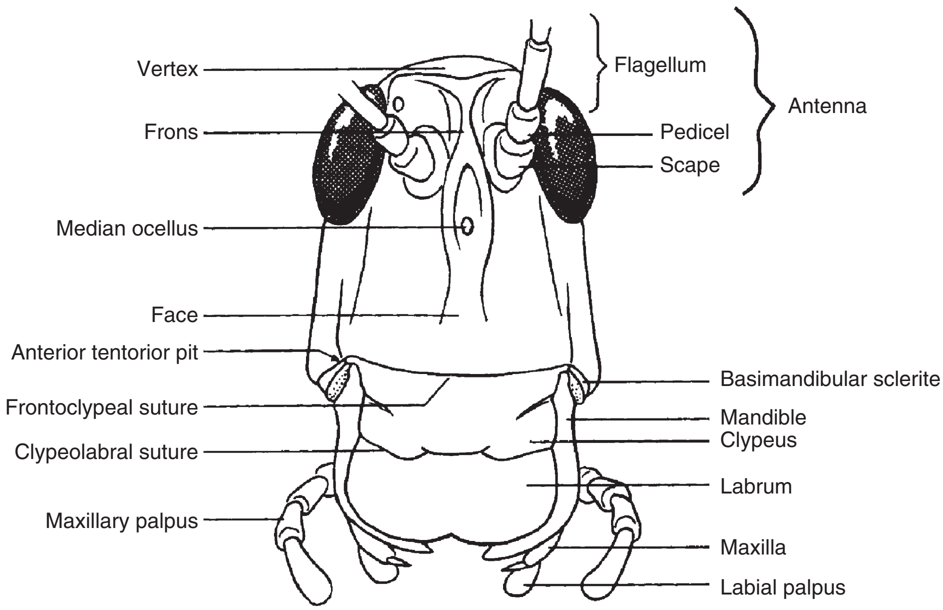
A family of flies (order Diptera).
► Flies

Vermipsyllidae

A family of fleas (order Siphonaptera). They sometimes are known as carnivore fleas.
► Fleas

Vertex

The top of the head between the compound eyes (Fig. 17).
► Head of Hexapods



Vertex, Figure 17 **Front view of the head of an adult grasshopper, showing some major elements.**

Vertical Transmission

Transmission of a pathogen between members of an arthropod species by movement from parent to progeny (transovarial or transovum transmission) or between instars within a generation (trans-stadial transmission). It is usually contrasted with horizontal transmission, in which a pathogen is passed among members of a species within the same generation, or within the same season.

Verticillium lecanii

This insect pathogen, which has long been known to be especially heterogeneous, has been reassigned to the genus *Lecanicillium* and divided into several species. Different strains and species of this group affect scale insects, whiteflies and aphids.

► *Lecanicillium*

Vesicating Species

Insect species that cause production of blisters on an animal that contacts the insect. This condition is sometimes caused vesicular dermatitis, and is most often induced by blister beetles containing cantharidin.

► Cantharidin

Vespidae

A family of wasps (order Hymenoptera). They commonly are known as paper wasps, yellow jackets, hornets, mason wasps and potter wasps.

► Wasps, Ants, Bees, and Sawflies

Vestigial

The remnants of a formerly functional organ, usually reduced in size.

Veterinary Pests and their Management

JEROME A. HOGSETTE
U.S. Department of Agriculture, ARS, Gainesville, FL, USA

Pests of veterinary importance are unique in their associations with animals hosts. Unlike the many pests that utilize plants or plant materials for their survival, pests of veterinary importance feed on hosts that can for the most part move from place to place. Thus, the hosts can live in a variety of habitats, move from one habitat to another during a daily cycle, and persist through a variety of climatic conditions during an annual cycle. The host range can be relatively small and associated with a central nest or burrow, or it can be practically endless in the case of herds of range cattle or migratory antelope. Likewise, the range of the pest can be limited geographically to certain locations, climates, or altitudes. Conversely, the pest can be cosmopolitan and affect similar hosts on almost every continent of the planet. Specifically, highly specialized pests can be limited to one or two host species, such as the sheep ked, *Melophagus ovinus*, a widely distributed parasite of sheep and goats.

Host Response

Pests of veterinary importance (Fig. 18) confront a host that has the ability to resist their presence through their blood chemistry and they must resist the host's attempts to wall them off and otherwise limit their feeding activities. Pests of veterinary importance also confront a host that has the ability to physically resist their presence, and most pests face the possibility of bodily injury or death each time they visit a host to feed. A number of recognized host responses may be elicited by the presence of a pest. These include muscle twitching, scratching, chewing, rolling on the ground, tail swishing, head tossing, bunching, foot stomping, and running away. The hematophagous pests are particularly vulnerable because they have no choice. There is no alternative food source. Without taking a blood meal, most cannot live or reproduce.

Economic Losses – Physical

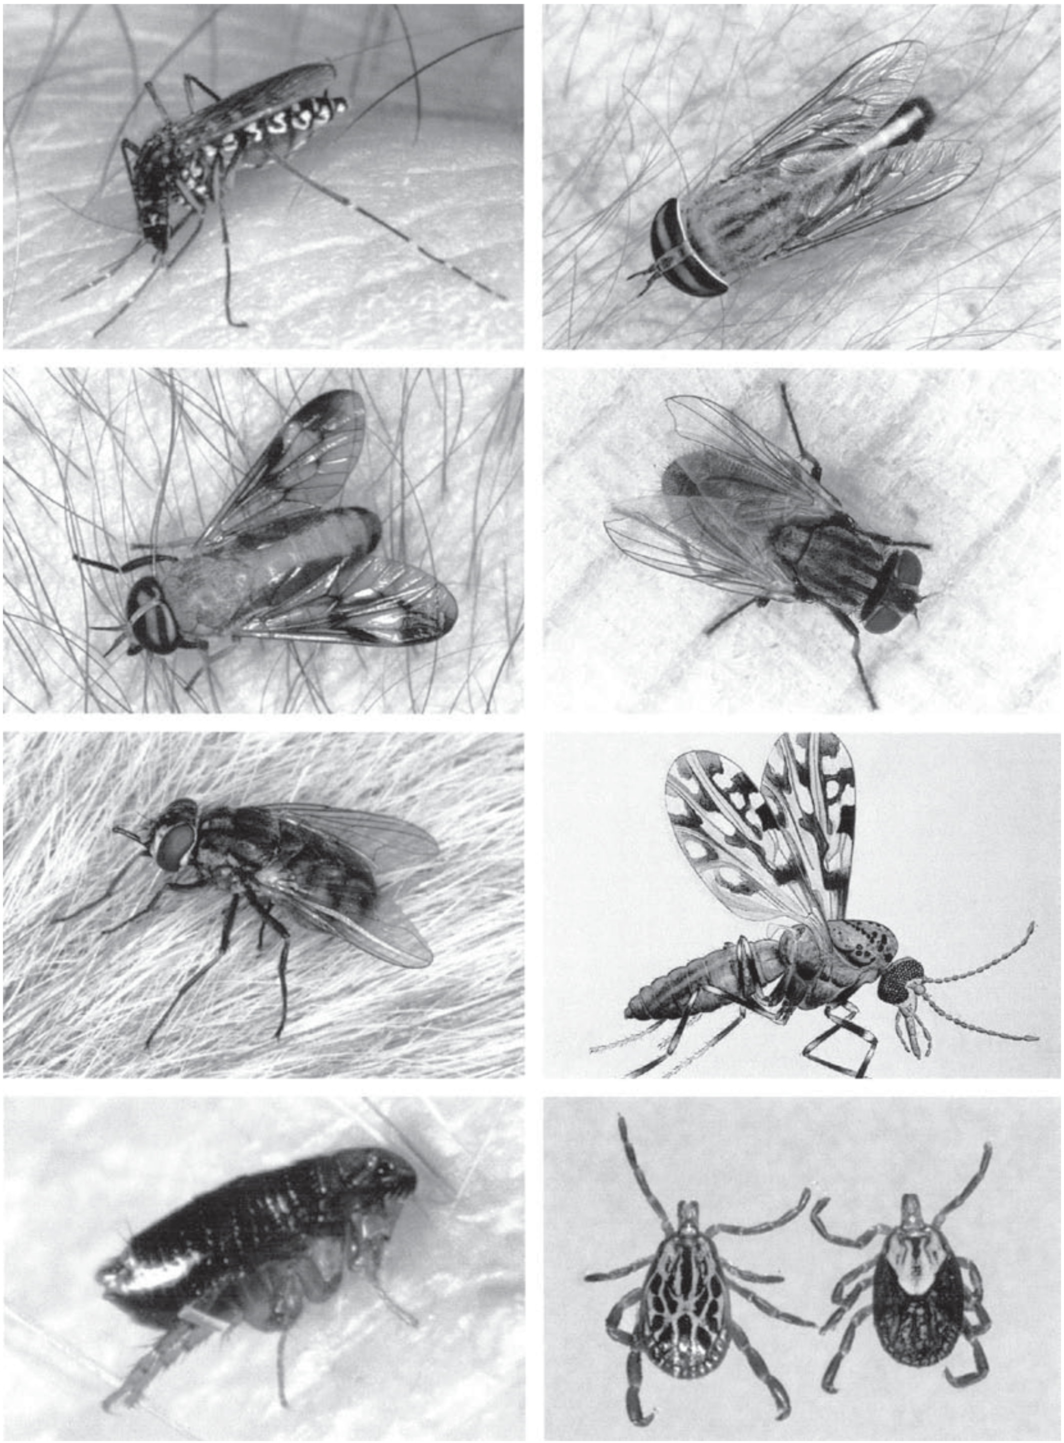
Besides the direct effects of the pest's feeding on hosts, the host response can add to, or be solely responsible for, economic loses from direct or indirect contact with the pest (Table 5). The feeding activities of some pests (e.g., lice and mites) cause itching, and host animals scratch or rub themselves incessantly, causing additional damage to affected areas as they try to gain relief. Fly worry can distract animals from eating or resting adequately, thus causing decreases in weight gains.

Economic Losses – Disease

Pests can also transmit diseases to the host, resulting in sickness or death (Table 6). Pests such as mosquitoes, phlebotomine sand flies and tsetse flies are the cause of incalculable amounts of suffering by humans and animals alike because of the disease organisms they transmit in so many parts of the world. Ticks constitute a major threat to livestock industries in many countries in the western hemisphere and in Australia and Africa. New threats arise constantly as little known diseases suddenly increase to epidemic levels (e.g., Lyme disease) and diseases prevalent in one part of the globe appear unexpectedly in another (e.g., West Nile Fever). Vector species reside in locations where associated disease organisms do not exist and the threat of infestation of the vector by the disease organism is always a possibility. Chances for dispersal of diseases and vectors have been increased greatly by international air travel.

Economic Losses – Mechanical

Host species can be killed by suffocation when certain insects, notably mosquitoes, black flies, and chironomid midges, enclose in large numbers. If insect numbers are not large enough to cause hosts to suffocate, the hematophagous pests such as mosquitoes and black flies can debilitate or kill hosts by exsanguination and/or by the amount of toxic saliva that is injected



Veterinary Pests and their Management, Figure 18 **Some arthropods of veterinary importance: *top left*, saltmarsh mosquito; *top right*, horse fly; *second row left*, deer fly; *second row right*, house fly; *third row left*, stable fly; *third row right*; biting midge; *bottom left,* flea, *bottom right*, tick (photos by J.L. Castner; biting midge by Dick Axtell).**

Veterinary Pests and their Management, Table 5 Physical loss factors caused by selected pests to livestock and poultry

Physical loss factors	Pests	Affected animals
Fly worry	Flies: *Musca domestica, Stomoxys calcitrans, Haemeatobia irritans, Hippelates* sp., *Musca autumnalis*	Cattle, horses, other livestock
Exsanguination	Flies: *Stomoxys calcitrans, Haematobia irritans,* Tabanidae, Simuliidae.	Cattle, horses, other livestock
	Mosquitoes: various species	
	Ticks: *Boophilous* spp., various species	
Suffocation	Flies: Simuliidae, Chironomidae, Mosquitoes: various species	Cattle, horses, other livestock
Disfiguration	Ticks: *Boophilous* spp., various species	Cattle, horses, other livestock
Itching/Skin Destruction	Mites: *Sarcoptes scabiei, Demodex* spp., *Psoroptes* spp., *Chorioptes* spp., *Ornithonyssus syilviarum*	Cattle, horses, poultry, other livestock
	Lice: *Haematopinus* spp., *Bovicola* spp., *Menacanthus stramineus, Menapon gallinae*	Cattle, horses, poultry, other livestock
	Flies: *Melophagous ovinus*	Sheep and goats
Gadding	Flies: *Hypoderma* spp.	Cattle

during feeding attempts. Ticks in large numbers can cause economic losses through disfiguration, blindness, and death, in addition to the possibility of transmitting diseases. Millions of dollars are spent for tick eradication programs in the US and other countries to protect the livestock industries.

Relationship Between Pest and Host

The relationship between the pest and the host can vary. Some pests remain closely associated with the host and rarely if ever leave the host. The horn fly, *Haematobia irritans*, is termed a continuous pest because after finding a host, it remains almost always on the host. The relationship with *H. irritans* is so close that adults will die if separated from the host for just a few hours. Other pests associate with the host only when feeding. The stable fly, *Stomoxys calcitrans*, is termed an intermittent pest because it takes a blood meal from the host then leaves the host until another blood meal is required. Stable fly mates, oviposits and performs daily activities other than feeding without any association with a host.

The face fly, *Musca autumnalis*, and the horn fly are so closely related with their host animal (i.e., cattle) that the immature stages of these flies can develop only in cattle manure. Horn flies are sometimes observed residing and feeding on hosts other than cattle, namely horses. However, these flies cannot lay eggs in horse manure and will therefore not produce more horn flies unless cattle are nearby.

Feeding Sites

Most pests of veterinary importance have preferred feeding sites on a host. With this approach, pests effectively divide a host and minimize feeding interference. On cattle, ticks such as *Amblyoma americanum* localize in the ears and around

Veterinary Pests and their Management, Table 6 Diseases transmitted by selected vectors and the hosts that are affected

Diseases	Vectors	Hosts
West Nile Fever	Mosquito: *Culex* spp., other species	Birds, Poultry, Horses, Humans
St. Louis Encephalitis	Mosquito: *Culex* spp.,	Birds, Humans
Equine Encephalitis	Mosquito: *Culiseta melanura, Aedes* spp., *Culex* spp.	Birds, Horses
Heartworm Disease (Dirofilariasis)	Mosquito: numerous culicine and anopheline species	Dogs, Cats
Bluetongue	Biting midges: *Culicoides variipennis, C. pallidipennis*	Sheep, Cattle
Sand Fly Fever (Leishmaniasis)	Sand fly: *Phlebotomus* spp. and *Lutzomyia* spp.	Dogs, Humans
Mastitis	Flies: *Haematobia irritans*	Cattle
Keratoconjunctivitis	Flies: *Musca autumnalis, M. domestica, Hippelates* spp.	Cattle
Nagana (Trypanosomiasis)	Tsetse fly: *Glossina morsitans* group	Domestic animals other than poultry
Plague	Flea: *Xenopsylla cheopis*, various other flea genera	Rodents, e.g., *Rattus rattus*, dogs, cats, humans
Babesiosis	Ticks: *Boophilus* spp., *Haemaphysalis punctata*, *Rhipicephalus* spp.	Cattle, Sheep, Goats
	Demacentor spp., *Anocentor nitens*	Horses
Anaplasmosis	Ticks: *Boophilus* spp., *Rhipicephalus* spp. *Ixodes* spp, *Demacentor* spp., Tabanidae (mechanical transmission by several species)	Cattle
Heartwater Fever	Ticks: *Amblyomma lepidum*	Sheep, Goats, Camels
Sarcoptic Mange	Mites: *Sarcoptes scabiei*	Humans
	S. scabiei varieties	Swine, Horses, Mules, Dogs, Sheep
Demodectic Mange	Mites: *Demodex folliculorum, D. brevis*	Humans
	Demodex spp.	Dogs, Cattle, Swine, Goats, Horses

the escutcheon beneath the tail. Horn flies feed mainly on the back or the undersides of the body. Stable flies feed mainly on the lower legs. Face flies, *Musca autumnalis*, feed around the head and eyes. Mosquitoes feed on the sides of the body. Lice are found on the neck and tail. Cattle grubs are found beneath the skin on the back.

Method of Attack

The method of attack or infestation can be unique, as is the corresponding host response. Some pests, like ticks, are able to crawl undetected up the legs and body of an animal and attach themselves in the ears. Other pests, like the adult cattle grub, are unable to cause the host direct bodily harm, yet their presence as they attempt to oviposit on the host may send the host galloping away in a panic. Mosquitoes inject an anesthetic as they probe the host. Painful effects of their feeding are thus reduced, but the subsequent allergic reaction at the bite site may persist for days. Stable flies inject no anesthetic when feeding and their bites are extremely painful. However, the pain usually ceases immediately when the fly stops feeding. Pests like the horse flies (family Tabanidae) inject not only an anesthetic, but also ample amounts of anticoagulant to keep the blood flowing. This often results in a host with dripping wounds long after the horse flies have finished feeding.

Myiasis

The infestation of living or dead tissues by fly larvae is called myiasis, and this type of development is found not only in the bots and grubs, but in other flies as well. The primary screwworm fly, *Cochliomyia hominivorax*, oviposits exclusively in open wounds on living animals. Larvae emerge to feed on the living tissues and cause debilitating to life-threatening effects on the host. By contrast, the secondary screwworm fly, *Cochliomyia macellaria*, generally oviposits on hosts that are dead. Some flies oviposit on necrotic tissues in living hosts and feed only on the dead tissues. These flies secrete an antibiotic, allantoin, and were used to clean battlefield wounds before the advent of pharmaceutical antibiotics in the 1940s.

Although most pests of veterinary importance are considered to be external parasites, several fall into the category of internal parasites. These include the bot flies of the genus *Gasterophilus*. Larvae are ingested orally or nasally and migrate to the intestinal tract, where they spend most of their lives. The larvae of cattle grubs, *Hypoderma* spp., migrate through the tissues of cattle and eventually lodge in the skin of the back with the posterior spiracles exposed to the air. Besides being painful to the host, this pest ruins the value of the hide. The human bot fly, *Dermatobia hominis*, actually captures hematophagous flies on their way to feed on a host, oviposits on them, and they in turn passively and inadvertently infest the host with *Dermatobia* larvae.

Management of Pests of Veterinary Importance

Management of the number and variety of pests has at times been difficult and it is still practically impossible to keep many of the economic pests at tolerable thresholds. During the latter part of the twentieth century, the most common form of management involved the use of pesticides. In the late 1940s and into the 1950s, DDT was relied upon for control of veterinary pests. DDT was followed by a succession of other pesticides in various pesticide groups as pests became resistant to one chemical after another. Chemical pesticides are still the basis of control for many pests (for example, ticks on cattle), but this approach becomes more difficult as resistance continues to intensify. The development of new pesticides has been stifled by the high cost of registration and the potential for a short effective period in the field because of resistance and cross resistance. The most common methods and devices for application of pesticides include sprays, dusts, dips, pesticide-impregnated cattle ear tags, back rubbers, wipe-ons, pour-ons, and baits.

Biological control, particularly for flies, has been investigated by many scientists and used most successfully in confinement poultry and swine operations. Many studies have been done with confined cattle, but results are difficult to evaluate because of the extreme variations in field conditions. The agents most commonly used are small parasitic wasps, such as *Muscidifurax raptor* and *Spalangia endius*, on poultry, dairy, and confined beef operations, and the facultative predator, *Hydrotaea aenescens*, on poultry and swine farms. The bacteria *Bacillus thuringiensis* var *israelensis* (Bti) and *B. sphaericus* have been used

Veterinary Pests and their Management, Table 7 Management of pests of veterinary importance

Management technique	Targeted pests	Situation
Pesticide		
space sprays	Flies	barns
surface applications	flies, mites	animal housing
animal applications		
sprays	flies, ticks, lice, cattle grubs, sheep keds, poultry mites, other mites	cattle, horses, pastured cattle, sheep, goats, caged laying hens, cattle, sheep

Veterinary Pests and their Management, Table 7 Management of pests of veterinary importance (Continued)

Management technique	Targeted pests	Situation
Entomophthora muscae	*M. domestica*	animal housing
Mechanical control		
trapping	*M. domestica; S. calcitrans*	confined livestock and poultry
	H. irritans	dairy farms
sanitation	*M. domestica*	dairy, poultry and swine farms
	S. calcitrans	dairy farms and cattle feedlots
manure management	*M. domestica*	dairy, poultry and swine farms, and cattle feedlots
habitat management	ticks	range cattle

successfully for mosquito management and the fungi *Entomophthora muscae* and *Beauveria bassiana* have been tested against house flies and a variety of pests, respectively, with varying degrees of success.

Growth regulators have also gained wide acceptance and are classified as biological control by some workers in the field. Growth regulators are used mainly for control of mosquitoes and flies in the immature stages, and their activity is based on interference with the chemicals involved with the molting process. Methoprene is widely used for mosquito control, and cyromazine is added to the feed of poultry and used successfully for controlling house flies and other nuisance Diptera. Diflubenzuron has also been tested for a number of uses in fly control.

Mechanical control, consisting mostly of sanitation and trapping, has been used, particularly for flies. Source reduction (i.e., removal of hay, manures, and other breeding sites) can be very successful for fly control on farms. Trapping programs have been advocated, but have not been widely accepted because of related costs.

Integrated pest management (IPM) has been discussed and used for many years and successful programs have been developed. Because of the variety in farm design, many IPM programs must be custom designed for each farm. The exceptions may be confined swine and poultry where the farms are quite similar because of standardized housing designs. IPM is usually based on mechanical and biological control methods, and the focused use of selected pesticides as needed.

Management (Table 7) can be very difficult because of the wide-spread movement of pests, such as flies. Also, the use by ticks, for example, of alternate hosts such as deer and other feral animals complicates management. Thus, the success of pest management on individual farms is not easy to assess. Area-wide treatment of animals has been tried with limited success because the ability of the pests to disperse has been under-estimated. However, this may be the method of the future if wide-spread pest outbreaks are to be contained.

Vibrational Communication

KENNETH W. STEWART
University of North Texas, Denton, TX, USA

Insects are small life forms in large macrocosms, and therefore require specific methods of communication to overcome the relatively large distances separating individuals from mates, food resources and optimal habitats. This small size poses the inherent problem of separation of the sexes by relatively huge distances. A voluminous literature exists on how various groups have evolved tactics and systems, largely acoustical, chemical or visual, to insure effective mate finding. The large diversity of insects suggests that other exciting and dynamic systems of communication may await discovery.

Intersexual communication using low-frequency, substrate-borne vibrations (Table 8) is a mode of communication that has long been recognized, but little explored in arthropods such as scorpions, spiders and insects. Only in the past few decades has there been much effort to differentiate this mode from air-borne sound communication, determine how widespread it is in insects and to explore its quantitative aspects and evolution in particular groups. Termites, ants and several families of land bugs use vibrations to signal alarm; hornet workers use them to stimulate oviposition by the queen; most of the other groups use vibrational signals for locating mates or in conjunction with copulation. Some bush and tree crickets and land bugs use a combination of vibrational signals and stridulation-produced acoustical songs for intersexual communication.

Substrate-borne vibrations are produced by insects in various ways including percussion (drumming, tokking), tremulation (body pushups or jerking), tymbal clicking, stridulation or combinations of these methods. Percussion involves striking some part of the body, usually the abdomen, directly against the substrate; this has traditionally been termed drumming or tokking (Afrikaans word meaning "to knock"). The contact may be quick, producing a single, low-frequency vibration wave in the substrate, or prolonged as a scrape or rub, producing a series of waves whose frequency and time intervals depend on the texture of the body part and substrate making contact. Such a rub is actually a body-substrate stridulation. Tremulation consists of some form of body movement (jerking, pushups or wagging) not involving direct contact with the substrate. Movement energy is transferred through the planted tarsi and converted to low-frequency, transverse waves in the substrate. Some genera of longhorned grasshoppers, katydids, crickets, stoneflies, female planthoppers, alderflies, and chloropid flies utilize tremulation in intersexual communication. An advantage of this over percussion is that it does not produce associated sounds in resonant substrates that might be audible and attractive to potential predators. Vibrations produced by stridulation and tymbal activity in some Hemiptera are of great importance for intersexual signaling, and their use by singing Orthoptera (crickets, grasshoppers, katydids) is widespread.

Vibrational Communication, Table 8 Insect orders known to use vibrational communication

Order	Primary method(s) of vibration production	Major function(s)
Orthoptera; Longhorned Grasshoppers, Katydids, Crickets	Percussion, Stridulation	mate finding
Blattodea; Cockroaches	Percussion, Stridulation	mate finding, mating inducement
Isoptera; termites	Percussion	colony alarm
Plecoptera; Stoneflies (representatives of all nine Arctoperlarian families)	Percussion, Stridulation, Tremulation	mate finding
Psocoptera; Booklice	Percussion	mate finding
Hemiptera/Heteroptera; True Bugs (representatives of 16 families)	Stridulation, Tremulation Tymbal Clicking	mate finding
Hemiptera; Leafhoppers, Planthoppers (representatives of 3 families)	Tymbal Clicking	mate finding
Neuroptera; Green Lacewings, Alderflies, Spongillaflies (representatives of 3 families)	Tremulation	mate finding, mating inducement
Coleoptera; Death Watch Beetles, Darkling Beetles	Percussion	mate finding
Diptera; Chloropid Flies	Tremulation	mate finding
Trichoptera; Caddisflies (representatives of 7 families)	Percussion, Tremulation	mate finding
Hymenoptera; Ants, Wasps	Percussion	colony alarm, queen Stimulation

A more detailed analysis of taxa, sexes or castes producing signals, signal functions and key references for each order were presented by Stewart (1997)

Vibrational communication is a viable, alternative evolutionary strategy for small insects that are limited in body size to house elaborate song-producing structures and the frequencies that can be effectively air-transmitted by them. The biophysical aspects of vibrations in solid substrates are complex, but the vibrations offer a good directional communication medium enabling location of a signal emitter by a receiver, and for recognition of various parameters of the emitters signal. In ways little researched and understood, one individual may be able to measure the vibrational output of another through some selectively arrived-at neuronal capacity encoded to respond only to a potential conspecific mate or sibling. Scorpions, and presumably insects, can determine direction of a signal emitter by integrating time delays as small as 0.2 ms received by sense organs of the different legs. The planted tarsi represent positions like points on a compass, and the source of a directional vibrational signal is read from the time delays of the signal in differentially reaching these positions. Distance to an emitter may be determined by intensity of wave signals received above some threshold.

A disadvantage for insects that have adopted vibrational communication is the complication of wave transmission in the heterogeneous substrates present in their habitats. The variety of waveforms produced (longitudinal, transverse, bending, surface) are distorted and dampened by natural substrates, restricting the range of communication, but this apparently has been overcome because transmission through plants, dead plant items and connected leaf mats has been demonstrated for distances up to 8 ms, that may translate to 800–1,000 times the length of the insects' bodies. Such substrates are, therefore, effective transmission mediums for vibrational signals.

Little is known of the energy cost of vibrational signaling, as an important component of reproductive effort, but in general it is considered less than for producing high-frequency airborne sounds. The cost of percussion-assisted mate-finding in some beetles is 10% or less than that of random searching over the communicable area. Such cost-saving must represent an advantage for vibrational communication and probably plays a major role in the early stages of behavioral evolution. The vibrational signals of most insects consist of simple volleys of evenly spaced signals. Out-group comparisons have indicated that these types of signals produced by percussion are ancestral, and that derived signaling to achieve species-specificity, and to possibly enable some degree of sexual selection for fitness, has involved evolution toward increased signal complexity. Complex signals have been arrived at through: (i) more sophisticated signaling methods, (ii) changes in the rhythm of signaling, or (iii) possibly increased selection of the type of natural substrates used for signal transmission. Modern species have either retained the relatively simple ancestral pattern, with slight time interval modification for species specificity, or have developed various complex systems using combinations of these three derived behaviors. The high degree of species-specificity of vibrational signals in insects make them valuable behavioral lines of evidence for delineating morphologically similar species and resolving phylogenetic relationships.

Viburnum Leaf Beetle, *Pyrrhalta viburni* (Paykull) (Coleoptera: Chrysomelidae)

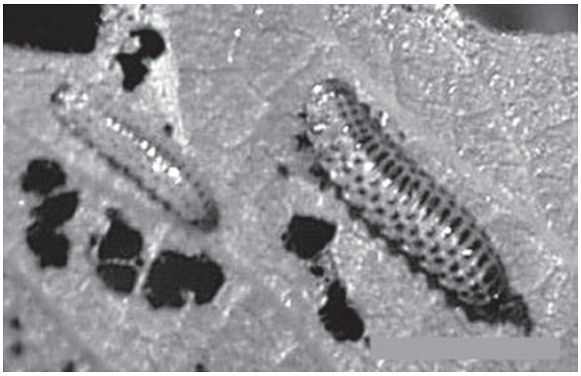
PAUL A. WESTON
Cornell University, Ithaca, NY, USA

Pyrrhalta viburni (Paykull), commonly known as the viburnum leaf beetle, is a landscape pest of Eurasian origin that is quickly spreading through the northeastern United States. Breeding populations actually became established in North America (near Ottawa, Ontario, Canada) in the late 1970s, but did not reach the U.S. until

1994, when it was discovered in Maine. The pest was found in New York State in 1966, apparently the result of a separate immigration event, because the two founding locations are very widely separated. As of 2001, the beetle could be found throughout the southern half of Maine, in many of the northern and western counties of New York, as well as the northwestern tip of Pennsylvania and the northwestern corner of Vermont. Given its distribution across continental Europe, it seems likely that this pest will become commonplace throughout much of the range of *Viburnum*.

The only known hosts for *P. viburni* are in the plant genus *Viburnum*. Within the genus, however, species differ greatly in susceptibility. Some species, most notably arrowwood (*V. recognitum*) and cranberrybush (*V. trilobum* and *V. opulus*) viburnums, are devoured by the pest and are killed after only a few years of repeated infestation, while others, especially leatherleaf (*V. rhytidiophylloides*) and Koreanspice (*V. carlesii*) viburnums and their relatives, are virtually immune. Arrowwood is particularly important in the spread of *P. viburni* because it is widely distributed in native habitats, especially along large bodies of fresh water. The spread of the pest has been most rapid in such habitats. Spread of the pest may also be hastened by transport of infested nursery stock since *P. viburni* is not subject to quarantine restrictions.

The insect is univoltine, and overwinters in the egg stage. Eggs hatch in early May in upstate New York, around the time of bud break of the host plant. Larvae crawl to the tips of shoots, and begin feeding on the underside of newly expanding leaves. The larvae (Fig. 19), which are at first pale yellow, go through three instars, changing to solid black between instars. As the second and third instars grow, the black sclerites form spots and stripes as the intersegmental membranes expand. The larvae complete their development in 4–5 weeks, then crawl to the soil and burrow down several centimeters to pupate. Adults emerge several weeks later.

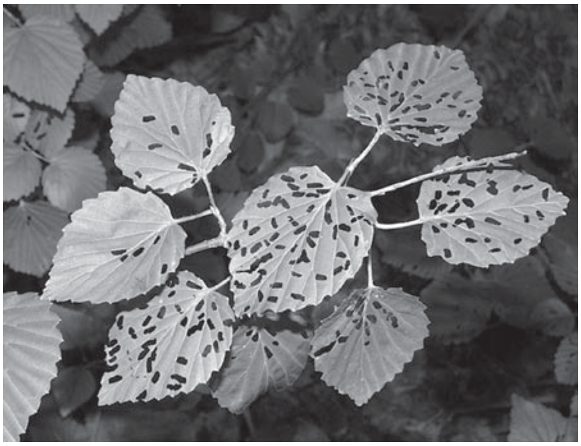


Viburnum Leaf Beetle, *Pyrrhalta viburni* (Paykull) (Coleoptera: Chrysomelidae), Figure 19 Larvae of *Pyrrhalta virburni*. Second instar is shown on left, third instar on right. (Photo by Paul A. Weston.)

Adults (Fig. 20), which resemble smaller, more drab versions of elm leaf beetle, feed on the leaves of the same host species as the larvae. Feeding damage by adults (Fig. 21) is distinctly different from that of larvae, however. Whereas larvae feed on leaf tissue between veins, leaving skeletonized leaves when populations are heavy, adults create oblong cutouts in the leaf, measuring about 2 mm wide by several mm long. Adults are active until late September or early October, all the while feeding and laying eggs on host plants. Oviposition sites of the beetle are quite distinctive; eggs are laid in masses on the underside of young shoots, generally in a linear array of several egg clusters per shoot. The female first chews a small hole into the pith of the stem, and then deposits about half a dozen eggs in the hole. She then caps the eggs with a mixture of feces and chewed foliage or bark. The caps protrude noticeably from the surface of the twig, and probably help to retain moisture and protect the eggs from natural enemies. The eggs remain dormant until the following spring.

Several species of parasitoids are known to use *P. viburni* as a host in Europe, but none of these natural enemies occurs in the U.S. Generalist predators, such as lady beetles and lacewing

Viburnum Leaf Beetle, *Pyrrhalta Viburni* (Paykull) (Coleoptera: Chrysomelidae), Figure 20 **Adult of *Pyrrhalta virburni* on twig. The adults range in size from 4.5 mm (male) to 6.5 mm (female), and are medium brown in color. (Photo by Paul A. Weston.)**



Viburnum Leaf Beetle, *Pyrrhalta Viburni* (Paykull) (Coleoptera: Chrysomelidae), Figure 21 **Feeding damage by adult *Pyrrhalta virburni*. Note that feeding occurs in discrete cutouts with rounded ends, randomly distributed across the leaf surface. (Photo by Paul A. Weston.)**

larvae, also feed on larvae, and at least one species of nematode (*Heterorhabditis bacteriophora*) effectively utilizes *P. viburni* as a host.

Vinegar Flies

Members of the family Drosophilidae (order Diptera).

► Flies

Vine Mealybug, *Planococcus ficus* Signoret (Hemiptera: Pseudococcidae)

RAKSHA MALAKAR-KUENEN, KENT M. DAANE
University of California, Berkeley, CA, USA

Vine mealybug, *Planococcus ficus* Signoret, is a recently introduced pest in California vineyards. Vine mealybug was first recorded from the Crimea region in the 1890s; currently, it is found in the Middle East, North African and Mediterranean countries, Pakistan, Argentina and California in the United States. While vine mealybug infestations are most damaging in vineyards, the mealybug is also an occasional pest of apple, avocado, banana, date palm, fig, mango and citrus. In the laboratory, vine mealybug can be reared on a number of hosts, including butter-nut squash (*Cucurbita moschata*) and potatoes (*Solanum tuberosum*). The vine mealybug is one of several mealybugs species that attack vineyards, e.g., *Pseudococcus maritimus* Erhorn (grape mealybug), *P. viburni* (Signoret) (obscure mealybug), *P. longispinus* (Targioni-Tozzeti) (long-tailed mealybug), and occasionally by *Planococcus citri* Risso (citrus mealybug) and *Maconellicoccus hirsutus* Green (pink hibiscus mealybug). Of these mealybugs, the vine mealybug is most closely related to the citrus mealybug. While they look very similar and can coexist in the same regions, citrus and vine mealybug populations can be separated by their sex pheromones.

Mealybugs are related to aphids and whiteflies and feed in a similar manner with long piercing-and-sucking mouthparts to remove plant juice. The vine mealybug can feed on the vine roots, trunk, canes, leaves and fruit. An adult female vine mealybug is 3–4 mm long, wingless, oval-shaped body, and covered by white wax. The secreted wax forms long filaments protruding along the body margin, which can be used to identify some mealybug species. The adult female lays from 300 to 500 eggs in a cotton-like (formed by secreted wax) ovisac. Under a controlled environment at 28°C, eggs hatch in 7–9 days. The emerging crawlers are bright-orange to yellow-orange colored. These crawlers, or first instars, are very mobile and move around the vine until they find a suitable feeding site. Once the crawler settles and begins feeding, the bright-orange body is covered by the waxy secretions and the mealybug takes on a more subdued pale white color. Females have four instars and, in the field, they can be distinguished only by their relative sizes. Each stage lasts 4–7 days, depending on temperature. Adult male mealybugs are very different in appearance. Males are about 2 mm long and have a pair of functional wings, and long caudal filaments. Males look similar to females in the egg and crawler stages, whereas the second and third instars are bit more narrow and oblong than females. Males pupate after the third instar, whereas females become reproductive in the apparent fourth instar. In California's San Joaquin Valley, there are six generations of vine - mealybugs per year.

Within-Vine Distribution

Vine mealybugs are found on all parts of the vine, including the roots. In spring, as soon as the leaf buds form and break, vine mealybug crawlers start to move up towards crown and the canes. By mid-summer, all stages of the vine mealybug can be found throughout the vine including the leaves. Starting in mid-summer and continuing through the harvest time, mealybugs begin to infest the grape bunches. (Infestation of the grape bunch begins earlier in the season as you move further south and into the desert agricultural regions in the Coachella Valley.) In heavy infestations, i.e., when the mealybug density is high, the pest can foul the grape bunches with honeydew, ovisacs, and live and dead bugs, making the fruits unmarketable. Excessive honeydew secretion also promotes the growth of sooty mold, further reducing marketability. After harvest and leaf drop, the mealybugs are found either on the trunk, typically deep under the bark or in feeding holes made by moth or beetle wood borers, or on the roots; there they remain at low densities until the following spring when the cycle is repeated.

Biological Controls

There are many species of ladybird beetles that feed on mealybugs, the most well-know is the mealybug destroyer, *Cryptolaemus montrouzieri* Mulsant (Coleoptera: Coccinellidae). Both larvae and adults of the mealybug destroyer can feed on all stages of the vine mealybug; however, the adult beetle prefers to feed on eggs in the mealybug ovisac to increase reproduction and egg deposition. The mealybug destroyer was first introduced into California from Australia in 1892. The beetles larvae also produce waxy filaments that cover the body and disguise the beetle as a mealybug destroyer (that can help the beetle evade ants which protect the mealybugs). The beetle larva can be distinguished by its distinct body segments and non-uniform length waxy filaments. Because the beetle prefers cool and relatively humid conditions, its numbers never increase to high levels in the interior parts of California where there is dry and warm climate. Lacewings also feed on mealybugs. There are brown and green lacewings resident in California vineyards. The green lacewings (*Chrysoperla* and *Chrysopa* species) are most common. Like the beetles, the lacewings are more effective when they attack the smaller mealybug stages. Both the mealybug destroyer and some green lacewing species can be purchased from commercial insectaries and released to suppress mealybugs.

Worldwide, there are several species of small (less than 2 mm) parasitic wasps (Hymenoptera: Encyrtidae) that have been found attacking the vine mealybug. These include *Anagyrus pseudococci* (Girault), *Allotropa* sp., *Leptomastidea abnormis* (Girault), *Leptomastix flavus* Mercet, *L. dactylopii* Howard, and *Coccidoxenoides peregrinus* (Timberlake). In the mid 1990's *A. pseudococci* and *L. abnormis* were released in California's Coachella Valley to suppress vine mealybug population growth and spread. *A. pseudococci* and *L. abnormis* have been recovered; however, parasitism levels rarely exceed 25%. Further north, in the San Joaquin Valley, we found that, by late-summer, resident *A. pseudococci* parasitized 80–95% of mealybugs that were exposed on leaves, bunches, canes, and trunk sections – although we have not seen any parasitized mealybugs on the roots or under refugia deep under the bark. *Allotropa* sp. contributed 1% to the total parasitism levels. *Anagyrus pseudococci* is a small wasp about 1.5 mm long. The female is brown in color and has white antennae with black at the base; the male is black, 0.7–0.9 mm long, and has hirsute, black antennae. *Anagrus pseudococci* can oviposit in second instar to adult stage mealybugs; with male offspring typically emerging from the smaller mealybugs (second to third instar) and female parasitoids emerging from the larger mealybugs. Parasitoid development time is about 18 days during the summer. *Leptomastidea abnormis* as another biological control is under investigation. It completes its life cycle in 20–22 days under laboratory conditions. *Leptomastidea abnormis* is about half the size of *A. pseudococci*, with two black bands on clear wings.

Both *A. pseudococci* and *L. abnormis* are commercially available. Researchers from University of California Berkeley and Riverside are currently investigating augmentation programs in the Coachella Valley and San Joaquin Valley. Augmentation may be needed because, although the percentage vine mealybug parasitism from naturally occurring parasitoids can be high, the parasitoids appear in the field, late in the season to effectively control the mealybug before the population moves up the vine and infests the grape bunches. Research is currently underway to investigate area-wide release programs early in the season (spring) and targeting the overwintered mealybug population.

Insecticide Controls

To control vine mealybugs, delayed-dormant insecticides (e.g., chloropyrifos [Lorsban®]) can be used to kill over-wintered mealybugs; however, control is incomplete as some over-wintered mealybugs may remain in protected regions of the vine. During the season, a number of foliar materials are available (e.g., methomyl [Lannate], imidacloprid [Provado®]) but control is still dependent on complete coverage. For this reason, one of the best insecticidal controls is a systemic application of imidacloprid [Admire®]. Effectiveness of this systemic material is dependent on good delivery to the entire root zone, which can be influenced by the irrigation system used or soil type and condition.

Cultural Controls

Sanitation is also a tool to prevent spread of the mealybugs. Weed control during the winter and early spring time may help prevent a build up of the mealybug population. Vineyard equipment, such as a grape harvester, used in an infested field should be washed thoroughly with water and bleach before moving into another field. Similarly, it is good idea for field crews to clean and change their clothing and shoes after visiting an infested field to remove any mealybugs that may cling onto their skin or clothes.

Sampling Methods

It is easy to detect the vine mealybugs during harvest in a heavily infested vineyard; the presence of shiny, honeydew and dark sooty mold on the vine and the leaves close to the trunk is an indicator of the presence of vine mealybugs on that vine in that year. For quick monitoring purposes, it is advisable to look for the sooty mold on the leaves just before the leaf fall and rain (October–November), and make plans for treatments accordingly. Currently, researchers are developing a vine mealybug sex pheromone that may greatly improve sampling for low-density mealybug populations. This is critically important because chemical treatment is recommended if only a few vines are infested in order to catch new infestations.

Other Mealybug Pest Species

The other mealybugs that are commonly found in the vineyards are grape mealybug (*Pseudococcus maritimus*), long-tailed mealybug (*P. longispinus*) and obscure mealybug (*P. viburni*). Long-tailed and obscure mealybugs are found only in the coastal grape growing regions of California. The grape mealybug is commonly found both inland and the Pacific coast of California as well as other grape growing regions like New York, Oregon and Washington states. Pears and apples are other host plants of grape mealybugs. These species can be distinguished by their two caudal filaments that are longer than the rest of the filaments and form a V-shaped tail. The grape and obscure mealybugs look very similar; however, they can be differentiated by the color of the ostiolar fluids, which are secretions from lateral ostiolar pores. The long-tailed mealybugs, as their name suggest, they have longer caudal filaments as compared with the other mealybug species.

The grape and obscure mealybugs generally have two to three generations per year, depending on temperature. The eggs and crawlers from second summer generation (August/September) overwinter. None of these mealybug species produce as much honeydew (or economic damage) as the vine mealybugs. Both obscure and long-tailed mealybugs produce very little honeydew compared to both vine and grape mealybugs.

Viral Flacherie

An infectious flacherie of silkworm larvae caused by a small nonoccluded virus.

► Flacherie

Virginopara

In aphids, the viviparous female occurring during the summer months (after the fundatrix generation).

► Aphids

Viremia

The presence of virus in the hemolymph or blood.

Virion

The mature virus, the ultimate phase of viral development. The virion is either a naked or an enveloped nucleocapsid. The term "virus" embraces all phases of the viral development, and it includes the virion.

Virulence

The quality or property of being virulent, or the ability of a pathogen to infect a host and cause disease; the quality of being poisonous; the disease-producing power of a microorganism.

Visual Attractants and Repellents in IPM

RONALD J. PROKOPY
University of Massachusetts, Amherst, MA, USA

In essence, Integrated Pest Management (IPM) is a decision-based process involving the coordinated use of multiple tactics for optimizing the control of all classes of pests in an ecologically and economically sound manner. Tactics available for use in the management of pest insects include insecticidal control and behavioral control. For insecticidal control, monitoring population levels of pest insects and their natural enemies is a key component in deciding whether or not insecticidal treatment is necessary. Visual traps that are attractive to pests or beneficial insects can be useful monitoring tools. For behavioral control, visually attractive traps, or visual repellents may be used in direct suppression of insect pests.

Development and effective deployment of visual attractants and repellents in IPM call for an understanding of several variables that influence attractancy and repellency. These include properties of insect vision, visual properties of resources sought by insects and the role of visual stimuli in the resource selection process.

Compound eyes contain the principal photoreceptors of insects. Photoreceptors of many insects are capable of perceiving a bandwidth of energy extending (in human terms) from ultraviolet (approximately 300–400 nm) through blue (400–500 nm), green (500–560 nm), yellow (560–590 nm) and orange (590–630 nm). Few kinds of insects are able to perceive red (630 nm and above). Insects with large compound eyes may possess a greater degree of visual acuity (and, therefore, are more capable of perceiving the visual properties of hosts against the background) than insects with small compound eyes. For most insects, visual acuity is highest under high intensity natural light (for example, full sunlight at midday) and lowest under low light intensity (for example, at dusk, nighttime and dawn).

There are three properties of resource items for insects that may serve as visual cues to foragers: spectral quality, pattern and dimensions. Resource items may absorb, transmit or reflect incoming light. It is the reflected light that provides the most useful information to foragers. The color of reflected light includes elements of brightness (intensity), hue (dominant wavelength) and saturation (spectral purity). The foliage of most plants reflects light at comparatively low intensity, with maximum reflectance at 550 nm and nearly no ultraviolet reflection. Some flowers may reflect moderate or high levels of ultraviolet light.

Insects may use a variety of stimuli as cues for finding resources. These include olfactory, visual and auditory stimuli. The distance at which each type of stimulus is perceived varies widely among different kinds of insects. Generally, however, olfactory and auditory stimuli are perceived at greater distances than visual stimuli, with the latter often being the principal close-range cue used by the forager. Thus, visual attractants and repellents in IPM usually are not operative at distances exceeding a meter or so (in exceptional cases, a few meters). The greater the degree of hue or intensity contrast between a visual stimulus and the background, the greater the distance at which the insect may be able to detect the stimulus.

Visually attractive traps developed to monitor pest or beneficial insects in IPM usually incorporate characteristics that mimic the color or pattern (shape) of the visual cues used in finding resources. Pests including aphids, whiteflies, leafhoppers, anthomyiid flies and some beetles, as well as beneficials including coccinellids and hymenopterous parasitoids, often are monitored by yellow traps that are believed to mimic the plant foliage used by these insects as a resource cue. Yellow may constitute a "super-normal" foliage type stimulus, because yellow emits peak energy at about the same bandwidth of the insect-visible spectrum as green foliage emits peak energy, but at a greater intensity.

Several kinds of pest thrips and some kinds of pest sawflies are monitored by white or blue traps whose reflectance mimics the color of the flowers from which the adults obtain nectar or pollen. Similarly, several kinds of biting flies are monitored by white or blue traps that appear to mimic the reflectance properties of either resting sites or host animals. In most cases, the absence of ultraviolet reflectance from white or blue traps enhances the capture of pest insects, but the converse is true in the case of some anthomyiid flies and biting flies.

The shape of a trap can be an important attribute in the monitoring of certain pests. For example, several kinds of scolytid beetles are monitored using vertical, black, cylindrical traps that mimic the trunks of coniferous (Fig. 22) host trees.

Visual Attractants and Repellents in IPM, Figure 22 **Black cylindrical funnel traps mimic the silhouette of pine trees and are used, in conjunction with odor baits, to capture bark beetles (photograph by J. Foltz).**

Similarly, some kinds of frugivorous tephritid flies are monitored using fruit-sized spheres that mimic the shape of the host fruit.

When baited with attractive odor, visually attractive traps can be used to achieve direct behavioral control of certain pest insects. The tsetse fly (*Glossina pallidipes*), for example, can be effectively suppressed in parts of southern Africa by deploying odor-baited, insecticide-impregnated targets of blue cloth at densities of 3–5 targets per km^2. Several species of tabanid flies can be suppressed by deploying large, odor-baited, dark-colored spheres, or other objects that roughly resemble the color and shape of potential hosts. The apple maggot fly, *Rhagoletis pomonella*, can be controlled effectively by ringing apple orchards with red spheres that are odor-baited and are either sticky or are treated with insecticide.

Visual stimuli have proven very effective in repelling aphids, whiteflies and thrips that vector viral pathogens of row plants. Rows of young plants are protected from viral inseminations when they are underlain (Fig. 23) with ultraviolet-reflecting mulch, such as aluminum foil, or materials sprayed with aluminum paint. Reflected ultraviolet light resembles sunlight and signals immigrating adults to keep on flying rather than settle on foliage. The use of ultraviolet-reflective mulch in protecting row crops against viral infection is expected to increase substantially when effective, biodegradable mulches replace the current non-degradable types.

Visual Mating Signals

JOHN SIVINSKI[1], STEVEN R. WING[2]
[1]USDA-ARS, Gainesville, FL, USA
[2]University of Florida, Gainesville, FL, USA

Evolution has sculpted and colored the surfaces of the arthropod body. Natural selection favored appearances that mislead predators through disguise and camouflage, i.e., "cryptic coloration," and those that warn enemies to stay away through bright advertisements of distastefulness or dangerous weapons, i.e., "aposematic coloration."' In addition, body surfaces may help modify the effects of the physical environment, e.g., to absorb or reflect heat. Certain colors, shapes and movements also influence the behavior of the conspecifics in contexts including social interactions, e.g., honeybee dances. Other signals evolved in the context of mating.

Visual Mating Signals, Figure 24 **There are dangers as a well as opportunities inherent in visual signals. The eye(s) of this spider may have first been caught by the firefly's bioluminescent sexual display (photo by Steven Wing).**

Sexual Selection and the Evolution of Displays

These sex-related signals, or "displays," are directed either toward rivals (usually males attempting to repel other males) or potential sexual partners (usually males attempting to attract mate-choosing females). Display surfaces, and the behaviors associated with their exhibition, have evolved through sexual selection, the process in which genes are favored because they give greater access to the opposite sex. Competition among members of one sex for access to the other results in "intrasexual selection," and mate choice and the displays directed to the choosing sex evolve through "intersexual selection."

Sexually selected displays presumably resolve competitions and/or facilitate mate choices because receivers evaluate and act on information contained in the display's colors, size and motions. The experimental evidence that arthropods perceive visual displays and then (Fig. 24) modify their reproductive activities is phylogenetically widespread. Some examples include the sexual response of fireflies (Lampyridae) to patterned electric lights, and female wolf spider's (Lycosidae) reactions to videotapes of the stylized foreleg movements the males perform during courtship.

The Basis of Sexually Selected Signals

Ultimately, both inter– and intrasexual selection occur because of differences in "parental investment" between the sexes. Parental investment is anything, material or behavioral, that a parent invests in an offspring that increases the offspring's chance of surviving at the cost of the parent being able to invest in other offspring. There is a fundamental sexual dimorphism in parental investment due to the female's initial investment in large, resource rich eggs, and the male's in small, inexpensive sperm. All other things being equal, a female's capacity to reproduce is limited by the resources she can obtain and use to produce her eggs. Multiple mates do not necessarily result in more offspring, although she may be able to choose a mate whose genetic or other qualities, sometimes illuminated through displays, result in her bearing more, or more fit, offspring. On the other hand, ejaculates are cheap and males invest little in the insemination of a female. The more females a male copulates with, the more offspring he will father. As a result, selection favors males that successfully compete with one another for access to mates, often through displays directed both to females and to other males.

There are exceptions to this "grand generality." For example, males of some species of katydids (Tettigonidae) and balloon flies (Empididae) provide females with nutritious "nuptial gifts," such as huge protein-rich ejaculates and insect cadavers. As a result, a female's reproduction is influenced by her ability to gain access to gift-bearing males. In these instances there may be sex-role reversals and males choose mates from among competing, displaying females.

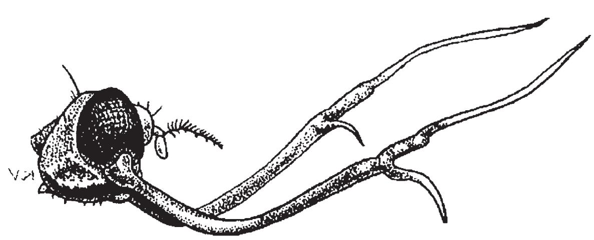
Sexual Dimorphism and Sexually Selected Displays

In some species, members of one sex differ in appearance from members of the opposite sex. Sexual dimorphism in color is suggestive of a display in one of the sexes. Charles Darwin, for example, was struck by the brilliancy of male butterfly coloration and the relative drabness of females. He, and subsequently others, proposed that sexual selection had generated colors of greater saturation and more precise demarcation in males because they were used in sexual communications while females maintained the ancestral, more cryptic, coloration. Some exceptions to the "rule" that females bear the more ancestral coloration tend to support the idea that sexual selection has been more important in the evolution of male than female coloration. There are instances in butterflies (Papilionidae), e.g., the African swallowtail, *Papilio dardanus*, where relatively palatable females are "Batesian mimics" of one or more aposematic-unpalatable species, but males maintain a pattern more typical of closely related species. It seems likely that male-signalers have conserved a coloration that is important in a visual display, and that females, either because they are the display-receiving sex or because they are not involved in intrasexual competitions, were free to abandon their ancestral coloration for one that offered more protection from predators.

However, not all sexual dimorphisms in color are the direct result of sexual selection. For example, male and female stick insects (Phasmatodea), such as *Diapheromera covilleae*, sometimes bear special resemblance to different types of foliage on their host plants, and while the two sexes look quite dissimilar, there is little in their mating behavior to suggest a visual display is the cause of the difference. On the other hand, surfaces and colors that are not sexually dimorphic may be used in displays. Movements of strikingly patterned (Fig. 25) wings are typical of sexual encounters in fruit flies (Tephritidae), but sexual dimorphism in wing coloration and marking is rare.

The Advantages and Disadvantages of Light in Communications

In comparison to chemicals and sounds, reflected light perceived as color and pattern has both advantages and disadvantages as a means of communication in insects. Among its advantages are its capacity to carry large amounts of reliable information. A signal is able to transmit a message through modulation, predictable and specific variations, e.g., Morse code, or a particular color pattern



Visual Mating Signals, Figure 25 **The head of a male antlered fruit fly *(Phytalmia cervicornis)* from New Guinea. The deer-like antlers projecting from the cheeks are as much visual propaganda as weapons (drawing by Kevina Vulinec from Sivinski 1997).**

on the surface of a wing. Visual cues may be more reliable in this sense than chemicals whose combinations and densities can be blended and obscured by even slight motions of the air. It is difficult to imagine a message consisting of patterned puffs of odor making sense to a distant receiver on a breezy day.

Some modes of communication work better than others in a given habitat and context. Among the potential disadvantages of visual displays are that they can be blocked by opaque objects that chemicals or sounds could go around, and are unlikely to reach as far as pheromones and acoustic signals. Visual signals also lack persistence in the absence of the signaler, e.g., ant recruitment trails. They can even be dangerous to the signaler, as they may be more easily tracked by predators than pheromones or sounds, and even provide an unusual opportunity for predators to lure mate-seekers. For example, fireflies (Lampyridae) can be tricked by "aggressive mimics" that produce the luminous sexual display-response that attracts males of other firefly species to their final rendezvous.

Arthropod visual signals are potentially detailed and informative, but only at short distances. The effective range of visual signals is generally limited because only a small body-surface area is available for a display and because of the poor resolution of the insect compound eye. Insect eyes can resolve details of little objects such as other insects, but only at extremely close range ("[compound eyes] & would give a picture about as good as if executed in rather coarse wool-work and viewed at a distance of a foot" [Henry Mallock]). One possible exception to the generally short range of arthropod visual signals is bioluminescence, e.g., the flashes of fireflies. An extreme example is the mass display of male *Pteroptyx* fireflies, which gather by the thousands in certain trees and flash synchronously.

Idiosyncratic details of a particular arthropod's vision also influence the forms of its visual displays. For example, jumping spiders (Salticidae) see colors and are able to detect motion while moving, but wolf spiders (Lycosidae) are color-blind and must be still to perceive movement. Jumping spiders use bright colors and "dances" in their displays, while wolf spider courtships consist largely of raising and waving darkly pigmented or hairy legs.

UV Markings

Human and arthropod vision differ in the range of light wavelengths perceived. Insects are generally insensitive to red, but can see ultraviolet light (UV). Insects that appear drab to us may, in fact, be brightly reflective in the ultraviolet range and able to communicate among themselves in color patterns that are invisible to us and perhaps invisible to some of their vertebrate predators (although diurnal birds typically see UV, as do some mammals). For example, males of certain butterflies (e.g., *Colias* spp. [Pieridae]) bear brilliant UV markings, but the extensive sexual dimorphism in these species was only discovered through specialized photography. As a result, use caution in interpreting a particular arthropod's colors until the entire spectrum is described.

The Content of Intrasexual Displays

As Charles Darwin noted, "The season of love is that of battle…," and conflicts among sexual competitors, usually males, are sometimes resolved by threats communicated through visual displays. The intensity of aggression ("agonistic behaviors"), and the investment in the colors, structures and behaviors that convey the sender's ability to fight, follows a pattern. The greater the control a male can exercise over females or the resources females require, such as oviposition or feeding sites, the more profitable it is for males to invest in weapons and advertisements of prowess. Typically, controllable resources are relatively small and rare and, thus, easily defended. As resources become common, large and spread out, they become less and less defendable and less and less likely to be associated with aggressive displays.

Antlered flies (Diptera) are classic examples of displaying males guarding a discrete resource. Projections from the head, either eye-stalks or horns sprouting from the cheeks, occur in species from nine families of flies. Perhaps the most elaborate are found in the large New Guinean fruit flies (Tephritidae) of the genus *Phytalmia*, one species of which the great nineteenth century naturalist Alfred Wallace described in the following manner: "The horns of (*P. megalotis*) are about one third the length of the insect, broad, flat, and of an elongated triangular form. They are of a beautiful pink color, edged with black, and with a pale central stripe. The front of the head is also pink, and the eyes violet pink, with a green stripe across them, giving the insect a very elegant and singular appearance."

Female *Phytalmia* oviposit in pinhole sized punctures in certain species of freshly fallen trees. These very small and rare resources attract females and are easily defended, and the owner's initial defense is accomplished through visual display. Resident (defending) and intruder males of *P. mouldsi* clash by rising up on their legs and pushing hard against each other's remarkable heads, although the antlers themselves do not play a major role in the battle. However, males whose horns are experimentally lengthened or shortened are respectively more and less likely to win fights. In addition, those whose antlers are removed altogether are treated by their rivals as females. Thus, antler-weapons serve to a great degree as displays whose size opponents appear to correlate with fighting ability.

Rival males pay attention to each other's visual displays when deciding how they will go about the all-important activities of holding resources and inseminating females. The reason is either the display is an accurate indicator of another's ability to defend its resource, or the opponent accepts that it is. "Honest advertisement" is an important principle in both intra- and intersexual signals. Over evolutionary time, a signal that exaggerates the capabilities of its sender will eventually be ignored by increasingly discriminating receivers. However, a signal that is expensive to build and display, or risky to use, is likely to honestly reflect the capacity of the sender for violence. Paradoxically, displays that "handicap" the emitter are the most useful in deciding whether it would be prudent to escalate a conflict or withdraw.

Stalk-eyes in flies are a case of what may have been a dishonest display evolving into a handicap and an honest advertisement. Smaller flies typically retreat from face-to-face confrontations with larger opponents and fights are normally between similar sized individuals. Suppose that the size of a rival is assessed by the breadth of the head, as gauged by the degree of (Fig. 26) overlap between the two sets of eyes. If so, males can appear large and conquer psychologically simply by broadening their faces. As deceitfully widened heads become more common, even further exaggeration is required, and the resulting "arms race" pulls the eyes farther and farther apart until they are at the ends of extraordinary stalks (in one 8 mm long species from Borneo, the combined length of the stalks is 20 mm). In the process, the stalks have become honest advertisements, genuine burdens that only the most robust males can produce and maneuver. Not only do males use stalk eyes to decide which opponents can be expelled and whether to fight or flee, but females also consider their size when choosing a mate.

Visual Mating Signals, Figure 26 The eyes of this male fly (*Achias* sp.) are at the ends of stalks whose combined width exceeds the length of its body. This condition, although usually less extreme, is found in a number of fly families and may be the result of trying to appear as large as possible in the opposing eyes of sexual rivals (drawing by Kevina Vulinec in Sivinski 1997).

The Content of Intersexual Displays

Location Cues: Long-Distance Signals

Because males usually benefit more from multiple matings than do females, they typically spend more energy and take greater risks than females to locate mates. When females are scattered through the environment, this often means males travel considerable distances searching for cues to find females. Because it is also in the female's interest to be found by one or more males and proceed with oviposition more quickly than other females, she may emit a relatively inexpensive signal that improves her chances of being located. Sexual pheromones are common female location cues that are typically produced in small, economical amounts and sent out with little risk as few predators or parasitoids specialize in tracking down the emitters of these chemically dilute and sporadic signals.

Modifications of female form or coloration that serve as signals to orient searching males may be less common than pheromones because the distance at which a visual cue can be perceived will generally be less than that of volatile chemicals. In addition, natural enemies without any special sensory adaptations might recognize visual signals as well as, or even better than, conspecific males. However, female location cues do seem to occur. For instance, in certain luminescent beetles like the phengodid *Phengodes nigromaculata*, larviform (Fig. 27) adult females retain the elaborate system of larval light organs that probably served as an aposematic advertisement of unpalatability. But the adult's lights are much brighter than the larva's and could act as a beacon to searching males whose large, complex male antennae suggest a female pheromone is produced as a longer distance signal as well. An alternative explanation for the brighter lights of adult females may be that chemical signaling requires more time spent exposed on the surface of the ground, and because of their greater vulnerability, females invest more in their aposematic display.

Competition among females to attract males from a distance typically will be less intense than competition among males to attract females. When males produce long-distance signals, whether chemical, acoustic, or visual, it is assumed that the signals are now more expensive than the travels females must undergo to reach the signaler, that the sender may be in greater danger from predators and parasitoids, and that females will be more likely to judge males on the basis of their signals than vice versa and respond selectively to the signals they deem most attractive.

Visual Mating Signals, Figure 27 A larviform female phengodid beetle (*Phengodes nigromaculata*) (a), and the same insect photographed by its own bioluminescence (b). The relatively bright lights of adult glow-worms may be beacons that help attract mate searching males (photos by J. Sivinski).

While there are many familiar male long-distance chemical and acoustic signals (e.g., Mediterranean fruit fly, *Ceratitis capitata*, and crickets [Gryllidae]), there seem to be fewer obvious visual examples. Part of the reason may again be the relatively limited range of vision in insects which is better suited to close-up examinations. Even so, there are a number of interesting male visual-location cues. The lights of perched male fireflies (Lampyridae) are visual equivalents of a katydid's (Tettigoniidae) song, and diurnal "beacons" that appear to advertise male positions occur in certain long-legged flies (Dolichopodidea). Male *Chrysotus pallipes* have much enlarged and shiny labial palps that emit silver flashes as they signal from the surface of leaves, and the reflected light from the tiny insect is surprisingly bright.

Courtship Displays

Courtship implies that the sender of a signal is attempting to overcome resistance in the receiver, and that the display will somehow influence (or manipulate) the receiver to copulate. This element of "seduction" can occur in long-distance signals as well, particularly those produced by males, and this blurs the distinction between long-distance beacons and courtship performances. However, greater amounts of detailed information, particularly visual information, would be available to insects in close proximity that are aware of each other's presence. Certain sexual behaviors will be unique to such close-up situations and so deserve separate consideration.

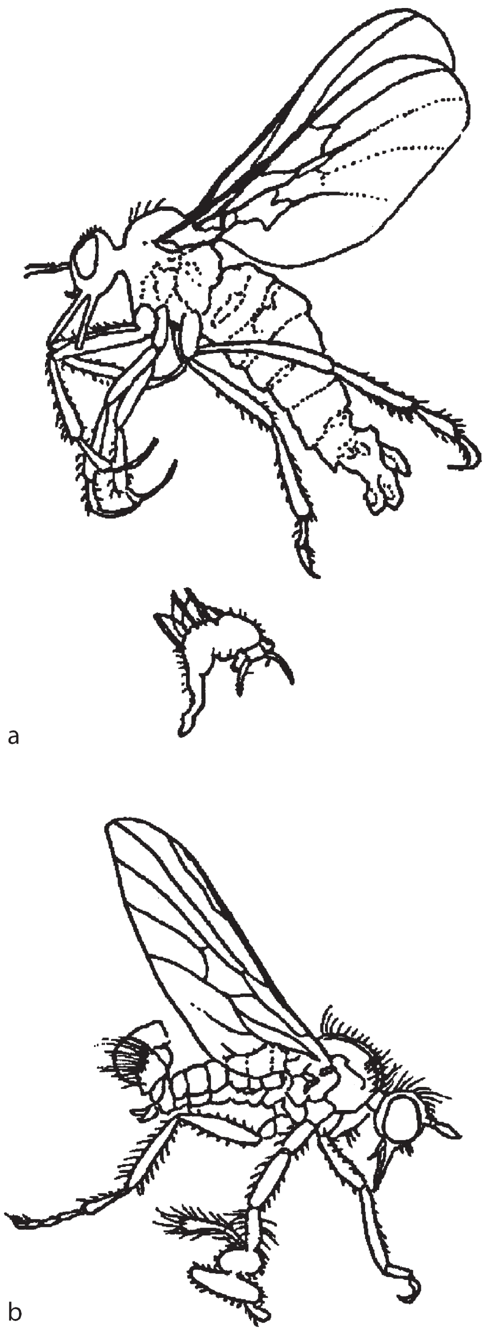
The meaning of communications with the opposite sex often is ambiguous, and there are several competing theories that attempt to explain the evolution of courtship displays. These hypotheses can be divided into the following categories: (i) displays promise a material benefit to the receiver, such as a nuptial gift of food or high female fecundity, (ii) displays advertise the genetic qualities of the performer through self imposed handicaps, and (iii) displays provide neither direct material nor genetic information, but are due to either genetic feed-back ("Fisherian run away selection") or manipulation of the receiver's perceptions ("sensory bias"). It may be that all of these are involved in the evolution of different displays.

Material Benefits

The exchange of "goods" from males to females, i.e., nuptial gifts, have been well documented in several insect groups. Examples include scorpionfly (Mecoptera) males that are required by females to produce captured prey of sufficient size, or else successful sperm transfer is not allowed. Some male Lepidoptera provide large, nutritious spermatophores during mating. The same is true of certain orthopteran males, while other orthopteran and coleopteran males provide nutritious secretions from the mouth or glands.

Such nuptial feeding invites deceit through false appearance. Things can be promised and then withheld to tempt another mate, or be promised but be completely absent. On the other hand, a female attempting to acquire a male's investment might exaggerate her fecundity, and appear to be a bigger mother and better recipient than she really is. When either sex has materials the other requires, be it protein or access to eggs, advertisements, including visual advertisements, they are likely to be elaborated through exaggeration. As in stalk-eyes, the expense of elaboration may eventually become a handicap and forge an honest display.

Empidid or dance flies (Diptera) provide examples of both male and female visual displays evolving in the context of sexual "commerce."' Predaceous male dance flies often provide mates with a (Fig. 28) prey item, but sometimes this is wrapped in a silk balloon that might have originally magnified the appearance of the gift and which, in some cases, may no longer hold anything and is perhaps only an empty promise. Even more peculiar are the odd outgrowths of the midlegs of male *Rhamphomyia scurissima*. This mass of swellings suggests the male has a small dead insect in its grasp,



Visual Mating Signals, Figure 28 **Males of many empidid species provide potential mates with an insect cadaver to eat (a). The peculiar outgrowths on the midlegs of the dance fly *Rhamphomyia scaurissima* (b) originally may have mimicked such a nuptial gift and attracted females through dishonest advertisement (drawing by Kevina Vulinec in Sivinski 1997).**

and, with this deception, he may be able to lure a gift-seeking female into a sexual encounter.

On the other side of sexual bartering are females whose apparent fecundity influences whether or not they are offered nuptial gifts. In some species, there are sex-role reversals where females swarm and males carrying insect prey choose the largest females to both feed and inseminate. Females may call attention to their abdomens, and the numbers of eggs they contain, with garish, bright silver markings. In several empidid genera, females inflate their abdomens with air until they are nearly spherical, and so may falsely appear to carry extraordinary numbers of eggs.

Genetic Benefits

Drosophila (Diptera) females that are free to pick their own mates produce more mature offspring over their lifetimes than do females that are provided with randomly chosen males. The implication is that certain males are better sires, and that females are able to recognize their genetic qualities. But what sort of qualities are they choosing and how are they recognized? It may be that phenotypes that have survived to old age or acquired the resources to attain unusually great size are reflections of an underlying genetic capacity to survive and forage effectively. For example, in certain tephritid fruit flies females prefer larger males, although the role of vision in judging size is unknown.

In general, the problem with signals that advertise such characteristics is that they can be exaggerated. Increasingly discriminating females will demand honest advertisements from prospective mates, and signals that are expensive, or dangerous, or otherwise impossible to counterfeit should become preferred. For example, it is hard for a male to appear to be more symmetrical than it actually is. The complexity of embryonic development often results in less than perfect bilateral symmetry, and the greater the number of deleterious recessive alleles in the genotype the more unlikely it becomes. As a result, "fluctuating asymmetries" in males are windows through which the value of their genes can be perceived and judged. Male *Calopteryx splendens* (Odonata: Calopterygidae) with more homogeneous wing spots perform more displays and obtain more mates, and male cerambycid beetles with more symmetrical antennae are more sexually successful. However, it is not always clear that female insects can visually discriminate fine degrees of asymmetry, and it is possible that they are attracted to male characteristics that co-vary with symmetry. For instance, a male that is more symmetrical may also have the physical capacity to signal for longer periods of time, and it is the signaling duration and not the symmetry that females find attractive.

Expense also insures honesty. A display that requires substantial material to produce, considerable energy to perform, and that places the emitter in danger is likely to be the production of a genuinely fit individual, one that had access to resources and was able to escape predators. Thus, displays are expected to be handicaps that are a burden to the insect outside of its sexual life.

Concentration on sexual matters can make males more vulnerable to predators, and it may be that the riveted attention that males focus on potential mates during courtship is in itself a handicap whose message is that "I possess such strength and agility that I can afford to give you my undivided attention and survive." Other physical trials might reveal genetic quality, e.g., females of the wolf spider *Hygrolycosa rubrofasciata* choose males on the basis of their leg-drumming rates which, in turn, are predictors of their viability.

In addition to risky, arduous or complicated behavior, physical structures may prove both costly to the signaler and attractive to the opposite sex. There are certainly any number of peculiar sexual dimorphisms in insects that could be both displays and handicaps. Many courting insects energetically use their wings, which are also important organs of predator-escape, in displays that might jeopardize their safety. For instance, potentially compromising wing motions are ubiquitous in the courtships of the tephritoid Diptera; e.g., *Callopistromyia annulipes* (Ulidiidae) males "strut" with wings upraised like a peacock's tail, and rapid wing movements are nearly universal in the sexual interactions of other large taxa like the parasitic Hymenoptera (such motions may also waft pheromones and/or produce acoustic signals).

Colors can attract both the opposite sex and the attention of predators, and in addition, some colors may be difficult or even dangerous to produce. In birds for instance, red pigments are derived from carotenoids that the animal cannot manufacture and must be obtained from food sources. Further, carotenoids are important components of the immune system and their removal from a vital health-function in order to be "painted" on the body surface may send a powerful message about both the foraging capacities and disease resistance of the signaler. Males often suffer more injuries and greater mortality than females, and this may be due to either more conspicuous colors or more risky mate-searching behaviors that expose them to predators. An illuminating case of dangerous bright coloration, as opposed to dangerous behavior, occurs in *Ischnura* damselflies (Coenagrionidae). Females may be either drably colored or brightly colored like the males ("andromorphs"). Brightly colored females are less likely to be recognized as potential mates and so avoid pestering by males. Because of their male-like appearance, they are able to lay their eggs more efficiently, but, unfortunately, they are also more likely to attract the attention of predators and, in some populations, they have only one-third the life expectancy of their plainer sisters.

Finally, color may indicate the ability of the signaler to avoid or survive debilitating diseases and larger parasites. Females may prefer such males either because they are likely to sire healthy offspring or because healthy males are less likely to transmit a disease during copulation. It has been suggested that the colors and forms of certain dung-feeding male scarab beetles might highlight the mite population they carry and allow females to choose males with lower mite loads.

Fisherian Run Away Selection

If the genes for the expression of a male trait (e.g., an element of a courtship display) and the female preference for the trait are linked, then females that choose the most extraordinary examples of the male characteristic will tend to have daughters with a still more extraordinary "taste" for the display. The extravagance of the display and the female demand for the extravagant will continue to increase hand-in-hand ("run away" in the sense of positive feedback) until the spiraling expense and danger of the signal are so great that natural selection puts an end to further elaboration. In this process, the display has no "meaning," females gain no insights into male genetic or material qualities from the display and choose mates only for their capacity to produce a more or less arbitrarily attractive set of colors, structures and behaviors.

Recently, the popularity of this theory of the origin of displays has suffered somewhat for two reasons. First, phylogenetic studies reveal that male displays have been lost in a number of lineages, much more frequently than previously had been imagined, and this loss is inconsistent with linked traits running away with one another. Second, displays increasingly are found to be reliable indicators of male quality and not simply matters of haphazard fashion. Particularly telling cases of informative signals occur when the same displays that males use to persuade females are also employed in competitive interactions with other males. A sexual rival has no reason to be intimidated by a structure or behavior that is only fashionable and not an advertisement of the ability to acquire a resource or to defend associated females. For example, in the stalk-eyed fly (Diopsidae), *Cyrtodiopsis whitei*, female harems "roost" in the company of individual males, and females prefer associations with long-stalked males because stalk-eye length is correlated to offspring quality. Eye stalks are also used in antagonistic interactions.

Sensory Bias

"Sensory bias" theories of the origin of displays suppose that male sexual displays take advantage of preferences that have evolved in females for other reasons, and so manipulate females into responding. This is another type of male signal that tells females nothing useful about male genetic or material qualities, at least in the early stages of its evolution. For example, females of the water mite *Neumania papillator* (Acari: Parasitengona) use vibrations to locate their copepod prey, and males make similar vibrations with their forelegs. Females move toward and clutch vibrating males, and are more likely to do so when they are hungry. It seems that males have exploited the female's feeding behaviors to increase their rate of sexual contact.

Manipulative visual displays occur in the wolf spider (Lycosidae) genus *Schizocosa*. Males perform leg-waving courtships, but the various species have different degrees of foreleg ornamentation. Female spiders will orient toward video tapes of male courtships, and prefer the images of males with tufts of hair on their legs, regardless of whether or not their conspecific males have such hair-tufts. Thus, females in both tufted and untufted species appear to have a pre-existing preference for hairy legs that males of some species take advantage of and that males of other species do not.

This taste for leg-tufts might be a byproduct of hunting behaviors where female spiders must orient toward and approach small moving objects in their environment. Because such a response is necessary for the display-receiver to obtain food, it is difficult for her to completely ignore the signaler, but females might become more discriminating over time and sensory bias signals could evolve to carry information about male quality. For example, female *Schizocosa* spp. are more responsive to males with symmetrical forelegs, and such symmetry may be the result of developmental stability or a successful fighting career. Foreleg displays that now are showcases for symmetry may be elaborations of what began as lures.

Copulatory and Postcopulatory Displays

A female insect may choose the sire of her offspring at several points prior to oviposition. Her responses to precopulatory courtships determine whether or not she will mate. But even while coupled, she may choose to direct sperm to different portions of her reproductive tract where they will either be used for fertilizations, or be shunted away into places where they will languish or perish. Following mating she may simply eject sperm from a particular male, or copulate again with a more suitable male whose new ejaculate will block the old sperm from reaching the ova.

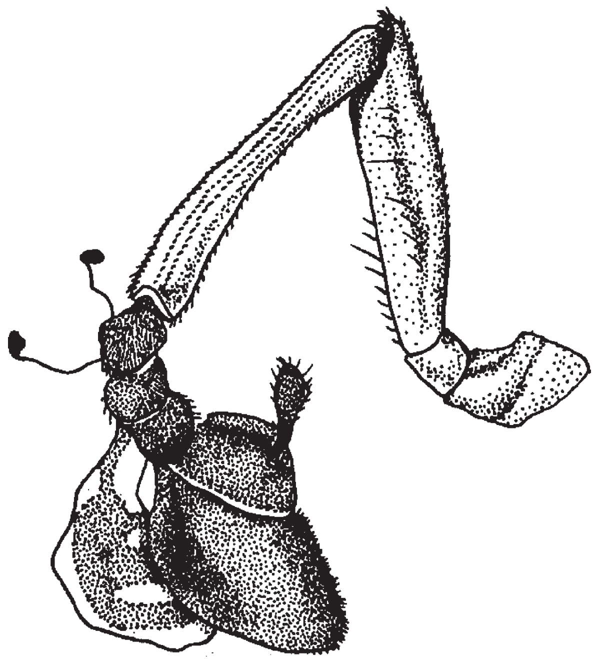
Because of these opportunities for "cryptic female choice," males may guard mates or continue courting mates with displays during and even after insemination. There are a number of male copulatory behaviors that might qualify as visual appeals to females making cryptic choices. *Sabathes cyaneus* is an unusually brightly colored mosquito whose mid legs end in a feathery "paddle" of elongate iridescent blue and gold scales. Males fly toward resting (Fig. 29) females with their paddles extended, land nearby, suspend themselves by their forelegs, and then swing and wave their ornaments. "Waggling," during which the midlegs continue to rise and fall, continues through the copulation. Mounted males of the long-legged fly *Scapius platypterus* (Dolichopodidae) insure their visual signals will be observed by resting their front legs over the female's head while the midlegs are held to the side near her eyes and waved back and forth. Males of the micropezid fly *Cardiacephala myrmex* close the gap between their foreleg motions and their mates by alternatively scratching and regurgitating on her eyes. Not only flies apply their ornaments to female

Visual Mating Signals, Figure 29 **Mosquitoes are rarely ornamented. An exception are males of the genus *Sabathes* whose midlegs are decorated with iridescent "feathers." This feather is waved before females both prior to and during mating (drawing by Kevina Vulinec in Sivinski 1997).**

eyes during copulation. Male wasps in the genus *Crabo* (Hymenoptera: Sphecidae) have the front tarsi dilated into horny plates punctured by membranous dots giving them a sieve-like appearance. During mating, these are placed over the female eyes, perhaps resulting in a specialized visual signal similar to what would be obtained by shining a light through an antique computer "punch card."

Mating Systems and Visual Displays

Arthropods seek mates in a number of ways and in a variety of places, some suited to the production of visual displays and others not. Swarms, where multiple males (or rarely females) fly in place, sometimes by the thousands, over a spot or "marker" are both common and seemingly poor places to advertise to potential mates. With numerous insects swooping about each other, signals, particularly pheromones, would be difficult to track back to their emitter. And, if the emitter cannot be identified, then cheaters who do not invest in a signal but fly about in another's "perfume-cloud," have an energetic advantage that would eventually lead to their increase and then to the collapse of the entire display system. Visual displays are somewhat more likely, but still suffer from a poor capacity for individual recognition. For example, swarming mosquitoes are typically drab, but non-swarming species are often colorful. However, if flight is slow enough and swarmers separate enough, then visual signals can and do evolve. Small species of Mayflies (Ephemeroptera) sometimes have glassy wings and their swarms resemble falling snowflakes in the sunshine. Some of the most remarkable insect ornaments occur in certain swarming, flat-footed flies (Platypezidae). Species of the North American genus *Calotarsa* have enlarged hindlegs that bear a curious collection of projections and glittering aluminum-colored flags. They fly in a slow and dignified manner while allowing their "hind feet to hang heavily downward and look as if they were carrying some heavy burden" (Fig. 30).



Visual Mating Signals, Figure 30 **Swarming insects are seldom in a position to emit visual signals. The intertwining flights of numerous insects are simply too confusing. However, there are exceptions and the hindlegs of the swarming flatfooted fly *Calotarsa insignis* are a spectacular example of insect ornamentation (drawing by Kevina Vulinec in Sivinski 1997).**

Aerial displays by non-swarming insects are easier to evolve and maintain because the complications of confusing neighbors are diminished. The brighter colors, and occasionally unique markings, of male butterflies are displayed in intrasexual encounters and some of these occur during aerial conflicts. In many species of *Photinus* fireflies (Lampyridae), males make nocturnal flights, advertising their availability with flash patterns. These patterns of flashes elicit response flashes from perched females, and through flash dialogues males locate females, land near them, and mating occurs. Some species of *Photuris*, another genus of fireflies, are aerial predators of signaling *Photinus* males. The flashing signal is more difficult for the predator to track in flight than a continuous glow. Flashing may have evolved from an ancestral continuous glow in response to this predation pressure.

Once courtship occurs on the ground or leaf surfaces or some other platform, there is finally a stable stage on which males can easily perform elaborate behaviors with complexly patterned ornaments and be relatively easily recognized as individuals with their own particular messages to send. Ground-based mating systems can consist of single males searching or occupying a signaling site (often a resource) or groups of males either aggregated at a resource or gathering in non-resource based "leks." Visual displays occur in these different mating systems. Many of the highly decorated male dolichopodid flies appear to be solitary, or at least not tightly aggregated. Striking sexual dimorphisms are also encountered in lekking species in other families. An unusual example of the latter is the scuttle fly, *Megaselia aurea* (Phoridae). Like most phorids, males are nondescript flies, cream and grey in color, but females are yellowish orange with an iridescent orange patch on their dorsal surface. In addition to their unusual coloration, females have the peculiar habit (for their sex) of gathering on leaf surfaces in groups of up to a dozen or so. Males visit these sex-role reversed leks, pair with a female, and fly off to copulate on nearby vegetation. The bright orange of the lekking females suggests a visual display directed either to female lek-mates or male visitors.

The Locations of Ornaments and Colors

The structures and colors used in visual displays occur all along the arthropod body, but there are certain points of concentration. Some display locations emphasize a particular body part. Female dance flies that call attention to, or exaggerate, the size of their ovaries enlarge and color their abdomens, and ornaments used in male-male interactions are often on the head, perhaps because the head is used in the pushing style of combat typical of Diptera. Elaborations such as eyes elongated into cow-like horns (*Zygotricha dispar* [Drosophilidae]) and antlers and eye-stalks may be embellishments of actual weapons that now also advertise sexual competitiveness.

Movement can be an important component of a signal either because receivers are likely to notice the motion and so be more likely to see the ornament, or because the motion itself is the message and the movement is made more obvious by the ornament. In either case, ornaments or motions could serve as "amplifiers" that attract the attentions of the opposite sex to the display. It has been argued that a simple preference for the first male a receptive female might see could select for such amplifiers, and that competitions among amplified males to be the first noticed might act as "mate-filters." On average, females would be most likely to couple with active, easily seen males whose apparency is a correlate of a good genetic constitution.

This premium on movement has served to concentrate signaling onto moveable body parts such as legs, wings, labial palps, antennae, and even the external genitalia. In dolichopodid flies, the male genital region is sometimes much enlarged (the hypopygium) and this may be raised and lowered during the male's courtship advance (e.g., *Dolichopus omnivagus*). In one unidentified species, males rise up on their long legs, beat their wings, lower the hypopygium until it hangs perpendicular to the body, and then slowly twirl their genitals. Dipteran legs are adorned with signaling devices that range from simple flags of enlarged setae to bizarre banners of hairy projections and strange devices. In yet another dolichopodid, *Campsicnemus magius*, the front legs are so swollen, pendanted and hairy that critics suggested the original specimens were deformed by fungi. Likewise, the fore tibia of the flower fly (Syrphidae), *Tityusia regulas*, are "enormously thickened, grooved, twisted and distorted" with an "extremely long, extremely matted" dark pile of fringe, and tarsi are extravagantly flattened with the lateral edges of the second, third, and fourth segments prolonged into narrow, down-curving lobes. Other examples occur outside of the Diptera, e.g., some male leaf-footed bugs (Coreidae) may use colorful expansions of both hind leg and antennae in defense of territories such as flower heads.

As noted earlier, while color can appeal to the opposite sex or deter rivals, it may also attract predators, and displays that can be produced only when the appropriate receiver is in a position to appreciate the signal may be safer than those that are on all the time. Ornaments on some moveable structures have the advantage of concealing and then revealing a signal in all its splendor. Consider any number of butterflies (e.g., the white M hairstreak, *Parrhasius m-album* [Lycaenidae] or the Florida purplewing, *Eunica tatila* [Nymphalidae]) whose outer wing coloration is dull and cryptic, but whose inner surface is dazzlingly bright. Such an insect at rest is difficult to detect, but with its wings opened while on its perch or in flight, it is an iridescent beacon (although one must consider the habitat, as periodic flashes of iridescence in the dappled light of a forest may be misleading or disguising).

The Phyletic Distribution of Visual Sexual Displays

Different arthropods have different capacities and opportunities for the production of visual sexual displays. Diurnal butterflies have a greater chance to employ visual signals than do nocturnal moths. As noted earlier, jumping spider (Salticidae) vision lends itself to the reception of color and complex movement, while the eyes of the related wolf spiders (Lycosidae) do not. The frenetic mass flights of small swarming flies are incompatible with visual signals, while the largely surface-bound foraging habits of dolichopodid flies may give them a ready stage on which to perform elaborate displays and so be the reason they are among the most ornamented Diptera.

As a result of these and other differences, there appears to be a clumped distribution of visual displays. There is hardly enough research to quantify this distribution, but it seems that the more derived flies (Brachycera) have a disproportionate number of apparent visual displays. Butterflies, luminous beetles and Odonata are other obvious hotspots of visual communication.

Conclusion

The diversity of arthropod visual signals is immense, owing to the evolutionary plasticity of the arthropod body and the behaviors used in combination with visual signals to modify and enhance their effects. Visual signals are adapted to a wide variety of habitats and contexts. As noted above, not all arthropod signaling evolved by sexual selection, as not all colorful arthropods are signaling to sexual partners or rivals. In fact, given the limitations of insect eyes, colors and patterns more often than not may be directed to visually acute predators such as birds and serve to startle, warn of unpalatability, or to mislead.

Vitamins

Vitamins are nutrients needed for normal growth of insects. Those required are thiamine, riboflavin, pyridoxine, niacinamide, pathothenic acid, biotin, folic acid and choline. Some insects also require carnitine, ascorbic acid, carotene, vitamin B-12, vitamin E, and others.

► Nutrition in Insects

Vitelline Membrane

A membrane surrounding the egg, which in turn is surrounded and protected by the chorion.

Vitellogenesis

PAUL D. SHIRK
USDA, Agricultural Research Service, Gainesville, FL, USA

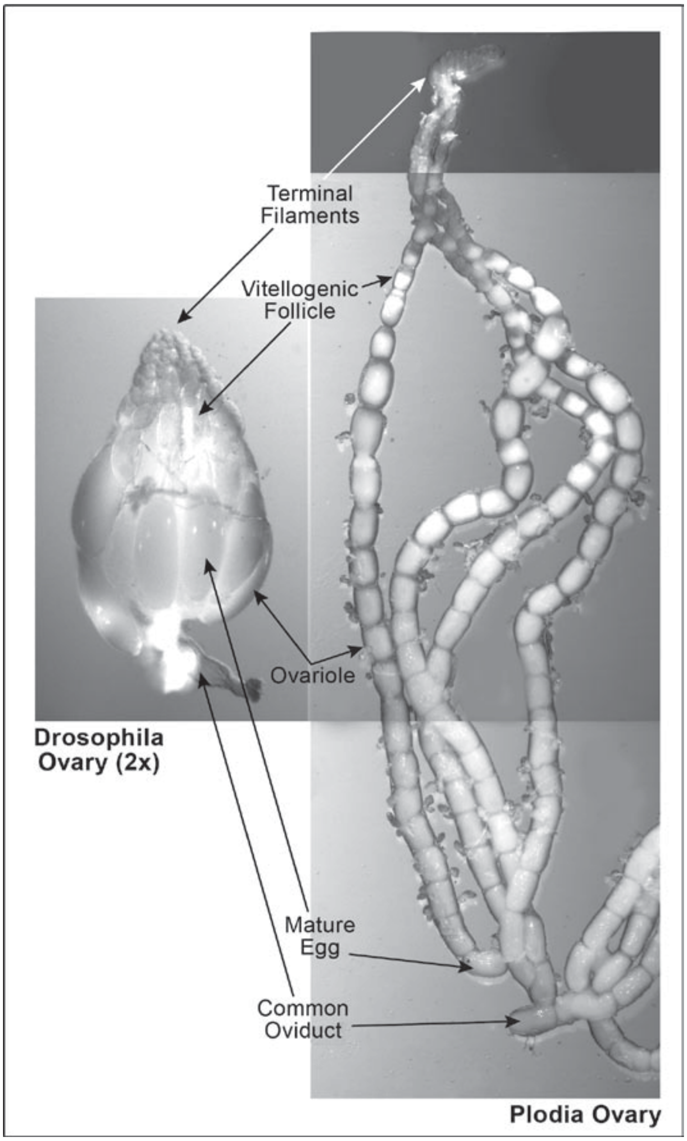
Vitellogenesis is the process of production and accumulation of yolk in a developing oocyte. Female insects seek out a nutritionally suitable environment that will potentially provide more than adequate food resources for her larvae. This behavior assures the propagation of the species. However, before the larva hatches onto its nourishing meal, each egg must come complete with all the developmental instructions (localized determinants), cytological machinery (e.g., ribosomes, mitochondria, and RNAs) and nutrients (yolk) necessary to complete embryogenesis and support the maturation of the embryo through larval hatching and into the first larval instar. The process of vitellogenesis or the production and packaging of nutrients, primarily vitellin or yolk proteins, into the developing oocyte within the ovary is critical to providing the egg with the nutrient resources to complete embryogenesis.

As described under oogenesis, the polytrophic ovary is comprised of ovarioles that contain an array of follicles in varying stages of development (Fig. 31). Each follicle within a polytrophic ovary contains an oocyte (germ cell) that is interconnected via a series of ring canals to a complement of sister nurse cells. This germ cell complex is surrounded by follicular epithelium cells that are somatically derived. After differentiation of the oocyte and nurse cells from a single blastocyst cell, the follicle goes through four stages before it completes the formation of an egg that is ready for fertilization. The previtellogenic stage provides a period of production of cytoplasmic organelles by the nurse cells and oocyte that will be required by the developing embryo. The vitellogenic stage begins with the initiation of patency, the opening of spaces between the follicle cells that permits the diffusion of materials from the hemolymph to the oocyte surface for uptake. The vitellogenic stage ends with the closure of the inter-follicular cell spaces, which is followed by the production of the vitellin membrane and the initiation of choriogenesis, the production of the eggshell or chorion. During the vitellogenic stage, the size of the oocytes increases tremendously due to the uptake of vitellogenin, nurse cell cytoplasm and water.

Vitellin, the Stored Protein of Yolk

Vitellogenesis in most insects involves the production of vitellogenin, the precursor protein of vitellin, by the fat body. Vitellogenin is secreted into the hemolymph to circulate through the body and eventually to the ovary where the protein is actively taken up by a vitellogenic oocyte via receptor mediated endocytosis and packaged in yolk spheres as vitellin.

Insect vitellogenins are phosoglycolipoproteins (proteins that have organic phosphate, sugar, and lipid moieties attached). Vitellogenins are found in other animals that deposit eggs, such as nematodes, shrimp, birds and amphibians, and the proteins all belong to a superfamily of lipoproteins that share a common evolutionary origin. Vitellogenin genes are relatively large and produce transcripts that code for polypeptides in the size range from 1,748 amino acids in the Gypsy moth, *Lymantria dispar*, to 2,139 amino acids in the *Aedes* mosquito. The vitellogenin gene is expressed in the fat body and contains a signal sequence that targets the polypeptide for processing in the endoplasmic reticulum, packaging



Vitellogenesis, Figure 31 **Vitellogenic polytrophic ovaries from the fruitfly, *Drosophila melanogaster*, and the Indian meal moth, *Plodia interpunctella*. The ovary of *Drosophila* (*left*) was dissected from a 5-day old adult. The ovary of the *Plodia* moth (*right*) was dissected from a newly eclosed adult.**

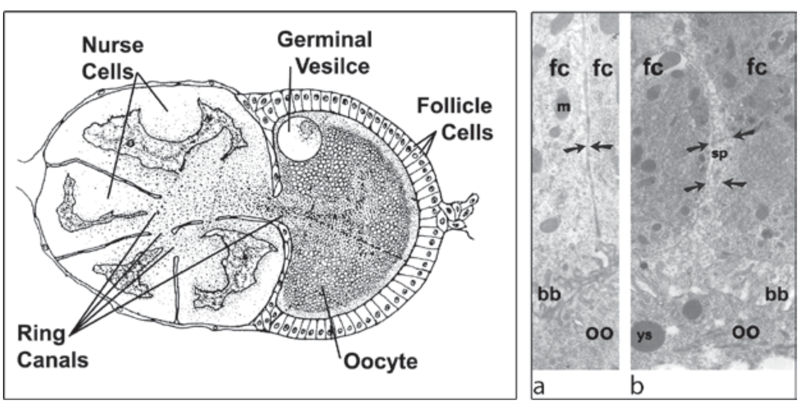
into secretory vesicles by the Golgi apparatus and secretion into the hemolymph. For most insects, the primary vitellogenin polypeptides are cleaved into a large subunit of approximately 150,000 Daltons and a small subunit of approximately 65,000 Daltons. These two subunits associate within the secretory vesicles and are secreted together into the hemolymph where they circulate to the ovaries.

The paradigm of vitellogenin production and uptake applies to most of the insect orders examined. However, the higher flies, cyclorrhaphan Diptera, utilize other proteins that are unrelated to vitellogenins as their primary source of yolk protein. While the eggs of mosquitoes contain vitellin, the eggs of the cyclorrhaphan flies contain from one to three small polypeptides that range from 40,000 Daltons to 50,000 Daltons that are produced by the follicular epithelial cells which surround the oocyte and/or by the fat body. The yolk protein genes are correspondingly small and are structurally related to genes for lipases. Thus in the cyclorrhaphans, it appears that the vitellogenin gene has been lost during evolution and the functional role of select lipases has been diverted to that of a yolk protein which replaces vitellin. This substitution of proteins appears to have been possible because lipase related proteins, such as egg specific protein (ESP) in the silkworm *Bombyx mori*, or the follicle cell yolk protein (FEYP) in the Indian meal moth, *Plodia interpunctella*, are normally secreted by the follicle cells taken up by receptor mediated endocytosis during vitellogenesis and contribute up to 50% of the proteinacious yolk in moths.

Vitellogenesis, the Period of Yolk Uptake

The follicles are arranged in the ovarioles in a linear manner and each follicle enters the vitellogenic period independently from the other follicles within the ovariole. In the previtellogenic stage, the follicular epithelium (Fig. 32) cells that surround the oocyte form tight junctions between the cells which does not allow for the entry of materials to the surface of the oocyte. As the vitellogenic stage begins, the follicle becomes patent for vitellogenesis, that is the follicular epithelium cells loosen the tight junctions which opens gaps between the follicle cells, thus allowing proteins and other nutrients within the hemolymph to penetrate to the surface of the oocyte for uptake. The vitellogenic stage lasts until the oocyte has been supplied with sufficient nutrients and determinants and the follicle cells begin the production of the vitellin membrane and the chorion.

Vitellogenin is taken up into the oocytes by receptor mediated endocytosis. The receptors for vitellogenins are large membrane-bound proteins that range from 180,000 to 214,000 Daltons. The vitellogenin receptors occur as homodimers that are localized in the clathrin pits on the oocyte plasma membrane. Once bound to the receptor, vitellogenin is carried into the endocytotic vesicles that coalesce to form yolk spheres. The vitellogenin



Vitellogenesis, Figure 32 **Vitellogenic follicles: (*left*) The generalized structure of a vitellogenic follicle from a polytrophic ovary. The germ cells, oocyte and nurse cells are connected via ring canals and surrounded by follicular epithelial cells. The germinal vesicle of the oocyte is the haploid nucleus of the germ cell. The nurse cells have polyploid nuclei. (*right*) Patency of the vitellogenic follicle. At the beginning of the vitellogenic period, the tight junctions (*part a*) between the follicular epithelial cells disappear and the intercellular spaces open (*part b*) to permit the penetration of diffusible hemolymph borne materials to the brush border of the oocyte. Opposing arrows show the plasma membranes of the follicular epithelial cells with tight junctions (a) and with open intercellular spaces during patency (b). Abbreviations: *bb* = brush border; *fc* = follicular epithelial cell; *m* = mitochondrion; *oo* = oocyte; *sp* = intercellular space; *ys* = yolk sphere.**

receptors have varying levels of specificity depending on the species of insect. In the tobacco hornworm, *Manduca sexta*, vitellogenin and lipophorin are endocytosed by two different receptors. However, in the silkmoth *Hyalophora cecropia*, the vitellogenin receptor also binds with lipophorin, and in the mosquito *Aedes aegypti*, the receptor can bind multiple ligands. Thus, the vitellogenin receptor may have a broad binding capacity in order to provide a broad spectrum carrier for the specific localization of proteins in the yolk spheres.

Endocrine Control of Vitellogenesis

The production and uptake of vitellogenin is endocrinologically regulated in various manners according to the feeding style and longevity of the adult. We can consider four different models of regulation: insects with long-lived adults that feed continuously, insects with long lived adults that feed intermittently, insects with short lived adults that feed, and insects with short lived adults that do not feed.

In the fruit fly *Drosophila melanogaster*, that has adults that are long-lived and feed often, the onset of yolk protein production is regulated by an increase in the level of juvenile hormone (JH) occurring just after adult eclosion. JH stimulates the progression of follicular development past the previtellogenic stage, stimulates yolk protein production from the follicle cells and stimulates ovarian synthesis of ecdysteroids. The ecdysteroids produced by the ovaries stimulate the fat body to produce large quantities of yolk proteins that provide the resources for the rapid growth of vitellogenic follicles. Once initiated, yolk protein production in the fat body is continuous throughout the adult stage and is dependent on a balanced maintenance of both JH and ecdysteroids and a continuous supply of food.

Alternatively, in the grasshopper *Locusta migratoria*, which has a long-lived adult, vitellogenesis is cyclic. Vitellogenesis and egg maturation are initiated by an increase in juvenile hormone after adult eclosion. As the follicles mature, they exert a feedback inhibition on juvenile hormone production which shuts off vitellogenesis. This results in a cycling of egg production throughout the adult life of this grasshopper.

In the anautogenous mosquito *Aedes aegypti*, which have long-lived adults that feed intermittently, egg production is dependent upon the acquisition of a blood meal. A complex hormonal cascade involving the gut, brain and ovaries is initiated when the mosquito has a blood meal, which results in a single cycle of egg production. Following the ingestion of blood, vitellogenesis consists of two phases. First there is an initiation phase where the arrested developing follicles become activated and the follicular epithelium cells resume mitosis and separate from the oocyte. This requires the release of egg development neurosecretory hormone (EDNH) from the brain that acts on the ovary to produce ecdysteroids. The ecdysteroids stimulate the fat body to initiate the second tropic phase that begins 5–6 hr after a blood meal and additionally on the adjacent secondary follicles to complete previtellogenesis in preparation for the next round of egg production. Under the influence of ecdysteroids, the fat body produces large amounts of vitellogenin that is taken up by the vitellogenic follicles. However, as the blood is digested, vitellogenesis declines due to hormonal feed back on the brain. A new cycle of egg production cannot be initiated until another blood meal has been taken by the female.

In the tobacco budworm, *Heliothis virescens*, which has short-lived adults that feed, the newly eclosed females must have a meal before vitellogenesis can be initiated. The meal triggers the production of JH which stimulates the fat body production of vitellogenin as well as the maturation of the follicles. Once begun, vitellogenin production by the fat body is continuous throughout the adult stage. Alternatively, the fall army worm, *Spodoptera frugiperda*, requires JH during the adult stage to stimulate follicle development and vitellogenin uptake as well as ecdysteroid production by the ovary.

Subsequently, the regulation of fat body vitellogenin production requires the ovarian ecdysteroids.

Finally, for insects that have short-lived adults that do not feed, such as the silkworm *Bombyx mori* or the Indian meal moth, *Plodia interpunctella*, vitellogenesis and oocyte maturation takes place during pharate adult development. Vitellogenin production by the fat body begins after the fall of the ecdysteroid peak that leads to adult development and is maintained continuously through the adult stage. For many of the follicles, vitellogenesis is completed during pharate adult development, and the adult female ecloses with most of her eggs completely developed and ready to be fertilized.

Vitellogenin

The major yolk proteins are called vitellogenins while being transported to the hemolymph, and consist of large glycolipoproteins which are produced by the fat body and secreted for uptake by maturing oocytes. Not all yolk proteins are vitellogenins, however, and in higher Diptera the yolk proteins are small polypeptides.

Walker, Francis

Francis Walker was born at Southgate, England, on July 31, 1809. He is known principally for his collecting and writing skills. His entomological publishing commenced in 1832 when he contributed a chapter on chalcids to the "Entomological Magazine." Shortly thereafter, he undertook the editorial management of the magazine, though he remained in this capacity for much more than a year. He collected a great amount of material for the British Museum, produced several catalogues such as "List of the specimens of the dipterous insects in the collection of the British Museum," and described numerous species from both Europe and North America. Between 1851 and 1856 he published "Insecta Saundersiana" in four parts. He prepared over 20,000 descriptions in several orders, though many have been found to be faulty. Indeed, his faulty descriptions caused something of a scandal at the British Museum. He is not identified with a particular group, having described neuropterans, orthopterans, termites, hemipterans, flies, wasps, moths and beetles, but he likely had more effect on the study of Coleoptera than any other group. Walker died at Wanstead, England, on October 5, 1874.

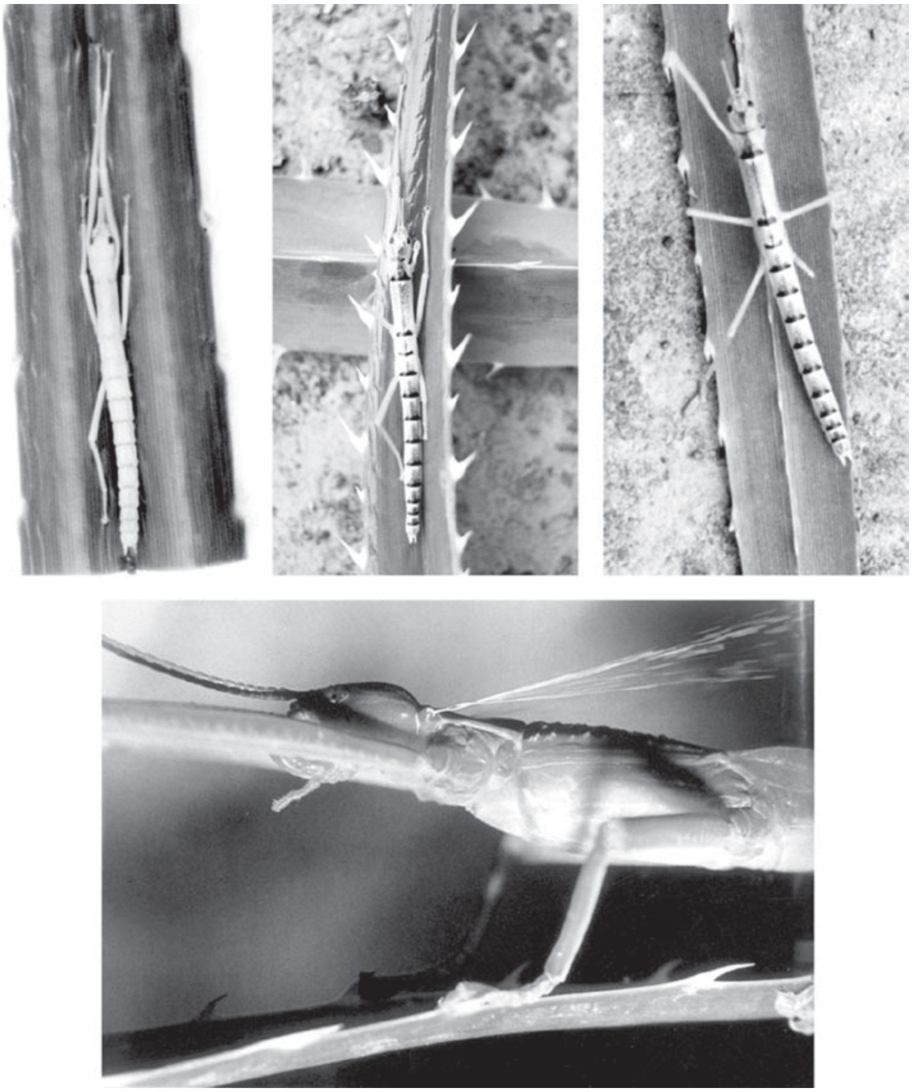
Walkingstick Defensive Behavior and Regeneration of Appendages

Y. S. CHOW

National Museum of Natural Science, Taiwan, Republic of China

Some 2,500 species, mostly from warmer parts of the world, comprise the order Phasmatodea, the so-called stick insects. Often up to 8 cm long and frequently apterous (wingless), stick insects are slow and clumsy and, for that reason alone, are vulnerable. Many, however, are cryptically colored, armed with spines, or protected by their resemblance to twigs and tree leaves. Others that comprise only a few known species, are protected by defensive glands. In Taiwan, the walking stick insect *Megacrania tsudai* Shiraki, causes considerable damage to screw pine along the southern coast. It has three distinctive characterizations. First it can secrete a monoterpene alkaloid actinidine as a defensive chemical. Secondly, it can regenerate lost appendages, and lastly, it can reproduce individuals parthenogenetically for long periods of time (Fig. 1).



Walkingstick Defensive Behavior and Regeneration of Appendages, Figure 1 **Regeneration of appendages (*top row*) in the larva of stick insect *Megacrania tsudai* Shiraki. (*Left*) First instar of the insect in which the right metathoracic leg was amputated. (*Right*) After ecdysis, the right metathoracic leg of the second instar appeared as a miniature leg. Meanwhile, the right prothoracic leg was amputated. (*Center*) The third instar 3 days after ecdysis. The right metathoracic leg looked like its normal left leg, but is short in length. Note that the regenerated right prothoracic leg was regenerated as a miniature leg. Female *Megacrania tsudai* Shiraki showing white discharge being sprayed (below) when the insect was tapped on the abdomen.**

Chemicals such as irrdodials, nepetalactone, benzaldehyde, benzothiazole, limonene and quinoline have been reported as defensive chemicals produced by other phasmid insects from different parts of the world.

Megacrania tsudai has two large bilateral thoracic glands and, when molested, it will spray a white discharge toward the disturbance. But unlike the other stick insects, the main chemical secreted was identified as a nitrogen containing alkaloid actinidine, with other related minor compounds such as boschniakine and two stereoisomers of 1-acetyl-3-methylcyclopentane. Gas chromatography-mass spectrometry was used in these identifications.

Another feature of the insect is its ability to regenerate an amputated leg as an immature. An appendage can be regenerated during subsequent instars, indicating that at least some of the cells surrounding an appendage are sufficiently undifferentiated to retain the ability to reform that appendage. Since regeneration of a leg requires a molt, it might be related to the combination of molting hormone, juvenile hormone and signal transduction (Fig. 1).

Megacrania tsudai can produce offspring by parthenogenesis. In an enduring study, female insects have been cultivated in a laboratory for more than 10 years, with no males present in the laboratory culture or in the field.

Waloff, Nadejda

"Nadia" Waloff was born at St. Petersburg, Russia, on September 2, 1909. Her family fled the Bolsheviks in 1919 and became refugees in Britain. In 1926 her mother died, and afterwards her father and oldest brother emigrated to Romania. Nadia and three siblings were taken in by Sir Boris Uvarov, director of the Anti-Locust Research Center in London. It is likely that this experience encouraged Nadia and her sister Zena to pursue careers in entomology. Waloff received a bachelor's degree from Imperial College and taught school for several years. In 1946 she began work on insect pests at Imperial College and the Pest Infestation Laboratory in Slough. Thus she embarked on a distinguished career at Imperial College and also attained a Ph.D. and Sc.D. before retiring in 1978. Both before and after her retirement, Waloff was known as an outstanding instructor. However, she conducted some very thorough and landmark research, alone and in collaboration, on flour moth diapause, population dynamics of grasshoppers, yellow meadow ant, and broom-infesting insects. She died on June 5, 2001.

Walsh, Benjamin Dann

Benjamin Walsh was born at Frome, Somerset, England, on September 21, 1808 (Fig. 2). He graduated from Cambridge University, Cambridge. His parents wished him to enter the ministry, but he disavowed the hypocrisies of the church. He emigrated to the United States in 1838 and settled into a farming life near Cambridge, Illinois, for about 12 years. In 1850 he moved to Rock Island, Illinois, and opened a lumber yard. He retired from this in 1858 and entered the real estate business and, to a lesser degree, politics. It is

Walsh, Benjamin Dann, Figure 2 **Benjamin Walsh.**

at this time in his life that Benjamin Walsh became interested in insects, and by 1860 he was reported to have given an extemporaneous 2-h lecture to the Illinois State Horticultural Society. Soon he began publishing in farm newspapers and scientific journals. He did such a fine job at publicizing the dangers from insects that the Illinois State Legislature appointed him state entomologist. Walsh and C.V. Riley started the "American Entomologist" from 1868 to 1880. It consisted of three volumes and was considered to be an outstanding popular periodical on insects. In November 1869 Walsh was absentmindedly walking along the railroad tracks when he was struck by a train, and perished a few days later, on November 18, 1969.

Walsingham, (Lord) Thomas De Gray

Thomas Walsingham was born at London, England, on July 29, 1843. He was educated at Cambridge University and served as a member of the British House of Commons. He succeeded to the title and estates of his father in 1870, and was appointed a trustee of the British Museum in 1876. His wealth allowed him to travel and to purchase specimens at will, and he developed considerable expertise in the Microlepidoptera. His collecting trips included most of southern Europe, northern Africa, and the western United States. Walsingham served as president of the Entomological Society of London, and was a member of numerous other scientific societies. Among his noteworthy publications are "Illustrations of the Lepidoptera Heterocera in the British Museum" (1879), and "North American Tortricidae" (1884). He died in London on December 3, 1919.

Wasmann, Erich

Erich Wasmann was born on May 29, 1859, at Meran, Austria. He studied for the priesthood and entered the Jesuit order in 1875. From 1890 to 1892 he studied zoology at the University of Prague. Wasmann suffered from a lung disorder and was advised to spend as much time as possible out-of-doors. This, perhaps, led to his interest in ants, and he eventually became an authority on myrmecophiles and termitophiles. He also wrote on instinct and intelligence of ants, and the relationship of ants to other animals. He authored 433 publications with over 280 on myrmecophiles and termitophiles. Noteworthy publications included "Kritisches Verzeichniss der myrmecophilen und termitophilen Arthropoden" (1894), "Die moderne Biologie und die Entwicklungstheorie" (1910), and "The Berlin discussion of the problem of Evolution" (1909). The University of Freiburg in Germany awarded him an honorary doctoral degree in 1921, and the Jesuits established a biological journal honoring him, the "Wasman Journal of Biology." He died on February 27, 1931, in Valkenburg, Holland.

Wasps, Ants, Bees and Sawflies (Hymenoptera)

VIRENDRA K. GUPTA
University of Florida, Gainesville, FL, USA

The order Hymenoptera includes insects commonly known as ants, bees and wasps. Most authors believe that the name has been derived from the Greek *hymen*, meaning "membrane" and referring to the parchment-like transparent wings, without any scales or hair, and which often may be clouded. However, it also has been suggested that the name is derived from *hymeno* = god of marriage (referring to the union of fore and hind wings) + *ptera* = wings.

The Hymenoptera is one of the largest orders of insects. It is estimated that about 300,000 species occur in the world, of which not more than 30% have been described. Most hymenopterans are useful and beneficial to mankind. The honey bees give us honey. They, along with other bees, are important pollinators of flowering plants that include commercial crops, particularly the fruit trees. There has been a process of co-evolution between the flowers and the hymenopterans, resulting in better pollination and fertilization, and the development of colorful and intricate flowers. Many hymenopterans are predators of insect pests, and a group of hymenopterans, commonly referred to as "parasitic Hymenoptera" are utilized in biological control projects for the control of insect pests. This method is environmentally friendly and minimizes the use of insecticides. On the other hand, phytophagous hymenopterans, such as the sawflies, have resulted in the destruction of many coniferous forests in North America. Some wasps and ants are dreaded because of their venomous stings, which cause serious reactions in some people, even resulting in death.

The order Hymenoptera is also biologically rather important. Members of the order exhibit great diversity in their way of life and behavior, and include the highly evolved social insects. The social organization of bees and wasps has been a subject of many books and comparisons with the social life of mammals, including man, and represents a peak of evolutionary behavior.

The Hymenoptera alone exhibit the haploid-diploid mechanism of sex determination. The males are haploid, having an unpaired set of chromosomes. The females are diploid, possessing a set of paired chromosomes. The females have a normal gametogenesis so that the eggs are haploid, while in the males the first meiotic division generally is abortive so that haploid sperms are produced. Normally, the unfertilized eggs develop into males, while the fertilized eggs develop into females.

The social Hymenoptera exhibit polymorphism, and sexual dimorphism is evident. They also exhibit a "caste system" where the majority of the individuals are "workers" which are undeveloped females lacking the capacity to reproduce. They are responsible for all the chores of the colony, including food gathering, maintenance of the colony, defense, etc. The "queen" is the normal female which is capable of reproducing and, depending upon the type of social organization, one to many queens may be in one colony. The haploid male is only responsible for the fertilization of the queen, and may develop and be tolerated in the colony for this function alone. The social hymenopterans also have developed the capacity to store food for the progeny in the colony. This behavior of the bees has been exploited to harvest honey from the bee colonies.

The solitary bees also provision their nests with food for their progeny. The progressive evolution of social behavior in Hymenoptera, and the mechanisms of communication amongst the members of a colony, have been studied by many entomologists.

Morphological Characters

Members of the order Hymenoptera have mouthparts adapted for biting and chewing, biting and lapping, or biting and sucking. The antennae usually are long, with ten or more segments (some exceptions), and often geniculate. There are two pairs of membranous wings; the hind wings are smaller than the fore wing and both wings are interlocked by means of hooklets called hamuli. The bases of fore wings are covered by a crescent-shaped sclerite called the tegula. The fore wing usually has a sclerotized thickened area midway along its anterior margin, called the stigma. The wings may be reduced or absent. Apterous forms occur in several families. Ants exhibit dimorphism with winged forms occurring during the swarming phase of their life cycle. The wing venation is greatly modified as many veins take a transverse course. There is often a fusion of principal veins, and in higher forms the venation is reduced. The leg is five segmented. In several families (commonly grouped as "parasitica") the base of the femur is cut off, giving the impression that there are two trochanters. This structure is called trochantellus but in most taxonomic publications the trochanters are said to be 1 or 2-segmented. The tarsus is typically 5-segmented, but in some chalcid wasps the number may be reduced. The basitarsus is modified into a pollen basket in bees. The abdomen is basally constricted, and either broadly or narrowly attached to the thorax.

One characteristic feature of the hymenopterans is that the first abdominal segment is fused with the metathorax to form the propodeum. This is quite evident in higher Hymenoptera. There is a flexible joint between the first and the second apparent abdominal segments. In the Symphyta (sawflies, etc.) the abdomen is broadly attached to the propodeum, while in Apocrita (ants, bees, wasps, etc.) the abdomen is narrowly attached to the propodeum by a short or long petiole.

The females have an ovipositor which is built on a lepismatid form from the ancestral appendages of abdominal segments 8 and 9. It is modified in different groups for sawing, boring, piercing, stinging, or it may be reduced.

There are two main types of larvae. The Symphyta larvae are caterpillar-like, with three pairs of thoracic legs and at least five pairs of prolegs on the second to sixth abdominal segments; these prolegs are devoid of crochets (found in lepidopterous larvae). They are seen crawling and feeding on foliage. The Apocrita larvae are legless, grub-like, living in nests, or in or on the body of other insects and spiders. The metamorphosis is complete (holometabolous). Pupation occurs in cocoons.

Classification

The classification adopted in *Hymenoptera of the world: an identification guide to families*, edited by Goulet and Huber (1993) is given below. They group many aculeate superfamilies and recognize only three: Apoidea, Chrysidoidea and Vespoidea. Also, they do not recognize the two convenient but informal groupings Aculeata and Parasitica. A beginner and a general reader is perhaps better served by recognizing the traditional classification of Hymenoptera into many superfamilies. The classification given in Borror, Triplehorn and Johnson (1989) is still a good general summary of the classification of the Hymenoptera.

An Outline of the Classification of the Hymenoptera

Suborder SYMPHYTA (= CHALASTOGASTRA) – sawflies, horntails
- Superfamily: CEPHOIDEA
  - Family: Cephidae – stem sawflies
- Superfamily: MEGALODONTOIDEA
  - Family: Megalodontidae
  - Family: Pamphiliidae – leaf-rolling and web-spinning sawflies
- Superfamily: ORUSSOIDEA
  - Family: Orussidae – parasitic wood wasps
- Superfamily: SIRICOIDEA
  - Family: Siricidae – horntails (Fig. 3)
- Superfamily: TENTHREDINOIDEA
  - Family: Argidae
  - Family: Blasticotomidae
  - Family: Cimbicidae
  - Family: Diprionidae
  - Family: Pergidae
  - Family: Tenthredinidae – common sawflies
- Superfamily: XYELOIDEA
  - Family: Xyelidae
- Unplaced
  - Family: Anaxyelidae
  - Family: Xiphydriidae
- Suborder: APOCRITA

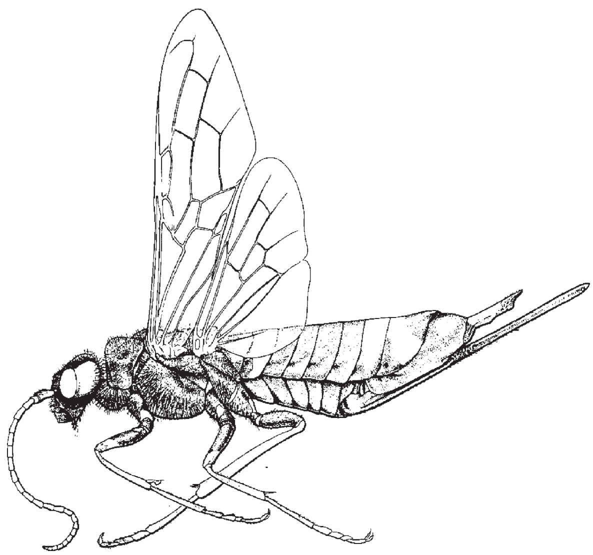
Group PARASITICA (not recognized in Goulet and Huber)
- Superfamily: CERAPHRONOIDEA
  - Family: Ceraphronidae
  - Family: Megaspilidae
- Superfamily: CHALCIDOIDEA
  - Family: Agaonidae
  - Family: Aphelinidae
  - Family: Chalcididae – chalcid wasps
  - Family: Elasmidae
  - Family: Encyrtidae
  - Family: Eucharitidae
  - Family: Eulophidae
  - Family: Eupelmidae
  - Family: Eurytomidae
  - Family: Leucospidae
  - Family: Mymaridae – fairy flies
  - Family: Ormyridae
  - Family: Perilampidae
  - Family: Pteromalidae
  - Family: Rotoitidae
  - Family: Signiphoridae
  - Family: Tanaostigmatidae
  - Family: Tetracampidae
  - Family: Torymidae
  - Family: Trichogrammatidae
- Superfamily: CYNIPOIDEA
  - Family: Charipidae
  - Family: Cynipidae – gall wasps
  - Family: Eucoilidae
  - Family: Figitidae
  - Family: Ibaliidae
  - Family: Liopteridae
- Superfamily EVANIOIDEA
  - Family: Aulacidae
  - Family: Evaniidae – ensign wasps
  - Family: Gasteruptiidae

Superfamily: ICHNEUMONOIDEA
Family: Braconidae – braconid wasps
Family: Ichneumonidae – ichneumon wasps
Superfamily: MEGALYROIDEA
Family: Megalyridae
Superfamily: MYMAROMMATOIDEA
Family: Mymarommatidae
Superfamily: PLATYGASTROIDEA
Family: Platygastridae
Family: Scelionidae
Superfamily: PROCTOTRUPOIDEA
Family: Austroniidae
Family: Diapriidae
Family: Heloridae
Family: Monomachidae
Family: Pelicinidae
Family: Peradeniidae
Family: Proctotrupidae
Family: Roproniidae
Family: Vanhorniidae
Superfamily: STEPHANOIDEA
Family: Stephanidae
Superfamily: TRIGONALYOIDEA
Family: Trigonalyidae
Suborder APOCRITA (= CLISTOGASTRA)
Group ACULEATA (not recognized in Goulet and Huber)
Superfamily APOIDEA – bees
Series: APIFORMES (formerly APOIDEA)
Family: Andrenidae – andrenid bees
Family: Anthophoridae – digger bees, cuckoo bees, carpenter bees
Family: Apidae – honey bees, bumble bees
Family: Colletidae – yellow faced bees; plaster bees
Family: Ctenoplectidae
Family: Fideliidae
Family: Halictidae – halictid bees
Family: Megachilidae – leaf-cutting bees
Family: Melittidae – melittid bees
Family: Oxaeidae
Family: Stenostritidae
Series SPECIFORMES (formerly SPHECOIDEA)
Family: Ampulicidae – ampulicid wasps
Family: Astatidae
Family: Crabronidae
Family: Heterogynaidae
Family: Mellinidae
Family: Nyssonidae
Family: Pemphredonidae
Family: Philanthidae
Family: Sphecidae – mud daubers, digger wasps
Superfamily CHRYSIDOIDEA (= Bethyloidea)
Family: Bethylidae – bethylid wasps
Family: Chrysididae – cuckoo wasps
Family: Dryinidae – dryinid wasps
Family: Embolemidae
Family: Plumaridae
Family: Sclerogibbidae
Family: Scolebythidae
Superfamily: VESPOIDEA
Family: Bradynobaenidae
Family: Formicidae – ants (formerly Formicoidea)
Family: Mutillidae – velvet ants, mutillids
Family: Pompilidae – spider wasps (formerly Pompiloidea)
Family: Rhopalosomatidae – rhopalosomatid wasps
Family: Sapygidae
Family: Scoliidae – scoliid wasps (formerly Scolioidea)
Family: Sierolomorphidae
Family: Tiphiidae – tiphiid wasps
Family: Vespidae – wasps, yellow jackets, hornets, etc.

Key to the Superfamilies

This is a simplified key to the superfamilies ignoring taxa showing exceptions to the general character states. Also, the traditional superfamilies are retained. It is based on the winged adults.

1. Abdomen joined broadly to the thorax (no waist or petiole). Hind wing with three or four closed cells (cells not open to wing margin). Fore wing with one or more distinct anal veins. Trochanters 2-segmented. Sawflies, horntails. SUBORDER SYMPHYTA.......2



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 3 **Drawing of horntail in the family Siricidae (Source: Hymenoptera of the world: an identification guide to the families. Agriculture and Agri-Food Canada, 1993. Reproduced with the permission of the minister of Public Works and Government Services, 2003).**

Abdomen joined narrowly to thorax (a narrow waist or petiole present, abdomen flexible). Hind wing with 0–2 cells at base. Fore wing without anal veins except rarely. SUBORDER APOCRITA 5

2. Fore tibia with two apical spurs. Ovipositor blade-like and usually short 3
   Fore tibia with one apical spur. Ovipositor usually long and thin 4
3. Hind tibia with one preapical spur or none. Pronotum in dorsal view with posterior margin strongly concave (narrowed medially behind) TENTHREDINOIDEA
   Hind tibia with 2–3 preapical spurs. Pronotum in dorsal view with posterior margin weakly concave (not strongly narrowed medially behind) MEGALODONTOIDEA
4. Last tergum of female and last sternum of male each with apical, median, cylindrical projection with concave tip. Pronotum somewhat rectangular with its hind margin concave. Costal cell present and distinct SIRICOIDEA
   Last tergum and last sternum of both sexes apically thin and without cylindrical projection. Pronotum somewhat triangular with its hind margin weakly concave. Costal cell absent or narrow CEPHOIDEA
5. Legs, at least the hind leg, with two trochanters (trochanter + trochantellus) 6
   Legs with one trochanter (Proctotrupoidea runs through either half of the couplet) 14
6. Antenna usually with more than 16 segments, not elbowed. Hind wing with usually two closed cells 7
   Antenna with 15 or fewer segments, often elbowed. Hind wing with one closed cell or none. [One family of Cynipoidea – Sclerogibbidae with 17–40 segments, then costal vein absent.] 9
7. Costal cell of fore wing absent; costal and subcostal veins touching each other ICHNEUMONOIDEA
   Costal cell present, may be narrowed in some rare families 8
8. Head with a crown of tubercles around median ocellus. Ovipositor long. Abdomen elongate. Costal cell narrow STEPHANOIDEA
   Head without tubercles. Costal cell broad. Ovipositor short. Stouter insects TRIGONALYOIDEA
9. Abdominal petiole with one or two scale-like or node-like projections. Females with a sting FORMICOIDEA
   Abdominal petiole without scales. Females with a sting or an ovipositor 10
10. Abdomen inserted high on propodeum much above the level of hind coxae EVANIOIDEA
    Abdomen attached normally, near hind coxae 11
11. Hind corner of pronotum not reaching tegula, separated from tegula by an extra sclerite, "prepectus." Middle tibia with one or zero spur. Antennae usually elbowed. Coloration often metallic greenish CHALCIDOIDEA
    Hind corner of pronotum reaching tegula, prepectus absent. Middle tibia often with two spurs. Antennae elbowed or not. Coloration never metallic greenish 12
12. Costal vein absent. Radial cell large and deep, surrounded by strong veins except often the

costal margin. Abdomen compressed laterally, often covered by a single large tergite CYNIPOIDEA

Costal vein present. Radial cell present or absent; if present, not as above 13

13. Fore tibia with one apical spur. Antennae inserted on face usually above clypeus. Abdomen rounded or margined laterally PROCTOTRUPOIDEA

Fore tibia with two apical spurs. Antennae inserted on face next to clypeus and abdomen rounded laterally CERAPHRONOIDEA

14. Hind wing with 1 closed cell or none.................15

Hind wing with two closed cells. Aculeata 17

15. Hind margin of hind wing nearly always with a sharp notch near base cutting off a basal lobe (anal lobe) CHRYSIDOIDEA

Hind margin of hind wing without a sharp notch, not cutting off an anal lobe 16

16. First hind tarsal segment 0.25 as long as second. Segments 2–4 of female abdomen separate, each very long. Male abdomen club-shaped PROCTOTRUPOIDEA: PELECINIDAE

First hind tarsal segment longer than second. Abdominal tergites 2–4 fused together PROCTOTRUPOIDEA

17. Hind corner of pronotum reaching tegula, the hind edge of pronotum without a semicircular projecting lobe just below the level of tegula 18

Hind corner of pronotum not reaching tegula, the hind edge of pronotum with a projecting lobe just below the base of tegula 23

18. Tergite 1 with one or two erect scales or nodes. Second recurrent vein absent. Hind wing without an anal lobe. ANTSFORMICOIDEA [Now included under VESPOIDEA]

Tergite 1 without scales or nodes. Second recurrent vein usually present. Hind wing usually with an anal lobe 19

19. First discoidal cell (1M or discal cell) of fore wing very long, much longer than submedian cell (1M + Cu1). Fore wing usually folded lengthwise. Wasps [except Masarinae] VESPOIDEA

First discoidal cell (1M) of fore wing shorter than submedian cell (1M + Cu1). Fore wing not folded lengthwise 20

20. Mesopleuron with a straight horizontal groove across its mid-height POMPILOIDEA [Now under VESPOIDEA]

Mesopleuron without a straight horizontal groove across its mid-height 21

21. Apex of antennal segments 3–8 or more with a pair of stout bristles on upper and inner sides. Tarsal segments 2–4 of female expanded VESPOIDEA: RHOPALOSOMATIDAE

Apex of antennal segments 3–8 without a pair of stout bristles. Tarsal segments 2–4 of female not expanded 22

22. Mesosternum and metasternum together forming a plate divided by a transverse suture, and overlapping bases of middle and hind coxae. Apical half of wing membrane with fine longitudinal wrinkles (imbrications) SCOLIOIDEA [Now under VESPOIDEA]

Mesosternum and metasternum not forming such a plate. Mesosternum with two lobe-like extensions projecting between and partly covering middle coxae. Hind wing with a jugal lobe, not imbricated VESPOIDEA: TIPHIIDAE

23. First segment of hind tarsus enlarged and more or less flattened. Head and body with branched or plumose hairs. Labium usually produced as a long tongue. Bees APOIDEA

First segment of hind tarsus not noticeably enlarged. Head and body with simple hairs (hairs unbranched or plumose). Labium usually not produced as a long tongue SPHECOIDEA

Suborder: Symphyta (Chalastogastra)

The abdomen is broadly attached to the thorax. There is no constriction between them. The first abdominal segment is only partly incorporated in the thorax. The venation is more complete with numerous cross-veins, forming many wing cells. The fore wing has at least one closed anal cell and most species have a closed anal cell in the hind wing. The metanotum has a pair of raised structures known as cenchri that engage with a scaly area on the underside of the fore wings and keep them in place. These are absent, however, in the superfamily Cephoidea. The ovipositor is adapted for sawing and boring. The syphytans are phytophagous except members of the family Orussidae. Members of this suborder commonly are called sawflies, horntails, etc.

Suborder: Apocrita (Clistogastra)

The abdomen is narrowly attached to the thorax by a short or a long petiole. The first abdominal segment (usually the tergite) is intimately fused with the metathorax to form the propodeum and the basal portion of the second morphological abdomen is constricted to form a short or a long petiole by which it joins the thorax (propodeum). The thorax thus has four segments and the first apparent abdominal segment is morphologically the second segment. Because of this confusion in counting the abdominal segments, many authors refer to the three hymenopteran body parts as prosoma (head), mesosoma (thorax) and metasoma or gaster (abdomen). The wing venation and wing cells are reduced. Sometimes there are no veins and cells.

Among the Apocrita two different groups may be distinguished. Because of exceptions, these groups, called Parasitica and Aculeata, have not been accorded formal status, but still they are useful groupings.

The Parasitica includes hymenopterans the larvae of which are parasitic in or on the immature states of other insects and arachnids and develop at the expense of their hosts. The adults are free living. These insects are referred to commonly as parasitoids. They have an ovipositor to lay eggs, usually have a trochanter and trochantellus (commonly referred to, though incorrectly, as having a 2-segmented trochanter), have long filiform antennae, and have reduced venation when compared to the Symphyta. They exert natural control of unwanted insects in forests and fields and often are used for the biological control of insect pests.

The Aculeata, on the other hand, usually are either social or solitary hymenopterans, construct hives or nests, provision their nests with food for the developing larvae, have a sting (modified ovipositor), and usually have a fixed number of antennal segments and lack a trochantellus. The venation is more complete when compared with the Parasitica. There are exceptions, however, as among the superfamily Chrysidoidea, some members are parasitoids but show characteristics of the aculeate hymenopterans. Aculeata includes ants, bees and wasps exhibiting social life, polymorphism, etc.

Treatment of Representative Superfamilies and Familiess

Suborder: Symphyta

Superfamily: Cephoidea

Family Cephidae – Stem Sawflies
The Cephidae is a small family occurring in the Holarctic Region, Old World tropics and Madagascar. The larvae are stem-borers and damage the growing tip of the stem. Several species attack cereal crops.

Superfamily: Megalodontoidea

Members of this superfamily are characterized by having a very large, almost prognathous head that is widest near the clypeus. Two families are recognized, the Megalodontidae and Pamphilidae. The Megalodontinae occurs in the temperate regions of Eurasia. Their antennae are either saw-like or comb-like, and tergites 2–5 are not folded above spiracles. The larvae feed on herbaceous plants. Members of the family Pamphilidae are characterized by having thread-like or filiform antennae and tergites 2–5 having a longitudinal fold above spiracles. They are Holarctic in distribution. The larvae roll leaves or spin silk to form webs in which they feed. The larvae are gregarious and attack conifers and fruit trees.

Superfamily: Orussoidea

Family Orussidae – Parasitic Wood Wasps

Members of this group are quite different from other sawflies. They are parasitic in habits. The adults are cylindrical in cross-section and have several spines around the median ocellus. The antennae are inserted below the ventral margin of the eye. The venation is reduced. The ovipositor is very long and thin, and coiled within the abdomen when the insect is resting. The Orussidae is a very small, relict, and widely distributed family. The members are seen with an ant-like gait over tree trunks. They are parasitoids of wood boring Coleoptera and Hymenoptera larvae.

Superfamily: Siricoidea

Family Siricidae – Horntails, Wood Wasps

This group contains large wood boring sawflies occurring in the Northern Hemisphere. They have been introduced accidentally into Australia and New Zealand and are serious pests of conifers. The tip of the abdomen is produced into a long horn-like projection, giving the name horntails to these insects. The adults are large (up to 50 mm long), brightly colored, and they also are referred to as wood wasps. The pronotum is transversely folded and is collar shaped. They have a strong, drill-like ovipositor by which they drill holes in hard wood or conifer trees and insert their eggs into dead or decaying trees. They also deposit spores of a symbiotic fungus along with the eggs (Figs. 3).

Superfamily: Tenthredinoidea

Members of the superfamily Tenthredinoidea are distinguished from other Symphyta by having a short pronotum that is concave posteriorly, the fore tibia having two apical spurs, and hind tibia with one preapical spur. The antennae are thread-like, usually with nine segments (varying from 9 to 15 in some cases). The scutellum has a transverse furrow cutting off triangular post-tergite posteriorly. The ovipositor generally hardly projecting beyond the apex of abdomen. This is the largest superfamily of Symphyta, and they are distributed worldwide.

Family: Tenthredinidae

Common sawflies. The adults are brightly colored, wasp-like insects, common during spring and early summer but some species occur also during late summer and early fall. The larvae feed gregariously on foliage orienting themselves in a characteristic manner. Some species are serious pests of coniferous trees and cause heavy defoliation of forests. A few species are gall makers and leaf miners. Many species exhibit sexual dimorphism.

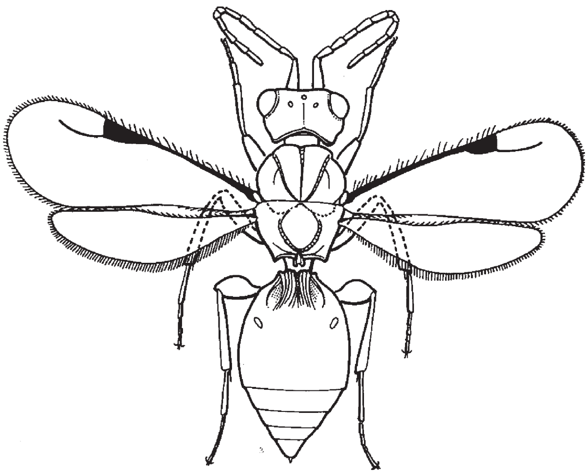
Suborder: Apocrita

Group: Parasitica

Superfamily: Chalcidoidea

The superfamily Chalcidoidea is probably the largest in the order, with about 2,500 known genera and 20,000 known species. It also contains the smallest known insects. The majority of the species are parasitoids or hyperparasitoids of other insects and of great significance in biological control. Non-parasitic, plant feeding chalcidoids are found in the families Agaonidae, Torymidae, Perilampidae and Eurytomidae. Some infest seeds and some produce galls. In the families Chalcididae and Leucospidae the hind femora are enlarged. In Mymaridae the wings have elongate fringe of hairs and these insects often are called "fairy flies."

The Chalcidoidea may be recognized by having an elongate antennal scape, so that the antennae appear elbowed. The flagellum usually is differentiated into a proximal funicle and an apical club. The pronotum does not extend back to the tegula and a triangular sclerite, prepectus, is present between the hind margin of pronotum and the tegula. The wing venation is highly reduced so that generally only one vein is present in the fore wing (Figs. 4–8).



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 4 Drawing of wasp in the family Megaspilidae (Source: Hymenoptera of the world: an identification guide to the families. Agriculture and Agri-Food Canada, 1993. Reproduced with the permission of the minister of Public Works and Government Services, 2003).

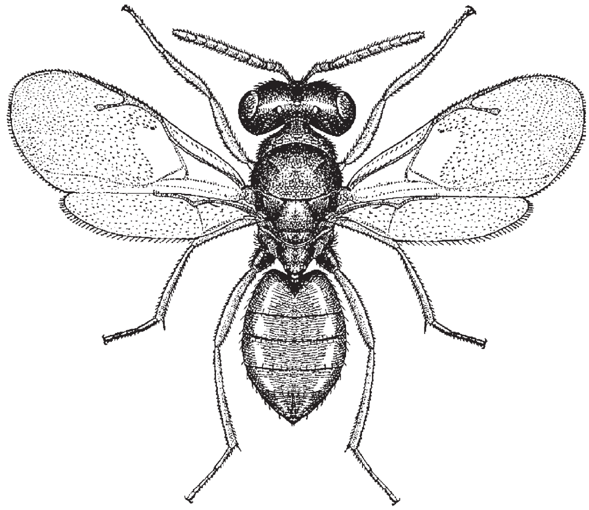
Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 5 Drawing of wasp in the family Eulophidae (U.S. Department of Agriculture).



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 7 Drawing of wasp in the family Pteromalidae (U.S. Department of Agriculture).

Superfamily: Cynipoidea

The cynipoids are generally small insects (except *Ibalia*), brown or black in color. The antennae are filiform, the pronotum extends back to the tegula, wing venation is reduced, with the radial cell triangular and pterostigma absent except in some rare families. The abdomen in laterally compressed (Fig. 6).

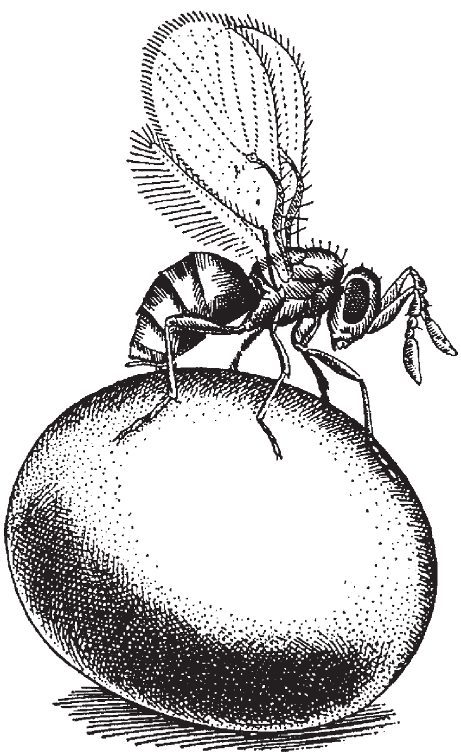
The majority of cynipoids are primary endoparasitoids developing in the larvae of holometabolous insects, or in the nymphs of Psylloidea. Most species of the family Cynipidae are gall producers and are called gall wasps. These galls commonly are seen on oak and other trees. In the family Ibalidae, the radial cell is very long and thin and the abdomen is strongly compressed and knife-like. Species of *Ibalia* may be up to 30 mm long (Fig. 7).

Superfamily: Evanioidea

In Evanioidea the abdomen is attached to the thorax high above the hind coxae, antennae are with 13–14 segments, fore wing is with a costal cell and the wing venation is fairly complete. Members of the family Evaniidae are called ensign wasps. These are black or black and red insects with the abdomen small and oval, carried like a flag high above the hind coxae. They are parasitoids of cockroach oothecae. Members of the family Aulacidae have a long, well exserted ovipositor and are endoparasitoids of wood boring coleopterous and hymenopterous larvae. In Gasteruptiidae the hind tibia is clavate, abdomen long, clavate, and ovipositor well exserted. They are ectoparasitoids of larvae of Sphecidae, Vespidae and Apidae.

Superfamily: Ichneumonoidea

This superfamily includes two families, the Ichneumonidae and Braconidae. These are small to very large insects, mostly usually fully winged, with antennae more than 13 segments, not geniculate or apically clavate. The pronotum extends back to the tegula. Wing venation is well developed and characteristic (Fig. 9).



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 8 **Drawing of wasp in the family Trichogrammatidae (U.S. Department of Agriculture).**

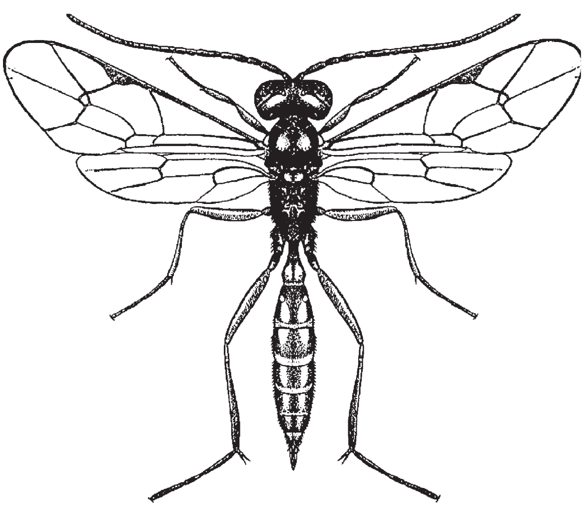
Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 9 **Drawing of wasp in the family Ichneumonidae (Source: Hymenoptera of the world: an identification guide to the families. Agriculture and Agri-Food Canada, 1993. Reproduced with the permission of the minister of Public Works and Government Services, 2003).**

The Ichneumonidae is perhaps the largest family of insects, with over 60,000 known species. Most species are ecto- or endoparasitoids of the larvae and pupae of holometabolous insects, particularly of Lepidoptera and Symphyta. Some others parasitize spider egg masses or attack bee larvae in hives. They are distinguished from the family Braconidae by the presence of second recurrent vein (2m-cu) and by the absence of the cubitus vein (1/Rs + M) in the fore wing. Abdominal tergites 2 and 3 are not fused. It includes Agriotypidae and Paxylommatidae, often considered as separate families (Fig. 10).

The family Braconidae appears to be the second largest family of insects with over 40,000 known species. It differs from the Ichneumonidae in the absence of the second recurrent vein (2m-cu) (except in Apozyginae), and by the presence of the cubitus vein (1/Rs + M) in the fore wing. Tergites 2 and 3 are fused (weakly so in Aphidiinae). It includes Aphidiidae, which are aphid parasitoids.

Superfamily: Proctotrupoidea

Members of this superfamily are parasitoids in the immature stages of other insects. They are small-sized insects with much reduced venation, but may be distinguished from the chalcids by the nature of the thorax and the abdomen. The pronotum in proctotrupids appears triangular in shape in lateral view and extends back to the tegula. The ovipositor issues from the tip of the abdomen.



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 10 Drawing of wasp in the family Ichneumonidae (U.S. Department of Agriculture).

One member of the family Pelicinidae, the North American *Pelicinus polytrurator* (Drury) is a large (the female about 50–60 mm long), shiny black insect. The abdomen is very long and thin. The males are rare and only about 25 mm long, with the tip of abdomen swollen. They are parasitic in the larvae of June beetles, and the adults emerge in summer. Members of the family Proctotrupidae are small, about 3–10 mm long insects, with a large pterostigma and a very narrow marginal cell. They are solitary or gregarious parasites in the larvae of Coleoptera and Diptera.

Superfamily: Platygasteroidea

These are small to minute, usually black and shiny insects, and usually are classified under Proctotrupoidea. Two families, Diapridae and Platygasteridae, are placed under it. Species of Diapridae have a shelf-like protuberance on the face. They are parasitoids of the immature stages of Diptera. Members of the Scelionidae attack eggs of spiders and several groups of insects. They have highly reduced wing venation and a flattened abdomen.

Superfamily: Stephanoidea

Only one family, Stephanidae, is included here, which was classified earlier under Ichneumonoidea. The head is spherical and with a crown of about five teeth around the median ocellus. There is a slender long neck. The hind coxae are elongate and the hind femora are swollen and toothed ventrally. They are common in tropics and are parasitoids of wood boring coleopterous larvae.

Suborder: Apocrita

Group: Aculeata

Superfamily: Apoidea

The superfamily Apoidea includes insects commonly referred to as the bees. They exhibit sexual dimorphism in the number of antennal segments – 13 in male and 12 in female. Tergite VII of the female is deeply cleft medially or separated into two lateral lobes. The female gonocoxite IX is constricted but not divided into articulating proximal and distal plates. The pronotum is not extending back to tegula, usually forming a lobe covering the mesothoracic spiracle. The body hairs are branched, plumose, and the hind tarsi are usually widened. They are anthophilous, solitary or social insects (Fig. 11). Two main groups of bees are recognized: the long tongued bees and the short tongued bees.

Family: Apidae

Long tongued bees: the honey bees and the bumble bees. The first two segments of the labial palp are elongate and flattened, glossa is long and slender, and the maxillary palp is vestigial. In addition, the hind leg is modified to have a "pollen basket" composed of the enlarged tibia and the first tarsal segment, and the hind tibia has an apical margin of short, stiff setae. The jugal lobe in hind wing is shorter, and there are three submarginal cells.

The bees are important pollinators of fruit and other important crops. Their role as pollinators far exceeds their importance as providers of honey and bees wax. There are three main subfamilies. The subfamily Apinae includes the honey bees. Three species are known in the world: *Apis mellifera*, the European honey bee, widely domesticated worldwide; *A. dorsata*, the wild honey bee that is ferocious and makes a single large hive high on trees, buildings, etc., in the tropics; and a gentle, timid honey bee, *Apis florea* that makes a single hive in bushes in the tropics. The subfamily Bombinae includes the bumble bees. They are large, robust, black with yellow hairs on thorax and abdomen. They nest in hollows in the ground, have annual colonies and are important pollinators of certain kinds of clover. Members of the subfamily Euglossinae are called "orchid bees." They are brightly colored metallic bees distributed in the tropical parts of the world.

Family: Anthophoridae

These insects are also long-tongued bees that are robust and hairy, about 10–20 mm long, and usually brownish in color. The hind tibiae have

Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 11 **Photographs of some Apidae: left, bumblebee, *Bombus* sp.; right, honeybee, *Apis* sp. (photos: JL Castner).**

apical spurs, genae are short and narrow, and the maxillary palps are well developed. They nest in the ground.

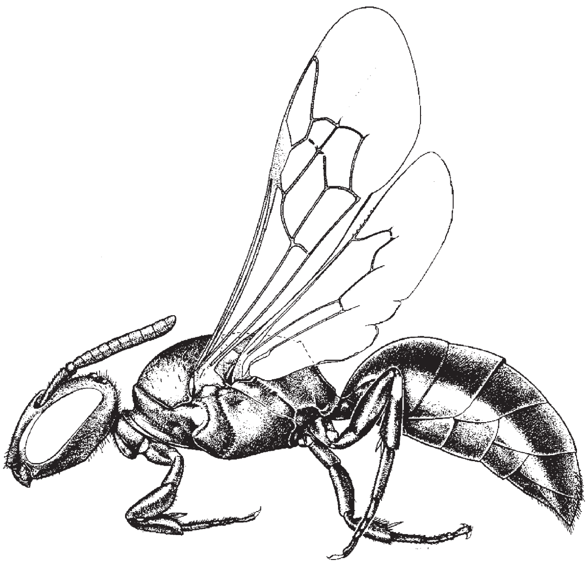
The family Anthophoridae is divided into several subfamilies. Members of the subfamily Nomadinae are called "cuckoo bees." They are parasitic in the nests of other bees, are wasp-like in appearance, and have fewer hairs on the body. Members of the common genus, *Nomada*, are reddish in color and are small to medium in size. The subfamily Anthophorinae contain bees known as "digger bees." They are robust and hairy. Most of them are solitary but some species nests in burrows in the ground, and the cells are lined with a thin wax-like substance. The subfamily Xylocopinae includes "carpenter bees." These bees nest in wood or stems of plants. The common genera are *Xylocopa* and *Ceratina*. *Xylocopa* species are large, black, shiny, resembling the bumble bees but without tufts of hair on the abdomen. The *Ceratina* species are small, about 6mm long, dark bluish-green in color.

Family: Megachilidae

These commonly are called the "leaf cutting bees." They are medium-sized, moderately robust bees, differing from other bees in having two submarginal cells in the fore wing that are about equal in size. The pollen carrying species have a tuft of hairs on the ventral side of the abdomen and not on the legs. They usually make nests in natural cavities in wood or ground and line their cells with neatly cut pieces of leaves. Most species are solitary. A few species are parasitic.

Family: Colletidae

They are "short-tongued bees." Segments 1 and 2 of the labial palp are short and not flat, similar to segments 3 and 4, the mesopleurum usually is without epistomal groove, and the volsella of the male genitalia is usually well developed. This family includes the yellow-faced bees (Hylaeinae) and the plaster bees (Colletinae). The glossa is bilobed or truncate. They nest in the ground or in various natural cavities (Fig. 12).



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 12 Drawing of bee in the family Colletidae (Source: Hymenoptera of the world: an identification guide to the families. Agriculture and Agri-Food Canada, 1993. Reproduced with the permission of the minister of Public Works and Government Services, 2003).

Family: Andrenidae

These are also short-tongued bees. The glossa is pointed and there are two subantennal sutures below each antennal socket. They also nest in burrows in the ground, often in colonies and usually in areas with sparse vegetation.

Family: Halictidae

Members of this family resemble other short-tongued bees but have only one subantennal suture below each antennal socket. The basal vein is rather strongly arched. They also nest in the ground and some species, the "sweat bees," are attracted to perspiration.

Superfamily Sphecoidea – Sphecoid Wasps

Members of this superfamily resemble Apoidea in having sexual dimorphism in the number of antennal segments and in the nature of the genitalia. However, they have simple body hairs that are not branched, the pronotum is short and collar-like, and hind tarsi are not widened. They are solitary in habits, mostly fossorial, but some construct mud nests. They are predacious and provision their nests with lepidopterous larvae, Hemiptera, Orthoptera, Arachnida, etc. The prey is stung and the eggs laid upon them in the cell. The adults visit flowers. They commonly are known as digger wasps and mud daubers. The classification of the superfamily differs considerably: some classify it into several families, while others accord subfamily status to most families.

Family: Sphecidae

Mud daubers; digger wasps. The posterior margin of the pronotum, in dorsal view, is straight. It appears like a collar. The hind margin of pronotum, in lateral view, ends in a rounded lobe that does not reach the tegula. The episternal sulcus on the mesopleurum is more vertical than horizontal. The inner margin of the eyes is not notched in most species.

Members of the Sphecidae are solitary wasps, although some species tend to nest in a small area. A small number of species in the tropics show a eusocial behavior. Most species nest in hollows in the ground and in plant stems, wood cavities, etc. Some construct mud nests. The females hunt for other insects and spiders that serve as food for the developing larvae. The prey is stung and paralyzed before placing it in the nest, and the eggs are laid upon them. The subfamily Sphecinae includes genera like *Sceliphron* and *Chalybion* that commonly are called mud daubers. They construct nests of mud and provide them with spiders. They have a very long and slender petiole. Another common species is *Sphex ichneumoneus* (L.), which is reddish brown in color with the abdominal tip black. *Trypoxylon* belongs to the subfamily Larrinae, and commonly is referred to as organ-pipe mud daubers because they construct long tubes, attaining the length of 25 mm or more. The Crabroninae contains small to medium sized species that have black and yellow markings.

Members of the family Nyssonidae includes the cicada killer, *Sphecius speciosus* (Drury). It is a large wasp, about 40 mm long, black or rusty brown with yellow abdominal bands. It provisions the nest with cicadas.

Superfamily: Chrysidoidea

In the superfamily Chrysidoidea, the number of antennal segments is the same in the male and the female, usually 10 or 11 (more than 19 in Sclerogibbidae); tergite VII of female is complete, not cleft medially; female gonocoxite IX consists of proximal and distal portions which articulate at their point of contact; the hind wing has an anal lobe, or if the anal lobe is unclear, then the body is metallic; the hind wing is usually without closed cells; the pronotum extends back to tegula except in some Chrysididae, and the hind femur is without a trochantellus. Some species are metallic in coloration. The cuckoo wasps (Chrysididae) are external parasitoids of full grown wasp or bee larvae. Others are parasitoids of larvae of Lepidoptera and Coleoptera (Bethylidae), or parasitoids of auchenorrhynchous Hemiptera (Dryinidae).

Family: Chrysididae

The insects belonging to the family Chrysididae commonly are called the cuckoo wasps. They are small, about 8–12 mm in length, metallic blue or green in color, and the body bears coarse punctures. The adults fly in bright sunlight, visiting flowers in search for nectar. They females are seen flying in search of holes and crevices in search of their hymenopterous host eggs and larvae (usually aculeate Hymenoptera) upon which they lay their eggs. Upon hatching, the chrysidid larva feeds on the host eggs or the larvae, as well as the stored food for the host's offspring. This phenomenon is called cleptoparasitism.

Family: Bethylidae

Members of the family Bethylidae are small to medium sized, usually black in color. The females of many species are apterous and ant-like but in other species both males and females are fully winged. These wasps are parasitoids of the larvae of Lepidoptera and Coleoptera.

Family: Dryinidae

The dryinids usually have 10-segmented antennae and large heads, and broad toothed mandibles. They are parasitoids of auchenorrynchous Hemiptera. They exhibit sexual dimorphism: the males are always winged but the females may be winged to apterous. The fore tarsi of females are developed into pincer-like chelae used to grasp and hold the planthoppers as hosts. Their life history is complex and interesting.

Superfamily: Vespoidea – Wasps and Ants

The antennae bear 12 segments in the female and 13 in the male. The pronotum extends back to the tegula, its posterodorsal margin shallowly to rather deeply concave, without any lobe covering the spiracle. The metapostnotum is short and transverse, fused with the propodeum. The legs are without trochantellus (second trochanter). The fore wing has 9–10 closed cells. The hind wing has two closed cells (sometimes fewer), and has a jugal (anal) lobe. Sternites 1 and 2 are separated by a constriction. The ovipositor is modified into a short sting, issuing from the tip of the abdomen and concealed at rest. The body is devoid of plumose hairs.

The current view is that the Vespoidea includes the ants, mutillids, vespids, pompilids, scoliids and the tiphiids, all which were earlier assigned their own superfamilies. The important families are treated below.

Family: Vespidae

Yellow jackets, hornets, paper wasps, potter wasps. The fore wing has a long discal (1M) cell, much longer than the submedian (1M + Cu) cell, usually about half as long as wing, and with three submarginal cells. Wings usually folded lengthwise at rest. Posterior margin of pronotum U-shaped.

This is a relatively large group including the well-known wasps. Most species are black and yellow colored. Some species are eusocial, living in colonies. The females and the workers have a well developed sting. The social species construct a nest made out of papery material consisting of chewed up wood and plant material. Some make nests of mud (Fig. 14).

The subfamily Vespinae includes the social wasps known as the yellow jackets and hornets belonging to the genera *Vespa*, *Vespula* and *Dolichovespula*. They construct papery nests consisting of many tiers of hexagonal cells, all enclosed in a paper envelope. These can become very large. They may be constructed in open branches, hollows in the ground or tree trunks, or at any other hollow space or projecting surface around houses. The subfamily Eumeninae includes solitary wasps that construct mud nests resembling pots (potter wasps, mason wasps), commonly seen attached to houses. Most species have an elongate petiole. The subfamily Polistinae are called the paper wasps. The nests consist of a single, horizontal comb of paper cells, hanging by a slender stalk. The common genus is *Polistes*.

Family: Formicidae

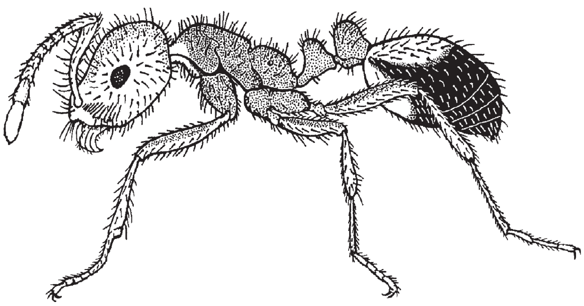
Ants. One of the most distinctive features of ants is the presence of one or two node-like protuberances on the petiole. The antennae usually are elbowed, with a long first segment, and the males may have filiform antennae. The ants are eusocial insects, living in colonies, where there are three distinctive castes: the queen, males and the workers. Winged forms, consisting of males and females, develop during the swarming season and after mating the females start a colony. The female sheds the wings, locates a nesting site, makes an excavation, and produces her first brood, which consists of workers. The workers are sterile females (Fig. 13).

Fire ants are notorious for their burning sting. Two species, *Solenopsis invicta* Buren and *S. richerti* Forel, are common in the southeastern United

States. These ants are rather aggressive and are quick to attack people and animals when disturbed. In some persons they may cause serious allergic reactions and may even lead to the death of the individual.

Family: Pompilidae

Spider wasps. The pompilids are slender wasps with spiny legs. They have a transverse suture across the mesopleurum. They prey on spiders, sting to paralyze them, and store them in their under-ground cells as food for the developing larvae.



Wasps, Ants, Bees and Sawflies (Hymenoptera), Figure 13 Drawing of an ant (family Formicidae) (U.S. Department of Agriculture).

Family: Mutillidae

Velvet ants. The females are wingless, ant-like, and are covered with dense hairs. The males are winged, usually larger than the females, and also have dense hairs. A usual distinguishing feature is a structure called the "felt-like" along the side of the second abdominal segment. Most mutillids are external parasitoids of the larvae and pupae of wasps and bees.

Water Balance

SUE W. NICOLSON
University of Pretoria, Pretoria, South Africa

The small size of insects carries a risk of dehydration in terrestrial environments due to the limited storage capacity for water in an insect's body and the relatively large surface area for losing it. However, small size also permits escape to microclimates in which the temperature and relative humidity are more favorable. The overall flux of water through insects (and other animals) is partitioned into different avenues of water loss and gain. These are discussed below, with examples which demonstrate that they vary greatly in both absolute and relative terms. The water conservation abilities of insects in arid environments have been well studied, and many show extremely low water turnover, but liquid diets and flight in large insects can lead to high water turnover.

Water Loss

Cuticle

The wax layer in the thin outer epicuticle of insects has been critically important in their colonization of dry terrestrial environments. Insect physiologists have long known that there is a correlation between cuticular water loss and aridity of the habitat, and between cuticular water loss and the quantity of lipids in the epicuticle. The lipids responsible for waterproofing are a diverse collection of non-polar, hydrophobic molecules, dominated by long-chain saturated hydrocarbons. Their composition has been found to vary between individuals, populations and species, and as a result of thermal acclimation. Melting points of the cuticle lipids also increase during acclimation to high temperatures, and this lowers the permeability. Cuticle lipids are seen to an extreme in some insects with "wax blooms."

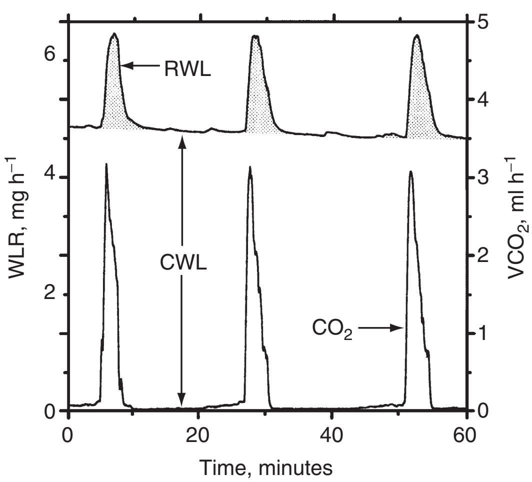
Respiration

Evaporation from insects also occurs via respiration. For some species, researchers can take advantage of the fact that periods of spiracle closure during discontinuous gas exchange allow cuticular water loss to be subtracted from total evaporative losses (Table 1). Because of spiracular control, which occurs to some degree in all insects, respiratory losses in resting insects are typically only 5–10% of total water loss. However, reduction of cuticular permeability in arid-adapted insects means that respiratory water loss assumes greater relative importance. Discontinuous gas exchange, although not universal in insects, has attracted much interest and was originally thought to function in water conservation in diapausing pupae and adult insects; however, its significance is still being debated (Fig. 15).

Respiratory water loss increases in active insects and especially during flight, when the volume of air ventilated through the tracheal system rises dramatically. Fortunately, the increased respiratory water loss is balanced to a greater or lesser extent by increased gains from metabolic water. For example, by flying at the appropriate altitude, migrating desert locusts are able to balance respiratory losses and metabolic water production during hours of sustained flight. For many insects, periods of flight are brief compared to periods of inactivity and the extra water loss due to flight will be minimal.

Water Balance, Table 1 The effects of temperature on water loss (mg per h) from the cuticle and respiratory system of the grasshoppers *Romalea guttata (microptera)* and *Taeniopoda eques* (adapted from Quinlan and Hadley. 1993. Physiol Zool 66:628–642). Note how increased temperature enhances water loss, that cuticular water loss is the principal source of water loss, and that water loss rates are significantly different even between related species. *Romalea guttata* inhabits moist climates and *T. eques* arid environments, so rates are consistent with need to maintain water balance in their normal habitat

Species and temperature (°C)	Cuticular loss	Respiratory loss	Total loss
Romalea			
15	4.62	0.11	4.72
25	8.62	0.27	8.89
30	13.28	0.52	13.80
Taeniopoda			
15	2.88	0.09	2.96
25	5.00	0.25	5.25
30	5.89	0.33	6.22



Water Balance, Figure 15 The pattern of carbon dioxide (CO_2) release (large spikes, lower portion of graph) characteristic of insects displaying intermittent or "discontinuous" ventilation, with a superimposed pattern of water loss (*smaller spikes, upper portion of graph*). The stippled areas represent respiratory water loss (RWL), which occurs when the spiracles are opened. The balance of the water loss is presumed to be cuticular water loss, and is the predominant form of loss in the grasshopper *Taeniopoda*, and most other insects (adapted from Quinlan and Hadley, 1993. Physiol Zool 66:628–642).

Excretion

The two-part excretory system of insects, consisting of Malpighian tubules and hindgut, plays a major role in water balance. The tubules secrete a fluid that is isosmotic to the hemolymph, but its volume and composition are modified during passage through the hindgut according to the water requirements of the insect. The functioning of both Malpighian tubules and hindgut is controlled by peptide hormones, but this is much better understood in Malpighian tubules. Hormonal stimulation of fluid secretion was first discovered in the blood-sucking bug *Rhodnius prolixus*, which jettisons excess water and salts in a rapid diuresis following a large blood meal. We now know that diuretic hormones are present in all insects, even when their function is not so clear, as in desert beetles. Currently the Malpighian tubules of *Drosophila melanogaster* are serving as a model system for researchers who can use the combination of physiology and genetics.

Fluid secreted by the Malpighian tubules passes into the hindgut; first through the ileum, where bulk reabsorption can occur, and then through the rectum, which is specialized for water recovery and is also responsible for ionic regulation. In most insects, rectal pads or papillae are involved in water reabsorption. Another structure with a similar function is the rectal complex, found in many Coleoptera, which produce very dry feces, and in larval Lepidoptera, where water recycling is less obvious, although the fecal water loss of caterpillars is closely regulated.

Water Gain

Food

There is huge variation in the water content of insect diets, from 2% in dry seeds to 99.9% in xylem sap. The water content of leaves varies from 50 to 90%, and phytophagous insects adjust their consumption to maintain a constant intake of dry matter. In caterpillars, preformed water in the food and fecal water loss are the two main components of the water budget – water fluxes through the gut of caterpillars are enormous – and evaporation and metabolism are therefore relatively insignificant.

Drinking

This aspect of water balance physiology has received little attention, but a surprising number of insects have been recorded drinking free water, at least under laboratory conditions. The control of drinking has been investigated in locusts and flies.

Metabolism

Metabolic water production occurs in all insects, but its importance varies with life stage and lifestyle. While the larval and adult stages of holometabolous insects usually have access to free water and preformed water in food, metabolic water is the only source of water for eggs and pupae. A beetle living in stored grain consumes dry food and has no access to free water, so metabolism becomes an important avenue of water gain. Large flying bees produce water by metabolism faster than they can lose it by evaporation, and must excrete the excess in order to avoid serious water loading.

Vapor Absorption

The ability to extract water vapor from unsaturated air is unique to certain arthropods. Different mechanisms show that this ability has evolved independently in different taxa. The rectal complex of tenebrionid beetles functions to dry the feces efficiently and its use in water vapor uptake is probably secondary. In ticks, the route of uptake is oral and involves salivary secretions. While the ability to absorb atmospheric water vapor was once thought to be confined to insects in arid conditions, soil collembolans have recently been shown to do it by accumulating organic solutes to high concentrations in their hemolymph.

Desiccation Resistance

The standard method of measuring desiccation resistance in the laboratory is to record the change in body mass of insects maintained in dry air. In addition to water loss, mass loss includes dry matter metabolized as CO_2, but in these conditions the insects are inactive and respiratory water loss is assumed to be negligible. Many studies have demonstrated higher desiccation resistance in species from arid environments. Coping with prolonged dehydration is a problem for diapausing or overwintering insects, and some show remarkable resistance to desiccation.

Behavioral Avoidance of Desiccation

Microclimates in soil and vegetation are especially important to insects with low desiccation resistance, as well as conferring thermal benefits. In general, the use of microclimates helps to reduce the costs of water regulation. Many insect herbivores living permanently on their food plants benefit from the microclimate around leaves: transpiration means that the lower leaf surface in particular develops a boundary layer of cool, humid air. Gall-forming and leaf-mining insects go further and create microenvironments within plant tissues. Aggregations of conspecific insects create their own microclimates, with evaporative and excretory water losses increasing the surrounding vapor pressure. Advantages for water balance are seen in the lower and more stable hemolymph osmolalities of group-living caterpillars, compared to isolated individuals. The benefits of manufacturing a microclimate and living in groups are taken to an extreme in social insects, whose complex nest design leads to precise control of both temperature and humidity.

Mechanisms of Desiccation Resistance in Fruit Flies

At the organismal level, desiccation resistance in insects depends on three traits: increased body water content, reduced rates of water loss, or tolerance of greater water loss. Variation in these traits has been studied in some detail in laboratory populations of *Drosophila melanogaster*, in which desiccation is a powerful selective force. Desiccation-resistant populations of flies are larger than control flies and contain more water (largely stored in the hemolymph). They lose water more slowly, mainly because of reduced respiratory losses (but not cuticular or excretory). However, the desiccation-resistant flies do not show increased tolerance of water loss. This laboratory selection has been compared with natural selection in cactus-dwelling desert *Drosophila* species, and there are some differences. In particular, wild flies do not store additional water, probably because the extra weight would hinder flight.

Water Penny Beetles (Coleoptera: Psephenidae)

HARLEY P. BROWN
University of Oklahoma, Norman, OK, USA

Anyone who picks up rocks out of streams or from lakeshores is probably familiar with water pennies, the tiny beetles that are found on the undersides of rocks in the water. The common water penny, larva of *Psephenus*, may be difficult to see because it resembles the surface of a rock and can cling tightly to the substrate. During daylight hours, water pennies are normally on the underside of stones, but at night they creep to the upper surface to dine upon the algae that thrive there in the sunlight. Over-wintering occurs during the larval stage. When mature, the larva crawls out of the water and settles upon a protected solid substrate such as the side or the underside of a rock near the water. Here, the larva becomes attached to the substrate all around the ciliated perimeter. The pupa then develops beneath the protective carapace of the larval skin. After 10–12 days, the adult water penny beetle emerges from the pupal skin. A median dorsal longitudinal crack in the tent-like larval carapace enables the adult to escape. Weather permitting, it flies to a rock projecting above the surface of the stream in a nearby riffle. If it is male, it joins the other male water pennies hurrying around in search of females. The females do not seek mates. They wait for the eager males to find them. After mating, the female water penny crawls down into the water and spends the rest of its life (a few days at most) seeking suitable oviposition sites and laying eggs on the underside of rocks in the riffles. The eggs, usually yellow, form a layer one egg deep. Clusters on small rocks may contain only a few dozen eggs, but clusters on large rocks usually contain hundreds of eggs, and may be deposited by several females.

After 10–15 days, tiny, almost invisible water pennies hatch. As they grow larger, they must shed their outgrown skins about six times before they leave the water to pupate. Their entire life span is about 21–24 months in Ohio and Michigan, but probably less in warmer regions. All significant feeding is done during the larval stage. Only one species of *Psephenus*, *P. herricki*, occurs in eastern and Midwestern United States and Canada, but several other species occur in western states, Mexico, and some Central and South American countries. In Neotropical regions and Asia, there are also other genera of Psephenidae with larvae like those of *Psephenus*.

The larvae of members of the subfamily Eubrianacinae are enough like those of *Psephenus* to share the common name, "water pennies." In both subfamilies, the larvae have paired, feather-like, tracheal gills on the ventral surfaces of four or more abdominal segments. *Eubrianax* occurs in all zoogeographic realms but Australia. Members of the subfamily *Eubriinae* (or to many coleopterists, the separate Family Eubriidae) are called "false water pennies." Larvae of some Eubriine genera (e.g., *Dicranopselaphus*) look so different that no one would be likely to call them "water pennies" of any sort, and they are too uncommon to be given a common name. Seen from above, the larvae of *Afroeubria* (residents of Africa) greatly resemble the larvae of *Psephenus*, but the underside of all Eubriine larvae gives them away. Instead of paired feathery gills on several abdomimal segments, as in *Psephenus* and *Eubrianax* larvae, Eubriines have a single, retractable, tripartite gill located medially on the underside of the last (ninth) abdominal segment (Figs. 16–18). Adult Eubriines are less conspicuously associated with water than are adult Psephenines.

None of the water penny beetles are of known economic importance to man, but they are of interest to most people who are familiar with them.

Water Pollution and Insects

Vincent H. Resh[1], David M. Rosenberg[2]
[1]University of California, Berkeley, CA, USA
[2]Freshwater Institute, Winnipeg, MB, Canada

The impact of human activities on water resources became clear with the advent of the Industrial Revolution. Prior to this, it was mainly a localized phenomenon. For example, in the eighteenth century, the River Thames, which flows through London, England, produced such a terrible stench from raw sewage that sheets soaked in vinegar were hung in the Parliament to offset the nauseating smell. However, the English government only started to control the sewage pollution that produced these odors in the face of typhoid fever and cholera epidemics. The protection of human health and the management of ecosystems to provide essential ecological services (e.g., drinking water, waste elimination, forestry products) remain the current basis of pollution control regulation and technology in the developed world.

Pollution has been defined in various ways, but essentially it is the wrong substance in the wrong concentration, at the wrong place, at the wrong time. Water pollution can have many sources, but the most common inputs are human sewage and outputs from industrial and agricultural practices. Typically, pollution is defined as the result of anthropogenic (or human-induced) activities.

Pollution can cause changes in the structure (e.g., biodiversity) and function (e.g., primary and secondary productivity) of ecosystems. Insects are one of the major, if not the major group of organisms, that has been studied in terms of pollution. Because they are at or near the bottom of food webs, changes in insect populations will affect the remainder of the food web. In addition, insects can mark the entry point of noxious chemicals into the food web, and the economic consequences can be profound. For example, the destruction or diminishment of insect populations in fresh waters will affect the vertebrate predators such as fish and waterfowl that feed on them.

The effects of pollution on insects have to be studied at a variety of spatial and temporal scales. Effects can occur at the molecular level in fractions of seconds (biochemical effects), at the ecosystem level over several decades, and at various scales in between these extremes.

Because some insect species are sensitive to various forms of pollution while others are tolerant of these pollutants, the responses of insects have been used to detect, measure, and judge environmental disturbance. Insects are useful in biomonitoring because they are ubiquitous and have many pertinent, readily measurable biological characteristics. Food is the principal source of many pollutants for terrestrial insects, whereas aquatic insects acquire residues from both food and the abiotic environment. In this entry, we will consider both the effects of water pollution on insects and the use of insects in the biological monitoring of water quality.

Detection of Pollution Effects in Insects

A pollutant may cause deleterious effects if it influences the physiology or behavior of an organism, alters its capacity for growth, reproduction, or mortality, or changes its capacity for dispersal. Successful identification of pollution effects in insects depends on a number of conditions surrounding most studies. First is the need for adequate baseline information. Long-term monitoring of undisturbed populations is a prerequisite for detection of disturbance because natural successional changes, catastrophes, and population fluctuations may be mistakenly interpreted as pollution-caused trends in short-term studies. Historical data or paleoenvironmental approaches may provide the needed information in the absence of active, long-term, field-monitoring programs.

Second, causation can only be proven using an experimental approach. Experiments can also pinpoint early stage responses to pollution through an understanding of initial changes at different spatial and temporal scales. There is a need to link laboratory results and field surveys through field experimentation, but the experimental design must be suitable to the questions being asked to provide unequivocal answers.

Third, the species is the basic biological unit, so it should be the level at which responses to pollution are measured. There are many examples of species in the same genus responding differently to the same pollutant and dose; the lumping of taxa is a disservice in studying pollutant effects. Better autoecological knowledge of species is a prerequisite to understanding of pollution effects. Having expressed the ideal situation, practical realities such as taxonomic problems and cost often mean that higher taxonomic levels are used in biomonitoring programs.

Many abiotic and biotic factors directly or indirectly affect an organism's response to a pollutant, so it is difficult to predict the effects of pollutants and their different doses in nature. Some of the abiotic factors include: type of pollutant, concentration, duration and degree of exposure (chronic acute, lethal versus sublethal), time of year (temperature), quality of the water and sediment in which the organism lives, and interactions with other pollutants. Some of the biotic factors include: life-cycle stage (instar, age, rate of growth and development), health of the organism (parasitized or not), genetic composition (resistance), behavior with regard to exposure (cryptic or directly exposed), interactions with other species, and host alterations (important for phytophagous insects). Some of these factors are discussed more fully below.

Acute toxicity may have locally or temporarily significant effects on mortality, but sublethal effects may be more important in terms frequency of occurrence and length of exposure. Sublethal effects include disturbed enzyme functions, reduced reproduction, and altered behavior, all of which act to reduce an organism's fitness and affect its survival.

Indirect effects of pollutants on ecosystems, as mediated by insects, are often more profound than direct effects. Pollutants can influence the functioning of ecosystems by reducing species diversity, modifying food chains, and changing patterns of energy flow and nutrient cycling. For example, numbers of insects in groups naturally suppressed by fish predation tend to increase if fish are reduced by pollution such as acidification. Increased numbers of insect predators can then consume substantial amounts of small crustacean zooplankton, changing the natural relationships among trophic levels and, perhaps, affecting secondary productivity.

Life-cycle stages vary in their sensitivity to pollutants. For example, eggs are generally resistant stages, except when the pollutant is heat. Early instars seem to be more susceptible than later instars, perhaps because early instars have higher surface to volume ratios, they are more active, and they have thinner cuticles. Diapausing and pupal insects are also usually resistant stages.

It is difficult to generalize about the effects of pollution for all but the best-studied insect taxa. Most typically, some species within an insect taxon will respond positively, some will respond negatively, and some will be unaffected by a pollutant. In aquatic habitats, midges (Chironomidae), especially members of the subfamily Orthocladinae, seem to be tolerant of metal pollution. Some species of midges thrive in habitats heavily contaminated by organic matter (sewage, nutrients). Some species of mayflies (Ephemeroptera), stoneflies (Plecoptera), and caddisflies (Trichoptera) are sensitive to a number of pollutants, and have been used as indicator taxa in biomonitoring activities. In addition, most pollutant-induced changes in predators are negative, whereas changes in herbivores are often positive and are mediated through the host plant.

Relationships among exposure, dose, and effects on individual organisms (the effects of pollutants on insect populations are mediated through individuals) are complex. Different species, sexes, and life stages may react in different ways to the same exposure for both genetic and environmental reasons. Biotic interactions between individuals in a population and species within a community are also complicating factors. Therefore, generalizations for most insect groups will only be possible with the acquisition of much more taxon-specific data.

Responses of Aquatic Insect Groups to Pollution

Aquatic insects comprise all or part of 11 orders of the class Insecta and characteristically show different responses to pollution inputs, both among orders and within orders. A study done in the 1970s even demonstrated that when water quality tolerances were available for more than a single species within the same genus, the majority of genera had species listed as tolerant, facultative, or intolerant to pollution!

Typically, at the order level, three groups are considered as particularly intolerant to pollution effects: the Ephemeroptera, the Plecoptera, and the Trichoptera. The "EPT" orders (initials taken from the first letter of each order name) are also among the best known taxonomically; consequently, differential responses have been the best studied. For example, mayflies are known to be sensitive to acidification, and show reduced densities and/or richness at low-pH sites, which often result from acid deposition through precipitation (i.e., acid rain). Stoneflies are intolerant of oxygen loss (and they tend to be only found in highly oxygenated, cool-water habitats). Caddisflies are sensitive to both organic and inorganic contaminants.

However, not all EPT species are sensitive to all pollutants. Some mayflies are among the most tolerant of all aquatic insects to acidification and metal pollution. Some caddisflies occur in heavily polluted sections of European rivers. If the EPT orders are considered the most sensitive of the insects to pollution, the Diptera represent the other end of the spectrum. Increases in the percentage composition of the insect community (or even the benthic macroinvertebrate community, which includes insects, mollusks, Crustacea and other invertebrates) typically occur below releases of poorly functioning sewage treatment plants, industrial plants, and other anthropogenic inputs. Typically, these increases are in individuals of the family Chironomidae, the bloodworms (based on the hemoglobin pigment that gives a bright red color to some of the larvae). However, as mentioned for EPT, there is a broad range of tolerances not only among the species in this order, but even in the family Chironomidae.

Among the other aquatic insect orders, pollution effects have been noted as well. Species of Odonata (dragonflies and damselflies) have had their distributional range reduced because of increased eutrophication caused by the discharge of nutrients from agriculture and sewage. Hemiptera (bugs) have surface-dwelling species that are adversely affected by inputs of soap and other surfactants, and many of the water-column dwelling taxa are known to be sensitive to pesticide applications (either direct or as runoff).

Although it is evident that pollution response is best explained at the species level, tolerance values for water pollution have been developed for the different families of aquatic insects.

Tolerance values for aquatic insects. Average values for all taxa of aquatic insects reflect water quality, with 0–3.7 Excellent; 3.8–4.2 Very good; 4.3–5.0 Good; 5.1–5.7 Fair; 5.8–6.5 Fairly poor; 6.6–7.2 Poor; 7.3–10.0 Very poor.

Responses of Aquatic Insects to Pollution

The continued presence of aquatic insects in a given habitat depends on their ability to survive the water quality and habitat conditions of the aquatic environment present there. Contaminants in the water can range from deficiencies (e.g., oxygen) to excess (e.g., copper) of certain components, to contamination with substances that are increasingly deleterious as concentrations increase (e.g., pesticides). However, while most species of aquatic insects react negatively to most contaminants (e.g., oil, sedimentation) there are some species that thrive. As a result, the characteristic response to contamination is that intolerant species decline, species tolerant to that specific type of contamination will appear over time or if present in low numbers increase over time, and the evenness of the community (or the distribution of individuals among the taxa present) and the composition change.

It is important to remember that, in addition to water quality, the continued presence of aquatic insects depends on habitat conditions as well. For example, if water quality conditions are not changed (i.e., no contaminants are added) but habitat declines (e.g., the riparian vegetation is removed), aquatic insect composition will change just as if water quality impairment occurred. Of course, habitat and water quality are related; for example, a change in bank stability will result in increased siltation, and consequent water quality changes caused by suspended sediments.

Below, we describe various pollution inputs that affect aquatic insects. The list is not all-inclusive and the individual effects where contaminants are co-occurring may not just be additive but may be synergistic. In each case described below, the response of insects depends on the severity of the contamination (which can vary depending on past history at a site), habitat conditions, and a variety of other factors. It is important to remember that in all these examples the response is similar: species that are intolerant of that contaminant will be eliminated, those that are tolerant will survive, those that are tolerant but not represented in the habitat before contamination may appear if they are present in the local species pool, and the composition of the aquatic insects will change.

The disposal of domestic and industrial wastes has been a major challenge of civilization. Anthropogenic inputs can be divided into three types: organic, which includes domestic sewage, industrial wastes from food processing plants, and fertilizers; chemical, which includes industrial byproducts and agricultural chemicals such as insecticides; and physical, which includes habitat disruption and its consequences (e.g., erosion and siltation). Each input differs in its effects on aquatic insects, depending on concentration, duration of exposure, and various other factors.

Organic Wastes

With inputs of organic material, the general effect is a decrease in dissolved oxygen. This effect has led to the development of the classic pollution-recovery pattern in streams that has been well known for over 100 years. In this pattern, dissolved oxygen concentrations, water conditions, and the fish, insect, and algae assemblages are described over zones that represent areas above the pollution source, within the source, below the source, and far below the source. In the upstream-most area, oxygen concentration is high, the water is clear, and fish populations are characterized by a mixture of predaceous, algivorous, and detritivorous fish; insect groups are dominated by species of Ephemeroptera, Plecoptera, and Trichoptera, and the periphyton includes *Navicula* diatoms and *Oedegonium* and *Dinobryon* algae. Where pollution inputs enter, oxygen decreases, the water becomes darker and turbid, and only tolerant fish occur – carp, buffalo, gar, and catfish. The insect assemblage becomes dominated by chironomid midge larvae and simuliid (black fly) larvae. *Paramecium*, *Beggiatoa* and *Stentor* dominate planktonic assemblages. As pollution worsens, oxygen drops to extremely low levels, the water is septic with noxious odors and floating sludge. No fish occur and only mosquito larvae (e.g., *Culex*), very tolerant dipterans such as *Eristalis*, the rat-tailed maggot, and oligochaetes such as *Tubifex* thrive. Pollution-tolerant plankton such as sewage fungus (the colonial bacteria *Sphaerotilus*), the blue-green algae *Oscillatoria* and the diatom *Melosira* predominate.

Of course, the solution to pollution has always been dilution. Recovery occurs downstream as oxygen concentration increases. If no new organic pollution sources are added, stream water quality returns through the second and then to the first pollution-recovery zone.

Probably the most widespread anthropogenic change to aquatic environments worldwide is the input of organic matter and nutrients such as nitrogen and phosphorus. Usually referred to as eutrophication, the typical causes of this type of pollution are sewage inputs containing human or animal wastes, agricultural fertilizers, or even industrial detergents. In North America and Western Europe, direct inputs of untreated sewage have been greatly reduced but inputs of mineral nutrients, which result in increases in algae, remain. Although algae produce oxygen by photosynthesis, their respiration requires oxygen and night-time reductions in oxygen concentrations are the result of eutrophication.

Chemical Wastes

In contrast to organic wastes, chemical inputs usually affect aquatic organisms through their direct toxic action, although indirect effects such as changes in pH or osmotic pressure may affect aquatic insects. Our understanding of the effects of chemical wastes on aquatic insects largely comes from toxicity tests conducted with single or multiple species of insects for either short or long durations. Toxicity testing is also a tool used in biomonitoring, and is described later.

Not unexpectedly, given that insects are their target organisms, most insecticides used to control agricultural pests exhibit toxicity to at least the aquatic insects that are related to the target pests. Even the widely used *Bti* biological insecticide (*Bacillus thuringiensis israelensis*) used to control black flies and mosquitoes shows some toxic effects on other, closely related Diptera.

A type of pollution that has caused major effects on aquatic insects is acidification. The main cause of this type of pollution is considered to be fossil fuel combustion and the long-distance transport of SO_2 and NO_x pollutants with their eventual deposition during precipitation. Acidification affects aquatic insects through changes in physiology, increases in trace metal concentrations that are toxic to some organisms, and indirectly through changing food availability by altering either photosynthetic or decomposition pathways.

Mayflies are the best studied of all invertebrates in terms of acid stress, and responses to low pH range from increases in drift rates (i.e., in which mayflies leave the substrate and “drift” downstream), reduced growth, higher respiration rates, and avoiding oviposition in acidic streams. While most Ephemeroptera species decline as pH is lowered, other more tolerant species may increase but, in general, there is an overall decrease in insect richness and productivity.

The differential responses of aquatic insects to changes in oxygen concentration and pH are evident from the results of numerous studies. Only Diptera predominate in the reduced oxygen areas of streams (the poly- and meosaprobic zones) and many mayflies are limited in their distribution to waters with pH > 5.0. Number of species in the different orders of aquatic insects showing different tolerance to organic pollution and acidification. “Poly” refers to the polysaprobic zone, which is a zone grossly polluted by organic matter; “α-meso” and “β-meso” refer to zones of increasing oxygen, and “oligo” refers to a zone of high oxygen content (from Rosenberg and Resh 1993) (Table 2).

Physical Wastes

The third category of pollution, physical wastes, generally affects aquatic insects by being abrasive or injurious to their gills, interfering with respiration, reducing food supply by reducing light penetration, or filling the interstitial spaces of substrates in which aquatic insects dwell. Habitat alterations that increase erosion are the major sources of these inputs.

Pollution sources range from municipal wastes and other consequences of urbanization, to livestock and other agricultural activities, to industrial inputs of toxic metals. To some, the changes induced by damming streams fall into the area of pollution, as does the issue of introduced species and their impact on native fauna. The literature on pollution is vast, and the individual pollutants are almost infinite in number. While specifics vary, the same pattern emerges: intolerant species are eliminated, tolerant species thrive, and the composition of aquatic insect communities under the stress is altered.

Use of Insects in Biomonitoring

Biological monitoring is the systematic use of living organisms, or their responses, to determine the quality of the environment. Biological monitoring has been a major component of water quality assessments for the past two decades. Although prior to this, assessments primarily involved chemical and physical measurements, the inclusion of a biological component has greatly improved the process. First, because water pollution is essentially a biological problem, it only makes sense to evaluate it by biological means. Second, and perhaps best explained by

Water Pollution and Insects, Table 2 Number of species in the different orders of aquatic insects showing different tolerance to organic pollution and acidifications. ‘Poly’ refers to the polysaprobic zone, which is a zone grossly polluted by organic matter; ‘α-meso’ and ‘β-meso’ refer to zones of increasing oxygen, and ‘oligo’ refers to a zone of high oxygen content (from Rosenberg and Resh 1993).

Order	Poly	α-meso	β-meso	Oligo	pH > 5.5	5.5 < 5.0	5.0 < 4.7	<4.7
Odonata	0	2	17	5	0	0	5	2
Ephemeroptera	0	6	20	23	21	20	9	13
Plecoptera	0	0	4	24	0	8	0	14

Trichoptera	0	4	18	31	1	10	7	33
Megaloptera	0	2	3	2	0	0	1	2
Diptera	4	44	36	62	9	3	35	41
Coleoptera	0	8	19	18	0	0	1	0

analogy, water quality monitoring that only involves chemical and physical measurements is akin to a photograph, an instantaneous documentation of conditions at the time a sample was taken. In contrast, biomonitoring is akin to a videotape; organisms are present through the range of environmental conditions present, so they add a temporal component of past conditions to the monitoring program.

Of all groups that have been recommended for use in water quality assessments (such as fish, algae, and protozoans), macroinvertebrates are the group most frequently used and recommended. Why is this so? First, they are ubiquitous in occurrence and consequently are affected by perturbations in many different kinds of aquatic habitats. Second, there is a large number of species (perhaps 25,000 species of aquatic insects in the US and Canada alone) that exhibit a range of responses to environmental stress. Third, their sedimentary nature (or the sudden departure from it) tends to illustrate the spatial extent of a problem. Finally, they have relatively long life cycles, relative to many other groups of organisms, which allow the examination over time of features such as age structure and abundance. To be fair, the use of macroinvertebrates in biomonitoring also has disadvantages, but most of these can be accounted for in the design of biomonitoring programs.

The tradition of biological monitoring is over a century old and initially was based on the idea of indicator organisms, in which the presence of certain types of organisms in themselves were indicative of pollution status. In part, this approach was an outgrowth of the lake classification system developed by German limnologists (especially August Thienemann) that described lake categories in terms of the dominant species of Chironomidae present. Today we think of the indicator concept as rather simplistic; the assemblage of organisms present is now viewed as the best measure indicating pollution.

In the past 30 years that aquatic insects have been used in biomonitoring, there has been a shift in the type of study that has been conducted in North America. In the 1970s, emphasis was on qualitative assessments with relative (rather than absolute, i.e., number of individuals/area) samples being compared from control and test areas. However, by the next decade emphasis had switched to studies involving replicated absolute (fixed-area) samples and using inferential statistical tests. By the 1990s, emphasis was again on non-quantitative sampling and analysis involving comparisons among sites in terms of specific measures (usually referred to as metrics) or multivariate statistics in which each taxon is a variable in the analysis. Part of the key to this shift was the development and use in the 1990s of Rapid Biomonitoring Protocols, an approach encouraged by the US Environmental Protection Agency, described in detail below.

The "reference-condition approach" (RCA) has provided a powerful approach for large-scale biomonitoring programs. The "reference condition" represents a group of minimally disturbed sites organized by selected physical, chemical, and biological characteristics. The RCA is an alternative to more traditional comparisons of control vs. impacted sites in bioassessment. Sites suspected of being impacted are compared to suitable reference sites using multivariate statistics. The underlying models produce output that shows the degree of impairment of impacted sites compared to reference sites. The RCA is currently being used in national biomonitoring programs using macroinvertebrates in countries like the United Kingdom and Australia. A slightly different RCA, using "multimetrics," has been developed for water quality monitoring in the U.S.A.

The Practice of Biomonitoring

Biomonitoring approaches are available that cover hierarchical scales ranging from processes that occur at the molecular level to those that occur at the ecosystem level. In practice, however, most biomonitoring with aquatic insects is conducted at the species assemblage and community levels, and these levels are what we will describe in detail. Biomonitoring approaches used at different spatial scales. EPT = Ephemeroptera, Plecoptera, and Trichoptera (Table 3).

Water Pollution and Insects, Table 3 Biomonitoring approaches used at different spatial scales. EPT = Ephemeroptera, Plectoptera, and Trichoptera.

Hierarchical level	Examples	Advantages/disadvantages
Molecular	Changes in enzyme activity of respiratory metabolism	Subcellular levels should be sensitive, early warning indicators of stress; limited by a basic knowledge of biochemical and physiological processes in most aquatic insects
Individual	Morphological deformities; deviation from normal behavioral patterns; survival, growth, and reproduction success	Methods well developed, but indicators of stress are often qualitative
Population	Numbers of individuals; size spectra of population	Taxonomic difficulty; separation of natural variability from that caused by perturbation
Species Assemblages	Proportion of individuals in perceived pollution-intolerant groups (e.g., EPT)	Most groups viewed as intolerant are actually a mixture of intolerant and moderately tolerant taxa
Community	Taxa richness; diversity and similarity indices; biotic indices	Taxonomic difficulties; sampling problems to adequately represent proportional occurrences
Ecosystem	Structure of food webs; chemical cycling; primary and secondary production	Provides holistic view of problem; time consuming and costly

Species assemblages and community level biomonitoring involves studies that include replicated sampling and statistical analysis. The distinction between qualitative and quantitative methods is often blurred in that many rapid bioassessment programs also involve replicate sampling.

Species Richness

No matter which approach is used, similar measures (or metrics) are commonly used to distinguish between impaired and unimpaired aquatic insect assemblages and communities. The most commonly used measure is that of species richness (i.e., the number of species present), whether used for the whole community or perceived intolerant groups such as the EPT taxa. The use of species richness is based on the premise that the number of taxa decreases as water quality decreases because of the elimination of the taxa that are intolerant of a certain type of pollution. An older idea was that the number of individuals of these taxa also decreased but current evidence indicates that elimination occurs. A difficulty with using species richness is that identification, or at least the ability to distinguish taxa to count them, is required.

Abundance

Enumerations of numbers of individuals (either of the whole communities or of insect assemblages such as EPT) are often used but, in practice, are often difficult to interpret because of the high natural variability in aquatic systems. Spatial variation in substrate, flow conditions, and a myriad of other factors produce high- and low-density patches of organisms.

A classic pattern in pollution response is the elimination of certain intolerant taxa and drastic increases in tolerant taxa. This response commonly occurs with certain species of Oligochaeta and even some chironomid midge larvae in response to severe pollution conditions, especially where high amounts of organic matter result in drastic decreases in oxygen concentrations. However, this type of pollution is not the only one that induces density increases. The chironomid midge larva, *Cricotopus bicinctus*, which tends to commonly occur in low densities, often increases by orders of magnitude when the habitats it occurs in are exposed to contaminants ranging from oil to chromium.

Evenness and Diversity

Shifts in abundance of insect populations are the basis for evaluating the evenness or diversity (as opposed to richness). Evenness refers to the distribution of individuals among the taxa present. For example, two communities of stream insects may each contain 10 species and 100 individuals; however, their evenness will differ if the first community has ten individuals of each species and the second has one species with 91 individuals and the rest with one individual each.

Evenness is often calculated along with diversity indices, an approach that was widely used in the 1970s but is considered as a less reliable tool for biomonitoring by many researchers today. Depending on the formula used for calculating the diversity of a community (or species assemblage), the index value can be weighted more towards the richness or evenness component.

Biotic Indices

Biotic indices are the evaluation tool that is both widespread in use and unique to water quality monitoring programs using aquatic insects. In calculating a biotic index score, organisms collected are assigned values according to their tolerance or intolerance (ideally) to the pollutant being evaluated, but in actuality most values are based on responses of the insect to organic pollution. Examples of tolerance values are often used at the family level for many rapid bioassessment procedures in North America but in the rest of the world they are usually used at genus or species level, an approach that is more commonsensical given that there is high variability in pollution tolerance and intolerance within aquatic insect families. The actual calculation of a biotic index score involves multiplying the number of individuals of each taxon by their tolerance values, summing them, and dividing this sum by the number of individuals collected.

Functional Feeding Groups

A recent addition to biomonitoring procedures has been the incorporation of functional feeding group (FFG) measures into programs. FFG measures differ from those described above in that the former emphasizes characterization of the structural aspects of the community, while FFGs emphasize the functional aspects. The use of FFGs in biomonitoring is based on the premise that organisms evolved certain morphological-behavioral food-gathering mechanisms and can be placed in particular groups. Consequently, each of these groups is expected to occur in proportionally higher abundance in accumulations of particular food sources (or habitat types). Most biomonitoring programs characterize the species encountered as belonging to one of several functional groups: scrapers (consume attached algae); shredders (consume decomposing vascular plant tissue); collectors (consume decomposing fine particulate organic matter); and predators (consume living animal tissue). Leaf packs, for example, should have a high proportion of shredders; algae-covered rocks should have more scrapers. Departures from expected proportions could indicate contamination or disturbance (e.g., a decrease in shredder abundance could indicate deleterious changes in the riparian zone that provides the food staples for the shredders to use).

A characteristic of community based approaches used in rapid bioassessment procedures involves calculation of combination indices of many of the measures described above. While this spreads the risk of incorrect assessments using single measures, it is also perceived as giving a balance to the various measures used. The inclusion of combination indices of the various measures has given rise to the name "multimetric approaches," which (incorrectly) has been considered as the same as rapid bioassessment procedures.

Other Techniques

Two other approaches must be mentioned in the use of aquatic insects in biomonitoring: toxicity studies and paleolimnological reconstruction. Toxicity testing has the longest history of any technique in biomonitoring, and is supposedly traceable to Aristotle placing a freshwater fish in seawater to observe its reaction! Today, toxicity tests form a continuum of complexity from single-species, laboratory-based, short-term exposures, to long-term single- and multiple-species tests, to field-based toxicity testing in outdoor experimental systems. Many species of aquatic insects are used in this testing, and results of studies are used to regulate discharges, compare toxicants, and predict environmental effects of their use.

Paleolimnological approaches to biomonitoring involve using sediment cores to reconstruct the history of aquatic systems that have been exposed to impacts such as eutrophication, acidification, or climate changes. This approach is confined to lakes and large rivers, and is not widely used by regulatory agencies.

Conclusion

Water pollution is a biological problem. Consequently, the effects of pollution on insects, the most speciose group usually present in fresh waters, is expected to be a significant outcome of anthropogenic impacts. Likewise, because they show varied responses to pollution, insects are the logical basis for monitoring effects. This fact has been recognized by the existence of thousands of government- sponsored and volunteer programs all over the world that use aquatic insects to monitor water quality.

Wax

A substance secreted by insects from glands located on various parts of the body (Fig. 19). Wax serves a protective function for most insects, but bees use wax to build cells in their hives. The term "wax," as generally applied to the lipids on an insect's cuticle, is a complex mixture of lipids, most of which do not fit the chemical definition of "wax."

Wax Channels

Narrow-diameter channels in the epicuticular layer of the insect integument. They deliver lipids to the surface.

Wax Scales

Some members of the family Coccidae, superfamily Coccoidae (order Hemiptera).

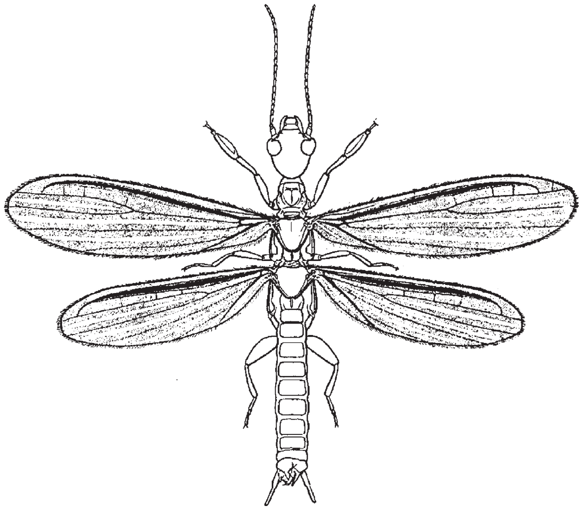
Webspinners (Embiidina)

EDWARD S. ROSS
California Academy of Sciences, San Francisco, CA, USA

Embiidina is the oldest name for a peculiar order of semi-social, largely tropical insects later named Embiodea, Embioptera, or Embiaria. They also are known as foot-spinners and embiids. With less than 500 named species, it is regarded as a small order, but worldwide collecting indicates that it is moderately large, potentially with about 2,000 species. Because embiids tend to remain in their self-produced silk galleries, they rarely are collected by usual methods except for males attracted to lights (Fig. 20). One must search for



Webspinners (Embiidina), Figure 20 Typical alate male embiid, *Oligotoma saundersii* (Westwood) (Oligotomidae), body length 10 mm.

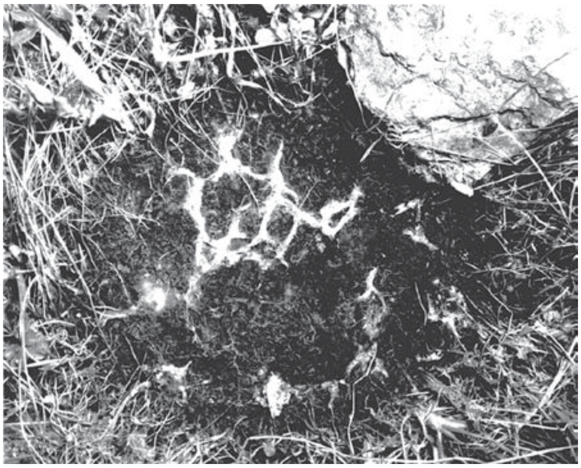
the often-obscure colonies and rear series, especially males, in laboratory cultures.

Characteristics

These are small insects, generally measuring 4–10 mm in length, though a few attain nearly one centimeter. Webspinners are soft-bodied and elongate, and pale to dark in color. They bear compound eyes, but lack ocelli. The antennae are filiform, and consist of 15–32 segments. They have chewing mouthparts. The prothorax is narrower than the head. The fore legs and hind legs are stouter than the middle legs. The tarsi have three segments, and the basal segment is markedly swollen on the forelegs. Female webspinners are wingless. Males are winged or wingless, and if winged they bear two pairs of smoky-colored membranous wings, with both pairs about equal in size and shape. The abdomen bears ten segments, and a pair of 2-segmented cerci is present at the apex. The immatures undergo four nymphal instars, and in the case of winged males, the last two bear wing pads. Webspinners display incomplete metamorphosis. All life-stages of all species have the basal segment of the fore tarsi greatly enlarged by scores of tightly-appressed, globular, multicellular silk glands. By means of a thread-like duct, the secretion of each gland is conveyed to one of a multitude of hollow, dermal, seta-like ejectors scattered on the ventral surface of the tarsus. With rapid, criss-cross strokes in many directions, even dorsally, the foretarsi produce dense-walled silk galleries ramifying in or on the food supply, usually the outer bark of trees, leaf-litter, and lichens on rocks. In arid regions, galleries are shielded beneath stones and extend down soil cracks (Fig. 21).

The galleries are just narrow enough to insure constant body hair contact with the walls and are increased in diameter as the embiids grow. Most of the order's peculiarities augment predation-escape by rapid reverse movement. These include a slender supple body with short legs, a forward-projected head, enlarged depressor muscles of hind tibiae to power reverse movement, highly sensitive cerci to guide such movement, and adaptations reducing friction of protruding structures, such as wings and ovipositor, against gallery walls.

Because females must live long enough to produce eggs and guard young, they gained maximum speed in reverse movement by becoming universally apterous by neotenic retardation of development of



Webspinners (Embiidina), Figure 21 Characteristic silk galleries under stone in a semi-arid environment, California.

adult structures (Fig. 22). In arid, open environments where flight would expose them to adverse conditions, especially predators, males of many species likewise are apterous, or subapterous, through degrees of neoteny. Fortunately, in all but one species, the male's genitalia fully develop and serve as the most useful characters in classification. Females are difficult to identify without associated adult males.

Evolution

Neotenic apterism appears to be a relatively recent adaptation. Undoubtedly, during early evolution of the order, perhaps in the Permian period, both sexes must have possessed wings. The first stage of reducing the "barb effect" of wings during reverse movement was evolution of flexibility, a weakening of most longitudinal veins. This enabled the wings to fold forward, even crumple, over the back and thereby reduce friction. However, because stiff-winged flight must have remained useful, wings evolved an ability to temporarily stiffen when extended in flight. The means was blood pressure in the full length of certain veins, particularly in the anterior radius (RA), which became a terminally closed sinus, termed radial blood sinus (RBS). Such a conspicuous vein characterizes the wings of all wing-bearing males of the order. Presence or absence of wings in males occurs throughout the order by random convergence, usually associated with climate.

Webspinners (Embiidina), Figure 22 Typical adult female, *Pararhagadochir trachelia* (Navás), body length 12 mm, from Argentina. Shows neotenic apterism of all females of the order.

Embiids primarily occur in subtropical and tropical environments from sea level to almost 4,000 meters. A few species range into temperate regions, but many suitable regions haven't been occupied due to female apterism and hazards of movement outside of galleries. Lack of dispersal of females by flight restricts the order to continental lands and explains the absence of the order on oceanic islands except for a few species, particularly of the genus *Oligotoma*, which have been widely spread in ancient and modern human commerce.

Although the order probably had an early origin, the fossil record is weak. The only possible pretertiary fossil, *Burmitembia venosa*, was found in Burmese amber (questionably Cretaceous). All Tertiary fossils, mostly in amber, are modern types.

Classification

There are various taxonomic arrangements possible, but the following eight families seem to represent a consensus currently:

- Class: Insecta
  - Order: Embiidina
    - Family: Clothodidae
    - Family: Embiidae
    - Family: Notoligotomidae
    - Family: Embonychidae
    - Family: Anisembiidae
    - Family: Australembiidae
    - Family: Teratembiidae
    - Family: Oligotomidae

Because so many taxa await description, it isn't possible to develop an adequate classification at this time. Species of Clothodidae, confined to South America, are the most plesiomorphic. The large family Embiidae is highly diverse and requires division into subfamilies and, perhaps, families. The large family Anisembiidae is confined to the Americas. Tropical Asia has a number of families, particularly Oligotomidae, and some very distinct families, such as Embonychidae. Australia also has many oligotomids, a few Notoligotomidae and an abundance of Australembiidae, a family confined to eastern Australia. The large family Teratembiidae is best represented in the Americas and Africa, with only a few Asian species. A number of additional families await description. Strangely, Madagascar doesn't appear to have endemic embiids. Apparently there are no Southern Hemisphere origins. No species is of economic importance.

Web-Spinning Sawflies

Some members of the family Pamphiliidae (order Hymenoptera, suborder Symphyta).

► Wasps, Ants, Bees and Sawflies

Webworms (Lepidoptera: Pyralidae)

Webworms are the larvae of Pyralidae (Crambidae) that web together vegetation, usually feeding within the rolled, folded or loosely webbed foliage. Sometimes they only rest within the silk, venturing forth to feed at night. Different species attack both grasses and forbs. Most, but certainly not all, of these larvae seem to be poorly defended chemically or physically, and perhaps derive some protection from predation and parasitism by living within the web. Certainly they are less visible to vertebrate hunters such as birds, but parasitoids often manage to locate and parasitize them.

Wedge-Shaped Beetles

Members of the family Rhipiphoridae (order Coleoptera).

Weeds in Crop Systems for Pest Suppression

ALLAN T. SHOWLER
U.S. Department of Agriculture, ARS SARC, Weslaco, TX, USA

Weeds are generally considered to be deleterious in crop systems because of their competition with crop plants for limited water, nutrients, light, and space, and occasionally because of allelopathy. Weeds are also known to be important reservoirs for some crop pests, including bacterial, fungal, and viral pathogens, nematodes, and arthropods. In addition, weeds can obstruct harvest operations. However, weeds support beneficial arthropod populations and vegetative diversity is associated with faunal diversity. Species diversity has been related to ecosystem stability and a lower frequency of pest outbreaks, although some pests [e.g., tsetse (*Glossina* spp.) and rhinoceros beetles, (*Oryctes* spp.)], maintain low, relatively stable densities that are still economically injurious.

Vegetational diversification in polycultures to suppress pest arthropods has at times produced positive results. For example, corn/bean (*Zea* *mays* L./*Phaseolus vulgaris* L.) dicultures sustained less injury by banded cucumber beetles, *Diabrotica balteata* LeConte; fall armyworm, *Spodoptera frugiperda* Smith; and leafhoppers, *Empoasca kraemeri* Ross., than corn monocultures. Maize/legume/squash (*Cucurbita* spp.) polycultures in tropical Mexico produced higher yields and harbored 38% fewer melonworms, *Diaphania hyalinata* (L.), larvae than squash monocultures. Cover crops, such as beans, *Phaseolus* sp., in apple, *Malus* sp., orchards, have been associated with reduced codling moth, *Cydia pomonella* L.; rosy apple aphid, *Anuraphis roseus* Baker; and leafhopper infestations. Modifications of the polycultural concept include [strip cropping] to accumulate natural enemy populations or to attract pest populations into concentrated areas where they can be sprayed with insecticides. Crop rotation is another mode of vegetational diversification, conducted on a temporal rather than on a concurrent basis. A modification of crop rotation was demonstrated when canola, *Brassica napus* L., and wheat, *Triticum aestivum* L., in the winter "relayed" aphid predators to sorghum in the spring, and from sorghum to cotton in the summer. Theories that attempt to explain the lower pest infestations in many vegetatively diversified crops include: (i) spatial dilution of the pest's primary food or shelter resource, (ii) chemical or structural interference with host location and use by herbivores, and (iii) enhanced natural enemy populations resulting from increased herbivore prey abundance and diversity.

Native weed species and communities have been linked with the suppression of insect pests in cropping systems, including fall armyworm in corn; imported cabbageworm, *Pieris rapae* L., cabbage aphid, *Brevicoryne brassicae* L., and cabbage whitefly, *Aleyrodes brassicae* (Wlk.) in Brussels sprouts, *Brassica oleracea* L. cv. "Brussels sprouts." Weed growth was associated with reduced infestations of the potato leafhopper, *Empoasca fabae* (Harris), in alfalfa, *Medicago sativa* L.; velvetbean caterpillar, *Anticarsia gemmatalis* Hübner, green stink bug, *Nezara viridula* L., and corn earworm, *Heliothis zea* Boddie, in soybeans, *Glycine max* (L.) E. Merrill; and green stink bug in macadamia, *Macadamia* sp., orchards. Two cropping systems, Louisiana sugarcane, *Saccharum officinarum* L., and south Texas cotton, *Gossypium hirsutum* L., are presented as case studies because they have been more extensively examined regarding weed interactions with arthropod populations than other cropping systems, and because they demonstrate different outcomes and principles.

Louisiana Sugarcane

The intrusion of weeds, especially the perennial johnsongrass, *Sorghum halepense* (L.) C. Persoon, can cause sugarcane yield losses of up to 84%. Most weeds in sugarcane are less competitive annuals that decline after crop canopy closure blocks sunlight, but even annual weed infestations, particularly hairy crabgrass, *Digitaria sanguinalis* (L.) J. Scopali, can reduce sugarcane density, biomass, and commercial sugar yield by 24, 19, and 15%, respectively.

The importance of natural enemies in sugarcane in Louisiana was emphasized when applications of non-selective and persistent insecticides were associated with increased populations of the sugarcane borer, *Diatraea saccharalis* (F.), the key pest. Sugarcane fields in Louisiana that were infested with monocot, dicot, or monocot/dicot mixtures were found to be significantly more diverse in terms of soil surface- and foliage-associated arthropods, including predators, than weed-free sugarcane habitats. Herbivorous prey arthropods, which support populations of natural enemies, were significantly more numerous on the ground, sugarcane stalks, and sugarcane leaves in weedy habitats, and the abundance of arthropod prey was significantly greater on weed foliage than on the soil surface, or sugarcane in weedy habitats (Fig. 23).

The red imported fire ant, *Solenopsis invicta* Buren, has been identified as the most important predator of the sugarcane borer, and was found to establish significantly more colonies per unit area

Weeds in Crop Systems for Pest Suppression, Figure 23 **Weedy fields such as this sugarcane field in southern Louisiana produce greater yields than weed-free crops because weeds harbor populations of beneficial insects that suppress key pests.**

(up to 85%) in weedy than in weed-free sugarcane habitats. Imported fire ant workers were significantly more abundant on the soil surface, sugarcane stalks, and weed foliage in weedy habitats. A study using a rare earth element (samarium) as a stable-activable tracer ingested by selected colonies in weedy sugarcane had 28% smaller foraging area (because of significantly greater prey availability) than weed-free sugarcane. The reduction in territorial area and the 25% increase in foraging activity per unit area permitted more dense colonization by fire ant in weedy habitats.

At least 18 other formicid species have been identified as being natural enemies of the sugarcane borer in Louisiana, and it has been suggested that a multiple predatory ant complex is more effective than one dominated by fire ant. One study determined that fire ant foraging activity among weedy and weed-free sugarcane habitats was negatively correlated ($r = -0.069$, $P \leq 0.05$) with the abundance of the formicids *Paratrechina vividula* Nylander, but failed to influence *Pheidole moerens* Wheeler. The fire ant has displaced other indigenous formicid species from many habitats throughout its distribution in the United States.

Spiders (Araneae) are the chief egg predators of the sugarcane borer, and second only to the fire ant among overall natural enemies of the sugarcane borer. Louisiana sugarcane fields are known to support at least 84 spider species in 18 families. Vegetational complexity involving weeds is associated with increased spider diversity and abundance on the soil surface and on sugarcane foliage. Predators of the sugarcane borer such as carabids, elaterid larvae, staphylinids, dermapterans, and neuropterans are found in Louisiana sugarcane, but weed cover has not been associated with increased populations of these insect groups.

Although grass species, including *Paspalum* spp., and johnsongrass can serve as hosts to the sugarcane borer, increased numbers of predatory arthropods in weedy sugarcane appears to have overridden any deleterious influence of weeds as secondary hosts of the pest. Sugarcane borer injury (numbers of bored internodes) was reduced by 28–42% in weedy sugarcane. Economic analysis and sugarcane biomass yields in weedy versus weed-free habitats were not consistently different in plots where the sugarcane borer was controlled with fenvalerate, a pyrethroid insecticide.

Also, soil incorporated aldicarb, used for nematode control, in weedy habitats resulted in low predator populations, particularly fire ants, that were similar to levels encountered in weed-free sugarcane habitats. Sugarcane borer injury was 19–32% greater in aldicarb treated weedy areas. Therefore, the hypothesis that plant chemical or structural complexity in weedy systems interferes with host location by herbivores does not adequately explain sugarcane borer infestations trends. Predation appears to be more important.

A study in southern Louisiana revealed that weedy sugarcane field plots, without chemical control of the sugarcane borer, can yield about 12% ($P \leq 0.05$) less commercial sugar per hectare than weed-free plots mainly because of weed-induced sugarcane stand reduction. Net return (US$dollar;/ha), however, was at least 14.6% higher than in the weed-free habitats. The same study suggested that research is needed to study the effect of limited areas of natural weed growth in sugarcane fields for enhancing natural enemy populations. Similarly, in sugarcane grown in Hawaii, the association of the dipteran sugarcane borer parasite *Lixophaga sphenopheri* (Villen.) with weeds resulted in reduction of New Guinea sugarcane weevil, *Rhabdoscelus obscurus* Boisd. It was suggested that weeds be permitted to grow in limited areas or "islands" within sugarcane fields to reduce pest populations.

The greenbug, *Schizaphus graminum* (Rondani), which can obtain sugarcane mosaic virus (SCMV) from infected weeds and transmit the disease to sugarcane, was more abundant in the weedy sugarcane habitats in Louisiana, and, possibly as a result, SCMV infection of sugarcane was 14% higher than in weed-free habitats. Weeds have also been reported to be associated with higher populations of the phytophagous nematodes *Criconemella* spp., *Meloidogyne* spp., and *Tylenchorhynchus* sp. collected from sugarcane rhizospheres in southern Louisiana. In the case of *T. annulatus*, populations appeared to be influenced by SCMV infection of the host sugarcane plant.

South Texas Cotton

In south Texas, the key pest of cotton production is the boll weevil, *Anthonomus grandis grandis* Boheman, which can commonly cause greater than 50% yield losses if populations are unchecked. In nature, boll weevils have been shown to reproduce on seven *Gossypium* spp., (including *G. hirsutum* and *G. barbadense* L.), three *Cienfugosia* spp., two *Hampea* spp., and *Thespesia populnea* (L.) D. Solander *ex* J. I. Corrêa da Serra in Texas, 486 boll weevils were examined and found to have ingested 8,900 pollen grains from 58 plant families of which the majority were in the families Salicaceae (28%), Fabaceae (13%), and Poac eae (8%).

Weedy cotton field plots in the Lower Rio Grande Valley were associated with significantly higher populations of nine of eleven prey arthropod groups counted, including cicadellids, herbivorous hemipterans, lepidopteran larvae, and dipterans; and nine of the thirteen natural enemy arthropod groups counted, including *Georcoris* spp., *Orius* spp., *Nabis* spp., and neuropterans. For the most part, differences among arthropod populations in weedy and weed-free cotton plots became more substantial as the season progressed and weed biomass increased as compared to biomass early in the season. Diversity among the arthropod groups that were counted did not differ for ground associated arthropods, but was significantly higher for samples collected from cotton plant canopies in weedy habitats than on cotton plant canopies in weed-free habitats. Numbers of ant colonies in the weedy and weed-free cotton habitats were low and did not differ, and were mainly comprised of leafcutter ants, *Atta* spp., and tropical fire ants, *Solenposis geminata* (F.). The most effective predator of boll weevils in Texas cotton is the fire ant. It is reported to cause an average of 84% boll weevil mortality as compared to 0.14, 6.9, and 7% caused by parasitism, desiccation, and egg infertility, respectively, and some researchers claim that the fire ant, originally from South America, prefers boll weevils to other food sources in the cotton agroecosystem. In weedy and weed-free cotton habitats in the Lower Rio Grande Valley, fire ants were not found in any samples. Examination of fallen boll weevil infested squares revealed that, in weedy and weed-free habitats, 50% of the boll weevils were killed by heat and desiccation as compared to eight and 2% killed by ants and disease, respectively (40% survived and emerged).

Silverleaf whitefly, *Bemisia argentifolii* Bellows and Perring, numbers were significantly higher on weed-free cotton plant foliage than on weedy cotton foliage and weed foliage in the later part of the growing season. This probably reflects the whitefly's preference for cotton plants over weeds. It is possible that dense weed growth might impede or deter some whiteflies from settling on cotton plants in weedy areas. It is also possible that parasitism of silverleaf whiteflies, reported to be higher on weeds (especially hirsute species) than on cotton, contributed to the lower whitefly populations on the weeds. Higher cotton aphid, *Aphis gossypii* Glover, densities in weedy cotton habitats might have resulted from the same conditions as for whiteflies. Ants and coccinellid beetles, both of which consume aphids, were more abundant in the weedy cotton habitats. Whether more abundant in weedy or weed-free habitats, heightened prey availability was associated with twelve of the fourteen predator groups counted.

Despite a general trend for higher populations of natural enemies in the weedy habitats, boll weevil oviposition injury to squares was unaffected. As a possible explanation, predatory arthropod populations built to significantly greater levels in weedy habitats during late May and June when weed biomass was highest and when most squares had become bolls that are less vulnerable to boll weevil oviposition. Also, most natural enemies indigenous to the United States are not considered to be major causes of mortality to boll weevils. The numbers of squares counted on cotton plants in the study were not significantly different between the weedy and weed-free treatments because boll weevil damage was unaffected by the treatments and because weed growth was too light in the early season to have caused a weed related decline in square production. The significantly fewer bolls counted in the weedy habitats later in the season resulted from reduced cotton plant densities caused by weed competition and lower plant heights that were likely induced by thigmomorphogenesis (shortening of internodes resulting from physical contact with objects or wind) and shading caused by taller weeds. The significantly lower (≥50%) cotton yields reflected the lower numbers of bolls.

The results found in the weed-diversified field cotton in the Lower Rio Grande Valley of Texas agree with polyculture research in Asia where cotton yields were either unaffected or reduced when interplanted with groundnuts, *Arachis hypogaea* L.; soybeans, *Glycine max* (L.) E. Merrill; greengram, *Phaseolus aureus* W. Roxburgh; and blackgram, *P. mungo* (L.) Hepper. Further, a study in Central America found that there were fewer lacewing (Chrysopidae) eggs on cotton plants intercropped with corn and weeds than in cotton monocultures. A study in Africa showed that yields of intercropped cotton and groundnuts grown on alternating ridges did not improve in low rainfall areas, but yields were better from intercropped plants in wetter areas.

Although boll weevil injury to cotton was not suppressed in the Lower Rio Grande Valley of Texas, other insect pests of cotton might be more vulnerable to natural enemies. The differences in weed biomass and the cost to lint production suggest that the quantity of natural weed growth needed to build significantly larger numbers of natural enemy populations in weedy habitats is detrimentally competitive with the cotton crop. Although the fire ant is a key predator of boll weevils elsewhere, the hot, dry habitat in the Lower Rio Grande Valley cotton fields appears to have limited fire ant colonization to the extent that it is not a factor in boll weevil mortality.

Weed communities in cropping systems can affect arthropod populations in a number of ways, as illustrated by the cases of sugarcane in Louisiana and cotton in the Lower Rio Grande Valley of Texas. Both cases, however, illustrate that uncontrolled weed growth is deleterious to crop yield, but in the case of sugarcane, this loss can be offset by the advantage conferred primarily by the substantially higher populations of the fire ant and associated reduction in sugarcane borer injury, and lower field maintenance dollar inputs in weedy habitats. In some situations, vegetative complexity might be associated with ecological stability. In others, various parameters have interceded, such as the introduction of an exotic pest without effective natural enemies in its new habitat, to render void the benefits of ecosystem richness. For weeds to become widely integrated into IPM strategies, development of techniques for maintaining appropriate densities and diversities of innocuous weed populations in or around cropping systems will likely be a key concern.

Weed Biological Control in Australia

HELEN SPAFFORD[1,2], RACHEL MCFADYEN[2]
[1]University of Western Australia, Crawley, WA, Australia
[2]Cooperative Research Centre for Australian Weed Management, Adelaide, SA, Australia

Australia has a long history in weed biological control, beginning in 1903 with the program to manage the prickly pear cactus, *Opuntia stricta* and other related cacti. Following the overwhelming success of this program, there have been over 180 insect biocontrol agents released against more than 50 species of weedy plants in Australia. Approximately 69% of these agents have established and are contributing to the management of the target weed; others have not established or are still under evaluation. These programs have targeted agricultural, pastoral, rangeland, aquatic and environmental weeds in tropical and temperate regions across Australia. Over the last one hundred years, Australia has had almost as many weed biocontrol programs as the USA and remains a world leader in the theory and practice of this discipline.

History

The potential risk of biological control agents to non-target plants was recognized from the start of biological control programs in Australia. The prickly pear biological control program was the first in the world to undertake proper host-testing trials, where the potential agents were confined to crop plants to determine if any feeding occurred. These tests are fully described in Alan Dodd's 1940 publication. No native Australian plants were tested, presumably because they were not perceived to have economic value. As there are no native Cactaceae in Australia, attack on additional cactus species was considered beneficial because these cacti were also actual or potential weeds.

Host specificity testing on plants of economic value using "no-choice" or starvation trials (where the feeding stage of the insect is confined in a cage until they die) continued to be used in all Australian weed biocontrol programs until the 1970s. Approval for the release of agents was granted by the Federal Plant Quarantine Authority and host-specificity testing protocols were gradually developed. Starting in the mid-1970s, test plant lists increasingly focused on plants related taxonomically and, later, phylogenetically, to the target weed. Since 1985, the federal conservation/environment authority also has to grant approval for release, and native plants are now included in the tests. Choice testing was increasingly used, where the potential agent is given a choice with the test plant and the target weed together in the cage. Since the 1990s, a mixture of choice and no-choice tests has become standard, and applications to release agents are made available on the internet for public comment prior to approval.

There have been very few instances of direct and significant non-target impacts recorded in Australia. One of the most notable is that of *Aconophora compressa* Walker (Hemiptera: Membracidae) from Mexico. In the 1990s this agent was released against *Lantana camara* L. (Verbenaceae), a major weed in Australia. Shortly after establishment it began feeding on certain ornamental (non-native) plants in

Brisbane, Queensland. This example highlights the necessity to conduct more research into non-target impacts and the refinement of host-specificity testing. In Australia, such work is currently underway under the auspices of the Cooperative Research Centre for Australian Weed Management.

Australia was also the first country to release a plant pathogen as a weed biocontrol agent. In 1970, the rust disease, *Puccinia chondrillina* Bubak and Syd., from Europe was released against skeleton weed, *Chondrilla juncea* L. (Asteraceae), a major weed of wheat crops. The release resulted in very successful control of the weed and has been followed by increased use of pathogens as agents, although not all have been as successful.

Conflicts of interest over the release of biological control agents to control the pasture weed Paterson's curse, *Echium plantagineum* L. (Boraginaceae), led to the introduction of the *Biological Control Act* in 1984. This Act is the first of its kind worldwide that specifically addresses the need to balance the interests of those who receive benefits from the weed and those who want the weed population reduced. The Act has since been used to resolve conflicts over the release of biological control agents for blackberry and also rabbits. However, most potential conflicts are minor and are resolved without resort to the Act.

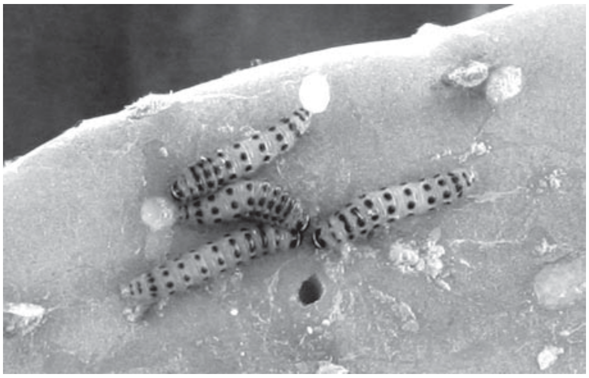
Programs Undertaken

The following examples of Australian weed biological control programs highlight the variety of invasive plants that have been targeted, the agents used and some of the issues related to weed biological control that have arisen:

Prickly Pear, *Opuntia* spp. (Cactaceae)

The first and iconic program was the biological control of prickly pear cacti, *Opuntia* spp. Prickly pear cacti were introduced into Australia in the 1800s as ornamental plants, as hedges and as the basis of a cochineal industry. There were several species introduced, including *O. stricta, O aurantiaca*, and *O. monacantha*. These plants have naturalized in Australia in semi-arid savannas, warm temperate, subtropical and tropical regions and in shaded and exposed areas. *Opuntia stricta* was first noted in rangeland areas in NSW in 1839 and by 1900 covered four million hectares. By 1926, it had expanded to cover 24 million hectares, rendering the land unusable for either grazing or cultivation.

The Commonwealth Prickly Pear Cactus Board was established in 1920 to address the cactus problem; although exploration for biological control agents began as early as 1903. As many as 150 potential agents were discovered, of which fifty were imported into Australia for host-testing. Of those released, twelve agents established. Within six years following the 1925 release of the moth *Cactoblastis cactorum* (Bergroth) (Lepidoptera: Pyralidae) (Fig. 24) more than 90% of prickly pear had been destroyed (Fig. 25). In areas where *C. cactorum* was not as effective, other agents have been effective at reducing vigor and stands of *Opuntia* spp. While there are still areas in Australia infested by prickly pear cacti, the impact of these plants is now minor and the patches are soon



Weed Biological Control in Australia, Figure 24 ***Cactoblastis cactorum*** **(Lepidoptera: Pyralidae) larvae on *Opuntia* cactus. This species is responsible for one of the most effective weed biological control programs in the history of biological control (photograph by Lorraine Edmunds).**

Weed Biological Control in Australia, Figure 25 **Prickly pear cactus pads collapsed following feeding by *Cactoblastis* larvae (photograph by Lorraine Edmunds).**

Weed Biological Control in Australia, Figure 26 ***Cyrtobagous salviniae* (Coleoptera: Curculionidae) effectively suppressed salvinia in Australia (photograph by Scott Bauer).**

identified by the biological control agents. It has been estimated that the investment of Au$19 million (2005 values) in the years between 1911 and 1930 resulted in a return of Au$3.1 billion in increased production, which equates to an astonishing cost-benefit ratio of 312:1.

Salvinia, *Salvinia molesta* D.S. Mitch (Salviniaceae)

Salvinia is a free-floating aquatic fern native to South America that was imported to Australia as an ornamental plant for ponds and aquaria. It was widely distributed and rapidly escaped into dams and waterways where it disrupted water flow, nutrient cycling and recreational use, and favored populations of disease-vectoring mosquitoes. The biomass in some areas was estimated to be 400 t/ha, and the plant is arguably the world's worst weed. During the 1960s and 1970s, unsuccessful attempts were made to control the weed in Africa using insects from northern South America. In 1977, the weed was correctly identified as *Salvinia molesta* from southern Brazil, and searches for agents were subsequently made in that area. The weevil *Cyrtobagous salviniae* Calder and Sands (Coleoptera: Curculionidae) (Fig. 26) was discovered, introduced into Australia in 1980, and very quickly established and controlled the weed. This success has since been repeated throughout the tropics where salvinia is a problem.

Lantana, *Lantana camara* L. (Verbenaceae)

This is a thicket-forming shrub native to tropical Central America. It was introduced into Australia as an ornamental plant in the 1800s and is now a highly invasive weed along the eastern coast of Australia. This plant severely reduces pasture productivity and is also toxic to livestock. Annual losses are estimated to be Au$104.3 million with an additional Au$10 million spent in control. In addition, lantana invades forest plantations and natural systems where it threatens plants and animals of conservational significance. It became the first weed in the world targeted for biological control in 1902, when agents were sought for infestations in Hawaii. Since then, lantana has been a target of biological control in several areas around the world. In Australia, the lantana biocontrol program began in 1914 and now 30 biocontrol agents have been released, 29 insects and 1 rust fungus, at an estimated cost of Au$13.6 million. Seventeen of the agents are considered established, but only four are believed to have any significant impact on the plant. The biocontrol program on lantana has contributed to an increase in pasture productivity and reduced the threat to natural environments, but the overall effect is minor, estimated at less than 10%. A related species, *Lantana montevidensis* (Spreng.) Briq., was also targeted for biocontrol, but only two species of agents were released and neither established.

Lantana is a particularly difficult weed to control because it is an artificially produced hybrid of two or more species from Central America. The hybrids were developed by gardeners in Europe in the 1700s and then planted around the world, and it has proved impossible to locate the parent plants in their native habitat. Modern genetic techniques are now being used to identify different lantana varieties and their parent plants, in the hope that this may lead to improved success.

Paterson's Curse, *Echium plantagineum* L. (Boraginaceae)

Paterson's curse is a winter annual weed in southern Australian pastures and can also be found along roadsides and bushland reserves. It was introduced to Australia as an ornamental plant in the 1800s and is currently found as a weed across large grazing areas, sometimes becoming the dominant plant. This highly competitive plant can be grazed in small quantities by sheep but is toxic to other stock. The search for biological control agents began in 1972 and the first of seven agents, the leaf-mining moth, *Dialectica scalariella* (Zeller) (Lepidoptera: Gracillariidae), was released in 1980. It failed to establish and was reintroduced in 1989 after which it did establish but has not contributed significantly to control. A crown feeding weevil, *Mogulones larvatus* Schultze (Coleoptera: Curculionidae), successfully established from releases in 1992 and is contributing to reductions in the weed. In 1993, the tap root-feeding species *Mogulones geographicus* (Goeze) (Fig. 27) was released and established and is also contributing to control. At the same time, four other insect species were introduced. Three have established, but only one of these, *Longitarsus echii* (Coleoptera: Chrysomelidae), appears to be exerting any significant pressure on Paterson's curse.

Weed Biological Control in Australia, Figure 27 (*top*) *Zygina* sp. leafhopper (Hemiptera: Cicadellidae) was released for suppression of bridal creeper in Australia (photograph by Rick Roush); (*bottom*) *Mogulones geographicus* (Coleoptera: Curculionidae) attacks the roots of Paterson's curse (photographer unknown).

Bridal Creeper, *Asparagus asparagoides* Druce (Asparagaceae)

Bridal creeper was introduced to Australia from South Africa in the 1800s as an ornamental plant and was used in bridal floral arrangements. Now a major weed across southern Australia, this creeper forms dense tuberous mats just below the soil surface and the foliage climbs over and smothers native vegetation. This plant can invade undisturbed native bushland, has become a significant problem in national parks and other conservation areas throughout southern Australia, and is thought to be responsible for the extinction of two native orchid species. It is also a problem in citrus orchards and pine plantations.

The first of three biological control agents was released in 1999. *Zygina* sp. (Fig. 27) (Hemiptera: Cicadellidae) nymphs and adults feed on the mesophyll cells of the cladodes and at high numbers can cause defoliation. The leafhopper is well-established and has had some impact on the plant. However, populations of *Zygina* have been reduced by a native parasitoid, an undescribed fairyfly, *Stethynium* sp. (Hymenoptera: Mymaridae), which lays its eggs in the leafhopper eggs. Nothing is known of the parasitoid's native hosts or of the impact of *Zygina* on the population dynamics of the wasp, and thus of its native hosts.

The second biological control agent, the rust fungus *Puccinia myrsiphylli* (Thuem.), was released in 2000 and is now having a significant impact on bridal creeper in most areas across southern Australia. A leaf beetle, *Crioceris* sp. (Coleoptera: Chrysomelidae) was released in 2002 and although establishment has been confirmed at a few release sites, it is too early to fully evaluate its impact on bridal creeper.

It is already evident that bridal creeper populations are beginning to be reduced; however, it appears that this plant has modified the communities in which it invades in such a way that additional effort to restore the native plant communities, following bridal creeper invasion and retreat, will be necessary. Replacement of bridal creeper by other plants of South African origin is already apparent.

Weedy Trees

Several woody trees have become weedy in Australia, and four have become targets of biological control programs: mimosa, *Mimosa pigra* L. (Fabaceae), parkinsonia, *Parkinsonia aculeata* L. (Fabaceae), prickly acacia, *Acacia nilotica* subsp. *indica* (Benth.) Brenan (Fabaceae) and mesquite, *Prosopis* spp. (Fabaceae). Mimosa first naturalized in the Darwin botanical gardens in 1891 and thereafter around Darwin as an inconspicuous tree. Parkinsonia, prickly acacia and mesquite were deliberately planted as shade trees in northern Australia around homesteads and watering points on cattle stations and have since become widespread in the Northern Territory, Western Australia and Queensland. Mimosa has been successfully contained to the Northern Territory and one small infestation in north Queensland. However, if unmanaged it will rapidly invade wetland areas throughout the north. These plants produce large numbers of seeds that are viable for decades. All three trees have large thorns and form dense impenetrable thickets that reduce pasture productivity, interfere with the mustering of stock and restrict access of stock to water. Mimosa is also a significant problem in conservation areas, and prickly acacia is a threat to native Mitchell grass plains.

The first releases of biological control agents against mimosa began in 1983. A total of 13 agents have been released at a cost of approximately Au$21.6 million (2005 values). Nine of these agents have established of which two, *Neurostrota gunniella* (Busck) (Lepidoptera: Gracillariidae), a tip-boring moth, and *Carmenta mimosa* Eichlin & Passoa (Lepidoptera: Sesiidae), a stem-boring moth, are already reducing the mimosa stands and restricting spread of infestations. Before *N. gunniella* was released it was noted that the moth was likely to attack non-target native plants in the genus *Neptunia* (Fabaceae). However, the cost of the potential non-target impact was weighed against the current and future impact of unchecked mimosa populations, and the release was approved. A recent study evaluating non-target impact on *Neptunia* revealed that only plants close to mimosa infestations are attacked by *N. gunniella*, and at a lower rate of attack than that on mimosa. Other studies have shown that mimosa is best managed through an Integrated Weed Management approach combining fire, herbicides and mechanical removal with the impacts of the biological control agents.

The parkinsonia biological control program has resulted in the release of three insect species but only one, the seed-feeding beetle *Penthobruchus* *germaini* Pic (Coleoptera: Chrysomelidae) has established. Unfortunately, the eggs of this beetle are heavily attacked by native parasitoids and as a result, impact on the weed is minimal.

The prickly acacia biological control program has resulted in the release of seed-feeding beetles that established but are ineffective. Other agents released in the 1990s failed to establish. A leaf-feeding moth, *Chiasmia assimilis* (Warren) (Lepidoptera: Geometridae), originating from South Africa has established and is causing severe damage to trees near the coast and is now spreading inland into more arid areas.

The mesquite biological control program began in 1992. Several insects have been released but only one, a leaf-tying moth, *Evippe* sp. (Lepidoptera: Gelechiidae), (Fig. 28) is having any impact. The moth causes defoliation of the plant and weakens it, making it more manageable by herbicides. Seed-feeding beetles released in the 1980s are also established but ineffective. As with mimosa and parkinsonia, Integrated Weed Management using several techniques is an essential approach for the control of mesquite. These plants cover large rangeland areas, where the costs of herbicides and mechanical control as the sole means of management are prohibitive.

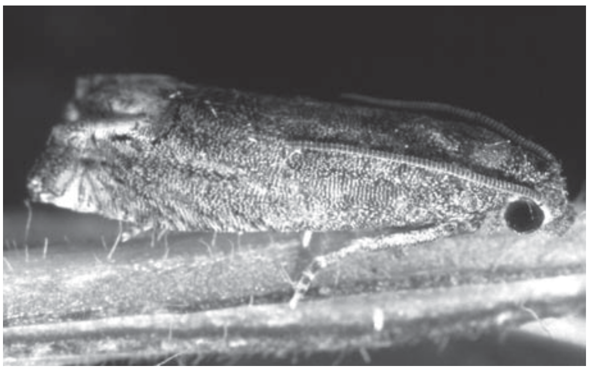
Weed Biological Control in Australia, Figure 28 Leaf damage to mesquite caused by the leaf-tying moth *Evippe* sp. (Lepidoptera: Gelichiidae) (photograph by Rieks Van Klinken).

Parthenium Weed, *Parthenium hysterophorus* L. (Asteraceae)

Parthenium is a short-lived annual herb native to Mexico. It was accidentally introduced into central Queensland in 1958 in pasture seed from the USA. It spread very rapidly until 1978 when a containment program was developed, which has slowed but not prevented further spread. Parthenium weed now infests most of the higher rainfall and semi-arid grazing and crop lands of central and north Queensland, with smaller areas in southern Queensland, which equates to a total area of at least 170,000 km^2. Parthenium is not eaten by stock and out-competes native and sown grasslands, reducing pasture productivity by 40–80%. The pollen is highly allergenic, and up to 20% of the people living in parthenium-affected areas will develop severe allergies ranging from hay fever to allergic asthma or skin conditions. Parthenium is also a serious weed of crops, but can be controlled with herbicides in grain crops, although not in sunflower. Herbicide control is not economic in pasture situations. Lost beef production from parthenium infestation was estimated in 1999 to be worth Au$17 million per year (2001 values).

Parthenium weed is a highly opportunistic annual plant with a very large persistent seed bank. Germination occurs after rain at any time of the year, and plants grow rapidly, flowering in six weeks during the summer. In winter, plants can persist as dormant rosettes to grow in spring. In the highly variable rainfall of central and north Queensland, there may be no living plants for nine months of the year. Storm rains can then lead to widespread germination, with flowering plants present in six weeks time. This presents significant challenges for biocontrol, as host-specific agents have to persist in a dormant state while the plant is absent, and emerge from dormancy at the same time as the young plants are present. For this reason, several different agents with different life cycles and dormancy strategies were introduced, in the hope that at least one would be effective regardless of the seasonal conditions.

The biological control campaign for parthenium started in 1977 and ran for 25 years, during which nine insect species and two rust diseases were imported from Mexico and from South America. All except one insect established, and all are contributing to control in some areas and seasons. The greatest benefit comes from four species: a tip-galling moth, *Epiblema strenuana* Walker (Lepidoptera: Tortricidae) (Fig. 29); a leaf-feeding beetle, *Zygogramma bicolorata* Pallister (Coleoptera: Chrysomelidae) (Fig. 30); a stem and root feeding weevil, *Listronotus setosipennis* (Hustache) (Coleoptera: Curculionidae); and a rust disease, *Puccinia melampodii* (Dictel & Holway). All four species are widespread and damaging, though their populations fluctuate with seasonal conditions. Two more species are also widespread though less damaging: a leaf-mining moth, *Bucculatrix parthenica* Bradley (Lepidoptera: Bucculatricidae), and a seed-feeding weevil, *Smicronyx lutulentus* Dietz (Coleoptera: Curculionidae). The second rust species, *Puccinia abrupta* Dictel & Holway *var partheniicola* (Jackson), and the other insects, a stem-feeding moth, *Carmenta* sp. nr. *ithacae* (Lepidoptera: Sesiidae), and a tip-galling weevil, *Conotrachelus* sp. (Coleoptera: Curculionidae), are still only present in small populations and so have minimal impact on the weed.



Weed Biological Control in Australia, Figure 29 **Moth of *Epiblema strenuana* (Lepidoptera: Tortricidae), a tip-galling caterpillar that affects parthenium weed (photograph by Rachel McFadyen).**

Weed Biological Control in Australia, Figure 30 **This leaf-feeding beetle, *Zygogramma bicolorata* (Coleoptera: Chrysomelidae) is one of the more effective biological control agents of parthenium weed in Australia (photograph by Rachel McFadyen).**

As a result of the combined effect of these agents, the impact of parthenium weed has been greatly reduced. The weed is now much easier to manage in both pastures and cropping situations, and spread has decreased significantly. Weed seed banks have reduced six-fold, from >37,000 germinable seeds/m^2 to <6,000 and they are still falling. By 1999, biocontrol had increased pasture production in affected areas by 4% and in 2006 net benefits were calculated to be worth Au$38.6 million. The impact of biocontrol continues to increase every year.

Looking Forward

The case studies presented above represent a small selection of some of the weed biological control programs in Australia. Undoubtedly, biological control can be and has been enormously successful, and has returned huge savings to the Australian economy as well as reducing the harm caused by invasive weeds and the chemical and mechanical methods used to manage them. There is a recognized need to improve the protocols and practice at each step along the path of a biological control program, from agent selection to release and post release monitoring. Australian practitioners and scientists are actively researching ways to improve selection, host-specificity assessment, establishment and evaluation of weed biological control agents. It is acknowledged that, as with other weed control tactics, there are potential risks. Every effort is made to minimize the risk and to improve the reliability of risk assessment, while concurrently aiming to improve the effectiveness of this technique. There is also a continuing effort to integrate biological control more fully into weed management plans in order to contribute to the overall health of Australian production and native systems.

Weevils, Billbugs, Bark Beetles, and Others (Coleoptera: Curculionoidea)

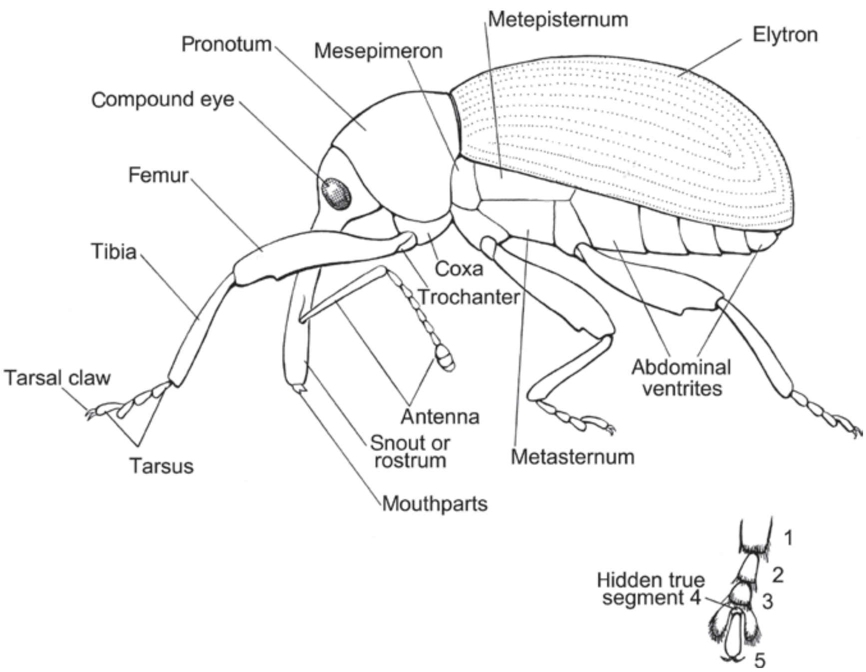
ROBERT S. ANDERSON[1], ROLF G. OBERPRIELER[2]

[1]Canadian Museum of Nature, Ottawa, ON, Canada

[2]CSIRO Entomology Canberra, Act, Australia

The superfamily Curculionoidea of the order Coleoptera is comprised of a number of related groups of beetles that, depending on the classification scheme adopted, number anywhere from 7 to 18 families. These classification issues generally focus on the ranks at which many groups are placed but placements of some groups are also disputed. The following classification represents a compromise but one must recognize that, as more evidence from immature stages and molecular methods is incorporated into analyses of relationships, this system is subject to change and refinement (Figs. 31–35).

- Order: Coleoptera
  - Superfamily: Curculionoidea
    - Family: Nemonychidae
      - Subfamily: Nemonychinae
      - Subfamily: Cimberidinae
      - Subfamily: Rhinorhynchinae
    - Family: Anthribidae
      - Subfamily: Anthribinae
      - Subfamily: Choraginae
      - Subfamily: Urodontinae
    - Family: Belidae
      - Subfamily: Belinae
      - Subfamily: Oxycoryninae
    - Family: Attelabidae
      - Subfamily: Attelabinae
      - Subfamily: Rhynchitinae
    - Family: Caridae
    - Family: Brentidae
      - Subfamily: Microcerinae
      - Subfamily: Brentinae (includes Cyladini)
      - Subfamily: Ithycerinae
      - Subfamily: Nanophyinae
      - Subfamily: Eurhynchinae
      - Subfamily: Apioninae (includes Antliarhinini)
    - Family: Curculionidae
      - Subfamily: Dryophthorinae
      - Subfamily: Brachycerinae (includes Ocladiini, Cryptolaryngini, Erirhinini, Raymondionymini)
      - Subfamily: Bagoinae
      - Subfamily: Cyclominae



Weevils, Billbugs, Bark Beetles, and Others (Coleoptera: Curculionoidea), Figure 31 Important elements in the morphology of Curculionoidea.

Subfamily: Entiminae
Subfamily: Hyperinae
Subfamily: Curculioninae
Subfamily: Ceutorhynchinae
Subfamily: Baridinae
Subfamily: Conoderinae
Subfamily: Lixinae
Subfamily: Molytinae (includes Mesoptiliini)
Subfamily: Cryptorhynchinae
Subfamily: Cossoninae
Subfamily: Scolytinae
Subfamily: Platypodinae

The weevils are one of the most diverse groups of organisms. Over 50,000 species have been described worldwide in the family Curculionidae, and their diversity among beetles is challenged perhaps only by Staphylinidae. Weevils are associated with virtually all kinds of plants and plant parts. Most feed on living plants, but some are saprophagous. Weevils are immediately recognizable by their elongate rostrum (or snout), with mouthparts situated at the apex, geniculate (elbowed) antennae (straight in the families of primitive weevils), a compact antennal club and have 5-segmented tarsi, although the fourth segment is usually very small and nestled between the lobes of the third making them appear 4-segmented. In the blind, soil-dwelling weevils of the tribe Raymondionymini of the Brachycerinae the tarsi are truly 4-segmented. The Curculionoidea are often called snout beetles but in some the head is scarcely prolonged and this name is less appropriate (e.g., Platypodinae and Scolytinae of the Curculionidae). The Curculionoidea were historically placed in a distinct subdivision of the Coleoptera called the Rhynchophora.

Certain other characters besides the development of a snout, form of the antennae, and tarsi distinguish the Curculionoidea from other beetles. The gular sutures are nearly always confluent, or lacking, with no gula developed (they are short but widely separated in the Nemonychidae). Notosternal sutures short and indistinct or deflected laterally, and in most groups the palps are rigid or not visible

and the labrum is absent (except in Nemonychidae and Anthribidae). The mouthparts are small and more or less hidden in most of these beetles. The mandibles, located at the tip of the snout, are usually the only mouthparts easily visible without dissection.

This is a large and important group of beetles. Practically all feed on plant materials, and most of the larvae are burrowing in habit, infesting, twigs, flowers, fruits and seeds. Plant associations within the superfamily appear to parallel the phylogenetic position of the weevil families. For example, many members of primitive groups such as Nemonychidae, Belidae and Caridae occur on gymnosperms such as conifers, and the hyperdiversification of the Curculionidae may have paralleled the evolution of the angiosperms. The larvae are whitish, usually C-shaped, more or less cylindrical, with legs present in the primitive weevil families but reduced or lost in the more derived groups. A great many weevil species are of considerable economic importance as pests of field or garden crops, of forest, shade and fruit trees, or of stored products. Recently, many species have been introduced worldwide for the biological control of various noxious alien or pest weeds.

Family Nemonychidae, Pine-Flower Snout Beetles

This is a small group, with about 70 species worldwide placed in 21 genera in three subfamilies. These beetles are 3.0–6.0 mm in length, the antennae are straight with a loose club, and the snout is usually about as long as the prothorax and apically somewhat flattened and narrowed at the base. They differ from nearly all other families of Curculionoidea (except Anthribidae) in having the labrum distinct and the palps flexible. Adults possess the unique feature of tergite 9 being desclerotized to a narrow, well-pigmented, sharply defined band arching over sternite 9. Larvae are recognized by the frons being produced forward into a pseudoclypeus, mandibles having a diagonal masticatory ridge, and the frontoclypeal suture being effaced (also in some Anthribidae). Larvae of these beetles develop in the male cones of various conifers (Araucariaceae, Phyllocladaceae, Podocarpaceae, and Pinaceae). Adults are also usually found on conifers, but may occasionally be found on flowers of other plants. European species in the genus *Nemonyx* develop on Ranunculaceae and South American species of the genus *Rhynchitomacer* are on *Nothofagus* (Nothofagaceae). Nemonychids are found primarily in Europe, North, Central and South America, Australia (including New Caledonia and Papua New Guinea), and New Zealand. They are most diverse in the northern and southern temperate regions with few species known from the tropics. Numerous fossils have been described from the Jurassic of Kazakhstan and several Lower Cretaceous deposits (Eobelinae), but the family is absent from the Cenozoic fossil record.

Family Anthribidae, Fungus Weevils

The anthribids are elongate-oval, 0.5–20.0 (usually less than 10.0) mm in length, with the snout short, broad and flattened, and the antennae not elbowed. A distinct labrum is present as in Nemonychidae. Some species have slender antennae that may be longer than the body (hence they look like some Cerambycidae), and others have short antennae with a three-segmented club. The elytra always cover the base of the pygidium, which is always partly exposed in lateral view but is usually not visible from above. Adults are unique in that their notosternal suture is represented by a weak and transverse line extended vertically to the notum. Larvae possessing more than five setae on the frons (also in Nemonychidae). There are just over 3,000 species worldwide placed in 374 genera in three subfamilies. They are widely distributed and often very common in tropical regions. Though some adults feed on pollen, most browse on fungi and lichens. Urodontinae are found in southern Europe, Asia and Africa where they are associated with various plants, the larvae developing in stems or seed capsules. Members of the Choraginae are associated with seeds whereas the Anthribinae occur in association with rotten wood, on dead twigs or beneath loose bark affected by fungi. The larvae vary in habits. Some develop in woody fungi, some are in the fungi of certain crops (for example, corn smut), some feed in seeds, and a few bore in dead wood. The widely introduced coffee bean weevil, *Araecerus coffeae* (F.) is an important pest of seeds, berries, and dried fruits. Some species of *Anthribus* are predators on eggs of coccid scale insects. Anthribidae are known in the fossil record from the late Lower Cretaceous and more commonly from the Cenozoic in Europe and the United States.

Family Belidae

This is an odd and small group of primitive weevils found in North, Central and South America, the West Indies, Australia (including Papua New Guinea, New Caledonia and adjacent islands), New Zealand, Canary Islands, Northern Africa, South Africa, Southeast Asia, and the Pacific Islands. The family contains about 375 species placed in 39 genera in two subfamilies. Adults vary in length from 2.0 to 20.0 (most 8.0–15.0) mm and quite markedly in form as well. Some are very long, slender and cylindrical (Australian Belinae; *Araiobelus, Leptobelus*) whereas others are oval and flattened, with large front legs in the males and the elytra short, exposing the last few tergites (Allocorynina). All are characterized by straight antennae, often basally situated on the long cylindrical snout, the foretibia with a broad, apical groove or impression covered in fine vestiture on the inner face, and the spermatheca sometimes atrophied or absent. Larvae have the head deeply and permanently retracted and attached to the prothoracic shield by heavy musculature. Plant associations in the group are particularly varied and interesting. The Oxycoryninae are associated with Arecaceae (*Metrioxena*; Southeast Asia), Zamiaceae (*Afrocorynus*; Africa), Vitaceae (*Hispodes*; Africa), Araucariaceae (*Oxycraspedus*, South America), Zamiaceae (Allocorynina, North and Central America, West Indies), and the root parasitic Balanophoraceae and Hydnoraceae (Oxycorynina, Central and South America). Larvae of Aglycyderini mostly feed under bark of dead or dying twigs and branches of a variety of plants but some *Proterhinus* larvae mine in living leaves. In the Belinae of Australia, plant associations include cones and branches of Araucariaceae, twigs or branches of *Acacia* (Fabaceae), some Proteaceae, and wood of *Eucalyptus*. South American Belinae appear to be associated with ferns. Adults of the tropical American *Rhopalotria* and *Parallocorynus* (Allocorynina) are intimately involved in pollination of cycads. No authentic fossils of Belidae have been recorded from the Mesozoic era, but Oxycoryninae are known from the Cenozoic.

Family Attelabidae, Leaf-Rolling and Tooth-Nosed Weevils

This family combines two subfamilies, the Attelabinae and Rhynchitinae. Despite their different structure and biology the two are grouped together based on unique features of the larvae (epicranium with hyaline posterior extension) and adults (males with the 8th sternite fused or articulated to the 9th sternite on each side beyond the arms). Both groups also share straight antennae and a unique feature of a nervous system with the abdominal ganglia fused into one conglomerate. There are about 2,500 species placed in 150 genera, almost equally divided between the two subfamilies. They are found almost worldwide (with the exception of New Zealand and the Pacific Islands other than New Caledonia) and are most diverse in the tropics. The family is almost exclusively associated with dicot angiosperms but a few Rhynchitinae are associated with the conifer families Pinaceae and Cupressaceae.

Attelabinae, the leaf-rolling weevils, are short and robust, mostly 3.0–12.0 mm in length. Many of them are black, reddish, or black with red markings. The most interesting characteristic of this group is their method of laying eggs, from which their common name is derived. When a female is ready to oviposit, she cuts two slits near the base of the leaf, from each edge to the midrib, and rolls the part of the leaf beyond these cuts into a neat and solid ball. A single egg is laid near the tip of the leaf, usually on the underside, before the leaf is rolled up. She then gnaws the midrib of the leaf (at the end of the basal cuts) partly in two, and the leaf roll usually eventually drops to the ground. The larva feeds on the inner portion of this leaf roll and pupates either in the roll or in the ground. Generally, young or freshly emerged leaves are preferred as food. Some tropical attelabids have a mutualistic relationship with fungi which grow in the leaf rolls. The Latin term "nidus" (nest), is used for such leaf-rolls.

American attelabine "thief" weevils of the genus *Pterocolus* are brood parasites of their relatives, the leaf-rolling weevils in the Attelabinae. Adults of these small metallic blue weevils enter leaf rolls of various attelabines, destroy the eggs, and lay their own eggs. The larvae then feed in the leaf rolls that were prepared by the host attelabines.

Attelabinae can be recognized by a number of unique features: prementum broad and heavily sclerotized with apical dentiform projections; tibiae without spurs but with a large uncus; tarsal claws connate; and thoracic spiracle of the larva situated on the mesothorax or the intersegmental fold in front.

Rhynchitinae, the tooth-nosed weevils, are so named because of the teeth on the outer edges of the mandibles. They are generally 2.0–8.0 mm in length and usually occur on low vegetation. This subfamily has a couple of unique features which allow for its recognition; thin and exodontous (toothed on the outer face) mandibles, and free appendiculate tarsal claws.

As with the Attelabinae, Rhynchitinae prepare a nidus for the development of their larvae. Most oviposit in buds or shoots that are made to wilt by gnawing a basal cut disrupting the sap flow of the plant. Such a damaged terminal shoot may fall off the plant immediately or after a period of time, or may remain on the plant. Larvae develop in the terminal shoot. Larvae of *Lasiorhynchites* tunnel inside the wood of the branches of their host plants. Some species of the tribe Rhynchitini use fruits or flower buds for oviposition and can be severe orchard pests. Some other tropical species are reported to develop in seeds. Species of the Eugnamptini are leaf-miners on fresh or fallen leaves.

Attelabidae appear to have adopted a series of behaviors allowing their larvae to feed "internally" on leaves without being subject to the constraints on body form and size placed on other leaf mining insects.

A few tentative fossils of Attelabidae are known from the early Upper Cretaceous of Botswana and the United States, but the family is well represented in the Cenozoic fossil record in Europe and the United States.

Family Caridae

This is a very small and only recently recognized family of problematic position. Only four (plus one that is not yet named) genera and about 20 species are known. They are found in Australia (including New Guinea, Tasmania), Chile and Argentina. Adults are less than 5.0 mm in body length, have straight antennae, have only five pairs of abdominal spiracles and also a club-like spermathecal gland. Larvae have legs with claws, a feature not found in any other curculionoids except *Nemonyx* (Nemonychidae). All appear associated with various Cupressaceae. A number of carid fossils have been found in Lower Cretaceous deposits in Russia and the United States but several others classified as such have been misinterpreted.

Family Brentidae, Straight-Snouted and Pear-Shaped Weevils

Despite their remarkably different sizes and appearances (compare representatives of Brentinae and Apioninae), this family combines six traditionally distinct groups, some of which are of very restricted geographic distribution and diversity. Collectively the group is recognized by straight antennae (geniculate in Nanophyinae), and especially by the features of an aedeagal tegmen which is almost or completely interrupted halfway up the sides, ventrites 1 and 2 of the abdomen more convex and protruding that ventrites 3–5, the labial palps reduced to only two segments or to one in Brentinae, with only four Malpighian tubules on the hindgut (six in most other weevils) and tergite 8 of the male (pygydium) capsule-like with an inflected, tongue-like posterior margin. Members of this group exhibit a wide range of plant associations and natural history features.

Brentinae are narrow, elongate, cylindrical beetles, 5.0–42.0 mm in length, usually reddish or brownish and shining, with the snout projecting straight forward. Sexual dimorphism is often marked with the snout generally longer and more slender in the female than in the male and the head, pronotum or other structures often of a very different shape or form. In some species the elytra of males have long caudal extensions. Males of a number of species may fight or joust with other males over the attentions of a female. This group is distributed worldwide and principally tropical with only a very few species extending into temperate regions. Most adults occur under the loose bark of dead or dying trees. The larvae are wood-boring and will sometimes attack living trees. Brentinae can be divided into three main groupings based on their biology; the true wood borers (eggs laid in bark or sapwood and larvae boring into the wood), those whose larvae bore tunnels in wood from eggs laid inside the tunnels of other wood boring insects (often scolytine and platypodine weevils, or Cerambycidae), and lastly, those species that are associated with ants (myrmecophiles). Few details on the nature of their associations with ants are known, but some species have bizarre structures, particularly of the hind legs and the apex of the elytra. Most Brentinae are active at night. In the fossil record, they are know only from Pleistocene African copal.

The predominantly African Cyladini, or sweet potato weevils, are here included in Brentinae. They are antlike, slender, elongate, and 5.0–6.0 mm in length. They are easily recognized by the straight antennae and basally pedunculate pronotum. The group comprises a single genus, *Cylas*, with 24 species. These weevils are not well known even though *Cylas formicarius* (F.) is a widely introduced tropical species that is a serious pest of sweet potatoes anywhere they are grown. Its larvae tunnel in the tubers and may continue to do so after they are harvested, and adults may emerge after the sweet potatoes are in storage or on the market. Other species also bore into sweet potato tubers, while the more globose species develop in the seed capsules of other *Ipomea* species (Convolvulaceae).

Apioninae are small (3.0–7.0 mm in length or less), somewhat pear-shaped, usually blackish in color. Most of the almost 2,000 species belong to the traditional genus "*Apion*" (based on features of internal morphology, now subdivided into 20 or more genera), nearly all of which occur on dicot angiosperms (notably Fabaceae and Asteraceae). Exceptions are a few localized species living on Pinaceae (*Podapion*; North America) and Cupressaceae (*Strobilobius*; New Zealand). Larvae bore into the seeds, stems, and other parts of the plant. Adults can easily be recognized by their black, small pear-shaped form, straight antennae and an elongate trochanter (also in Nanophyinae). Some species have been introduced for biological control of pest weeds. For example, in North America, two species of *Exapion* have been introduced for biological control of gorse, *Ulex europaeus* L. and scotch broom, *Cytisus scoparius* (L.) (both Fabaceae), and one species of *Omphalapion* for control of scentless chamomile, *Matricaria perforata* Mérat. A few other species are adventive (introduced accidentally by humans into areas where they are not native). The earliest fossils date to Upper Eocene deposits in the United States and Europe.

Apioninae here include Antliarhinini, a small group of exclusively African species comprising only two genera and seven species. Some species exhibit extreme sexual dimorphism of the rostrum with the male snout short and stout but that of the female almost ridiculously long and slender (especially in *Antliarhinus zamiae* [Thunberg]) and used for drilling deep oviposition holes into cycad cones. Unique morphological features appear to be associated with life in the tight spaces in cycad cones. Species are associated only with cycads of the genus *Encephalartos*, an association that appears to be little changed since perhaps the Late Cretaceous. Their larvae develop in female cones boring in the sporophylls (scales) and central axis and sometimes the seeds. No confirmed fossils are known; one species described as such, *Antliarhinites gracilis* Heer, is a hemipteran.

Microcerinae are a distinct group of sub-Saharan African weevils comprising only three genera and 67 species. They are most diverse in the arid regions of South Africa. They are recognized by the unique features of the ovipositor, featuring flat to slightly scooped, pointed hemisternites with a lateral, non-setose stylus and also their mostly dense covering of scales and a short, stout rostrum. Some other characters suggested as unique to the group, for example, labial palps set in pits or grooves, are shared with other Brentidae. They are flightless and their elytra are fused, and they are very cryptic on the stony or sandy substrates of their habitats. Little is known about biology but larvae, as known, feed on roots in the soil. Once considered to be related to Brachycerinae and basal groups of the Curculionidae, larval characters now suggest a placement within Brentidae. No fossils are known.

The Ithycerinae includes a single species, the New York weevil, *Ithycerus noveboracensis* (Forster), which occurs in eastern North America. This beetle is shiny black, clothed with patches of gray and brown pubescence, and a yellowish scutellum. It is quite large at 12.0–18.0 mm in length. The adults occur principally on the limbs and foliage of hickory (Juglandacae), oak (Fagaceae), and beech (Betulaceae) trees. The larvae feed on the roots of these same trees. This species is often placed in its own family. Despite its rather different appearance, its genitalia and several other features indicate a relationship with Brentidaeas has been suspected for many years.

Most often confused with true Curculionidae because of their small size (3.0–6.0 mm) and geniculate antennae, Nanophyinae number about 300 species in 30 genera. They are found almost worldwide except for Central and South America. They are closely related to Apioninae and share the unique feature of an elongated trochanter. Little is know about their natural history, but most Palearctic species are associated with plants of the family Lythraceae, especially the genus *Lythrum*. Other host plants are Cupressaceae, Crassulaceae Dipterocarpaceae, Tamaricaceae and Ericaceae. Australian species live on aquatic plants and some African species develop in *Acacia* seeds. Larvae are associated with the fruits, leaves and stems and many appear to cause galls. Species have been introduced into North America for biological control of purple loosestrife, *Lythrum salicaria* L. A single fossil has been described from the Oligocene in Europe but needs reassessment.

Eurhynchinae are a small group of rare brentid weevils found exclusively in Australia and New Guinea. Only three genera and 30 species are known, although the New Guinean fauna has been very poorly explored. Within Brentidae, the Eurhynchinae possess a large number of primitive features but are characterized by the unique features of an emarginate protibial apex, submedially inserted labial palps, and a pair of bar-like sclerite in the membrane of the ovipositor. Very little is known of their natural history, but adults on leaves and larvae tunnel in the stems of plants in the families Proteaceae and Lauraceae and perhaps also Myrtaceae. Two fossil taxa are described from Southern Africa and possibly South America.

Family Curculionidae, Snout Beetles Including Bark and Ambrosia Beetles

The members of this family are by far the most commonly encountered Curculionoidea. They may be found almost everywhere, and although more than 50,000 species in more than 4,600 genera are known, this is probably only a small portion of the true diversity of the group. Weevils occur in all climates and all world regions from the extreme High Arctic of Canada to the far southern Subantarctic Islands. The subfamilial classification is outdated and needs a comprehensive phylogenetic revision. Herein, 16 subfamilies are recognized.

Members of this family are plant feeders in both living and dead plants, and many are serious pests. Almost every part of a plant may be attacked, from the roots upward. The larvae usually feed inside the tissues of the plant (including leaves) but some (Hyperinae, Ceutorhynchinae, Cionini, Gonipterini) feed externally on plant foliage. Adults may feed on leaves or parts of developing reproductive structures. Most species are host plant specific to some degree, often at the plant generic level. Both terrestrial and aquatic plants are used as hosts. Monocot plants are rarely fed upon by other Curculionoidea but numerous taxa of Curculionidae count them as hosts. Many weevil species have been introduced globally as biological control agents of weeds. A very few species appear to be associated with ants (some Cossoninae; Acamptini: and Cryptorhynchinae; *Crematogasterobius* in tropical America, *Myrmecolixus* in southern Africa). Larvae of the Australian genus *Tentegia* (Cryptorhynchinae) develop in dung, the adults rolling the fecal pellets of marsupials with adaptations (such as long hind legs) similar to those of the dung rolling scarab beetles. Only one known weevil, the South American *Ludovix fasciatus* (Gyllenhal), is a predator of grasshopper egg cases deposited into stems of the water hyacinth *Eichhornia crassipes*.

Most weevils, when disturbed, will draw in their legs and antennae, fall to the ground, and remain motionless. Many are cryptic and colored like bits of bark or dirt, and when they remain motionless they are very difficult to see. Many species (especially Conoderinae) are involved in mimicry complexes with other insects. A great variety of weevils are able to stridulate by rubbing the dorsum of the terminal abdominal segments against file-like ridges on the underside of the elytra. These sounds are often extremely weak and usually can be heard only by holding the insect close to one's ear.

Weevils show considerable variation in size, shape, and the form of the snout ranging from as long as the body (e.g., Curculioninae: *Curculio*) to absent (e.g., Scolytinae, Platypodinae and some Cossoninae). Diversity in other features of morphology is immense. Geniculate antennae, a tightly compact antennal club, spermatheca with gland and duct distinctly separate and the structure of the metendosternite characterize adult weevils. Larvae have frontal sutures that do not meet the mandibular membrane and the antennae are not completely enclosed by the frontal plate, legs are absent (expanded pedal lobes are present in some species), there are three or four dorsal abdominal folds, postoccipital condyles of the head are present and conspicuous, antennae are 1-segmented on a basal membranous cushion, and the mandibular mola is generally undeveloped.

The diversification of Curculionidae may be best attributed to their parallel evolution with angiosperms as well as the coaptation of the snout for use as an ovipositor facilitating the circumvention of evolutionary barriers to a plant-feeding way of life (i.e., host plant structural defenses, desiccation in the immature stages, and initiation and maintenance of attachment to host). The oldest known fossil curculionids are recorded from the Upper Cretaceous of Botswana and Kazakhstan (yet undescribed); older forms from the Late Lower Cretaceous of Russia assigned to Curculionidae are probably misinterpreted.

There are numerous differences of opinion regarding the limits of the family Curculionidae. Some classifications recognize Brachycerinae, Dryophthorinae and Erirhininae as separate families based on the primitive structure of their male genitalia. The Scolytinae and Pladypodinae, traditionally recognized as distinct families, are now considered to be best classified within Curculionidae. Relationships between most remaining Curculionidae are very poorly known and the classification used herein is traditional and without a strong modern phylogenetic basis.

Subfamily Dryophthorinae – Billbugs, Palm and Grain Weevils

These beetles are stout-bodied and cylindrical, usually red and/or black, and range in size from 3.0 to 30.0 mm or more. There are about 1,200 species in some 150 genera. Some of the largest weevils known belong to this group. The group is primarily tropical with some species (mainly of the genus Sphenophorus) extending into temperate zones. The antennae arise close to the eyes, and the apex of the scape reaches posterior to the eye, the basal two-thirds or more of the antennal club are smooth and shining and the prementum is deeply sunk into the oral cavity. Specialized internal features are the concealment of the 8th tergite under the seventh, the eighth sternite lacking an apodeme, the ninth sternite being reduced in size and form or absent, the tegmen with strong vertical ring and lacking parameres, and the aedeagus basally with a lateral line below the insertion point of the apodemes. The male genitalia are of a primitive type with the ventral pedon and dorsal tectum mostly still discernible (though not as distinctly as in Brachycerinae and all primitive Curculionoidea), not fused into a cylindrical tube as in other Curculionidae. There are few doubts as regards their monophyly but this latter feature of primitive genital structure has led some authors to remove Dryophthorinae from Curculionidae and to give them familial status, thus preserving a more likely monophyletic Curculionidae (as defined by their advanced genital structure).

Nearly all species are associated with monocot angiosperms, especially palms (Arecaceae) and grasses (Poaceae) and sedges (Cyperaceae) and their relatives. Orchids, bromeliads and pandans are also attacked. Larvae generally mine the fleshy stems or roots but some species occur in decayed wood or dried stored products. One of the largest species is *Rhynchophorus palmarum* (Linnaeus), which may be over 30 mm in length and occurs on palms. The diverse genus *Sphenophorus* includes the corn billbugs, which occur on various grasses including timothy and corn. The adults feed on the foliage and the larvae bore into the stalks. Among the most important pests in this group are the granary weevil, *Sitophilus granarius* (L.), and the rice weevil, *S. oryzae* (L.). These are small brownish beetles, 3.0–4.0 mm in length, that attack stored grain (wheat, maize, corn, rice, and so forth). Both adults and larvae feed on the grain, and the larvae develop inside the grains. Other dryopthorine species are pests of bananas, palms, sugarcane, bromeliads and orchids.

Subfamily Brachycerinae

This is a small group of weevils of an interesting and important phylogenetic position. Traditionally it has included only the African and circum-Mediterranean genus *Brachycerus* (and a few close relatives) but its concept here incorporates the Ocladiini, Cryptolaryngini, Erirhinini and the blind, soil-dwelling Raymondionymini. All share the primitive tactopedal form of male genitalia with a separate pedon and tectum. As with Dryophthorinae, some authors separate them as a distinct family or families.

Brachycerini have generally been related to the Microcerinae (here and now generally treated as Brentidae) but based upon the derived features of larvae lacking legs and having 3–4 abdominal folds, they are here considered as Curculionidae. The completely flat larval antennal sensorium characterizes the tribe as monophyletic (although the feature is shared with Byrsopina). As in Entiminae, adult Brachycerini possess deciduous mandibular processes used by newly emerged adults to escape the earthen pupal cells. It is unclear whether these character agreements are phylogenetically significant or convergent in these two groups. Where known, Brachycerini are associated with succulent Liliaceae and related monocots, the larvae feeding in the underground bulbs or stems of the plants. There are around 500 species in 13 genera.

The African and Asian Ocladiini are also placed near the Brachycerini. Evidence for a close relationship between Brachycerini and Ocladiini is in the form of the male genitalia and structure of the larvae. *Ocladius* occurs mainly in arid regions of Africa and the Mediterranean, its larvae, where known, developing in grasses, whereas the larva of *Desmidophorus* tunnels in stems of *Hibiscus* (Malvaceae) in southeast Asia. Another small aberrant group are the Cryptolaryngini of southern Africa (*Cryptolarynx*) and central Asia (*Perieges*), but their relationships to each other and to other brachycermes remains to be elucidated.

Adults of the Erirhinini are usually found near or in water, as the larvae of most species develop in various aquatic plants including horsetails and mosses. They are recognized by their primitive genital structure but otherwise are externally very similar to other Curculionidae and are difficult to characterize. Derived features are that the tectum of the aedeagus is represented by only a narrow strip or membrane, and a rostrum which is strongly deflexed ventrally from the base (shared with some Dryophthorinae). In recent years, many species of the Tanysphyrina have been widely introduced for the biological control of aquatic weeds (e.g., salvinia, water lettuce, and water hyacinth). Many species are good swimmers and they represent the most successful group of aquatic weevils. As presently recognized there are around 50 genera in the tribe.

Raymondionymini are a small group of pale, eyeless weevils presently known from western North America, the circum-Mediterranean region, Europe, Central and northern South America, New Zealand and Australia. They are generally difficult to find because of their very small size and soil-dwelling habits and are likely more widespread than presently documented. Little is known about their natural history and their immature stages are not known. The tarsi of these tiny weevils have only four segments. Adults are generally collected in leaf litter or by soil washing. They are now generally considered as hypogean relatives of the Erirhinini. There are around 10 genera and 50 species known.

Subfamily Curculioninae

This subfamily is a large assemblage of taxa of unresolved relationships. It includes some 20 tribes, the better known of which are Curculionini, Anthonomini, Derelomini, Eugnomini, Mecinini, Otidocephalini, Rhamphini and Tychiini.

Within Curculionini, the acorn and nut weevils of the genus *Curculio* are usually light brown in color and have a very long and slender snout that may be as long as the body or longer. The adults bore into oak acorns (*Quercus*; Fagaceae) and other nuts with their long snouts and lay their eggs in these feeding holes. Larvae develop inside the nut. Tropical species in Africa, southeast Asia and Australia are usually associated with Moraceae (*Ficus*). There are around 11 genera and 500 species recognized.

Anthonomini occur worldwide except Africa and Australia and several are important pests of cultivated plants. The adults usually feed on fruits and lay their eggs in the feeding pits, and the larvae develop inside the fruits or reproductive structures. Some species form galls and some are associated with mistletoes. Most species occur in the Central and South American tropics. The cotton boll weevil, *A. grandis* Boheman, is a well-known and serious pest of cotton. Other species of economic importance in this group are the strawberry weevil, *A. signatus* Say; the cranberry weevil, *A. musculus* Say; the apple blossom weevil, *A. pomorum* L., and the apple curculio, *A. quadrigibbus* Say. There are some 800 species in more than 70 genera.

Derelomini are a widespread pantropical group represented by some 265 species placed in 40 genera. These are small weevils, nearly all of them associated with the flowers of palms (Arecaceae) and the Neotropical unrelated Cyclanthaceae. Some feed on fruits and seeds but some feed on other floral structures and are important pollinators of the plants. The African oil palm, *Elaeis guineensis* Jacq., is pollinated exclusively by derelomine weevils of the genus *Elaeidobius*. It has been necessary to introduce the weevils along with the palms in commercial plantations.

Flea weevils, Rhamphini, are so called because of their jumping habits. The hind femora are expanded and adults can often jump substantial distances. The larvae mine the leaves of various trees, most notably oaks (Fagaceae), willows and poplars (Salicaceae) and a number of tropical plant families. The group is widely distributed throughout North America, Europe, Africa, Asia and Australia. There are some 200 species in more than 20 genera.

The larvae of most Tychiini feed on the seeds of various legumes (Fabaceae), and the adults occur on the flowers. Species are found worldwide although some genera are probably misplaced in it. There are some 35 genera and over 800 species.

The Otidocephalini are small, black shiny weevils that have the prothorax oval and narrowed at the base and thus resemble ants in general appearance. Some species develop in galls on oak formed by cynipid wasps, but most develop in twigs and stems. This group of weevils is found only in the Americas. There are 5 genera and around 200 species.

Mecinini are a small group of weevils associated mainly with Scrophulariaceae. They occur in Europe, Asia and Africa but a few species have been introduced to various countries. They feed mainly in the seed capsules of the plants. There are 13 genera and about 300 species known.

Eugnomini show a southern hemisphere (Gondwanian) distribution with species in Australia, New Zealand, New Caledonia and South America. Many species are found on flowers but larvae develop in living and dead plant tissues. There are 23 genera and approximately 200 species.

Subfamily Bagoinae

There are eight genera and slightly fewer than 300 species found almost worldwide. Adults are found in aquatic and semi-aquatic habitats. A few species have been introduced for biological control of hydrilla, *Hydrilla verticillata* (Hydrocharitaceae). They have a varnish-like coating on the body and are very similar in appearance to the aquatic Erirhinini with which they were formerly classified.

Subfamily Baridinae

This is one of the largest subfamilies of the Curculionidae, with about 4250 species placed in more than 500 genera. They are found worldwide but are exceedingly diverse in the American tropics. These small weevils are usually black, shining and stout-bodied and can generally be recognized by the upward-extending mesepimera, which are generally visible from above between the base of the pronotum and elytra. Most species feed on various herbaceous plants; a few attack cultivated plants. The potato stalk borer, *Trichobaris trinotata* (Say), attacks potato, eggplant, and related solanaceous plants. *Trichobaris mucorea* (LeConte) feeds on tobacco. Much work needs to be done on this group of weevils.

Subfamily Ceutorhynchinae

This is a large and widely distributed group with around 100 genera and over 1,000 species. It includes some important agricultural pests, particularly of Brassicaceae (e.g., cabbage, canola). The species are small in size and rounded in form, and like Baridinae, they possess upward-extending mesepimera, which are sometimes visible from above. Adults are associated with various plants, mostly Brassicaceae but also Polygonaceae and can be found in terrestrial and freshwater aquatic or semi-aquatic habitats. Larvae are associated with plant reproductive structures or are stem or root miners. Larvae of some species feed externally on plant foliage (as do larvae of Hyperinae). The grape curculio, *Craponius inaequalis* (Say) feeds on the foliage of grape and the iris weevil, *Mononychus vulpeculus* (Fabricius), attacks iris. The genus

Ceutorhynchus is a diverse array of some hundreds of species. Species in the genera *Phrydiuchus, Microplontus, Mogulones* and *Trichosirocalus* have been deliberately introduced for the biological control of pest weeds. It has recently been suggested that Ceutorhynchinae are closely related to Baridinae and Conoderinae based on wing venation and various internal characters.

Subfamily Conoderinae

Formerly known as Zygopinae, this is a widely distributed group represented throughout the world by some 2,000 species placed in over 200 genera. They feed on various herbaceous plants, mostly composites, and trees (including a few conifers). They are easily recognized by their large, dorsally situated eyes. Many are fast and active flyers and in some species males stage contests over the attention of females. Some tropical American species are thought to be involved in mimicry complexes, particularly with ants and flies.

Subfamily Cossoninae-Broad-Nosed Bark Weevils

The Cossoninae can usually be recognized by the broad short rostrum and the long curved spine at the apex of each tibia. They are usually 2.0–7.0 mm in length, and most of them are black and shiny. They occur (often in great numbers) under the loose dead bark of trees and under logs and a few occur under driftwood and along the seacoast. Some are associated with dead, fibrous leaves or stems of palms, tree ferns and *Agave*. They are found worldwide with over 1,700 species in some more than 300 genera.

Subfamily Cryptorhynchinae

Members of this very diverse, worldwide subfamily are easy to recognize as the rostrum fits into a channel between the front legs that exten posteriorly onto the mesosternum where it ends in a cup-like structure. However, such a rostral canal occurs in other weevil groups, and even within Cryptorhynchinae it is differently formed in the various groups. Together with other differences, this indicates the subfamily is an artificial group of several unrelated taxa. When these weevils are at rest, the snout is usually drawn back into this groove. Many have the elytra rough and tuberculate and look like small pieces of fungi, bark or wood. Adults and larvae are usually associated with dead wood although some are found in living plants and some in seeds. Some species are found in aquatic habitats. The Psepholacini has genera with a short and broad rostrum that dig into wood with the entire body, as do bark and ambrosia beetles, and some cossonines. Many small flightless species are found in leaf litter and at least two genera (*Crematogasterobius, Liometophilus*) are associated with ants. There are about 6,000 species in about 600 genera.

Subfamily Cyclominae

This subfamily is a composite of questionably related weevils and as such is difficult to characterize. It includes the African Cyclomini, Hipporhinini and Gronopini, the Australian Aterpini and Amycterini and the more widespread Rhythirrinini and Listroderini, together numbering more than 1,000 species placed in some 175 genera. Most of the weevils found in the high Andes Mountains are Cyclominae. A few, such as members of the South American genus *Listroderes*, are pests of vegetables and have been introduced to other parts of the world. Some members of this group breed in aquatic or subaquatic plants, and the adults are found near water.

Subfamily Entiminae-Broad-Nosed or Root Weevils

The members of this subfamily (which includes upwards of 50 tribes in some classifications) are commonly called the broad-nosed weevils, because the snout is generally short and broad, not elongate and cylindrical as in most other weevils. They are also sometimes called the root weevils because the larvae of nearly all of them feed underground in or on the roots of various plants. Pupation takes place in an underground cell constructed of soil and held together by larval secretions. Adults generally feed on plant foliage or flowers. Most of them are flightless with the elytra fused together along the suture and the hind wings are vestigial. This is a large, worldwide group containing some 12,000 species placed in over 1,000 genera. Unlike most other weevils, which exhibit a relatively high degree of host plant specificity, many Entiminae feed on a variety of host plants from many different plant families and as such are important agricultural or garden pests. Some important species in this group are the white-fringed weevils of the genus *Naupactus*, and the strawberry root and black vine weevils of the genus *Otiorhynchus*. Many Entiminae are parthenogenetic with males known only from some populations or not at all.

Entiminae are among the most diverse and common weevils in arid habitats. The fused elytra may help to present desiccation and some have developed adaptations for sand-dwelling dwelling that include dense long hairs over the body and broad legs adapted for digging. This group includes the weevils most often found at higher elevations and is one of the few groups of weevils inhabiting the subantarctic islands. Many species, particularly of the genus *Otiorhynchus*, are among the most common weevil species to have been accidentally introduced worldwide. Their often-parthenogenetic nature and their broad range of acceptable host plants would appear to facilitate establishment following such introductions.

Aside from the form of the snout, entimines are easily recognized by the presence of an elongate cusp on the mandibles of the adults that appear to be used by the adults to escape from the earthen pupal cells. These cusps are very rarely seen in adults as they are deciduous and break off very early in the adult life, generally before the adult emerges from the soil. They do, however, leave a flat scar indicating their point of attachment that is quite obvious at the ends of the mandibles.

Subfamily Hyperinae-Clover Weevils

Most members of this small group of some 400 species placed in slightly more than 30 genera feed on various clovers and are important clover pests. They are found throughout the world but are most diverse in Europe and Asia. Larvae of most species feed externally on the foliage of host plants and pupate in loosely woven silken cocoons attached to the surface of the leaves. The alfalfa weevil, *Hypera postica* (Gyllenhal), and the clover leaf weevil, *H. punctata* (Fabricius), feed on the growing tips of the plant and skeletonize the leaves; *H. meles* (Fabricius) feeds in the clover heads.

Subfamily Lixinae

These generally large (10–20 mm in body length) weevils are represented by some 1,500 species placed in about 100 genera. The most common beetles in this group are those in the genus *Lixus*, which are elongate and cylindrical, with the curved rostrum nearly as long as the prothorax. In temperate regions, many occur on weeds near water but tropical species occur in various habitats. Members of the tribe Cleonini are generally found in arid regions and are particularly diverse in Africa and central Asia. Many Lixinae feed on Asteraceae and species in a number of genera have been introduced for biological control of some pest weed species.

Subfamily Molytinae

As with the Curculioninae, this group brings together a number of questionably related taxa previously placed in other subfamilies (e.g., Hylobiini, Prionomerini, Cholini, Lepyrini, Lymantini and Pissodini). Most notable is the reclassification of a number of weevils from the Cryptorhynchinae (Ithyporini) as Molytinae. The group is also difficult to differentiate from Cossoninae and Lixinae. Some 35 tribes have been recognized by some authors and its concept as a subfamily is obscure. This subfamily includes the large American genus *Conotrachelus* and its relatives, and also the Mesoptiliini, recognized by some as a distinct subfamily.

Most members of the Molytinae are dark-colored and of moderate size (8.0–12.0 mm in body length). They are found worldwide and there are around 2,500 species placed in about 250 genera. Most are associated with woody plants and have an elongate spur at the inner apex of the tibia that appears to be used to hold onto the host plant. Many have a prosternal channel to receive the rostrum but generally this does not extend onto the mesosternum and is only evident on the prosternum between the front legs. Larvae generally tunnel in woody plants but a number are associated with seeds and fruits. Many species are found in leaf litter and some are eyeless and depigmented. Some species of *Hylobius, Pissodes* and *Magdalis* are pests of pine and other conifers and some, for example in the genus *Conotrachelus*, are pests of fruit. Members of the Neotropical Cholini are associated with various monocots including palms, heliconias and their relatives.

Subfamily Platypodinae-Pin-Hole Borers

The status and position of these weevils is still disputed by various authors. Some consider them as a distinct family related to primitive Curculionoidea, others consider them as basal within Curculionidae and related to Dryophthorinae, and some regard them as a subfamily of Curculionidae but related to the Scolytinae with which they have traditionally been linked. They were originally classified with the Bostrychidae, a totally unrelated family of beetles. They number almost 1,500 species placed in some 30 or more genera.

Platypodinae are elongate, slender, and cylindrical with the head lacking a snout and being slightly wider than the pronotum. They are brownish in color and between 2.0 and 8.0 mm in length. The tarsi (which each have five distinct segments) are very slender, with the first segment longer than the remaining segments combined. The antennae are short and geniculate and have a large unsegmented club. Internally, platypodines are characterized by numerous reductions, especially in the female reproductive structures and the male genitalia, which are reduced in size and complexity.

Platypodinae are wood-boring in living trees, but seldom attack a healthy tree. They appear to attack only dicot angiosperms. The larvae feed on ambrosia fungi that are cultivated in their galleries and which represents the sole food of the larvae and adults.

Subfamily Scolytinae-Bark Beetles or Engravers, and Ambrosia Beetles

The scolytines are small cylindrical beetles, rarely more than 6.0–8.0 mm in length, and usually brownish or black in color. The antennae are short and geniculate and have a large, flat, usually annulated club. There are about 6,000 species placed in some 225 genera. The subfamily contains two groups in terms of their biology: the bark beetles, which feed on the inner bark of trees, and the ambrosia beetles, which bore into the wood of trees and feed on ambrosia fungus, which they cultivate in their galleries. Bark beetles differ from ambrosia beetles in having a large spine or projection at the apex of the front tibiae.

Bark beetles usually live within the bark of trees, generally right at the surface of the wood, and feed on the succulent phloem tissue. Some species, especially *Ips* and *Scolytus*, deeply score the sapwood and are often called engravers. Bark beetles live in many different types of plants and some even mine other plant parts, such as the petiole of large leaves. Most of the economically important temperate scolytines belong to three genera: *Dendroctonus, Ips,* and *Scolytus*, although *Xyleborus* and others are more important pests in tropical regions. The death of an infested tree is brought about by the fungi introduced by the adult beetles and spread by the larvae. As adults and larvae interrupt the flow of nutrients by feeding in the phloem, the fungus spreads inward and clogs the water transport vessels in the sapwood, suppressing the flow of lethal pitch into the beetle galleries. The destructive bark beetles exhibit a remarkable coordination of their flying population in a tightly synchronized mass attack, overwhelming the tree's defenses by sheer numbers. Both males and females respond to a combination of odors from the resin of the host tree and chemical signals (aggregation pheromones) from the first colonists. As a result, thousands of beetles may infest the same tree simultaneously.

Bark beetles can be monogamous or polygamous in their breeding habits. In monogamous species such as *Dendroctonus pseudotsugae* Hopkins, the Douglas fir beetle, the female bores the gallery, releases pheromone, and accepts one male as her mate. In polygamous species such as *Ips pini* (Say), the pine engraver, the male does the initial boring but constructs only a nuptial chamber in which to mate with the several females he accepts into his harem. Each female bores her own egg gallery out from the nuptial chamber.

As a female bark beetle constructs her egg gallery, the male cooperates with her by following along behind her, removing boring dust and shoving it out the entry hole. The female lays her eggs in little notches at intervals along the sides of the gallery. When the eggs hatch, the tiny, C-shaped, legless larvae begin eating their way through the phloem at right angles to the egg gallery. As the larvae grow and molt, moving farther away from the adult gallery, the frass-filled larval mines become larger, forming characteristic patterns. When the larvae complete their growth, they pupate at the ends of their mines. The adults emerge through round holes they bore through the bark. After a brood emerges, the surface of an infested tree appears peppered with shot holes.

Bark beetles have a greater impact economically on the timber-producing forests of North America than any other group of insects, being credited with the death of more than 4 billion board feet of sawtimber annually, over 90% of the total insect-caused mortality. Most of the tree mortality caused by bark beetles is caused by five species of *Dendroctonus*.

Each species of bark beetle has a characteristic pattern of adult and larval galleries and a rigid preference for a particular tree species. Dutch elm disease, transmitted by elm bark beetles, is caused by a fungus introduced from Europe with the smaller European elm bark beetle, *Scolytus multistriatus* (Marsham). These beetles have spread the disease across the United States completely eliminating American elms in many urban areas. One agriculturally important species of bark beetle is the clover root borer, *Hylastinus obscurus* (Marsham), which often causes serious damage to clover. The larvae tunnel in the roots of clover and kill them.

Ambrosia beetles bore into the wood of trees, forming galleries in which both adults and larvae live. Only living or freshly killed trees, with a high moisture content, are infested. Although these beetles do not eat wood, the fungi that they cultivate stain the wood, reducing its value. The presence of these beetles can cause entire shiploads of timber or lumber to be refused at a foreign port. The larvae of ambrosia beetles develop in small cells adjoining the main galleries, and in most species the larvae are fed by the adults. Each species usually feeds on one particular type of fungus. When the females emerge and fly to another tree, they carry conidia of the fungus from the natal tree to the new host and introduce the fungus into the gallery they excavate. After the eggs hatch, the females care for the larvae until they are full grown and pupate, keeping the larval niches supplied with fresh fungus or "ambrosia," and preventing the niche from being choked with frass or excess growth of fungus.

Western Balsam Bark Beetle, *Dryocoetes confusus* Swain (Coleoptera: Curculionidae, Scolytinae)

JOSE F. NEGRON
USDA Forest Service, Ft. Collins, CO, USA

The western balsam bark beetle is distributed throughout the range of its host, subalpine fir, *Abies lasiocarpa*, in western North America from British Columbia and Alberta to New Mexico and Arizona. Apparently, it is the only species of the genus that is capable of causing tree mortality of healthy trees. Populations may increase after windstorms provide suitable downed host material for the insects to exploit or during prolonged periods of drought. To a lesser extent it also attacks other species of *Abies* and Engelmann spruce, *Picea engelmanni*. Akin to other tree-killing bark beetles, this insect causes tree mortality by feeding and developing in the phloem of the tree. Utilization of the phloem for habitat and nourishment results in girdling of the tree so that translocation of nutrients is impeded. In addition, upon invading its host, the insect inoculates the tree with a pathogenic fungus, *Ceratocystis dryocoetidis*. It is most likely the combined action of the insect and the fungus that cause the tree to succumb. Extensive mortality of subalpine fir, which is typically not a long-lived species, has occurred throughout its range over the last five decades to a number of disturbance agents including the western balsam bark beetle and its associated fungus.

Initial symptoms of attack include; an accumulation of a mixture of light brown boring dust and frass at the base of the tree and resin flow from the bole of the tree. Copious resin flow may also indicate that the insects have been prevented from successful entry into the tree, commonly referred to as a pitch out. Western balsam bark beetles do not produce the characteristic pitch tubes, an accumulation of resin and frass at the point of entry into the tree, that many bark beetles produce. Attacks are often seen above 2 m on the bole. Identification of successfully attack trees is often difficult. As the tree dies, the foliage changes in color to a light yellow and then a brick colored red before falling off the tree. In some areas, foliage fading can take 2–3 years to become noticeable.

Adult beetles are reddish brown to black and 3–4 mm in length. The females have a prominent, erect, dense, circular brush of red-brown to yellow setae in the frons. In British Columbia, and most likely throughout most of its range, the insect has a 2-year life cycle. However, under certain climatic conditions a 1-year life cycle may occur. The primary dispersal flight occurs during the end of June and July. A second, smaller peak in flight activity also occurs in the fall. Males initiate tree attack, excavate a nuptial chamber, and mate with several females. Invasion and infestation of a new tree involves the use of pheromones and host chemicals. Each female then constructs an egg gallery; with females radiating from the nuptial chamber commonly producing 4–9 galleries. Soon after initiation of gallery construction the females begin ovipositing on the sides of the gallery. This process continues into the fall. Eggs begin hatching in the summer and this brood spends the first winter as a young larvae. The following year the larvae resume development, pupate by late summer, and become adults by the fall but remain in the tree until the following spring. After the first year of attack, egg-laying mated females overwinter in the galleries and continue egg gallery extension and egg laying well into the second year. These females may re-emerge from the tree and attack a new tree or the same tree to deposit a third compliment of eggs.

In a British Columbia study, the average diameter of subalpine fir killed by the western balsam bark beetle ranged from 31 to 60 cm; and mortality was concentrated around the largest trees in the stands. In a Wyoming study from the Bighorn Mountains, average subalpine fir diameter of infested areas was 20 cm; but mortality did not appear to be concentrated around the largest trees. The Wyoming study also indicated that increased mortality levels were observed in dense stands with a higher host type component.

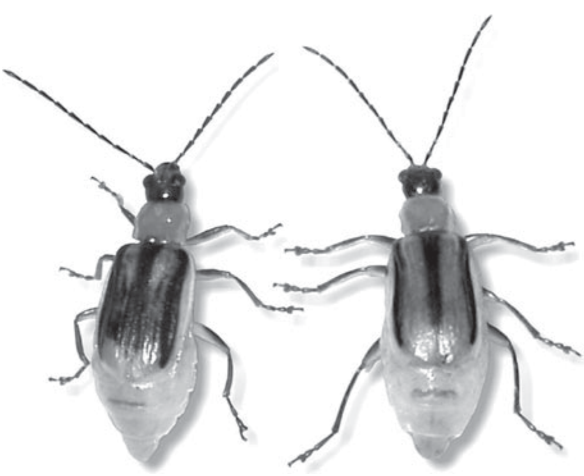
Western Corn Rootworm, *Diabrotica virgifera virgifera* Leconte (Coleoptera: Chrysomelidae)

LANCE J. MEINKE
University of Nebraska, Lincoln, NE, USA

The western corn rootworm, *Diabrotica virgifera virgifera* LeConte is one of the most economically important pests of corn in the U.S. Corn Belt and southern Canada. Larvae can cause substantial injury by feeding on corn roots. Larval tunneling interrupts the integrity of root systems and may destroy individual roots or root nodes. Root feeding by larvae can adversely affect plant growth and development and reduce plant stability and grain yield. If extensive root injury coincides with heavy rains and strong winds, plants may lodge (lean over), reducing light interception by plants and resulting in mechanical harvest losses. Adults are less likely to cause economic loss in field corn, but if high beetle densities are present when silks emerge, excessive silk feeding (i.e., silk clipping) can occur which may lead to reduced pollination.

D. v. virgifera is widely distributed from northwest Mexico into the southwest U.S., across much of the north central to northeastern U.S., and is present in southern Canada. This chrysomelid beetle also has become established as an invasive species in central Europe. A subspecies, the Mexican corn rootworm, *Diabrotica virgifera zeae* Krysan and Smith occurs from Central America to Oklahoma in the U.S. The subspecies are closely related; they are morphologically very similar with no pheromonal or structural barriers to mating, and there is no ecological or temporal isolation between them. However, when male *D. v. virgifera* from a South Dakota (U.S.) population have been mated with female *D. virgifera zeae* from Texas or central Mexico many eggs are laid but most do not hatch. The reciprocal cross always produces fertile eggs. A *Wolbachia* bacteria strain that is present in most U.S. populations of *D. v. virgifera* is the cause of the unidirectional reproductive incompatibility between subspecies. *Wolbachia* could be functioning as an isolating mechanism between the subspecies in hybrid zones.

The western corn rootworm is a univoltine insect species. In the north central U.S., eggs are laid in soil (up to 30 cm deep) from late July to mid-September. Eggs are white to light yellow (size: 0.3 × 0.5 mm), remain in diapause over the winter, and hatch over approximately a 5 week period beginning in late May to early June. Newly hatched larvae are about 3 mm long and move short distances through air filled pores in the soil to locate and establish on suitable plant roots. Larval development progresses through three instars. Larvae move off of roots for brief periods to molt between instars. Third instar larvae (approximately 12 mm long) are cream colored, with a sclerotized head capsule and anal plate. When larval development is complete, larvae pupate in earthen cells. White exarate pupae remain in earthen cells for 6–13 days before adults emerge. Rate of development of immature stages is temperature and density dependent. Adults can be present from late June to September. Adults have an elongate body



Western Corn Rootworm, *Diabrotica virgifera virgifera* (Coleoptera: Chrysomelidae), Figure 36
Western corn rootworm females; examples of the variability in the black elytral pattern that can occur in a population. (Photo by L. Campbell and J. Kalisch.)

shape and range from 4.2 to 6.8 mm long. The elytra are typically straw to yellow with black markings. The black elytral pattern can be reduced to distinct vittae on the inner (sutural) and outer (humeral) margins or cover most of the elytra except for the outer edge and a patch at the apex.

The western corn rootworm has a narrow larval host range that is restricted to certain grass species but appears to be ecologically monophagous on corn. This is primarily because the western corn rootworm exhibits a strong affinity for corn fields as feeding and ovipositional sites. The generally accepted hypothesis is that the western corn rootworm evolved with corn and corn relatives in Mexico and/or Central America and only moved into the U.S. after corn was introduced. Adults are highly mobile, with dispersal occurring on two scales. Adults exhibit local or trivial movement within and among adjacent fields during the entire time adults are present. A small portion of most populations also exhibits migratory behavior which leads to dispersal over longer distances. Migrating females often are mated, but have not yet developed mature eggs. Many migration events occur during or just after peak emergence, but long-range movement has been observed throughout the adult activity period. The mobility of adults enables rootworm populations to quickly colonize first-year cornfields that do not have a resident rootworm population. A recent dramatic eastern range expansion of this species occurred from western Kansas and Nebraska (eastern range limit in 1940s) to the U.S. eastern seaboard in less than 50 years. Corn had been grown in the eastern U.S. for many years prior to the range extension by *D. v. virgifera*.

Many factors can interact to determine adult *D. v. virgifera* population densities in a cornfield at different times during the season. The number of beetles emerging within a cornfield is often a primary contributor to the total population level in the field. Planting date significantly affects when beetle emergence begins. In late planted fields, as compared to early planted fields, initial emergence is often delayed and total emergence reduced. The relative attractiveness of food sources can greatly affect immigration and emigration rates. Adult *D. v. virgifera* feed preferentially on succulent reproductive tissues of corn (i.e., pollen, silks, kernels) but will feed on corn leaves and other pollen sources when preferred corn tissues are unavailable, or present in a less preferred phenological stage. Pollinating corn fields are highly attractive to adult *D. v. virgifera*. If corn in a field pollinates later than corn in surrounding fields, beetles often move into the pollinating field from the fields that have finished pollination. Contrasts in plant phenology within and among fields can significantly affect *D. v. virgifera* distribution patterns.

The female preovipositional period is at least 10–14 days when optimal food is available (e.g., corn silks, pollen). Maximum egg production per female under optimal conditions ranges from 800 to 1,000 eggs. In most of its range, the western corn rootworm will oviposit in cornfields. In the eastern Corn Belt (i.e., area centered around east central Illinois, northwest Indiana) a population of western corn rootworm has adapted to the long-term practice of rotating corn and soybean (larval host to non-host plant) by annually depositing a significant number of eggs outside of corn. Beetles in this area also exhibit much movement back and forth between corn and soybean which is not seen in other geographic areas where *D. v. virgifera* occurs.

Biotic and abiotic factors can influence immature and adult corn rootworm survival. Although various vertebrate and arthropod predators, parasitoids, and pathogens have been reported as natural enemies of *Diabrotica* species, none appear to regulate population densities in commercial cornfields. Weather patterns can greatly influence *D. v. virgifera* survival. In the northern parts of the *D. v. virgifera* range, prolonged cold temperatures during winter can kill a high percentage of eggs. Very wet conditions (e.g., water-logged soils) during the larval/pupal period can reduce larval establishment on plants or kill larger larvae and pupae.

Various western corn rootworm management options are available to producers. Rotating corn with a crop that is not a suitable larval host will effectively prevent larval injury in most parts of the species range (exception is in the U.S. eastern Corn Belt where crop rotation has become ineffective as a management tool, see previous discussion). If corn is planted in a field for two or more successive years (continuous corn), a corn rootworm beetle scouting program and available economic thresholds can be used to determine if a chemical control tactic is needed. When necessary, chemical control tactics can be directed toward larval or adult stages. A commonly used strategy is to apply a soil insecticide at planting or first cultivation to reduce larval feeding damage and protect the primary root structure of the corn plant. Newer technologies that also target the larval stage include insecticide-treated seed and corn rootworm protected transgenic plants (i.e., corn tissues express a toxin that is lethal to rootworm larvae). An alternative strategy targets the adult stage. Insecticide applications are used to suppress beetle populations and reduce egg-laying so that larval populations the following year will not cause economic loss. To date, natural enemies (i.e., predators, parasitoids) have not been useful as biological control agents for *D. v. virgifera*. Biological agents often have provided insufficient or inconsistent control and have been too cost prohibitive to include in commercial management programs.

Western Grapeleaf Skeletonizer *Harrisina brillians* Barnes and McDunnough (Lepidoptera: Zygaenidae)

W. J. Roltsch, B. Villegas
California Department of Food and Agriculture Biological Control Program, Sacramento, CA, USA

The western grapeleaf skeletonizer is one of only several species in the genus *Harrisina* in North America. Western grapeleaf skeletonizer is native to the southwestern United States and northern Mexico. Its original distribution is believed to include regions of Arizona, New Mexico, Colorado, Nevada and the Mexican states of Sonora, Chihuahua, Coahuila and San Luis Potos.

The other common species, *Harrisina americana* (Guérin), occurs over the eastern half of North America and is an occasional vineyard pest. Its biology is very similar to the western grapeleaf skeletonizer. In fact, it is attracted to the (R)-(-) enantiomer form of the primary sex pheromone component attractive to the western grapeleaf skeletonizer.

Grape production in California was first impacted by the western grapeleaf skeletonizer soon after its introduction into southern California in 1941. Although severe damage in San Diego County vineyards was reported for several years, western grapeleaf skeletonizer densities decreased by the mid-1950s because of several biological control agents.

In 1961, the western grapeleaf skeletonizer infestation extended into the San Joaquin Valley of central California. Despite attempts at eradicating this pest, first in the 1940s in southern California and later in the San Joaquin Valley, the western grapeleaf skeletonizer became firmly established in both locations.

Both in southern and central California, western grapeleaf skeletonizer populations expanded slowly from their initial points of introduction. The slow increase in their range is mainly attributed to the tendency of moths to remain near where they developed as immatures if adequate vegetation is present. The inability to eradicate this pest in the San Joaquin Valley may be due in part to several features of its biology; for example, a small percentage of the population enters diapause during early seasonal generations, and some pupae may remain in diapause for over 18 months.

Western Grapeleaf Skeletonizer *Harrisina brillians* Barnes and McDunnough (Lepidoptera: Zygaenidae), Figure 37 Western grapeleaf skeletonizer female moth adjacent to recently laid egg cluster.

Life Stages

Western grapeleaf skeletonizer eggs are laid in clusters commonly containing 50–150 eggs. Eggs are cream to light yellow in color and shaped like capsules. They are laid on their sides and do not touch one another. Moths oviposit almost exclusively on the bottom surface of leaves located most commonly at the basal portion of each shoot in the spring, and on new, fully expanded leaves as the season progresses. Healthy females lay nearly 300 eggs during their lifetime (Fig. 37).

Although there are typically five larval instars, a few individuals have only four instars. The first instar has a cream-colored head capsule and pronotal shield that is difficult to see with the unaided eye. Their body is light cream and no color pattern is present (Fig. 38). Second instar head capsules are dark, and the body lacks dark pigmentation until larvae are close to molting, at which time a faint brown mottling is visible. Furthermore, second instar larvae have pronounced body hairs. Third instars are identified by their distinctive medium brown bands that become more pronounced through the course of this life stage. Bands become blue as third instars develop. Head

Western Grapeleaf Skeletonizer *Harrisina brillians* Barnes and McDunnough (Lepidoptera: Zygaenidae), Figure 38 Grape leaf with early instar larvae.

capsules in third and later instars are retractile and relatively difficult to see, but the pronotal shield is dark and prominent. Fourth and fifth instars have distinct black and blue bands upon a bright yellow background (Fig. 39).

Although early instars have body hair, later instars (third to fifth) have urticating hairs that are

Western Grapeleaf Skeletonizer *Harrisina brillians* Barnes and McDunnough (Lepidoptera: Zygaenidae), Figure 39 Late stage larvae demonstrating atypical feeding pattern signifying a viral infection.

highly irritating to human skin, and of particular importance to farm workers when harvesting grapes. Urticating hairs are characteristic of the family Zygaenidae. The irritating factor is believed to be hydrogen cyanide, resulting from the breakdown of cyanoglucosides.

Fifth instar western grapeleaf skeletonizer larvae pupate under the bark of grapevine trunks or at the base of trunks in dried leaf litter or most anything that provides cover. The process of moving from a feeding site to a pupation site and initiation of spinning a cocoon occurs within 36 h. The cocoons are a cream color and have an anterior flap-like portion used as an exit by emerging moths. This "flap" can be teased open with forceps for removing pupae that can be relatively easily sexed.

Adult western grapeleaf skeletonizer moths are bluish-black in color. Males have a slender abdomen terminating in a v-shape as a result of soft spines. The female abdomen is considerably broader throughout with a distinctively square shaped terminus. Although both male and female moths have antennae with lateral bristles, male bristles are longer and have fine lateral hairs.

Life Cycle

The western grapeleaf skeletonizer has a very restricted host plant range. It seldom infests plant species other than several in the family Vitaceae, including commercial and wild grape (*Vitis* spp.), Virginia creeper (*Parthenocissus quinquefolia* (L.)) and Boston ivy (*P. tricuspidata* (Plauchon)).

In Arizona, western grapeleaf skeletonizer has three generations each year. Moths first occur in May, and the first brood of larvae is present during June and early July.

In Fresno County, California, moth emergence corresponding to the first seasonal flight is initiated approximately 71% of the time from mid-March to early April. Moth emergence then increases gradually and continues into early May. The second flight of moths in California's Central Valley commonly begins in early June. A 1-to-2-week period occurs between the end of the first and beginning of the second moth flights, during which time virtually no moths are caught in traps. The third moth flight period commonly begins during the last week in July. There is a small degree of overlap between second and third moth flights. Pheromone trap data suggest that a small fourth generation occurs during some years.

In San Diego County coastal areas and cooler highland areas, western grapeleaf skeletonizer spring moth flights occur approximately 1 month later than in the Central Valley. As a result, only 2–3 generations occur each year in the cooler regions.

Western grapeleaf skeletonizer egg, larval and pupal development share similar, lower and upper temperature thresholds (combined life stage estimate: 9.0 and 28.2°C, respectively). Moth longevity is about 7 days. Although longevity has been noted to vary in relation to mean daily temperature, longevity and oviposition schedules are only loosely linked to daily temperatures under climatic conditions in California's San Joaquin Valley. Male flight activity occurs almost exclusively from sunrise to late morning, whereas female flight activity gradually increases from late morning to early afternoon. It has been suggested that daytime flight behavior and black coloration enables this species to thermoregulate, thereby having a similar level of activity over a broad range of moderate to high temperatures under clear skies. This is likely to differ in coastal climates subject to frequent cloudiness. Western grapeleaf skeletonizer larvae feed extensively, if not exclusively, during daytime hours.

Pheromone Systems

The primary component of the western grapeleaf skeletonizer sex pheromone is [sec-butyl-1-(z)-7-tetradecenoate (racemic)].The pheromone is very stable when contained in a rubber septum or sheet-like polymer laminate, and effective for 4 weeks during high ambient temperatures.

Wing, delta and bucket traps (unitrap) work well for catching western grapeleaf skeletonizer moths. The bucket trap is very convenient and is capable of catching far more moths. Traps are particularly reliable in identifying when early season moth emergence first occurs, and work well when located upwind, several rows into a vineyard and approximately five vines down the row.

Biological Control

In southern California, two parasitoids have played an important role in western grapeleaf skeletonizer biological control. A braconid wasp, *Glyptapanteles harrisinae* (Muesebeck), and a tachinid fly, *Ametadoria misella* (Wulp) [= *Sturmia harrisinae* (Coquillett)], were introduced in the early 1950s. The wasp was collected in southeast Arizona, while the fly was obtained from Arizona and Mexico. *Ametadoria misella* established rapidly in the San Diego area, and parasitism of 30–70% was common within a year of release. *Glyptapanteles harrisinae* also established rapidly, however, parasitism levels dropped several years following initial establishment.

Parasitoids were first released in the San Joaquin Valley in the mid-1970s, with an intensive release effort occurring in the late 1970s. Parasitism occurred at low levels (less than 1.0%) during the first several years following initial releases. By the early 1990s, parasitism levels of 30% by *A. misella* were common.

A granulosis virus of western grapeleaf skeletonizer (HbGV) has played a key role in controlling western grapeleaf skeletonizer in the southern and interior valley regions of California. It was introduced inadvertently as a contaminant associated with parasitoids imported from Arizona and Mexico. Viral disease symptoms are very evident in most life stages of infected individuals. During oviposition, infected females frequently lay eggs in unorganized groups, with the eggs clumped into small groups several layers high. In addition, infected young larvae feed as unorganized groups, within which dead individuals are common. The appearance of the leaf area fed upon by young and old infected western grapeleaf skeletonizer larvae is considerably different from that resulting from feeding by healthy larvae. Feeding by young infected larvae on grape leaves occurs in small, more or less individual patches that do not result in well formed feeding "windows" (translucent areas consisting of leaf epidermis) typical of early feeding by healthy uninfected larvae. Fourth and fifth instar feeding by infected individuals is also patchy. This contrasts greatly with feeding by healthy larvae of similar age, in which all leaf tissues are consumed except primary and secondary leaf veins.

Within Field Distribution of Western Grapeleaf Skeletonizer

Larvae are commonly observed in greatest abundance along vineyard perimeters. This is particularly apparent where light infestations result in damage that is almost exclusively on the edge of vineyards. In contrast to the well defined edge effect in cases of low to moderate abundance, populations are readily observed throughout the vineyard when population densities are high.

For research purposes, western grapeleaf skeletonizer pupae can be monitored easily using corrugated cardboard with cell diameters equal to the diameter of fifth instars (approximately 5 mm). The corrugated cardboard can be cut into 4–8 cm wide strips and placed as bands around canes or trunks. When seeking a pupation site, the larvae will readily (if not preferentially) enter the cell-like entrance holes along the edge of a band and pupate inside.

Pheromone Traps as Monitoring Tools

Pheromone traps can be used for several purposes, including the determination of first emergence of western grapeleaf skeletonizer moths in spring, identifying the duration of primary activity during a flight period, and providing a rough approximation of relative population density. For these data to be of greatest value, they should be compared to previous years of data from the same site. To successfully identify the first date of emergence, traps should be placed in the field by mid-February in central California. Early trap placement and checking traps twice each week are necessary to accurately determine first moth emergence. For most uses, checking traps at 6 or 7 day intervals and estimating emergence as having occurred midway between intervals is adequate.

Simulation Phenology Model

A computer simulation model was developed for predicting western grapeleaf skeletonizer seasonal phenology. The model incorporates a logistic spring emergence function, a non-varying estimate of moth longevity (i.e., 7 days), and a schedule of percent daily oviposition by an average moth over a 7 day life span. In addition, egg, larval and pupal development is based on degree-day sums required to complete each life stage (145, 385, 278 degree-days, respectively). Degree-days per day are calculated from minimum/maximum temperatures utilizing a lower threshold of 9.0°C and a high temperature, horizontal threshold of 28.2°C.

The western grapeleaf skeletonizer model is initialized with the date of the first pheromone trap catch (i.e., the BIOFIX point) signifying initiation of the first annual moth flight.

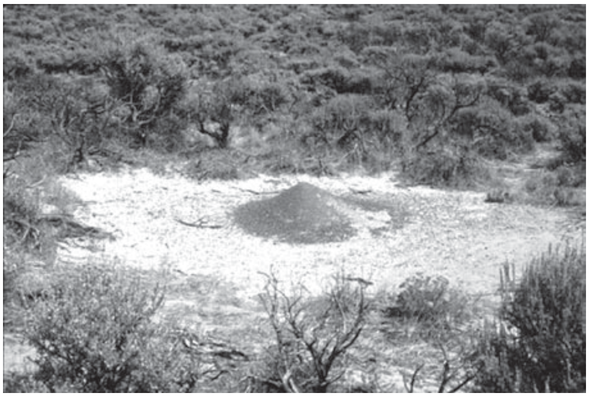
Western Harvester Ant, *Pogonomyrmex occidentalis* (Cresson) (Hymenoptera: Formicidae)

THOMAS O. CRIST
Miami University, Oxford, OH, USA

The western harvester ant is common in semi-arid shrublands and grasslands throughout much of the western interior of North America. This species, like others in the genus *Pogonomyrmex*, is called a harvester ant because the workers collect seeds for food. The western harvester ant also removes plants near nests by clipping leaves and stems. Nests of the western harvester ant are large, conical soil and gravel mounds, surrounded by a circular area cleared of vegetation. In some western rangelands where soils are favorable, the population densities of this harvester ant may exceed 50 colonies per ha and the denuded area due to nest clearings may affect 10% of the total ground surface area. Ants may also harvest a considerable portion of the seeds produced by plants. The western harvester ant is therefore both ecologically and economically important, and is sometimes considered a rangeland pest because of the reduction in the plant forage available for grazing by livestock. These ants can also inflict a painful sting when their nest is disturbed.

The significance of the mound-building and plant-clearing habits of the western harvester ant has been the subject of considerable speculation, but is likely related to temperature regulation within their nests. The conical nest mound is noticeably flattened on the side with the nest entrance, which usually faces southeast to maximize exposure to the morning sun. Removal of surrounding plants also reduces shading of the nest, especially when the sun is at a low angle. The adult workers move larvae up or down within the nest mound daily in a manner that reflects a optimal range of temperature for brood development (Fig. 40).

The foraging activity of the workers is also influenced by the soil temperature. Most seed harvesting by ants occurs when the surface temperature is between 30 and 40°C, but some foraging may be observed over a more extreme range of temperatures (20–50°C). When soil temperatures are high (40–50°C), ants frequently collect arthropods that apparently die of heat stress on the surface. Thus, although the western harvester ant is primarily seed eating, it also scavenges considerable amounts of arthropod forage, plant litter and feces.



Western Harvester Ant, *Pogonomyrmex occidentalis* (Cresson) (Hymenoptera: Formicidae), Figure 40 Nest mound and clearing of the western harvester ant, *Pogonomyrmex occidentalis* (Cresson), in the sagebrush steppe of southwestern Wyoming.

Ants harvest a wide variety of seeds available in their foraging areas, but workers consistently prefer, or avoid, the seeds of some plant species. This selective seed harvesting, along with soil modification of the nest site, often results in a different admixture of plant species near ant nests compared to surrounding areas. Ants attract nestmates to dense patches of preferred seeds by laying a recruitment pheromone along the soil surface. Workers are recruited to seeds by detecting differences in the concentration of the pheromone with their antennae as they move sinuously along the chemical trail.

The reproductive behavior, life cycle and colony longevity of the western harvester ant are similar to those in most other *Pogonomyrmex* species. During the summer, ant colonies produce numerous winged males and females ("alates") that are reproductively viable and morphologically distinct from the sterile workers. In contrast to the iron-red color of the workers, male alates are black and have disproportionately smaller heads. Female alates resemble workers in color and proportion, but are 2–3 times larger in size. In most areas, alates leave the nest between late July and early August for their nuptial flights. Alate flight activity is synchronous among colonies, usually occurring in the late morning on 2 or 3 days following a significant rainfall.

The alates aggregate on hills or cliffs, and in the uppermost portions of shrubs, trees, or structures such as fenceposts, windmills, or buildings. Males "lek" together in groups (form mating aggregations) of 5–20 individuals, and females are attracted to male aggregations by a sex pheromone. Females typically mate with several males, a behavior that later results in genetically variable workers after the queen begins reproducing in colony establishment.

After locating a suitable site, the foundress queen sheds her wings and digs a simple, vertical tunnel 10–15 cm deep. During the first few weeks, the queen must rear the first brood as well as forage for food. Most foundress queens die before the first offspring develop into adult workers. Colony mortality continues to be high during the first year when there are few workers, especially if a young colony is in close proximity to older, larger ones with well-established territories. Over time, this selective mortality near existing colonies tends to produce a regular spacing pattern between neighboring ant colonies, although territories often overlap and foraging trails may interdigitate. If a colony survives for 2 years, then it generally has a low mortality and may persist for 10–50 years. A thriving colony typically has 2,000–3,000 workers, but larger ones may harbor 10,000 workers. Colonies are monogynous (one queen) and a single queen (except for the foundress queen) lives for the entire lifespan of the colony.

Because colonies may occupy a site for several years, the digging activity of ants gradually alters the chemical and physical characteristics of soils. Levels of nutrients essential for plant growth are usually higher in nest soils than in surrounding areas. The numerous tunnels and chambers in nests also increase water infiltration from the surface, and higher levels of organic matter facilitate the retention of soil water and nutrients. As a result, the size and species of plants adjacent to nest clearings or on abandoned nest sites may differ from surrounding areas. Ants, therefore, have beneficial effects on soil productivity and plant species diversity.

The western harvester ant is usually found in deep, well-drained soils with a sandy or gravelly texture because ants excavate some nest tunnels and chambers 2–3 m deep in soil. Colony densities are highest where these soils occur, usually on upland plains or sloping terraces. In contrast, ants are often absent from shallow soils, or fine-textured clays where workers are precluded from digging deep nest tunnels, or where soil expansion and contraction makes the tunnels unstable. Repeated soil disturbance, such as heavy erosion or trampling by livestock, is also unfavorable to ants because workers spend more effort on nest reconstruction and maintenance at the expense of food collection. Under these conditions, ants are present in low densities due to high rates of colony mortality or nest abandonment. From the standpoints of soil productivity and integrity, therefore, high densities of the western harvester ant indicate a healthy range condition rather than a degraded one.

The effects of harvester ants on total plant production are usually insufficient to justify broad-scale chemical controls of ants on western rangelands. Control measures using chemically treated baits are economically feasible only on intensively managed ranches, or in rural settlements where humans commonly encounter ant colonies. Given its potential roles in soil productivity, plant species diversity, and as an indicator of soil disturbance, the absence of the western harvester ant actually might be less desirable than its presence on western rangelands.

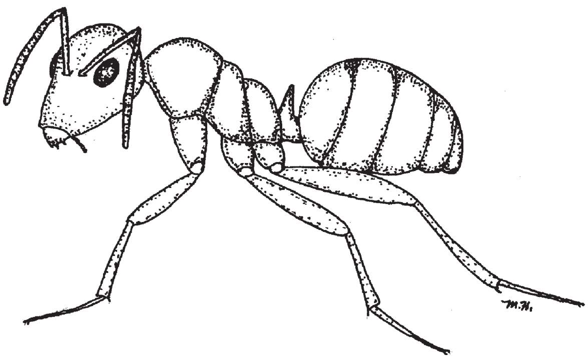
Western Thatching Ant, *Formica obscuripes* (Forel) (Hymenoptera: Formicidae)

MARK HEADINGS
The Ohio State University Agricultural Technical Institute, Wooster, OH, USA

The western thatching ant, *Formica obscuripes*, is a relatively large mound-building ant. Its distribution reportedly extends from northern Indiana and Michigan westward across the northern United States and southern Canada to Oregon and British Columbia. This ant also is found in an area extending southward including Utah, Colorado, northern New Mexico and California. The host range of the western thatching ant includes various vegetation types, such as forested areas, grasslands, and sagebrush. The dome-shaped nests may vary considerably depending on age of the colony and the habitat; however, they are typically 0.5 m in height and 1.0–1.5 m in diameter. The main brood chambers typically extend to a depth of 1 m or more below the soil surface, and the thatch to a depth of one-third of a meter or less. The thatch nests are constructed from dry plant materials found in the area, such as pine needles and twigs in a pine forest or sagebrush twigs and grass in a semi-arid region. The thatch may frequently be surrounded by a sandy or bare soil ring. Another characteristic of the ant is that it constructs slightly excavated, and even partially covered, trails on the ground leading in nearly straight lines from the nest to feeding sites in trees or other plants. The ants feed upon honeydew collected from homopterous insects such as aphids, and also consume other arthropods. Ants are one of the groups of social insects that practice a division of labor, each working for the good of the whole.

The life cycle of the ant is one of complete metamorphosis, with egg, larva, pupa, and adult stages (Fig. 41). The eggs are about 0.6 mm in length and 0.3 mm in diameter. Larvae are about 6 mm in length at maturity. Worker pupae range from 3.5 to 7 mm in length, and sexual male and female pupae about 9mm. The larvae are small legless white worms. The adult ant workers appear to have at least two, and maybe three, different morphological forms. The major (maxima) workers are larger than the media workers, which in turn are larger than the minor workers (minima). The major workers are approximately 6 mm or more in length and have an orange-red head and thorax, and a black abdomen. The smaller media and minor workers (tenders) typically collect honeydew from homopterous insects (such as aphids, treehoppers, and scales on trees and low growing vegetation) and also carry brood in the nest. It has been suggested that the small black minor workers are largely restricted to working in the primary nests. They have been observed, however, along with media workers, to transport honeydew from homopterous insects on plants to small secondary ant nests in soil surrounding the basal area of plants. These secondary nests may then be utilized as transit sites for subsequent honeydew transport to larger primary nests. The small minor workers may also perform other duties in the primary nest, especially as nurse-maids for the brood and queens. The major orange-red and black workers are known to then collect honeydew



Western Thatching Ant, *Formica obscuripes* (Forel) (Hymenoptera: Formicidae), Figure 41 Western thatching ant, *Formica obscuripes* (Forel).

from smaller workers and transport it along ant trails leading to primary nests. These workers have larger crops (stomachs) and can therefore accommodate transporting larger amounts of honeydew. They also collect other arthropods (mostly insects) to use as food for the colony, and are extensively involved in nest repair. It is thought all three morphological forms can perform the same duties when necessary. During cold months of the year adult ants hibernate in the nest below ground (Fig. 42).

It has been estimated that the number of adult workers per colony may reach as high as 35,000–40,000. There is apparently a minimum spacing requirement between colonies that will be tolerated by the ants. If that space is violated, colonies tend to disperse. When disturbed, this ant species can release a stream of formic acid from the distal end of the abdomen. This appears to be a defensive mechanism, but could also serve some other function as well. It has been noted these ants will chew off the bark from the base of some plants, especially when in close proximity to the nest, and then eject formic acid directly onto the cambium layer. This seems to facilitate eventual death of the plant. As the plant dries, branches and stems break off, which may subsequently be used to further enlarge the thatch on the nest. In addition to workers, other members of the ant colony include queens and males. The number of queens per colony may vary; however, it is thought there are typically two or more in each colony. Alate (winged) sexual forms appear on top of the mounds at specific times of year. This may vary from May to August depending on the region and climatic conditions. Once the fertilized alate queen returns to earth from her nuptial flight, she breaks off her wings and then commences to seek an appropriate place to establish a new colony. This is a natural process of propagating new colonies within given species. It has been noted, however, that nuptial flights of *Formica obscuripes* may not occur in all regions of its range. The queens may live for a number of years; however, once they die, the colony will generally die within a few months. The male ants die shortly after the mating flights have been completed. Eggs that have been fertilized develop into female ants and unfertilized ones into males. The type of nutrition larvae receive is thought to have some effect on whether fertilized eggs become queens or workers. Pheromones are used very effectively as means of communication between members within the colony.

Western Thatching Ant, *Formica obscuripes* (Forel) (Hymenoptera: Formicidae), Figure 42 Mound of western thatching ant, *Formica obscuripes* (Forel) (approximately 0.6 m high and 1.5 m in diameter at base).

The western thatching ant should be considered a beneficial insect. It tunnels into the soil at its nesting site, thereby facilitating mixing and aerating of the soil. These ants feed upon a number of other insect species, including some pest species such as the western spruce budworm. It has been noted that nectaries of North American black cherry are most active during several weeks following budbreak. The western thatching ant is attracted to the nectar as a food source. Young eastern tent caterpillars, which may also be present at that time, may be captured and fed upon by these ants. In addition to feeding on other insects, including some pest species, these ants provide a measure of protection for the nectar-secreting homopterous insects they tend. This relationship may be viewed as a mutualistic one between the host plant, the aphids (for example), and the ants. Some defoliating insect pests are fed upon by the ants, thereby benefiting the ants and the plant. The ants protect aphids from their natural enemies and receive honeydew in return;

and finally, the plant provides food for the aphids and thatch material for the ant nest.

West Nile Fever

FELIX P. AMERASINGHE
International Water Management Institute, Colombo, Sri Lanka

West Nile Fever is an arthropod-borne human illness characterized by fever, headache, rash, muscle pains, swollen lymph nodes, and rarely, meningoencephalitis. The disease is caused by the West Nile virus. This was one of the earliest arboviral infections to be documented, the virus being isolated from the blood of an infected woman in the West Nile province of Uganda – hence the name of both the virus and the disease.

West Nile virus belongs to a group of viruses commonly known as arboviruses because they are carried (transmitted) by arthropods (jointed-legged invertebrates such as insects, ticks, etc.). It is scientifically classified under the *Flavivirus* genus within the family Flaviviridae. It is related to other encephalitis-causing viruses like Japanese encephalitis virus, Murray Valley Encephalitis virus, Saint Louis encephalitis virus and eight other viruses that form the West Nile subgroup (complex) of viruses.

West Nile virus has been isolated from vertebrates and/or arthropods in some 25 countries within the Ethiopian, Palearctic and Oriental regions of the world, extending from Portugal in the west, to South Africa to the south, and Russia and India to the east. Very recently, in 1999, it spread to North America. Apart from humans, infected vertebrate animals include cattle, sheep, horses, goats, dogs, rabbits, hares, rodents, game animals, chickens, pigeons, sparrows, and wild birds (especially wetland and migratory birds). The generally accepted view of virus transmission is that it cycles between mosquitoes and birds. Most birds are unaffected by the virus, but can amplify the virus in their blood and thus pass it on when mosquitoes bite. Periodic transmission occurs to other vertebrates and humans when mosquitoes bite them accidentally or as a result of changing their feeding behavior.

Most of the virus detections from arthropods have been in mosquitoes and ticks. Mosquitoes are recognized as the major vectors of the virus. *Culex univittatus* has been implicated as the major mosquito vector with *Culex pipiens* and *Culex neavei* as secondary vectors in the Ethiopian zoogeographical region. *Culex modestus* and *Culex pipiens* have been implicated as vectors in the Palearctic region, and *Culex tritaeniorhynchus* and *Culex quinquefasciatus* as vectors in the Oriental region. Many other species of *Culex*, *Aedes* and *Anopheles* mosquitoes are experimentally capable of transmitting West Nile virus to mammal or bird hosts, but their importance in natural transmission is unknown. West Nile virus also has been isolated from wild caught ixodid and argasid ticks in the Palearctic region, but the role of ticks in natural transmission has not been clearly defined.

The prevalence of West Nile virus infections in humans varies with geographical region, but generally ranges from 20 to 80% in endemic countries. Infection is most often without symptoms, but sporadic cases, or clusters of cases or outbreaks of West Nile fever do occur. When disease occurs, the incubation period is 1–6 days. The onset of illness is abrupt, with fever, headache, and swollen lymph nodes being the most common symptoms. Muscle, eye and abdominal pains, sore throat and vomiting may occur. A rash appears on the trunk and upper extremities of the body during or toward the end of the period of fever. Recovery usually occurs after about 5–6 days. The clinical course of the disease can be more severe or even fatal in the elderly. Meningoencephalitis is a well known complication of West Nile fever. This is associated with neck stiffness, vomiting, confusion, abnormal reflexes, disturbed consciousness, tremor of extremities, convulsions and coma.

There has been a recent upsurge of a more severe form of West Nile fever in Europe. An outbreak in 1996/1997 in Bucharest, Romania, involved more than 500 cases and a case fatality rate of almost 10%. There are reports of an outbreak in Israel involving more than 150 cases and 12 deaths in September 2000. The virus has now crossed the Atlantic ocean: an outbreak of West Nile fever occurred for the first time ever in New York City, USA, in September 1999, involving 56 cases and 7 deaths. Dozens of crows in the area also died (crows are especially sensitive to the virus), and West Nile virus was isolated from several birds, including crows and exotic birds from a local zoo. To date, some 18 species of birds including crows, robins, blue jays, and bald eagles have been infected throughout the eastern United States. Clearly, the virus is there to stay. This underscores an important current issue in public health – the rapid and frequent spread of microorganisms into new areas as a result of modern air travel and international trade. The danger is that microbes invading new territory often find hosts with no immunity, with catastrophic consequences to the hosts. West Nile fever is a relatively mild disease but its recent spread is a warning of trouble to come when more dangerous pathogens find their way into new areas.

Weta (Orthoptera: Anostostomatidae, Rhaphidophoridae)

DARRYL GWYNNE
University of Toronto, Toronto, ON, Canada

Weta are flightless New Zealand ensiferan Orthoptera in the families Anostostomatidae and Rhaphidophoridae. The common name is derived from the Maori word wetapunga, “God of ugly things,” that referred to the anostostomatid, *Deinacrida heteracantha*, one of the giant weta. The most familiar weta are very large insects including a number of species of long-legged cave weta (Rhaphidophoridae). Anostostomatids are the true weta and are known for gigantism and sexual dimorphism, the latter owing mainly to elaborate cephalic weapons in males. All species are omnivores, eating leaves, fruits, seeds and insect prey. When disturbed, many species stridulate and exude foul-smelling feces. Life cycles are lengthy with development from egg to adult (7–10 instars) taking at least 2 years. Adults live for a year or more, particularly alpine species which can live several years as adults, and are freeze-tolerant.

The subfamily Deinacridinae, in particular, is known for gigantism, with some *Deinacrida* female giant weta weighing in over 30 g. Four particularly large arboreal and ground-dwelling *Deinacrida* are virtually extinct on mainland New Zealand due to predation by introduced vertebrates such as rats: *D. rugosa, D. heteracantha* and *D. fallai* survive on certain islands largely due to conservation efforts including translocation of weta and eradication of alien mammalian predators; *D. mahoenui* survives in a very restricted area of dense gorse bushes on the mainland of the North Island. The other seven *Deinacrida* species are on the South Island and survive using diurnal retreats in crevices, burrows or under rocks.

Other large deinacridine anostostomatids also dig burrows or live under rocks and are known for cephalic weaponry exhibited by males. This includes the elephantine tusks of a large tusked weta *Motuweta isolata*, found only on two of the Mercury islands, and two closely related smaller species on the mainland, *M. riparia* and *Anisoura nicobarica*. Tree weta males in the genus *Hemideina* sport very long sexually selected mandibles (Fig. 43). This genus is closely related to *Deinacrida* and several *Hemideina* species are common on the mainland, often in areas of human habitation, as indicated by the common names Auckland and Wellington tree weta. Most tree weta modify beetle holes in trees into galleries, and so are common in firewood. One alpine species lives under rocks. Mating habits of deinacridines vary greatly. *Hemideina* males use their lengthy mandibles to defend harems of females in galleries from rival males; hind femur-on-abdomen stridulation may also be involved in male–male competition. Copulation occurs in association with the gallery and a small spermatophore is transferred. Both *Hemideina* and *Deinacrida* males appear to move frequently in search of mates; *Hemideina* males search for new galleries and *Deinacrida* for individual roaming females, probably detecting their mates using chemical cues. *Deinacrida* pairs remain together throughout the day and the male transfers a dozen or more spermatophores to the female in repeated copulations. For both genera eggs are laid in soil.

Weta (Orthoptera: Anostostomatidae, Rhaphidophoridae), Figure 43 **Male of a Wellington tree weta, *Hemideina crassidens*, showing the lengthy mandibles.**

Also common in New Zealand are ground weta, about 30 species of a small (about 1.5 cm) anostostomatid genus *Hemiandrus*. There are seven described species, so most are undescribed. These members of the subfamily Anostostomatinae differ from deinacridines in lacking tibial tympana and in aspects of reproduction. Pair formation follows vibrational communication between the sexes (abdominal drumming on leaves). During copulation, a spermatophylax gift that the female eats is deposited (in some species) on the female's abdomen following male attachment to secondary genitalia on the female's mid-abdomen. In these species, the ovipositor is reduced and the female lays and cares for eggs (and nymphs) in burrows over several months. Other *Hemiandrus* species have long ovipositors and oviposit in soil.

Anostostomatids share several characters including structure of the proventriculus and certain molecular characters. Phylogenetic analysis supports the family as a natural (monophyletic) group. The current geographic distribution, mainly anostostomatine species, is congruent with Gondwanaland origins for the family. They are typically known as king crickets outside of New Zealand

and are found in Australia (mainly rainforest on the east coast), southern Africa, South America, Madagascar and New Caledonia. Australian species tend to be scavengers of food on the forest floor. A number of species show gigantism and sexual dimorphism similar to New Zealand deinacridines. This includes the extended mandibles in *Henicus, Libanasa* (Africa), and *Anostostoma* (Australia), reaching 2.2 cm in length in the 8 cm-long *Anostostoma australasiae*. Long mandibles are also found in male *Libanasidus* (Africa), including the 6 cm long "Parktown prawn," *L. vittatus*, often common in the suburbs of Capetown. Most species lay eggs in soil, although an undescribed Australian species with a short ovipositor lays eggs in chambers similar to New Zealand ground weta. Some species have tibial tympana and an elaborate spermatophylax-bearing spermatophore.

Westwood, John Obadiah

John Obadiah Westwood was born at Sheffield, England, on December 22, 1805. He studied law, was admitted to the bar, and became a partner in a law firm. However, his principal interests were archaeology and entomology. Westwood was a noted dipterist, working on such groups as Mydidae, Bombyliidae, and Acroceridae, but possessing immense and broad knowledge on many aspects of Diptera. His artistic ability was a particular strength, and his illustrations were noted for accuracy. Of particular note is his publication "An introduction to the modern classification of insects" (1840), in which he proposed a systematic arrangement of the British insect genera. Other noteworthy publications include "Arcana entomologica," "Oriental entomology," and "Exotic insects." In 1858, a wealthy patron of Westwood's (Hope, see above) established a professorship in invertebrate zoology at the University of Oxford. Westwood was named to the professorship, where he continued his taxonomic work for 35 years. He died at Oxford on January 2, 1893 (Fig. 44).

Wheat Pests and Their Management

FRANK B. PEAIRS
Colorado State University, Ft. Collins, CO, USA

Bread wheat, *Triticum aestivum* L., is one of the major cereal crops, along with rice and corn. One of the first domesticated crops, it is widely grown in temperate climates, and accounts for approximately one-fifth of the acreage devoted to cereal production. Wheat is often referred to as the "staff of life," and accounts for about 20% of the calories in the human diet.

There are several other types of wheat, e.g., durum wheat and club wheat, and there are several other cereal crops with similar growth habits and production practices. Arthropod pests of wheat commonly attack these related crops as well. Barley, *Hordeum vulgare* L., is a widely adapted temperate cereal. It is used primarily for feed and in the production of malt. Oat, *Avena sativa* L., is similar to barley in adaptation, and is used primarily as a feed grain. Rye, *Secale cereale* L., is notable for its adaptation to harsh environments. However, its production is declining due to concerns about grain quality, weediness, and poor agronomic traits. Triticale, *X Triticosecale* Wittmack, is a new crop derived by crossing wheat and rye in an attempt to combine the grain quality of wheat with the hardiness of rye. It has become a useful feed and forage crop in certain areas.

Wheat may be sown either in the fall (winter wheat) or spring (spring wheat). Winter wheats are preferred over spring wheats because of greater yield potential, with the latter predominating where climatic conditions preclude the use of winter types. Seeding rates are quite flexible relative to other crops, because of the wheat plant's ability to compensate for changes in competition from its neighbors. Wheat generally responds to nitrogen fertilization, while phosphorus and potassium requirements vary with local soils. While wheat has few equals as a dryland crop, irrigated production systems are important in some regions. Most systems are designed to optimize grain production; however, wheat is also a high quality forage and is sometimes grown in dual purpose systems intended to optimize both animal and grain production.

Growth and development of wheat and related crops begins with germination and emergence of the seedling. After the appearance of several leaves, the plant enters the tillering phase, in which additional stems (tillers, culms) are formed. The spike (head, ear) starts to form near the end of the tillering phase. A rapid stem elongation phase follows. The end of stem elongation is marked by the appearance of the flag leaf (highest leaf on the stem) and the emergence of the spike. The final phase before maturity and harvest is kernel (seed) growth.

Yield of these crops is determined by the relative magnitude of three components. The priority of pest management should be to protect these components to the point that is economically feasible.

1. Spikes per unit area is determined by the number of plants established during emergence and by the number of stems formed during the tillering phase. Pests that might affect this process include wheat bulb fly, *Delia coarctata*, and wireworms.
2. Number of kernels per spike is determined during stem elongation. Pests that might affect this process include Hessian fly, *Mayetiola destructor*, and Russian wheat aphid, *Diuraphis noxia*.
3. Kernel size is determined during the period from spike emergence to plant maturity. Pests that attack the flag leaf or that feed on the developing kernels, e.g., Sunn pest, can reduce kernel size.

Various pests are important to the production of wheat and related cereal crops because of their ability to affect one or more of these yield components. Table 4 lists some of the more important wheat pests. Some are currently major pests and other have been in the past or have the potential to cause important yield reductions. Some are shown in Figures 45–47.

Wheat production systems vary greatly in the amounts of external inputs, e.g., fertilizers and pesticides, used as well as in the degree of mechanization. Limited resource growers in the Middle East, for example, produce wheat with few inputs or mechanization. Production in western North America is highly mechanized because of the large acreages involved, but other inputs are limited because of low production potential. European production is very input intensive because land is scarce and production potential is high. These differences will determine, in large part, the best pest management approaches to employ in a given production system.

Pest management strategies can be categorized as either preventive, or reactive (therapeutic). Low input wheat production systems tend to achieve pest management objectives through low cost, preventive strategies such as plant resistance, biological control or modified cultural practices. More input-intensive systems tend to emphasize the judicious use of chemical controls.

Plant resistance can be defined as the management of crop pests through the use of cultivars that are relatively resistant to a given pest. This is a relatively inexpensive but effective method employed to prevent losses to such key pests as Hessian fly and Russian wheat aphid. Limitations to this approach include the lack of resistance genes to a given pest, as well as the time required to develop an agronomically acceptable resistant cultivar. Recent advances in molecular biology may help overcome some of these obstacles.

Biological control can be defined as the use of one organism to control another. In the case of crop pests, the controlling organism typically is another arthropod or a pathogen such as a bacterium, fungus or virus. The most common strategy in wheat and similar crops is to conserve naturally occurring biological control agents. Less common are releases of biological control agents into a pest's environment. Releases may be inoculative (i.e., sufficient agents to establish a population), augmentative (i.e., sufficient agents to raise an existing population to an effective level), or inundative (i.e., sufficient agents to control the pest infestation). Releases into wheat tend to be inoculative or augmentative in nature.

Modified cultural practices can be defined as changes in normal crop production operations that are intended to either make the crop environment less conducive to a given pest or more favorable for biological control agents. Examples in wheat production systems might include delayed sowing dates to avoid pest infestation, or increased crop diversification to provide additional food and shelter for biological control agents.

Wheat Pests and Their Management, Table 4 **Insect and Mite Pests of Wheat and Related Crops**

Common name[a]	Scientific name	Order	Family
Wheat curl mite	*Aceria tosichella* (Keifer)	Acari	Eriophyidae
Winter grain mite	*Penthaleus major* (Dugès)	Acari	Eupodidae
Banks grass mite	*Oligonychus pratensis* (Banks)	Acari	Tetranychidae
Brown wheat mite	*Petrobia latens* (Müller)	Acari	Tetranychidae
Grasshoppers	*Melanoplus* spp. (usually)	Orthoptera	Acrididae
Grain thrips	*Limothrips cerealium* (Haliday)	Thysanoptera	Thripidae
Say stink bug	*Chlorochroa sayi* (Stål)	Hemiptera	Pentatomidae
Sunn pest (and other common names)	*Eurygaster integriceps* (Puton), other *Eurygaster* and *Aelia* spp.	Hemiptera	Scutelleridae
Bird cherry-oat aphid	*Rhopalosiphum padi* (L.)	Hemiptera	Aphididae
Corn leaf aphid	*Rhopalosiphum maidis* (Fitch)	Hemiptera	Aphididae
English grain aphid	*Sitobion avenae Fabricius*	Hemiptera	Aphididae
Greenbug	*Schizaphis graminum* (Rondani)	Hemiptera	Aphididae
Rose-grain aphid	*Metopolophium dihrodum* (Walker)	Hemiptera	Aphididae
Russian wheat aphid	*Diuraphis noxia* (Mordvilko)	Hemiptera	Aphididae
Western wheat aphid	*Holcaphis tritici* (Gillette)	Hemiptera	Aphididae
Army cutworm	*Euxoa auxiliaris* (Grote)	Lepidoptera	Noctuidae
Armyworm	*Pseudaletia unipuncta* (Haworth)	Lepidoptera	Noctuidae
Pale western cutworm	*Agrotis orthogonia* (Morrison)	Lepidoptera	Noctuidae
Wheat head armyworm	*Faronta diffusa* (Walker)	Lepidoptera	Noctuidae
Wheat ground beetle	*Zabrus tenebroides* (Goeze)	Coleoptera	Carabidae
Cereal leaf beetle	*Oulema melanopus* (L.)	Coleoptera	Chrysomelidae
Wheat wireworm	*Agriotes mancus* (Say)	Coleoptera	Elateridae
Plains false wireworm	*Eleodes opacus* (Say)	Coleoptera	Tenebrionidae
Wheat bulb fly	*Delia coarctata* (Fallén)	Diptera	Anthomyiidae
Hessian fly	*Mayetiola destructor* (Say)	Diptera	Cecidomyiidae
Lemon wheat midge	*Contarinia tritici* (Kirby)	Diptera	Cecidomyiidae
Wheat midge	*Sitodiplosis mosellana* (Géhin)	Diptera	Cecidomyiidae
Frit fly	*Oscinella frit* (L.)	Diptera	Chloropidae
Wheat stem maggot	*Meromyza americana* (Fitch)	Diptera	Chloropidae
Black grain stem sawfly	*Trechelus tabidus*	Hymenoptera	Cephidae
European wheat stem sawfly	*Cephus pygmaeus* (L.)	Hymenoptera	Cephidae
Wheat stem sawfly	*Cephus cinctus* (Norton)	Hymenoptera	Cephidae
Wheat jointworm	*Tetramesa tritici* (Fitch)	Hymenoptera	Eurytomidae
Wheat strawworm	*Tetramesa grandis* (Riley)	Hymenoptera	Eurytomidae

[a]Common names approved by the Entomological Society of America are used where possible

Most reactive or therapeutic measures for pest management in wheat involve chemical control, the application of insecticides or miticides to control existing pest infestations. Chemical controls are unique in that they are capable of eliminating existing infestations over large areas in a relatively short time span. However, insecticides and miticides are poisons, and their use has associated health and environmental risks. Also, chemical controls are expensive, and are cost effective only if they are applied when the economic return from the treatment is expected to be greater than the treatment cost.

There are many examples of pests adapting to a given type of control, particularly resistant cultivars and insecticides, rendering them ineffective. In addition, many preventive controls are not sufficiently effective to completely control pest infestations. For these and other reasons, a combination of controls is generally recommended for the management of wheat pests. This multi-tactic approach is often referred to as integrated pest management or IPM.

Wheat Curl Mite

The wheat curl mite, *Aceria tosichella* (Kiefer), is found throughout Europe and North America. It is most important as a vector of Wheat Streak Mosaic virus disease. However, it can damage wheat directly by curling leaves. Leaf curling is a tight roll of the leaf margin in contrast to the looser roll of the entire leaf caused by Russian wheat aphid. The emerging spike may become trapped in the flag leaf if the latter is tightly curled.

Wheat curl mite is member of a group of microscopic, wormlike plant-feeding mites known as eriophyids. They have two pairs of legs and a few setae. Eriophyid mites are very difficult to identify because of their size and simplified external morphology, and there are many unresolved questions regarding the identities of the eriophyids associated with a given plant species.

Eggs, immature stages, and adult wheat curl mites are found in the winter on wheat and other nearby perennial grasses. As temperatures rise in the spring, mite populations develop under leaf sheaths, inside newly emerged leaves, and eventually within the wheat head glumes. Eggs are placed in rows along leaf veins. An average complete generation requires 10 days. Most mites are found on the terminal leaves and move to each new leaf as it emerges.

As the wheat plant dries down, the wheat curl mites congregate on the upper parts of the plants where they are picked up by wind currents and are carried to their oversummering grass hosts. As summer hosts start to dry down, the reverse process occurs and mites are carried by winds to newly emerged winter wheat.

The wheat curl mite attacks a wide variety of grasses, mostly in the *Agropyron*, *Elymus*, *Hilaria*, *Hordeum*, *Lolium*, *Muhlenbergia*, *Triticum*, and *Zea* genera. Corn, volunteer wheat and wheat grasses are potential important oversummering hosts. This species is also associated with garlic, onions, and other bulb crops.

Destruction of volunteer wheat and the maintenance of a volunteer-free period prior to planting winter wheat in the fall is the most effective management practice for this mite and the diseases that it vectors. Some effective varietal resistance (due to resistance to the mite) is available. Chemical control of wheat curl mites has not been shown to be an effective or economical practice.

Winter Grain Mite

The winter grain mite (also known as blue oat mite or pea mite), *Penthaleus major* (Dugès), is found in temperate areas throughout the world. It has higher moisture requirements than other mite pests of winter wheat and thus is found in more humid production regions. Crops heavily infested with winter grain mite take on a grayish or silvery cast. Plants may be stunted. Leaf tips appear scorched and entire leaves or plants can be killed.

Winter grain mite is a large dark brown to black mite, with reddish legs. A tan or orange spot is often visible on the back. This mite has two generations per year. In North America, the first begins in the fall as the oversummering eggs hatch after rains provide adequate moisture. Feeding peaks in December or January. Second generation feeding peaks in March or April. Populations decrease and oversummering eggs are produced as temperatures become unfavorably warm.

Newly-hatched mites feed on leaf sheaths and tender shoots near the ground. Older immatures and adults feed higher up on the plants at night and on cloudy or cool days. They move to the soil surface and into the soil to seek moisture and to avoid warm temperatures. Winter grain mite activity is greatest between 5 and 21°C. On hot, dry days it may be necessary to dig 10–12 cm into the soil to find the mites. The mites are not harmed by high humidity, rainfall, short periods of sleet or ice cover, or by ground frozen to a depth of several inches.

Favored hosts include small grains and grasses. Winter grain mite also has been reported to damage legumes, vegetables, ornamental flowers, cotton, peanut, and various weeds.

Little is known about winter grain mite management. Crop rotation is recommended. Infestations probably should exceed several mites per plant before chemical treatment is considered.

Banks Grass Mite

The Banks grass mite, *Oligonychus pratensis* (Banks), is a spider mite that feeds on grasses in many parts of the Americas and Africa. It attacks a wide variety of grasses, and is considered to be a serious pest of corn and an occasional pest of grass hay, sorghum, turf and wheat in irrigated crops grown in semi-arid regions.

Damaged wheat leaves are chlorotic and small plants may be killed. Damaged areas on larger plants may have a bright yellow appearance. Infested plants in the fall are often near drying corn. The undersides of infested leaves may be covered with noticeable amounts of webbing.

In North America, fertilized female Banks grass mites move into winter wheat in the fall as their summer hosts, primarily field corn, begin to dry down. Overwintering mites are bright orange. With the onset of winter conditions the mites move to the crowns of wheat plants where they feed until spring. Small pearly white eggs then are laid that mature into pale to bright green male and female adults. Mites then breed continuously on wheat and summer hosts until their return to winter wheat in the following fall. Banks grass mites produce heavy webbing to protect colonies consisting of eggs, immatures and adults. Colonies usually are found on the undersides of leaves. The time required to complete a generation varies with temperature and is usually 10–20 days.

Damaged leaves first become yellow, then brown and necrotic. Heavy populations can kill small plants and reduce kernel size in larger plants.

Crop rotation patterns that place corn adjacent to wheat should be avoided. Biological control is quite useful when Banks grass mite is on its summer host. Chemical control is commonly used against it in higher value crops, e.g., irrigated field corn.

Brown Wheat Mite

The brown wheat mite, *Petrobia latens* (Müller), is a pest of wheat and similar crops in most small grain-producing areas of the world. The economic importance of this species has been difficult to determine because it is closely associated with drought conditions. Brown wheat mite has also been reported from many other cultivated plants, including turf grasses, sorghum, onions, fruit trees, carrots, cotton, lettuce, iris, alfalfa, and clover.

Wheat leaves damaged by brown wheat mite have a finely mottled appearance, and may have chlorotic tips. Heavily infested crops appear drought stressed, and often have an overall yellowish to bronzed discoloration.

In North America, brown wheat mite spends the summer in the soil as a white egg resistant to hot, dry conditions. In the fall, as cooler, wetter conditions return, these eggs start to develop and hatch after a 10-day incubation. Adult brown wheat mites can be distinguished from other mites found on wheat by their extremely long front legs. Female mites mature after feeding on wheat for about 2 weeks and then lay round, red eggs which give rise to further fall (one or two) and spring (two or three) generations. Males have not been observed in this species. As summer conditions return, white oversummering eggs again are produced. Both red and white eggs are placed on soil particles adjacent to wheat plants.

Brown wheat mites feed on plant sap during the day and spend the night in the soil or under surface debris. Their activity peaks at about mid-afternoon on warm, calm days. This mite is not affected by cold temperatures, but populations are quickly reduced by driving rains of about 1cm or more.

Management of volunteer wheat is an important preventive measure for brown wheat mite, as it is with many winter wheat pests. Any management practices that serve to minimize drought stress also are important. Once an outbreak occurs, however, chemical control is the only effective management practice. It is often difficult to justify a chemical treatment because brown wheat mite infestations are associated with drought stress. Also, if white eggs are present and red eggs are mostly hatched, the population is in natural decline and treatment is not economically justifiable.

Thrips

Several thrips attack wheat and other small grains throughout the world, including the barley thrips, *Limothrips denticornis* (Haliday), grain thrips, *Limothrips cerealium* (Haliday) and wheat thrips, *Haplothrips tritici* (Kurdjumov). Thrips feeding results in discolored or distorted leaf tissue. More importantly these thrips feed on developing grains, resulting in sterility or poorly formed or discolored kernels.

These thrips overwinter as adults. Females are light brown to black in color, elongate, and have fringed wings. Males are smaller, and, in the case of *Limothrips*, wingless. Fertilized females move to cereals and other grasses in the spring and begin to feed on the youngest leaves. They insert their eggs in leaf tissue in sheaths or axils, and in the spike when it becomes available. Wheat thrips oviposition tends to be near or on the spike. The pale yellow (*Limothrips*) or red (*Haplothrips*) nymphs are similar in shape to the adults, and feed in leaf sheaths or in the spike. Pupation occurs in the soil. Females mate and then disperse to overwintering sites after the cereal host matures. There are one to two generations per year.

The only available management strategy for these thrips is the use of well-timed insecticide applications. Treatments must be made before flowering, and should be based on scouting and an economic threshold, if available.

Say Stink Bug

The Say stink bug, *Chlorochroa sayi* (Stål), is likely a complex of species which also includes *C. granulosus* and *C. uhleri*. Much of the research on this pest group was conducted before recent taxonomic studies revealed that three species were involved. The name Say stink bug will be used for all members of this group. It is found in the western United States and Canada, and attacks several crops including wheat, barley, alfalfa, and cotton. Russian thistle appears to be an important non-cultivated source of food and shelter throughout the year.

Damage to wheat and barley is caused by feeding on developing seeds. This results in reduced numbers of grains and shrunken, discolored and shriveled grain, and therefore reduced yield and quality. The type and amount of damage is closely related to the stage of plant and grain development, with greatest vulnerability between spike emergence and the grain "dough" stage.

Stink bugs are so called because they release a foul-smelling fluid when disturbed. The Say stink bug is large, reaching about 20 mm in length as adults. They are shield-shaped and bright green in color, and they are marked on the back with raised white dots on back as well as three white or orange spots. Say stink bug eggs are barrel-shaped and marked with white circles, when viewed from above. The eggs are usually attached to the leaf in two-row clusters.

Adult Say stink bugs overwinter in sheltered areas such as underneath tree bark or at the base of native grasses. They become active in the spring and move to various host plants, including Russian thistle, where they feed, mate and lay eggs. As their original hosts are depleted or mature, they move to cultivated crops, particularly small grains. Large groups of adults may move from field to field, remaining only as long as grains are in an acceptable developmental stage. There may be several generations during the summer before the adults move to overwintering sites in the fall.

Because of the sporadic and transitory nature of Say stink bug infestations in small grains, management strategies are generally limited to chemical control. Treatment thresholds are not well defined, but they are quite low because of the great damage potential per individual stink bug.

Sunn Pest

The Sunn pest, *Eurygaster integriceps* Puton, is the most important member of a group of shield bugs that are major pests of small grains in eastern Europe and the Near and Middle East. The information given here applies to *E. integriceps*, but the other species in the complex are quite similar in appearance and biology. These insects feed on all aboveground parts of wheat and other cereals, but the most important damage is due to direct feeding on developing grains. This results in loss of kernels and shriveled or discolored kernels. Damaged kernels have very poor baking quality, and can affect the baking quality of undamaged kernels when milled together.

Sunn pests are large insects, about 1.5 times longer than they are wide. They get their family name (shield bugs) from the fact that the scutellum (part of the thorax) extends back to cover most of the abdomen. Sunn pests are quite variable in color, ranging from yellow-brown to black.

Sunn pest has one generation per year. Eggs are laid in small clusters on leaves of cereals and many other grass hosts. Nymphs feed on leaf tissues until maturation, which usually coincides with kernel development. After 2 weeks or so of feeding, the adults fly to higher elevations to spend the summer and following winter. In more northern latitudes this period is spent in deciduous forests. In the fall they tend to move to protected overwintering sites, where large numbers can be found clustered in relatively small areas. In the spring, adults return to cereal fields and other host locations to mate and reproduce.

Chemical control is the predominant management strategy. Biological control with egg parasitoids and cultural controls, primarily the use of short season cultivars and modified harvest practices, have also been recommended.

Bird Cherry-Oat Aphid

The bird cherry-oat aphis, *Rhopalosiphum padi* (L.), is an important pest of cereals in most production areas of the world. It is important for the damage that it causes as well as for vectoring Barley Yellow Dwarf virus (BYDV). Yield loss relationships are complex, being affected by crop type, crop growth stage, crop condition, presence of other aphid species, and presence of BYDV. Grain yield losses as high as 50% have been observed in winter wheat infested at the two leaf stage.

The wingless form of the bird cherry-oat aphid is broadly oval in shape, is yellowish-green to dark green in color often with a reddish patch at the rear, and long, black-tipped cornicles. The life cycle is complex where severe winter conditions and suitable primary hosts are present. Reproduction occurs on the primary host, several species of *Prunus* trees, in the fall, and the winter is passed in the egg stage. Colonies are formed on new growth in the spring, which give rise to winged females that disperse to grasses for the summer. Their progeny are wingless, parthenogenetic females, and this form predominates on various grass hosts throughout the spring and summer. Winged males and winged, parthenogenetic females are produced in the fall for the return flight to the primary host. If winter conditions are sufficiently mild and *Prunus* plants are absent, then a simplified life cycle of parthenogenesis on grass hosts is followed throughout the year.

Management strategies include modified cultural practices such as delayed planting to avoid virus transmission and promotion of biological controls. In more intensive production systems, chemical controls based on economic thresholds are often used.

Corn Leaf Aphid

The corn leaf aphid, *Rhopalosiphum maidis* (Fitch), is an important pest of cereals in many production areas of the world, particularly in warmer climates. It is more important as a vector of viruses such as Barley Yellow Dwarf virus (BYDV) than for the plant damage it causes. Corn leaf aphids prefer to feed on the young leaves of many types of grasses, including small grains and maize. Yield losses in wheat or other cereals have not been well documented.

The wingless form of the corn leaf aphid is elongate and varies in color from yellowish green to bluish green with black legs, antennae and cornicles. The antennae and cornicles are relatively short. The cornicles are long and black in color. A simplified life cycle of parthenogenesis on grass hosts is followed in most parts of the world, although males are observed occasionally.

Management strategies include cultural practices such as modified planting dates to avoid virus transmission. Biological controls are often effective. Chemical controls are rarely recommended because of this aphid's limited damage potential.

English Grain Aphid

The English grain aphid, *Sitobion avenae* (Fabricius), is an important pest of cereals in many production areas of the world. It is important for the damage that it causes to the plant, as well as for vectoring of Barley Yellow Dwarf virus (BYDV). English grain aphids prefer to feed on upper leaves and the spikes, once they have emerged. Late season infestations can reduce grain yield and quality. Yield loss relationships are complex, being affected by crop type, crop growth stage, crop condition, presence of other aphid species, and presence of BYDV. Grain yield losses greater than 30% have been observed in wheat.

The wingless form of the English grain aphid is moderate in size and spindle-shaped. It is generally green to brown in color. The cornicles are long and black in color. The life cycle occurs entirely on grasses. Sexual reproduction and overwintering eggs occur where severe winter conditions are present. If winter conditions are sufficiently mild then a simplified life cycle of parthenogenesis on grass hosts may be followed throughout the year.

Management strategies include cultural practices such as modified planting dates. Biological controls can be effective in some situations. Plant resistance has been identified but not used commercially. In more intensive production systems, chemical controls based on economic thresholds are used.

Greenbug

The greenbug, *Schizaphis graminum* (Rondani), is an important pest of cereals in many production areas of the world. It is most important for the damage that it causes to the plant, but is also a vector of Barley Yellow Dwarf virus (BYDV). Leaf tissue affected by greenbug is often discolored yellow or red due to the phytotoxic nature of its saliva. Yield loss relationships are complex, being affected by crop type, crop growth stage, crop condition, presence of other aphid species, and presence of BYDV. Grain yield losses greater than 50% have been observed in several crops.

The wingless form of the greenbug is relatively small and more elongate than oval in shape. It is generally light green in color, with a darker green dorsal stripe. The cornicles are mostly colorless with darker tips. The life cycle occurs entirely on grasses. Sexual reproduction and overwintering eggs occur where severe winter conditions are present. If winter conditions are sufficiently mild then a simplified life cycle of parthenogenesis on grass hosts may be followed throughout the year.

Management strategies include modified cultural practices such as delayed planting to avoid virus transmission and reduced tillage. Biological controls can be effective in some situations. Greenbug resistant varieties have been used widely in sorghum, but the development of biotypes has limited the sustainability of this approach. In more intensive production systems, chemical controls based on economic thresholds are often used; however, greenbug resistance to carbamate and organophosphate insecticides has been documented.

Rose-Grain Aphid

The rose-grain aphid, *Metopolophium dirhodum* (Walker), is an important pest of cereals in many non-tropical areas of the world. It is important as a direct plant pest as well as a vector of Barley Yellow Dwarf virus (BYDV). Rose-grain aphids prefer to feed on the upper leaves of wheat and other grasses, but rarely on the spike. Yield loss relationships are complex, being affected by crop type, crop growth stage, crop condition, presence of other aphid species, and presence of BYDV. Grain yield losses of 10–20% have been observed in wheat.

The wingless form of the rose-grain aphid is spindle shaped, and is yellowish green to green with a dorsal stripe on the abdomen. The antennae, legs and cornicles are generally pale. The life cycle is usually complex, although a simpler life cycle of parthenogenesis on grasses is common in western Europe. Reproduction occurs on the primary host, several species of *Rosa*, in the fall, and the winter is passed in the egg stage. Colonies are formed on new growth in the spring, which give rise to winged females that disperse to grasses for the summer. Their progeny are wingless, parthenogenetic females, and this form predominates on various grass hosts throughout the spring and summer. Winged males and winged, parthenogenetic females are produced in the fall for the return flight to the primary host.

Management strategies include modified cultural practices such as delayed planting to avoid virus transmission and promotion of biological controls. In more intensive production systems, chemical controls based on economic thresholds are often used.

Russian Wheat Aphid

The Russian wheat aphid, *Diuraphis noxia* (Mordvilko), is an important pest of wheat and barley in western North America and South Africa. It also damages these crops sporadically in North Africa, southern Europe, the Middle East, Central Asia, Chile and Argentina. It is important for the direct damage that it causes to its hosts, but is not considered an important vector of plant viruses. Damage symptoms include tightly rolled leaves, white or purple leaf streaking and stunted plants. Yield loss relationships are complex, being affected by crop type, crop growth stage, crop condition, and the presence of other aphid species. Grain yield losses as high as 80% have been observed in malt barley.

The wingless form of the Russian wheat aphid spindle-shaped, light green in color, and may have a somewhat waxy appearance. The antennae are short and the cornicles are greatly reduced. The supracaudal process is unique among the cereal aphids. In the New World and South Africa a life cycle of parthenogenesis on a variety of cool season grass hosts is followed. Sexual reproduction and an overwintering egg stage are commonly observed in Old World populations. The closely related western wheat aphid, *Diuraphis tritici* (Gillette), is found in western North America, has a similar life cycle and causes similar damage.

Management strategies include modified cultural practices and promotion of biological controls. Resistant varieties have been developed in wheat and are grown widely in areas with consistent Russian wheat aphid infestations. In more intensive production systems, chemical controls based on economic thresholds may be used.

Army Cutworm

The army cutworm, *Euxoa auxiliaris* (Grote), occurs in the cereal production areas of much of western North America. This is a climbing cutworm found feeding at night and on cloudy days on the aerial portions of small grains and many other plants. Yield loss relationships are poorly understood, with the degree of loss being particularly influenced by crop growth stage, plant population and drought stress. Losses in winter wheat in excess of 30% have been observed. More losses observed when there is relatively little foliage, which increases the likelihood of damage to the crown.

Army cutworm larvae are nearly 5 cm long when fully grown, generally colored light gray with lighter markings and a pale stripe running down the back. Adults are small moths, with a wingspan of about 3–4 cm. They are nuisance invaders of homes and other structures during their spring migration to higher elevations.

The army cutworm has one generation per year. Eggs hatch in the fall following a rainfall. The winter is passed as partially grown caterpillars, which feed on warmer days. They feed more frequently in the spring and develop more rapidly. As daytime temperatures rise, the army cutworm is found under soil clods and other debris during the day. This is a climbing cutworm that always feeds above ground during the night and on cloudy days. Pupation occurs in a small chamber constructed several inches below the soil surface. Moths emerge in May and June and migrate to higher elevations to escape high summertime temperatures. In late summer and early fall, the moths return to the plains to lay their eggs in wheat fields and other cultivated areas.

Because of the sporadic nature of outbreaks, management strategies are mostly limited to insecticide treatments based on economic thresholds. Pyrethroid insecticides, as a group, have been quite effective.

Armyworm

The armyworm, *Pseudaletia unipuncta* (Haworth), is a pest of small grains and other grass crops in North America east of the Rocky Mountains. Armyworm outbreaks occur only occasionally, more commonly during cool, wet springs, because natural population regulation usually prevents the development of economically significant infestations. The common name comes from this species' habit of moving in mass once they deplete local food sources. Damage commonly occurs when armyworm larvae defoliate the lower portions of various crops, although complete defoliation may occur during severe infestations. Defoliation is often complete, with only the leaf midribs left uneaten. Armyworm feeding in small grains near crop maturation is even more serious because it can result in spikes being clipped off and lost when larvae chew through the last remaining green tissue just below.

Mature larvae are about 4 cm in length, smooth-bodied, and dark grey to greenish-black. They have five stripes, three on the back and two on the sides, running the length of the body. While the stripes on the back are variable in color, the stripes on the sides are pale orange with a white outline. The head capsule is remarkable for its "honeycomb" of black markings.

Armyworms pass the winter as partially grown larvae in the southern part of their range. Armyworm moths migrate to the northern part of their range in early summer. The moths have grayish-brown forewings, each with a white spot near the center, and grayish-white hind wings. The wingspan is approximately 4 cm. Armyworm moths lay their eggs in rows or clusters on the lower leaves of various grass crops. They prefer dense, lush vegetation for egglaying. Newly hatched larvae move with a looping (inchworm) action. Larvae feed at night and on cloudy days, and hide under crop debris during sunny periods. One or more generations may occur per year.

Pale Western Cutworm

The pale western cutworm, *Agrotis orthogonia* Morrison, occurs in North America from the western High Plains to the Pacific and from Canada to New Mexico. It is a more consistent problem in the northern plains states and southern Canada. It is potentially one of the most devastating insect pests of wheat in the region. Pale western cutworm is a subterranean cutworm, and feeds on stems below ground just above the moisture line. In drier soils larvae tend to feed further down on the stem and consume little tissue before moving to the next stem. This results in many severed stems and entire fields may be lost in a matter of days. In moister soils larvae feed further up on the stem and consume most of a single stem, which results in less overall damage to the crop.

Pale western cutworm larvae have greyish white, unmarked abdomens. They are distinguished from other similarly unmarked cutworms by the presence of two distinct vertical brown bars on the front of the head capsule. Eggs are deposited in loose soil. Some eggs may hatch within a few weeks, but most wait until the following spring when air temperatures at the soil surface reach 21°C. Hatch may be delayed for up to several months if moisture and temperature conditions are unfavorable. Larvae prefer loose, sandy or dusty soil and are found most easily in the driest parts of the field, such as hilltops. Pupation occurs in chambers constructed several inches below the soil surface. Emergence of the gray to brownish white adult moths occurs in late summer and fall. They have an approximately 3–4 cm wingspan and are distinguished from other cutworm moths by the white undersurface of the wings.

Outbreaks are associated with dry conditions in the previous spring, because rainfall events of more than 6–7 mm tend to drive the cutworms to the soil surface and expose them to increased predation and parasitism. If the preceding May and June had fewer than 10 days with 6–7 mm or more inches of rainfall, then pale western cutworm population densities can be expected to increase. If the preceding May and June had more than 15 such days then pale western cutworm abundance will be greatly reduced.

Because of the sporadic nature of outbreaks, management strategies are mostly limited to insecticide treatments based on economic thresholds. Pyrethroid insecticides, as a group, have been quite effective.

Wheat Head Armyworm

The wheat head armyworm, *Faronta diffusa* (Walker), is found in most cereal production areas of North America north of Mexico and east of

Arizona. Wheat head armyworm feeds on various grasses and small grains crops, with the first observed outbreaks occurring on timothy. While wheat head armyworm is considered to be a minor pest, its habit of feeding on developing spikes and grains gives it significant damage potential. Damaged kernels have the attachment end gouged out, as if they had been damaged in storage by *Sitophilus* spp. weevils.

Little is known about the life history of this insect. It spends the winter as a pupa in the soil. The small brown moths emerge to lay eggs in rows within leaf sheaths in the spring, and larvae can be found in wheat in June. First generation larvae feed on the heads of wheat at night and hide near the base of the plant during the day. Fully grown larvae are variable in color, ranging from light green to brown. They are tapered towards the rear, and have several stripes that vary in width and color.

No chemical control data or economic threshold studies are available for this insect. Infestations often are limited to field margins. If an outbreak occurs, any registered contact insecticide should be effective against this insect.

Wheat Ground Beetle

The wheat ground beetle, *Zabrus tenebroides* (Goeze), is an important pest of seedling winter wheat in many parts of Europe. Larvae feed on the leaves of young plants, causing a frayed or skeletonized appearance, or tunnel in the crown. Loss of plant stand often results. Adults feed on developing grains, but this damage is not considered to be as important as that caused by the larvae. Yield loss relationships can be significant under conditions unfavorable for compensatory plant growth.

The adults are small (about 1 cm) reddish brown ground beetles. Eggs are laid in soil when moisture content is adequate, usually from July through September. The larval stage is found from late September through the following spring, when the adults appear. The larvae, up to 3 cm in length, have a whitish body and brown head, thorax and legs. They overwinter in chambers in the soil, and feed actively on host plants during periods of active crop growth.

Management strategies emphasize cultural practices including adequate fertilization to encourage crop compensation in thinned stands, and crop rotation. Insecticide treatments targeting the larvae also are recommended.

Cereal Leaf Beetle

The cereal leaf beetle, *Oulema melanopus* (L.), has been known in Europe as an occasional pest of small grains for more than a century. It was introduced into North America in 1962, and has spread to most cereal production in the northern half of the United States. Adults and larvae defoliate small grains, especially those sown in the spring. Losses as high as 75% in barley and oats have been reported. Reduction in malt barley quality is of special concern.

Adult cereal leaf beetles prefer to feed on young, actively growing leaves. They chew completely through the leaf, between the veins, resulting in linear streaking of the leaf. This damage is easily confused with that of flea beetles. Larvae feed only on the upper surface of the leaves. They feed down to the leaf cuticle, staying between the veins, resulting in distinctive linear "window-pane" damage. Larval feeding differs from adult damage in that it is wider and limited to the upper surface of the leaf. Tips of damaged leaves may turn white, and heavily infested fields may have a frosted appearance.

Adult cereal leaf beetles are about 5–7 mm long, with a metallic blue head and wing covers, a red pronotum (neck) and orange-yellow legs. The eggs are less than 2 mm long, yellow when first laid, but darkening to yellow-brown when about to hatch. Larvae appear dark and slug-like. Their skin is yellowish brown, and is covered by a mass of slimy, dark fecal material.

Cereal leaf beetles spend the winter in protected sites like grass crowns, grain stubble, wooded areas, or under house siding. They become active when air temperatures are above 10°C. They feed on wild grasses and move to small grains when available. Females mate in the spring, and begin to lay eggs about 2 weeks later. A single female may lay up to 300 eggs over a 6 week period. The eggs hatch in 4–23 days, depending on temperature. Larvae feed for 10–21 days, depending on temperature, before crawling down the plant to pupate in the upper two inches of soil. The larval feeding period can last up to 2 months, due to continuous overwintering adult emergence and egg laying. The pupation period lasts 2–3 weeks.

Newly emerged adult beetles feed for 2–3 weeks on the new succulent growth of a wide variety of grasses, after which they disperse to overwintering sites where they enter dormancy. Winter mortality, due extreme temperatures and natural enemies, ranges to from 40 to 70%. There is one generation of cereal leaf beetle per year.

Effective biological controls are available, and are used preventively and successfully. The larval parasite *Tetrastichus julis* (Walker) has been an effective biological control agent in the western United States. The egg parasite *Anaphes flavipes* (Forester) has worked well in combination with larval parasites in the eastern United States. Insecticide treatments are used to control existing infestations based on the potential for economic losses greater than the cost of treatment.

Wireworms and False Wireworms

Wireworms and false wireworms attack wheat in most production regions of the world. Important North American wireworm species include the wheat wireworm, *Agriotes mancus* (Say), the prairie grain wireworm, *Ctenicera aeripennis destructor* (Brown), and the Great Basin wireworm, *C. pruinina* (Horn). Important false wireworms include several *Eleodes* species, such as the prairie false wireworm, *E. opacus* (Say), are found in drier production regions of North America. Wireworms and false wireworms damage wheat by feeding on seeds, seedlings and young plants, resulting in lost stand. Yield losses occur if plant population losses are large enough to overcome the compensatory ability of the crop.

Adult wireworms are known as click beetles, which get their name from the sound they make as they jump. They are elongate brown or grey beetles, with parallel sides and rounded at the head and rear. The damaging larval stage is cylindrical, slender, hard-bodied, usually a shiny brown or pale yellow in color. The flightless adult false wireworms are known as darkling beetles. These are large black or reddish brown beetles, which can be recognized by the odd angle that the body is held at when they run. The larvae are similar in appearance to wireworm larvae.

Wireworm adults lay their eggs in soil and most of the life cycle is spent in the larval stage. Larvae will be found at varying depths in the soil, depending on temperature and moisture. Life cycles are variable, lasting from 1 to 9 years. The false wireworms have a similar life cycle, although most are completed within 3 years.

Management strategies emphasize cultural practices that promote rapid germination and seedling growth to shorten the period that the plant is most vulnerable to attack. Insecticidal seed treatments also are commonly used.

Wheat Bulb Fly

The wheat bulb fly, *Delia coarctata* (Fallén), is an important European pest of wheat and other small grains. It is also found in North America, but generally is not considered to be an important pest there. Larvae tunnel in the base of the main stem or tillers, resulting in the loss of plants or spikes.

The adults are small, slender gray flies with relatively large wings and a bristly appearance. They lay their eggs in the soil in mid summer. The elongate white eggs hatch during the winter and the larvae move to grass hosts and bore into the base (bulb) of the main stem or one of the tillers. After several weeks, when about 3/4 grown, the maggots move to another stem, either on the same plant or a new plant. Pupation occurs in late spring, and within a few weeks adults emerge from the soil to mate and lay the eggs of the next generation.

Management strategies include early planting of winter crops to obtain larger more tolerant plants at the time of larval hatch, and delayed planting of spring crops to avoid the hatch and infestation period. Chemical controls include treatment of the seed, seedbed and plants. Expert systems and other decision support tools are available to help improve the efficacy and cost effectiveness of insecticide treatments.

Hessian Fly

The Hessian fly, *Mayetiola destructor* (Say), has spread from its original home in the Caucasus region of Eurasia to most major wheat producing regions of the world. It has been a pest of wheat in the United States since the eighteenth century, and is considered to be one of the most serious pests of wheat in the world. Damage to the plant is caused by the larval stage, which sucks juices from the plant. Feeding results in stunted and dead tillers and plants, and broken stems resulting in unharvestable grains. Hessian fly prefers wheat but also attacks barley and rye.

The adult is a small grey or black midge. The eggs are cylindrical and glossy red in color. The wormlike larvae vary in color, but are greenish white when fully grown. Pupation occurs within a glossy brown protective case (puparium) referred as a "flaxseed."

In the fall, adults emerge from stubble and volunteer winter wheat to lay several hundred eggs on the leaves of young plants. The adults die within a few days of emergence. At about the same time the eggs hatch and the larvae move to the crown of the plant to feed. The larvae usually finish their development before the onset of cold weather. Winter is passed in the "flaxseed" stage. Pupation and a second flight of adults occurs in the spring at about the time of jointing. Larvae of the spring generation feed in leaf sheaths and then form the puparia in which they spend the summer.

The use of resistant varieties is the most effective method of managing Hessian fly in areas where it is a key pest. However, Hessian fly biotypes often develop in response to the deployment of resistant varieties. Delaying planting to avoid the short egg-laying period is also an effective management practice. The "fly-free" date is a term for the time after which wheat can be planted to avoid Hessian fly infestations. Destruction of volunteer wheat also helps to reduce Hessian fly infestations.

Wheat Midge

The wheat midge, *Sitodiplosis mosellana* (Géhin), is found in most wheat production areas in the Northern Hemisphere, and can be a key pest of wheat under favorable conditions. The lemon wheat blossom midge is a related species, *Contarinia tritici* (Kirby), that is similar in appearance, life cycle and damage. However, its distribution is limited to Europe and Asia. Wheat midge larvae feed on developing kernels of wheat and other grasses, causing them to shrivel, crack and become deformed. These losses in yield and quality can be great enough and the midge difficult enough to control in certain areas that ceasing wheat production is the only economic solution.

The adult wheat midge is a small, fragile orange fly with prominent black eyes, long legs, and oval fringed wings. They emerge from the soil in late June or early July. Females are active during the evening hours, laying eggs on freshly emerged spikes. The orange maggots hatch within 1 week and move to the interior of the spike to feed on the surface of a developing kernel. After 2–3 weeks, fully grown larvae drop to the soil to overwinter. However, under dry conditions they may enter a resting stage that may last even to the time of harvest. Overwintering larvae remain in the soil for one to several winters, usually in the top several inches, until conditions are favorable for pupation.

Larvae then become active and move to the soil surface to pupate.

Management of wheat midge has relied on insecticide treatments to control adults and prevent egg laying, and to kill larvae before they enter the spikes. The most effective treatments are applied between 70% spike emergence and flowering. Larval surveys may be used to assess wheat midge risk and the advisability of sowing an alternate crop. Some sources of resistance in wheat to wheat midge have been identified.

Frit Fly

The frit fly, *Oscinella frit* (L.), is found in cereal production areas throughout the Northern Hemisphere, but is considered to be an important pest only in Europe. The nature of the damage caused by frit fly depends on the growth stage of the crop. Infestation of small plants results in dead plants or stems, while damage to the spike by later generations results sterility.

The adult is a small, robust black fly. Elongate, white eggs are deposited on cereals and other grass hosts. The pale yellow larvae mine leaves when newly hatched and later bore in stems or feed on undeveloped florets. Pupation occurs on the plant. There typically are three generations per year, with adults active in April–May, June–July and August–September.

Management recommendations include control of volunteer plants and other alternate hosts, as well as early sowing of spring grains to promote larger, more tolerant plants at the time of first generation infestation. In Europe, insecticides may be used to protect seedlings.

Wheat Stem Maggot

The wheat stem maggot, *Meromyza americana* Fitch, is found throughout North American cereal production areas. Damage to small plants results in dead tillers or plants, and damage to larger plants results in white, sterile spikes. Yield losses of 10–15% have been observed in heavily infested fields.

Wheat stem maggot passes the winter in the larval stage, in the lower parts of the stems of wheat and other hosts. They pupate in the spring and the greenish yellow, striped adults emerge in June. The white, cylindrical eggs are laid on the leaves and stems of wheat and other hosts. The newly hatched pale green maggots of this generation enter the leaf sheaths and tunnel into the tender tissues of the stem. Tunnels in wheat are usually 5–8 cm in length, and result in white, sterile spikes. Another generation of flies emerges in midsummer to lay eggs on volunteer cereal plants and other grasses. The fall generation emerges in late August to early September and lays eggs in the new winter wheat crop.

The use of delayed planting, following the dates recommended to escape Hessian fly infestations, is an effective management practice. Destruction of volunteer plants is also recommended. The effectiveness of chemical control is unknown, and currently not recommended.

Sawflies

Three sawflies attack cereals in the Northern Hemisphere: The black grain stem sawfly, *Trachalus tabidus* (Fabricius); the European wheat stem sawfly, *Cephus pygmaeus* (L.); and the wheat stem sawfly, *Cephus cinctus* Norton. The wheat stem sawfly is prevalent in western North America, particularly in the northern Great Plains, while the other two species are found in eastern North America and Europe. All three have similar field biology and cause similar damage. The following information is specific to wheat stem sawfly but should apply in general to the other species as well.

When they are mature, wheat stem sawfly larvae move to the base of the stem and gnaw a ring around the inside of the stem. The weakened stems break easily, making grain unavailable for harvest. Complete crop losses have been observed.

The wheat stem sawfly overwinters in the larval stage within wheat stems in a ground-level tunnel. Pupation occurs in May and the slender black and yellow adult sawflies are present from mid June to mid July. Females place single white, crescent-shaped eggs within stems of cereals and other host grasses. These hatch into pale yellow, legless worms similar in appearance to a caterpillar. The sawfly larvae tunnel up and down the stem. Mature larvae move to the base of the stem to form their overwintering chamber. The inside of the stem is chewed away, and the stem usually breaks at the point of this damage. The larvae then plug the area just below the break, forming the chambers in which they will pass the winter and pupate the following spring.

The use of solid stem wheat varieties is the most common management recommendation for wheat stem sawfly. Solid stems are, however, associated within lower yield potential. Several cultural controls also have been suggested, including destruction of stubble in the late fall or early spring. This is effective in reducing sawfly overwintering, but may conflict with soil and water conservation goals. Delayed planting of spring wheat and the use of trap crops are additional recommended cultural practices. Biological controls are considered to be of limited effectiveness. There are no effective chemical controls.

Wheat Jointworm

The wheat jointworm, *Tetramesa tritici* (Fitch), is most common in eastern North America and the Pacific Northwest. Once considered one of the major wheat pests, on a par with Hessian fly, it is now thought to be of only minor importance. Larval feeding causes the formation of small stem galls, resulting in malformed tillers prone to breakage.

The wheat jointworm overwinters in the pupal stage within stem galls in wheat stubble. The small black adult wasps gnaw their way out of the pupal chambers in April and May and spend the following month in wheat laying their eggs in wheat stems just above one of the nodes. The small white larvae form cells in the stem wall where they feed on plant sap. The swelling formed by the presence of the cell is referred to as a stem gall. Larvae cease feeding at about the time of wheat ripening.

The only available management recommendations are late fall or early spring stubble destruction and growing the current year's crop at some distance from the previous year's crop. Effective insecticide treatments are not available.

Wheat Strawworm

The wheat strawworm, *Tetramesa grandis* (Riley), is found in most North American wheat production areas. Once considered one of the major wheat pests, on a par with Hessian fly, it is now thought to be of only minor importance. Spring generation larvae feed on and destroy the developing spike. Summer generation larvae feed within the stem, just above one of the nodes, reducing yield and quality to an undetermined degree.

The wheat strawworm overwinters in the pupal stage within a feeding cell in the wheat stem, usually located near a node. In the spring, the small, black wingless spring adults emerge and lay the small, white, bulb-like eggs near the growing point of a tiller. The robust, pale yellow larvae hatch and destroy the growing point and form a feeding cell at the base of the tiller. Pupation occurs within the cell, and within 2 weeks the larger, winged summer adults (females only) emerge. The summer adults lay their eggs near one of the upper joints where the larvae feed and mature within the stem. Summer-form larvae are longer and more slender than those formed in the spring generation. A cell is formed near one of the joints where the larvae pass the summer and fall until pupation.

Recommended cultural controls include late fall or early spring stubble destruction, growing the current year's crop at some distance from the previous year's crop, and control of volunteer wheat plants. The use of early maturing varieties allows escape from the summer generation. No chemicals controls are known to be effective.

Several species of sawfly (Hymenoptera: Cephidae) are pests of wheat and other cereal crops worldwide. The Cephini, the tribe to which these agriculturally important species belong, includes 50–60 grass-feeding species. This tribe evolved in the Old World, and only four species are found in

North America: *Calameuta clavata* (Norton), a non-pest species, *Cephus cinctus* Norton, the wheat stem sawfly, *C. pygmaeus* (L.), the European wheat stem sawfly, and *Trachelus tabidus* (F.), the black grain stem sawfly.

Cephus cinctus is widely distributed across North America, from California to the Mississippi River and British Columbia to Manitoba. Many authorities consider it a native North American insect which adapted to wheat as European settlers began large-scale cultivation of cereal crops. Alternatively, there is some evidence that *C. cinctus* may have been inadvertently introduced into North America from northeastern Asia. A sawfly species from eastern Siberia, *C. hyalinatus* Konow, has recently been synonymized with *C. cinctus* using morphological features in preserved specimens. This has greatly expanded the distribution of *C. cinctus* to include northeastern Asia. Several other species, including *C. camtschatcalis* Enslin and *C. zahaikevitschi* Ermolenko, may also be conspecific with *C. cinctus*. The co-occurrence of *C. cinctus* in Asia and North America, and preponderance of *Cephus* species in Asia, suggests the possibility that *C. cinctus* may have been introduced from Asia to North America (Fig. 48).

Cephus pygmaeus and *Trachelus tabidus* are found in Europe, Asia and North Africa. *Cephus pygmaeus* has a wider distribution than *T. tabidus*, but the latter species appears to be more common in the Mediterranean region. Both species were introduced into North America in the late 1800s, and became pests of small grain crops. In North America, *C. pygmaeus* has been found from northern Virginia to Ontario, but not west of Pennsylvania. *Trachelus tabidus* spread east and south from a probable point of entry somewhere between New York City and Richmond, Virginia, and is now found in Ohio, Pennsylvania, Maryland, Delaware, Virginia and North Carolina, but apparently not in Canada. Following a successful biological control effort against *C. pygmaeus* and *T. tabidus* in the 1930s, these two species were reduced to non-economic status.

Wheat Stem Sawflies: *Cephus cinctus* Norton, *Cephus pygmaeus* (L.) and *Trachelus tabidus* (F.) (Hymenoptera: Cephidae), Figure 48 **A female wheat stem sawfly (*Cephus cinctus*) ovipositing into a wheat stem.**

Host Plants

Wheat, barley, and rye are the main cereal crops attacked by sawflies, though infestation in other small grains such as triticale, spelt, and others have been observed. Cultivated oats do not support sawflies. Until recently, in western North America, *C. cinctus* attacked primarily spring wheat, while winter wheat suffered less damage because of its earlier sowing date and more advanced growth stage when sawflies emerge. Winter wheat now sustains extensive damage in the northern Great Plains. The choice of host plant appears to be related as much to stem diameter and phenological growth stage as to particular grass species. *Cephus cinctus* feeds on a number of grasses including species of Agropyron, *Bromus*, *Elymus*, and *Elytrigia*, in addition to cereal crops. The known host range for *Cephus pygmaeus* is wider than reported for *C. cinctus* and includes *Agropyrum*, *Avena*, *Bromus*, *Hordeum*, *Phleum*, *Secale*, and *Triticum*. The range of non-cultivated host plants for *T. tabidus* is unknown.

Biology

The biology of the agriculturally important sawflies is very similar and, at least for the three pest species found in North America, has been well studied. Females deposit eggs into the elongating stems of host plants in early summer and the developing larvae feed by moving up and down the length of the stem. Though several eggs may be laid within a stem, only a single larva survives to maturity. As the plant matures, and usually prior to harvest, the larva moves down to the base of the stem and chews a V-shaped notch around the inside of the stem. The stem lumen is plugged with frass and sawdust below the notch, forming a chamber or hibernaculum. The notch weakens the stem, which usually breaks, producing a "stub" that remains anchored in the ground. The sawfly larva undergoes an obligatory diapause within this chamber during the winter or the dry season. The stub is often covered with debris or soil, and is therefore well protected from excessive cold or dry conditions. The diapausing larva is contained within a thin membranous cocoon. Diapause is broken as temperatures, moisture levels and/or photoperiods increase in the spring. Post-diapause development includes prepupal and pupal stages lasting approximately 2–30 days depending on ambient temperatures. Adults emerge from the cocoon and use their mandibles to exit the stub through the plug. The agriculturally important species have a single generation per year, with a short-lived (7–10 days) and apparently non-feeding adult stage.

Damage and Yield Loss

Feeding by sawfly larvae reduces vascular efficiency resulting in fewer kernels per head and lower kernel weight, and can also reduce the protein content of the grain. Additional grain loss is the result of lodging after the inside of the stem is girdled. *Cephus cinctus* was first reported as a pest in Canada's Prairie Provinces in the late 1890s, and continues to be a key constraint to cereal production in the northern Great Plains. Damage is greatest in Montana, North Dakota, Alberta, Saskatchewan, and Manitoba. Infestation levels of more than 70% have been recorded with the weight of grain per head reduced by more than 20%. Losses of approximately 80% have been reported from central Montana. Annual losses to wheat, barley, rye, triticale and other cereal crops may exceed US $100 million in the region.

Prior to the successful biological control campaign against *C. pygmaeus* and *T. tabidus*, infestation levels as high as 45% for *C. pygmaeus* and 65% for *T. tabidus* were reported in eastern North America. *Trachelus tabidus* may have caused greater damage to wheat than *C. pygmaeus*, though the latter species is more widely distributed. Neither species is currently considered a serious pest of wheat in North America. Pest surveys from the 1980s detected less than 5% infestation in wheat from *C. pygmaeus*.

Cephus pygmaeus is also a pest in Europe and the North Africa/Mediterranean region, with reported infestation levels of up to 40% in Morocco, and reductions of 6–17% in kernel weight and 30–45% in kernel number. Damage and grain weight reductions of more than 45% have been reported from Switzerland, France, Germany, Belgium, Poland and Romania.

Several other sawfly species are pests of small grains in other parts of the world. Wheat yield losses in China of 6% have been reported for *C. fumipennis*, with some cultivar losses exceeding 30%. The lack of published literature on many of these other species may result from being less well studied or may be due to incorrect field identification.

Natural Enemies

The most important sawfly natural enemies are parasitic Hymenoptera, though 5–10% of overwintering sawfly larvae may be killed by pathogenic fungi. There are also unpublished reports of at least one predator attacking sawflies but predators and pathogens have relatively little impact on sawfly population dynamics compared to parasitoids. The list of parasitoids attacking cephids appears extensive, though little is known about most species. Many species attack other hosts found in grasses or are obligate or facultative hyperparasitoids. Primary parasitoids of gramivorous Cephidae are found in the following families: Braconidae, Eulophidae, Ichneumonidae, and Pteromalidae. The most important, and the most well-studied are the braconids and ichneumonids. Most natural enemy complexes include one or more members of each family. The exception is the natural enemy complex attacking *C. cinctus*. Thus far, no ichneumonids have been recovered from *C. cinctus*. This is interesting because ichneumonids dominate the natural enemy complexes of other *Cephus* species. In terms of biology, the braconids are larval ectoparasitoids, while the other species are larval or egg-larval endoparasitoids.

Management

Management of wheat stem sawfly has focused on the development of resistant wheat cultivars, various tillage operations to destroy larvae and/or pupae in the stubble, and biological control using exotic parasitoids. Pesticides are generally too costly, given the relatively low value of wheat, and are ineffective because the larvae are concealed within the stem. Efforts to develop resistant wheat cultivars with solid-stems began in the 1930s following earlier reports that this trait provided resistance to *C. pygmaeus* in Europe. The first solid stemmed cultivar ("Rescue") was released in 1946, and this has been followed by a number of other solid stemmed cultivars. The performance of these cultivars has been variable. Sawfly larvae apparently suffer higher mortality and/or cause less damage in solid stemmed versus hollow stemmed cultivars, though resistant cultivars generally have lower yield and protein content than alternative hollow stemmed cultivars. Recent studies suggest that there may be a negative association between protein content and stem solidness but that yield per se should not be affected by the solid stemmed character. In addition, the degree of stem solidness in a given cultivar may be reduced by light, temperature, moisture supply, and plant spacing. The variable field performance resulting from interactions among environmental variables and resistant cultivars has reduced farmers' confidence in these cultivars.

Tillage, either in the spring or fall, has also produced equivocal results with significant limitations. Several reports indicate that tillage can reduce populations of wheat stem sawfly. A number of tillage implements have been evaluated, but the critical factor seems to be separating soil from the base of the wheat stem. Soil attached to the base of the stem insulates sawfly larvae from low temperatures and low humidity. Unfortunately, though tillage operations may be somewhat effective in controlling wheat stem sawfly, there are several important disadvantages associated with this strategy. Tillage requires an additional field operation, increasing wheat production costs and reducing profitability. Second, tillage operations also increase soil erosion rates, and run counter to no-till recommendations.

Biological control efforts have been directed against the three agriculturally important sawfly species in North America: *Cephus cinctus*, *C. pygmaeus*, and *T. tabidus*. Exotic parasitoids were established against the latter two species, and continue to maintain host populations below economic levels. Some authors have questioned whether the introduced natural enemies are the key regulating factor, or whether other factors may be involved, but without further study this question cannot be answered. All attempts, including three different projects covering more than 15 years, to find and establish exotic natural enemies against *C. cinctus* have ended in failure. There has been a renewed interest in North America to manage wheat stem sawfly using exotic natural enemies, particularly from eastern Asia.

Wheeler, William Morton

William Morton Wheeler was born on March 19, 1865, at Milwaukee, Wisconsin, USA. He had a diverse career, but established himself as one of the foremost authorities on ants and other social insects. Wheeler's early schooling in Milwaukee was marked by behavioral problems, so his father enrolled him in a strict German school with a reputation for extreme severity of discipline. He stayed on to attend the German-American College, which led to a position in 1884 at Ward's Natural Science Establishment in New York, a vendor of natural history supplies to schools and museums. Wheeler returned to Milwaukee in 1885, taught high school for 2 years and became custodian of the new Milwaukee Public Museum. There he developed proficiency in morphology, embryology and cytology. He left in 1890 to accept a fellowship at Clark University. He began to publish on insects and received his Ph.D. from Clark in 1892. He followed his professor, C.O. Whitman, to the University of Chicago, where he became an instructor. Following a study trip to Europe, Wheeler was made an assistant professor of embryology, though his entomological interested began to expand to include more than embryology. In 1899 he was made professor of zoology at the University of Texas. In 1903 he became curator of invertebrate zoology at the American Museum of Natural History, which allowed him to devote most of his time to ants. In 1908 Wheeler returned to teaching, and became professor of economic entomology at Harvard University, and where he became dean of the Bussey Institution. Wheeler traveled over much of the world, and published prodigiously, authoring almost 500 publications. Among his noteworthy publications are "Ants: their structure, development and behavior" (1910), "Social life among the insects" (1923), and "A study of insect behavior" (1930). Wheeler died On April 19, 1937, at Cambridge, Massachusetts.

Whiteflies (Hemiptera: Aleyrodidae)

This group consists of only about 1,200 species, though it occurs mostly in the tropics and is not well studied, so this is likely an underestimate of its actual size. There are 126 genera described, but only seven have more than 50 species, and many genera contain only a single species. Because adults are so similar, classification is based on the structure of the fourth instar, the "pupal case." Though there are advantages to this system, one of the serious disadvantages is that the form of the pupal case is affected by the form of the host plant cuticle, resulting in variable appearance. The classification is as follows:

Order: Hemiptera
- Suborder: Sternorrhyncha
  - Superfamily: Aleyrodioidea
- Family: Aleyrodidae
  - Subfamily: Udamoselinae?
  - Subfamily: Aleurodicinae
  - Subfamily: Aleyrodinae

The Udamoselinae is based on a single specimen (which has subsequently disappeared), and has never again been collected; thus, its existence is questionable. The Aleurodicinae are found principally in South America, are relatively large for whiteflies, and are considered to be primitive. The wing venation is not as reduced as in Aleyrodinae, and the pupal cases are more complex.

Appearance and Biology

Whiteflies typically are only 1–3 mm in length. The wings are transparent, or clouded. Wing venation is always reduced. The adult is often covered with a powdery white wax, the basis for the family name. However, not all species are white, and some are black (e.g., citrus blackfly, *Aleurocanthus woglumi*). Adults have two pairs of wings. The antennae usually are 7-segmented. The tarsi bear two tarsomeres, with the apical tarsomere bearing two claws and possessing an empodium between the claws. The immatures resemble scale insects; they are flattened, oval, and secrete a waxy material. A conspicuous fringe is sometimes present. The anal opening (vasiform orifice) of the immature opens dorsally on the last abdominal segment, and has diagnostic value.

Parthenogenesis occurs in some species. Females deposit their small, oval or elongate eggs on a short stalk that is inserted into the leaf tissue of the host. Sometimes the female deposits waxy material near the eggs, or deposits the eggs in a circle on the surface of a plant leaf. The first instars are very small, but have long legs and antennae, and crawl actively. They are transparent to translucent. Thereafter the appendages are reduced and the two nymphal stages are sessile. This is followed by the so-called pupal stage, during which some feeding occurs. Pupae often have large dorsal setae, though a few are present in nymphs. The adult typically emerges from a T-shaped slit on the dorsal surface of the pupal case. The mouthparts of the piercing-sucking type; both sexes feed.

Damage

Whiteflies can be very destructive pests, particularly in the tropics and subtropics. They injure plants directly through their feeding (removal of plant sap) and indirectly through transmission of plant viruses. To a much lesser degree, the production of honeydew by these insects (and subsequent growth of sooty mold) also affects the value of crops because it coats the foliage and other plant parts.

Whiteflies are the tropical equivalent of the aphids found in more temperate regions. They are vagile and opportunistic, building to high densities when weather and host plant condition are suitable. They feed almost entirely on angiosperms, avoiding gymnosperms. Among angiosperms they feed mostly on dicotyledonous plants, though the Graminae, Palmae and Smilacaceae among the monocots support whiteflies. The whiteflies do not display a great degree of host specificity.

Some of the more common, and important species, are treated below:

Greenhouse Whitefly, *Trialeurodes vaporariorum* (Westwood)

Greenhouse whitefly is found widely around the world, including most of the temperate and subtropical regions North America, South America, Europe, Central Asia and India, northern and eastern Africa, New Zealand and southern Australia. It does not thrive in most tropical locations, and occurs in colder regions only by virtue of its ability to survive winter in greenhouses. In colder areas, it overwinters only in such protected locations, but in mild-winter it survives outdoors throughout the year. The origin of this species is not certain, but is thought to be Mexico or the southwestern United States.

Host Plants

This species has a very wide host range, with over 300 species recorded as hosts. However, some hosts are more suitable. Vegetable plants often serving as good hosts are bean, cantaloupe, cucumber, lettuce, squash, tomato, eggplant, and occasionally cabbage, sweet potato, pepper, and potato. Among greenhouse-grown vegetables, the most common hosts are tomato, eggplant, and cucumber. When adults land on a favored host plants such as eggplant, they almost always remain to feed and oviposit; on a less preferred host such as pepper they usually take flight after tasting the plant. Many ornamental plants serve as good hosts, including ageratum, aster, chrysanthemum, coleus, gardenia, gerbera, lantana, poinsettia, salvia, verbena, zinnia and many others.

Natural Enemies

Natural enemies of greenhouse whitefly are numerous, but few are consistently effective, especially under greenhouse conditions. Greenhouse whitefly is attacked by the common predators of small insects, including minute pirate bugs (Hemiptera: Anthocoridae), some plant bugs (Hemiptera: Miridae), green lacewings (Neuroptera: Chrysopidae), brown lacewings (Neuroptera: Hemerobiidae), and ladybirds (Coleoptera: Coccinellidae). Parasitic wasps attacking greenhouse whitefly are largely confined to the family Aphelinidae, but many species are involved and they vary regionally. Those known from North America, including Hawaii, are *Encarsia formosa* Gahan, *Aleurodophilus pergandiella* (Howard), *Eretmocerus haldemani* Howard, *Prospaltella transvena* Timberlake, and *Aphidencyrtus aphidivorus* (Mayr). Although these agents exercise considerable control on whitefly populations in weedy areas or on crops where insecticide use is minimal or absent, they do not survive well in the presence of most insecticides. *Encarsia formosa* has been used successfully under greenhouse conditions, and to a lesser extent field conditions, to affect biological suppression; for more information, see the section on biological control.

The pathogens of greenhouse whitefly are principally fungi, particularly *Aschersonia aleyrodis*, *Paecilomyces fumosoroseus*, and *Verticillium lecanii*. All occur naturally and can cause epizootics in greenhouses and fields, and also have been promoted for use in greenhouses as bioinsecticides. *Aschersonia* is specific to whiteflies, *Verticillium* has a moderately wide host range, and *Paecilomyces* has a broad host range. For optimal development of disease, high humidity is required. *Aschersonia* is spread principally by rainfall, so often fares poorly in greenhouse environments.

Life Cycle and Description

The development period from egg to adult requires about 25–30 days at 21°C. Thus, because the preoviposition period of adults also is short, less than 2 days above 20°C, a complete life cycle is possible within a month. Greenhouse whitefly can live for months, and oviposition time can exceed the development time of immatures; this results in overlapping generations. Optimal relative humidity is 75–80%. The developmental threshold for all stages is about 8.5°C.

Eggs are oval in shape, and suspended from the leaf by a short, narrow stalk. The eggs initially are green in color and dusted with white powdery wax, but turn brown or black as they mature. The eggs measure about 0.24 mm in length and 0.07 mm in width. Eggs are deposited on the youngest plant tissue, usually on the underside of leaves in an incomplete circular pattern. Up to 15 eggs may be deposited in a circle which measures about 1.5 mm in diameter. This pattern results from the female moving in a circle while she remains with her mouthparts inserted into the plant. This pattern is less likely on plants with a high density of trichomes because plant hairs interfere with the oviposition behavior. Duration of the eggs stage is often 10–12 days, but eggs may persist for over 100 days under cool conditions. When cultured at 18, 22.5, and 27°C, egg development requires an average of 15, 9.8, and 7.6 days, respectively. Maximum fecundity varies according to temperature; optimal temperature is 20–25°C regardless of host plant. When feeding on eggplant, greenhouse whitefly produces over 500 eggs, on cucumber and tomato about 175–200 eggs (Drost et al. 1998).

The newly hatched whitefly nymph is flattened, oval in outline, and bears functional legs and antennae. The perimeter is equipped with waxy filaments. The first instar measures about 0.3 mm in length. It is translucent, usually appearing to be pale green in color but with red eyes. After crawling one cm or so from the egg it settles to feed and molt. Development if the first instar requires 6.5, 4.2, and 2.9 days, respectively, when cultured at 18, 22.5, and 27°C. The second and third nymphal stages are similar in form and larger in size, though the legs and antennae become reduced and nonfunctional. They measure about 0.38 and 0.52 mm in length, respectively. Duration of the second instar requires about 4.3, 3.2, and 1.9 days whereas third instars require 4.5, 3.2, and 2.5 days, respectively when cultured at 18, 22.5, and 27°C. The fourth nymphal stage, which is usually called the "pupa," differs in appearance from the preceding stages. The fourth instar measures about 0.75mm in length, is thicker and more opaque in appearance, and is equipped with long waxy filaments. The pupal stage actually consists of the fourth nymphal instar period, which is a period of feeding, plus the period of pupation, which is a time of transformation to the adult stage. Thus, pupation occurs within the cuticle of the fourth instar. Duration of the fourth instar period and pupal period are 8.7 and 5.9, 5.9 and 4.0, and 4.5 and 2.8 days, respectively, at 18, 22.5, and 27°C.

Individuals of greenhouse whitefly which develop on lightly or moderately pubescent leaves tend to be relatively large and to have four pairs of well developed dorsal waxy filaments. In contrast, whiteflies developing on densely pubescent leaves tend to be smaller, and to bear more that four pairs of dorsal filaments. These morphological variations are not entirely consistent, and have led to considerable taxonomic confusion.

Adults are small, measuring 1.0–2.0 mm in length. They are white in color, with the color derived from the presence of white waxy or mealy material, and have reddish eyes. They bear four wings, with the hind wings nearly as long as the forewings. The antennae are evident. In general form, viewed from above, this insect is triangular in shape because the distal portions of the wings are wider than the basal sections. The wings are held horizontally when at rest; this characteristic is useful for distinguishing this species from the similar-appearing silverleaf whitefly and sweetpotato whitefly, which hold their wings angled or roof-like when at rest. Mating may occur repeatedly, though females can also produce eggs without mating.

Damage

Adult and nymphal whiteflies use their piercing-sucking mouthparts to feed on the phloem of host plants. This results in direct damage, resulting in localized spotting, yellowing, or leaf drop. Under heavy feeding pressure wilting and severe growth reduction may occur. Whiteflies also secrete large amounts of sugary honeydew, which coats the plants with sticky material, and must be removed from fruit before it is marketed. The honeydew also provides a substrate for growth of sooty mold, a black fungus that interferes with the photosynthesis and transpiration of plants.

Greenhouse whitefly is, as the common name suggests, primarily a pest in greenhouses, and is a serious limitation to the production of plants grown in such structures. However, it can also be a field pest, often in warmer climates but also in cool climates when seedlings contaminated with whiteflies are transplanted into the field. For example, in Hawaii field-grown tomatoes suffered a 5% reduction in fruit weight with as few as 0.7 whiteflies per square cm of leaf tissue, and a 5% reduction in grade-A fruit due to contamination with honeydew at densities of about 8.3 whiteflies per square cm of leaf.

Greenhouse whitefly is capable of transmitting viruses to plants, but is not considered to be a serious vector, particularly relative to the *Bemisia* spp. However, greenhouse whitefly transmits beet pseudo-yellow virus to cucumber in greenhouse culture.

Management

Although whitefly nymphs and adults can be detected readily by visual examination of foliage, most monitoring systems take advantage of the attraction of adults to yellow, and use yellow sticky traps to capture flying insects. Sticky cards or ribbons are suspended at about the height of the crop for optimal monitoring. Traps must be placed close to plants or close to the ground or population densities will be underestimated.

Applications of insecticides are often made to minimize the effects of whitefly feeding on crops in greenhouses. Greenhouse whitefly feeds on the lower surface of foliage and is sessile throughout most of its life, habits that minimize contact with insecticides, and resulting in frequent applications and effectiveness mostly against the adult stage. In greenhouse culture, application intervals of only 4–5 days are common, and sytemic insecticides are often used to increase the likelihood of insect contact with toxins. Thus, whitefly resistance to nearly all classes of insecticides is known, and rotation of insecticide classes is encouraged. Mixtures of insecticides are often used, which is indicative of high levels of resistance among whiteflies to insecticides. Field populations of greenhouse whitefly invariably are derived from greenhouse populations, and possess similar resistance to many insecticides. Applications of petroleum oils and biological control agents help to avoid difficulties with insecticide resistance.

Few cultural practices are available, but disruption of the whitefly population with host-free periods is important. Continuous culture of plants allows whiteflies to move from older to younger plants. Similarly, weeds may allow whiteflies to bridge crop-free periods, and should be eliminated.

Seasonal inoculative release of the parasitoid *Encarsia formosa* Gahan into crops infested with greenhouse whitefly has been used extensively for suppression of whiteflies on greenhouse-grown vegetable crops. Excellent suppression of whiteflies is attainable, but on host plants such as cucumber and eggplant, which are very favorable for whitefly reproduction and have hairy leaves that interfere with parasitoid searching, frequent releases must be made. Alternatively, cucumber varieties with reduced trichome density have been developed which favor parasitism. Another critical factor is temperature, because low greenhouse temperatures are more suitable for whitefly activity than parasitoid activity. Daytime temperatures of about 24°C seem to be optimal; temperatures of 18°C or less suppress parasitoid searching. A cold-tolerant *Encarsia* strain that is active at 13–17°C has also been used to overcome this temperature problem. Interference from pesticides can markedly affect parasitoid survival, so other pests such as mites must be managed biologically also. Lastly, release rates are important because if too many parasitoids are released the host whiteflies are driven nearly to extinction, leading to disappearance of the parasitoids; this is most likely to occur in small greenhouses. Alternatively, parasitoid releases can be made throughout the season, irrespective of whitefly presence. Although the protocols and technologies for whitefly management using *E. formosa* have been perfected for use in greenhouses, management under outdoor conditions awaits further research.

Silverleaf Whitefly, *Bemisia argentifolii* Bellows and Perring and Sweetpotato (or Cotton) Whitefly, *Bemisia tabaci* (Gennadius)

Silverleaf whitefly and sweetpotato whitefly are closely related whitefly species which cannot be distinguished easily by appearance, although there are some biological differences. Much literature from tropical environments around the world referring to sweetpotato whitefly probably pertains to silverleaf whitefly and other closely related species. Until the identities of these species are accurately determined, their distribution will remain unknown and some aspects of their biologies will remain confused. Cooler climates do not experience major problems with silverleaf whitefly except when overwintering in greenhouses occurs or vegetable transplants originate from whitefly-infested areas.

Host Plants

Silverleaf whitefly has a very wide host range. There may be 500 worldwide. Sweet potato, cucumber, cantaloupe, watermelon, squash, eggplant, pepper, tomato, lettuce, broccoli and many other crops are hosts, but suitability varies. For example, sweet potato, cucumber, and squash are much more favorable for whitefly than are broccoli and carrot. Various weeds and field crops may favor survival of whiteflies during vegetable-free periods. Wild lettuce, *Lactuca serriola*, and sowthistle, *Sonchus* spp., are examples of suitable weed hosts. Cotton, soybean, and to a lesser degree alfalfa and peanut are field crop hosts. Sweetpotato whitefly has a narrower host range than silverleaf whitefly.

Weather

Silverleaf whitefly thrives under hot, dry conditions. Rainfall seems to decrease populations, although the mechanism is not known. Silverleaf whitefly is not a strong flier, normally moving only short distances in search of young tissue. However, under the proper weather conditions dramatic, long-distance flights involving millions or billions of insects are observed. Such flights normally occur in the morning as the sun heats the ground, and the insects invariably move downwind.

Natural Enemies

Numerous predators, parasitoids, and fungal diseases of silverleaf whitefly are known. General such as minute pirate bugs (Hemiptera: Anthocoridae), green lacewings (Neuroptera: Chrysopidae), and ladybirds (Coleoptera: Coccinellidae) are important, as are many parasitic wasps, particularly in the genera *Encarsia* and *Eretmoceris* (both Hymenoptera: Aphelinidae). While these agents exercise considerable control on whitefly populations in weedy areas or on crops where insecticide use is minimal or absent, they do not survive well in the presence of most insecticides.

Life Cycle and Description

Silverleaf whitefly can complete a generation in about 20–30 days under favorable weather conditions. In tropical countries up to 15 generations per year have been reported, but in the United States there are considerably fewer.

The egg is about 0.2 mm long, elongate, and tapers distally; it is attached to the plant by a short stalk. The whitish eggs turn brown before hatching, which occurs in 4–7 days. The female deposits 90–95% of her eggs on the lower surfaces of young leaves.

All instars are greenish, and somewhat shiny. The flattened first instar is mobile, and is commonly called the "crawler" stage. It measures about 0.27 mm long and 0.15 mm wide. Movement is usually limited to the first few hours after hatch, and to a distance of 1–2 mm. Duration of the first instar is usually 2–4 days. The feeding site is normally the lower surface of a leaf, but sometimes greater than 50% of the nymphs are found on the upper surface, and feeding location seems not to affect survival. The second and third instars are similarly flattened, but their leg segmentation is reduced and they do not move. Duration of these instars is about 2–3 days for each. Body length and width are 0.36 and 0.22 mm, and 0.49 and 0.29 mm, for the second and third instar, respectively. The sessile fourth instar is usually called the "pupa" although this is not technically correct because some feeding occurs during this instar. The appearance of the fourth instar is variable, depending on the food plant; this stage tends to be spiny when developing on a hairy leaf but has fewer filaments or spines when feeding on smooth leaves. The fourth instar measures about 0.7 mm in length and 0.4 mm in width. Duration of the fourth instar is about 4–7 days. Total pre-adult development time averages 15–18 days in the temperature range of 25–32°C, but increases markedly at lower temperatures. The lower and upper developmental thresholds are considered to be about 10 and 32°C.

The adult is white in color and measures 1.0–1.3 mm in length. The antennae are pronounced and the eyes red. Oviposition begins 2–5 days after emergence of the adult, often at a rate of about five eggs per day. Adults typically live 10–20 days and may produce 50–150 eggs, although there are records of over 300 eggs per female. Females may reproduce without fertilization but males are common, sometimes outnumbering females, so most females are probably fertilized.

Damage

Adult and nymphal whiteflies use their piercing-sucking mouthparts to feed on the phloem of host plants. This results in direct damage, which is manifested in localized spotting, yellowing, or leaf drop. Under heavy feeding pressure wilting and severe growth reduction may occur. Systemic effects also are common, with uninfested leaves and other tissue being severely damaged as long as feeding whiteflies are present on the plant. A translocated toxicogenic secretion by nymphs, but not by adults, is implicated. Usually it is the young, developing tissue that is damaged by whiteflies feeding on older tissue. Once the whiteflies are removed, new plant growth is normal if a disease has not been transmitted. Damaged foliar tissue, however, does not recover once injured. Among leafy vegetables and crucifers, white streaking or discoloration, especially of veins, is common. Studies in Texas and Arizona demonstrated similar losses, and indicated that yields could be optimized if plants were treated with insecticide at whitefly densities of 3 adults per leaf or 0.5 large nymphs per 7.6 cm^2 of leaf area.

A disorder called irregular ripening affects tomato fruit when whiteflies feed on tomato foliage. Although the tomato foliage is not damaged, the internal portions of the fruit do not ripen properly and the surface is blotched or streaked with yellow.

Squash silverleaf, a disorder responsible for the common name of *B. argentifolli*, has been known from Israel since 1983. Silverleaf symptomology includes blanching of the veins and petioles, and eventually the interveinal areas of the leaf. The fruit of both yellow and green fruited varieties also may be blanched.

In addition to direct damage, silverleaf whitefly also causes damage indirectly by transmitting plant viruses. Over 60 plant viruses, most belonging to a group called geminiviruses, are known to be transmitted to crops by silverleaf whitefly. Some viruses, such as tomato yellow leaf curl virus, cause more damage than the insect feeding alone, so the effects are devastating. Unfortunately, unlike the case with the phytoxemia caused by the whitefly salivary secretions, once viruses are inoculated into the plant there is no recovery by the host even if the whiteflies are eliminated.

Lastly, whiteflies cause injury by excreting excess water and sugar in the form of honeydew. This sticky substance accumulates on the upper surface of leaves and fruit, and provides a substrate for growth of a fungus called sooty mold. The dark mold inhibits photosynthetic activity of the foliage, and may also render the fruit unmarketable unless it can be washed thoroughly and the residues removed.

Management

Eggs tend to be concentrated on young foliage and mature larvae on older foliage. Large nymphs are a good stage for population assessment because they do not move and are large enough to see without magnification. Adults tend to be concentrated close to the soil. Such distributions must be considered in population assessment prior to initiating management practices. Visual observation of the lower leaf surface and vacuum sampling are less time consuming, and in some cases more precise, than yellow sticky traps.

In southern states, where silverleaf whitefly can be the most important insect problem on some vegetable crops, frequent applications of insecticides are often made to minimize the direct and indirect effects of whitefly feeding. Whitefly resistance to nearly all classes of insecticides is known, and rotation of insecticide classes is encouraged. Mixtures of insecticides are often used, which is indicative of high levels of resistance. Most agriculturalists suggest that whitefly numbers be maintained at low levels because once they become abundant they are difficult to suppress; this, of course, exacerbates development of insecticide resistance. The phytotoxemia and disease transmission potential of this insect exaggerates its damage potential, further justifying frequent application of insecticides.

Silverleaf whitefly feeds on the lower surface of foliage and is sessile throughout most of its life – habits that minimize contact with insecticides. Frequent insecticide application also disrupts naturally occurring biological control agents. In an attempt to minimize the cost and disruptive effects of insecticides, and to reduce the evolution of insecticide resistance, soaps and oils have been extensively studied for whitefly control. The mechanism of control by surfactants such as soaps and oils is not clearly understood, but disruption of the insect cuticle, physical damage, and repellency are postulated. In any event, mineral and vegetable oils alone, or in combination with soaps and detergents, can provide some suppression of whiteflies. Combination of insecticide and oil often enhances whitefly control.

Although a great number of predators, parasitoids, and fungal diseases are known to attack silverleaf and sweetpotato whitefly, no biotic agents are known to provide adequate suppression alone. Under greenhouse conditions, parasitoids can be released at high enough densities to provide some suppression, especially when insecticidal soap and other management techniques are also used. Under natural field conditions, parasitism does not usually build to high levels until late in the growing season. Insecticides often interfere with parasitoids, of course, and effective use of biological control agents will probably be limited to cropping systems where insecticide use is minimized and other management techniques are used which favor action of predators, parasitoids, and disease agents. *Verticillium*, *Paecilomyces*, and other fungi similarly show some promise under greenhouse conditions, but are limited by low humidity under field conditions.

Cultural controls can be vitally important in managing silverleaf whitefly. Incorrect crop management, in particular, can create or exacerbate whitefly problems. Whiteflies can move from crop to crop, and area-wide crop-free periods help diminish populations. Thus, prompt tillage of land and destruction of crop residues after crop maturity is recommended. Similarly, weeds can harbor whiteflies, whitefly-transmitted diseases, and whitefly parasitoids, so weed management is a consideration. Trap crops such as cucumbers can be used to provide temporary protection to less preferred crops such as corn.

Row covers and other physical barriers can reduce infestation of crops, and infection with disease. Screen hole sizes of about 0.19 square mm or smaller are required to successfully exclude silverleaf whitefly. Colored and aluminum mulches provide only temporary reduction in whitefly abundance and disease transmission.

Disease Transmission

Growers generally rely on whitefly suppression to manage disease incidence. This is not entirely satisfactory, however, and removal of virus-infected plants is often suggested to minimize within-field spread of viruses. Since whiteflies may transmit disease from one crop to another, or from weeds to crops, vegetation management is important. As noted above, reflective mulches have not produced economic benefits consistently. Mineral and vegetable oils inhibit virus transmission. Row covers or other physical barriers can substantially prevent disease transmission, but are often not practical.

Whitefly Bioecology and Management in Latin America

LUKO HILJE[1], FRANCISCO J. MORALES[2]
[1]Tropical Agricultural Research and Higher Education Center (CATIE), Turrialba, Costa Rica
[2]International Centre for Tropical Agriculture (CIAT), Palmira, Colombia

Though some 1,200 whitefly (Hemiptera: Aleyrodidae) species have been described to date, only a few species are economically important agricultural pests. In Latin America (which for the purposes of this article includes Mexico, Central America, the Caribbean region and South America), less than a dozen whitefly species have historically caused economically-important damage to crops. The important species include *Aleurocanthus woglumi* (on citrus), *Aleurocybotus occiduus* (rice and sorghum), *Aleurodicus dispersus* (bananas), *Aleurodicus talamancensis* (bananas), *Aleurothrixus floccosus* (citrus, guava and other fruit trees), *Aleurotrachelus socialis* (cassava), *Bemisia tabaci* (many crops), *Bemisia tuberculata* (cassava), *Trialeurodes vaporariorum* (many crops), and *Trialeurodes variabilis* (cassava and papaya).

The most damaging and widespread whitefly species worldwide, and in Latin America, are *B. tabaci* and *T. vaporariorum*. The former species is by far the most important pest and vector of many plant viruses, particularly in the lowlands and mid-altitude (up to 1,200 m) valleys of the tropics. *Trialeurodes vaporariorum* is also a major pest of many crops in the tropical highlands (above 1,000 m of altitude) and temperate regions of the world, and is known to transmit several economically important plant viruses.

Damage and Economic Importance

All *B. tabaci* and *T. vaporariorum* life stages (eggs, nymphs and adults) are normally found on the underside of leaves. Crawlers emerging from eggs barely move from the point of hatching, after which they settle for the remainder of their lives, until the adult stage emerges.

Both nymphs and adults use their long mouthparts (stylets) to reach the phloem of the leaves and remove sap (rich in sugars and amino acids) that is continuously excreted. The sweet substance ("honeydew") covers the plant parts where the whiteflies are feeding, providing a suitable substrate for some superficial fungi known as "sooty molds." These fungi cover the leaves and other photosynthetic tissues of the affected plants, blocking sunlight. The sooty molds also reduce the quality of the produce, particularly in the case of cotton lint, which cannot be processed when covered by the honeydew and mycelium of the fungus.

In recent years, a new biotype ("B") of the whitefly *B. tabaci* appeared in Latin America. It is known to inject toxicogenic substances present in nymph's saliva that can induce physiological disorders such as uneven ripening of tomato, squash silverleaf, pumpkin white stem, white streaking in cole crops, as well as pod and stem blanching of snap beans and lettuce, respectively. Some authors have proposed that the new biotype is actually an entirely new species (*Bemisia argentifolii*), but this has not gained wide acceptance among entomologists (Fig. 49).

However, the main damage caused by *B. tabaci* is associated with its notable capacity to transmit over 200 different plant viruses, belonging for the most part to the genus *Begomovirus*, family *Geminiviridae*. *B. tabaci* also transmits viruses in other genera, namely, *Carlavirus*, *Crinivirus*, *Ipomovirus* and *Potyvirus*. These viruses affect many food and industrial crops, particularly in the tropical and sub-tropical regions of the world. *T. vaporariorum* has also gained some notoriety as a vector of some important plant viruses, particularly in sub-tropical and high-altitude tropical environments, but the number of these viruses is still low when compared to the number of viruses transmitted by *B. tabaci*. *T. vaporariorum* is the main vector of criniviruses (*Closteroviridae*).

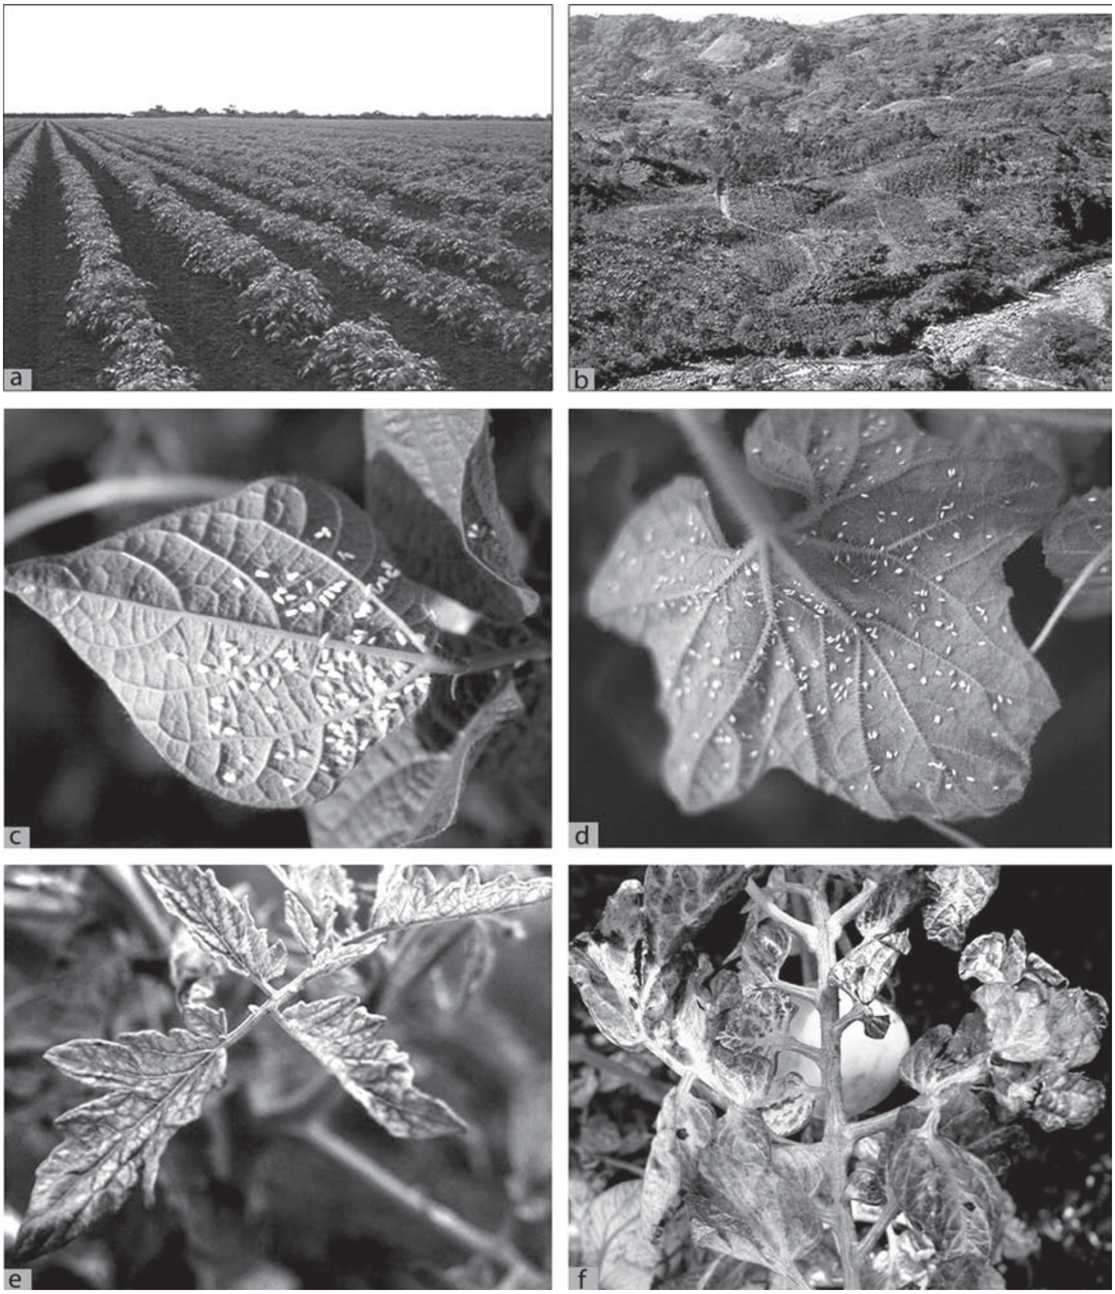
So far in Latin America, 35 crops (23 of them fully confirmed) have been reported as feeding and/or reproductive hosts of *B. tabaci*, including mainly annual but also perennial crops (see Table 5) in 14 plant families: Apocynaceae, Asteraceae, Caricaceae, Convolvulaceae, Cruciferae, Cucurbitaceae, Euphorbiaceae, Fabaceae, Malvaceae, Myrtaceae, Passifloraceae, Pedaliaceae, Solanaceae and Vitaceae. The principal hosts, considering their socioeconomic importance, area covered and damage levels, are tomato, common bean, melon, watermelon, cotton, bell pepper and hot peppers. *Trialeurodes vaporariorum* feeds on more than 250 plant species. The crops most affected by *T. vaporariorum* are dry and snap beans, tomato, peppers, cucumber, squash, eggplant, potato, pea (*Pisum sativum*), broad bean (*Vicia faba*), and cotton.

The feeding and/or reproductive performance of *B. tabaci* on a given host also depends on the particular biotype involved. For instance, in some Latin American countries where the "A" biotype still predominates, it does not colonize tomato to a significant extent, whereas huge numbers of eggs and nymphs are frequently observed on bell pepper. This situation is completely reversed in the case of the "B" biotype, which colonizes tomato, but does not lay eggs in most pepper cultivars.

Bemisia tabaci and *T. vaporariorum* also feed and/or breed on hundreds of wild plant species. Worldwide, *B. tabaci* has been observed on at least 500 plant species belonging to 74 families, but its full host range remains unknown both in Latin America and worldwide, and will certainly keep increasing due to the ability with which the "B" biotype adapts to new host plants. Despite its well-documented polyphagous nature, *B. tabaci* shows a distinct preference for members of certain families, such as Fabaceae, Asteraceae, Malvaceae, Solanaceae, Euphorbiaceae and Cucurbitaceae. *Trialeurodes vaporariorum* is mostly found on plant species in the Solanaceae, Fabaceae, and Cucurbitaceae.

Bioecological Characteristics

There are several biological and ecological characteristics of *B. tabaci* that can be important for its management in terms of assessing the risk of damage and the potential for successfully controlling it. Three key characteristics are discussed here: genetic plasticity reproductive potential and virus transmission.



Whitefly Bioecology and Management in Latin America, Figure 49 ***Top row***, **contrasts between current cropping systems in Latin America: a large tomato monoculture in Bahía, Brazil (a), and a "mosaic" of beans and vegetables interspersed between coffee and sugarcane plantations in Turrialba, Costa Rica (b) (Photos by Luko Hilje). Middle row, large whitefly populations: *T. vaporariorum* on common beans in Colombia (c), and *B. tabaci* on melons in Guanacaste, Costa Rica (d) (Photos by Luko Hilje and CIAT, respectively). Bottom row, plants affected by whitefly-borne viruses: tomato yellow mosaic virus (ToYMoV), transmitted by *B. tabaci* to tomatoes in Grecia, Costa Rica (e), and an undetermined crinivirus vectored by *T. vaporariorum* to tomatoes in Colombia (f) (Photos by Luko Hilje and CIAT, respectively).**

Whitefly Bioecology and Management in Latin America, Table 5 Host crops of *Bemisia tabaci* reported to date in Latin America[a]

Scientific name	Family	Common name
Abelmoschus (= Hibiscus) esculentus	Malvaceae	Okra
Capsicum annuum	Solanaceae	Bell pepper
Capsicum frutescens	Solanaceae	Hot pepper
Carica papaya	Caricaceae	Papaya
Citrullus lanatus	Cucurbitaceae	Watermelon
Cucumis melo	Cucurbitaceae	Melon
Cucumis sativus	Cucurbitaceae	Cucumber
Cucurbita argyrosperma	Cucurbitaceae	Pipián
Cucurbita maxima	Cucurbitaceae	Squash
Cucurbita moschata	Cucurbitaceae	Ayote
Cucurbita pepo	Cucurbitaceae	Squash
Fernaldia pandurata	Apocynaceae	Loroco
Glycine max	Fabaceae	Soybean
Gossypium hirsutum	Malvaceae	Cotton
Lycopersicon esculentum	Solanaceae	Tomato
Manihot esculenta	Euphorbiaceae	Cassava
Medicago sativa	Fabaceae	Alfalfa
Nicotiana tabacum	Solanaceae	Tobacco
Passiflora edulis f. flavicarpa	Passifloraceae	Passion fruit
Phaseolus acutifolius	Fabaceae	Tepary bean
Phaseolus vulgaris	Fabaceae	Common bean
Solanum melongena	Solanaceae	Eggplant
Vitis vinifera	Vitaceae	Grape
To be confirmed		
Arachis hypogaea	Fabaceae	Peanuts
Brassica oleracea var. capitata	Cruciferae	Cabbage
Brassica oleracea var. italica	Cruciferae	Broccoli
Brassica oleracea var. botrytis	Cruciferae	Cauliflower
Helianthus annuus	Asteraceae	Sunflower
Ipomoea batatas	Convolvulaceae	Sweet potato
Lactuca sativa	Asteraceae	Lettuce
Phaseolus lunatus	Fabaceae	Lima bean
Psidium guajava	Myrtaceae	Guava
Raphanus sativus	Cruciferae	Radish
Sesamum indicum	Pedaliaceae	Sesame
Solanum tuberosum	Solanaceae	Potato

[a]Based upon Anderson and Morales (2005) and Hilje (2003), but including only those crops recorded by either whitefly taxonomists or specialists working with molecular techniques. Crops to be confirmed include those which have been reported as hosts elsewhere and on which whiteflies closely resembling *B. tabaci* have been collected, but still requiring full confirmation.

Genetic Plasticity

The remarkable plasticity of *B. tabaci* makes its management extremely difficult. For instance, *B. tabaci* can rapidly develop resistance to insecticides, including novel ones, as has occurred in recent years with some neonicotinoids and insect growth regulators. Also, it has expanded its geographic range by adapting to higher altitudes and latitudes. *Bemisia tabaci* can be found at altitudes over 2,000 m in Costa Rica, which is unusual for this species. The altitudinal dissemination of *B. tabaci* is often aided by the movement of propagative material from the lowlands to the highlands.

Bemisia tabaci can also give rise to a series of races or biotypes that vary in their host-plant relationships, as well as in their ability to induce physiological disorders. The efficiency of transmission of plant viruses by *B. tabaci* also differs among biotypes, though the original biotypes were usually more efficient vectors. So far, some 23 biotypes have been detected worldwide by means of molecular and biochemical methods. The most widely distributed in Latin America is the new "B" biotype, followed by the original "A" biotype, as well as an undetermined number of regional biotypes (Table 6).

So far, the "A", "B" and "Q" are the only biotypes that have received some degree of attention in terms of understanding their life cycles, physiology, behavior, and host-plant relationships. Such studies are crucial, not just because of their academic value, but also due to their practical consequences. For instance, in contrast to the "A" biotype, the "B" biotype can feed or breed on cole crops (cabbage, cauliflower and broccoli), lettuce, citrus and papaya, and can successfully develop on tomato; its nymphs can induce the aforementioned syndromes on tomato, squash, cole crops and lettuce. The "B" biotype also has a higher (two-fold) fecundity, and is more cold-tolerant. Interestingly, some biotypes can coexist on the same plant species and even on the same plant, as it has been noticed in Guanacaste, Costa Rica, where individuals of the "A" and "B" biotypes have been collected along with other undescribed biotype on the same jalapeño pepper plants.

Trialeurodes vaporariorum is also capable of developing genetic resistance to insecticides, but it does not seem to exhibit the high genetic variability of *B. tabaci*. However, in highly disturbed and chemically contaminated agro-ecosystems, *T. vaporariorum* can attack an unusually large number of cultivated and wild plant species.

Reproductive Potential

This characteristic depends on the insect's fecundity, generation time, sex ratio, and longevity, but these parameters can vary depending on the biotype, temperature and relative humidity, as well as the quality and age of the host plant species or cultivar.

For *B. tabaci* raised under controlled conditions (25°C and 65% relative humidity) in Venezuela, average fecundity (number of eggs/female) was 194 (possibly corresponding to the "B" biotype); generation time (interval elapsing between two successive generations) was 42 days; sex ratio (females: males in the offspring) varied from 3:1 to 1:1, but females can show arrhenotokic parthenogenesis (unmated females can give rise to a 100% male offspring); and adult longevity typically ranges from 11 to 20 days. For *T. vaporariorum* raised at 23°C and 80% relative humidity in Brazil, average fecundity was 186 eggs; generation time was 23 days; sex ratio also varied; and adult longevity was about 24 days.

Tropical regions offer a unique agroecological environment for *B. tabaci* to fully express its reproductive potential. Temperature, rainfall and air humidity are normally much higher than in temperate areas, and photoperiod varies only slightly throughout the year. Since temperature is fairly constant but quite high, and insects are poikilothermic, *B. tabaci* can breed continuously, giving rise to very high densities and overlapping generations.

Optimal temperatures for *B. tabaci* development range between 30 and 33°C. At these temperatures,

Whitefly Bioecology and Management in Latin America, Table 6 **Distribution of *Bemisia tabaci* biotypes in Latin America to date**

Country	Region	Biotypes
Mexico	North	A, B
Guatemala	Central	A, B and others
Belice	Central	B
El Salvador	Central	A, B
Honduras	Central	A, B and others
Nicaragua	Central	B and others
Costa Rica	Central	A, B and others
Panama	Central	A, B
Cuba	Caribbean	B
Dominican Republic	Caribbean	A, B
Haiti	Caribbean	B
Puerto Rico	Caribbean	B
Jamaica	Caribbean	B
Colombia	South	A, B
Venezuela	South	A, B
Ecuador	South	A, B
Peru	South	A, B
Brazil	South	B
Bolivia	South	B
Chile	South	B (?)
Uruguay	South	?
Paraguay	South	?
Argentina	South	A, B and others

fecundity increases and generation time shortens, leading to very rapid population growth. Such temperature values are easily reached during the dry season, when thermal accumulation ("physiological time") is high. This is particularly true in irrigated, hot and dry areas devoted to export crops such as melons, watermelon and vegetables, where furrow or drip irrigation provides enough moisture for nymphs to complete their development. On the contrary, sprinkler irrigation, which mimics rainfall, has adverse effects on whitefly populations, due to dislodgment of adults from plants. There also are possible negative effects of increased relative humidity on the immature stages, or increased incidence of entomopathogenic fungi, associated with sprinkler irrigation.

Populations of *B. tabaci* are normally lower during the rainy season. Nevertheless, it is not unusual to observe tomato and bean fields 100% affected by whitefly-borne viruses, even during the rainy season. This typically occurs when farmers plant soon after the dry season and when whitefly populations are still high, or whenever the rainfall levels are lower than normal.

Trialeurodes vaporariorum is adapted to much cooler environments than *B. tabaci*, and is more characteristic of sub-tropical and temperate agro-ecosystems than true tropical environments.

However, this whitefly species causes total yield losses in several crops grown in the tropics at altitudes higher than 1,000 m, where the temperature is cool or cold and humidity can range from very dry to very humid within the year. *Trialeurodes vaporariorum* populations also increase rapidly during dry periods of the year.

Virus Transmission

In contrast to the majority of whitefly species, *B. tabaci* has the ability to acquire and transmit over 200 different viruses, mainly begomoviruses, which cause significant yield losses in important crops such as tomato, bell and hot peppers, beans, and various cucurbits including melon and squash. *Bemisia tabaci* can rapidly disseminate viruses in the field even when populations are not appreciable, and cause severe crop damage in susceptible plantings. Hence, economic thresholds are not recommended for whitefly vectors of plant viruses.

As expected due to the high levels of biodiversity inherent to the neotropics, there are many endemic whitefly-borne viruses yet to be discovered and named. In fact, any one of these crops may be affected by several types of viruses either in different countries or different areas within a given country, as it occurs with tomato, which is affected by at least 17 types of begomoviruses in America. Moreover, sometimes they appear in mixed infections, giving rise to complex synergistic interactions.

However, some of these native viruses could eventually be displaced by more competitive exotic viruses, as has already occurred in several countries with *Tomato yellow leaf curl virus* (TYLCV), an Old World virus that was accidentally introduced in the Caribbean Basin. TYLCV was first detected in the Dominican Republic, and then moved rapidly into Haiti and other Caribbean islands (Puerto Rico, Cuba, Bahamas, Jamaica and Guadeloupe). This virus then emerged in Florida, USA and in Yucatan, Mexico. So far, TYLCV has been managed through the use of virus-resistant tomato cultivars and novel insecticides. Curiously, TYLCV has not adapted well in Yucatan, Mexico. Nevertheless, TYLCV has caused millions of dollars worth of direct damage to tomato plantations in the Dominican Republic and Haiti, and considerable damage to the tomato paste industry of that island during the initial epidemics suffered in the early 1990s.

The higher degree of pathogenicity and virulence shown by exotic Old World viruses such as TYLCV may be related to their long-term association with mixed cropping systems and aggressive vectors, such as biotype "B" of *B. tabaci* in the Old World. The significant damage caused by TYLCV in the Dominican Republic may be also associated to the coincidental introduction of TYLCV and the "B" biotype in a country that was beginning to promote both traditional and non-traditional export crops, including common bean, tomato, melons, eggplant, peppers, and other susceptible crops. On the other hand, the arrival of TYLCV in other Caribbean islands and in Yucatan, has not caused a rapid displacement of the existing neotropical begomoviruses of tomato, probably because of the more traditional cropping systems in these latter locations.

It is important to note that these pathosystems often involve at least four components: *B. tabaci* biotypes, begomoviruses, crops, and whitefly and virus hosts. Each element is an important biological variable that, when combined, could give rise to unmanageable, severe outbreaks of highly damaging virus problems.

Northern Mexico, Guatemala and Brazil are examples of countries where the diversification of cropping systems, with a view to producing export crops, resulted in major pandemics of begomoviruses. Several crops were affected, and significant crop losses caused by the whitefly-transmitted viruses brought the diversification effort to a halt. For instance, the 1990s witnessed severe attacks of different begomoviruses in several crops grown for export in northern Mexico, including common bean, tomato, cucurbits, and peppers. In 2001, over 1,000 ha of melon were severely damaged in Zacapa, Guatemala, with unexpected high losses. Common bean, tomato and peppers were also severely attacked in the lowlands and mid-altitude valleys of southeastern Guatemala. In Brazil, a major campaign to promote high value horticultural crops for export in the mid-1990s met with a similar disastrous fate, resulting in loss of hundreds of thousands of hectares to whitefly-transmitted viruses.

Trialeurodes vaporariorum has gained notoriety as a vector of plant viruses only in the last two decades, particularly in temperate regions. However, this whitefly species has now been shown to transmit criniviruses in the tropical highlands of South America, affecting important crops such as potato and tomato.

Management Alternatives

Historically, insecticides have been the first line of defense against *B. tabaci* and *T. vaporariorum* in both their roles as direct pests and virus vectors. This pattern is seen not only in Latin America, but in most agricultural regions of the world. Unfortunately, the first insecticides used to control whiteflies were conventional, broad-spectrum products applied singly or, more often, in mixtures of organophosphates and pyrethroids, known as "cocktails." These products soon failed to control these whitefly pests due to the outstanding genetic capacity that whiteflies have to develop resistance to insecticides of different nature. Farmers soon reacted to this situation by spraying three times a week, and even daily against these pests. Obviously, these insecticide applications were not a cost-effective approach, and increased production costs by at least 30%. For instance, in Guatemalan cotton fields, *B. tabaci* had developed resistance to 16 different insecticides by 1987, reaching resistance levels as high as 980X for biphenthrin and cyhalothrin, and over 2000X for quinalphos and deltamethrin.

In view of this situation, new chemistries such as neonicotinoids (e.g., imidacloprid, acetamiprid, thiamethoxam, nitenpyram and thiacloprid) and insect growth regulators (e.g., buprofezin and pyriproxyfen), were developed and widely used despite their higher prices. Unfortunately, insecticide abuse (excessive number of applications) and misuse (active ingredient diluted with other products) still occurs in several Latin American countries, which along with the lack of complementary IPM programs (like the ones so far implemented in Israel, southwestern USA and elsewhere) pose a high risk for the emergence of new whitefly populations possessing resistance to the new compounds.

Despite the presence of many native natural enemies (parasitoids, predators and entomopathogenic fungi) of *B. tabaci* and *T. vaporariorum* in Latin America, including at least ten different species of the parasitoid *Eretmocerus*, and two species of *Encarsia*, biological control agents have not been widely used or observed to be effective control agents in whitefly-affected agricultural regions. The explanation for this observation is the slow action of biological control agents, as compared to insecticides. In general terms, biological control can only be effective in areas where neither insecticide abuse nor viruses vectored by whiteflies occur.

Alternative whitefly control strategies are available and can be highly effective when used properly. Some of these IPM practices include:

Phytosanitary Campaigns

In past years, successful whitefly control measures were implemented in the Dominican Republic, Mexico and Cuba, supported by legal measures that required the strong participation of the affected farmers. These campaigns were mostly based on the implementation of a susceptible or host crop-free period.

In the early 1990s, the processing tomato industry in the Azua Valley and other production areas of the Dominican Republic were critically affected by production drops due to the introduction of TYLCV. The cultivated area in the Azua Valley dropped from 8,805 ha in 1989 to 3,729 has in 1993, whereas yield decreased from 21.6 to 11.3 MT/ha within the same period. This situation forced the nascent tomato paste industry in the Dominican Republic to import tomato paste from Chile. The enforcement of legal measures that banned cultivation of *B. tabaci* reproductive hosts up to 90 days before the main tomato growing season, along with crop rotations with non-whitefly hosts, such as sorghum, significantly diminished begomovirus incidence in Azua. These legal measures were complemented by planting of TYLCV-tolerant hybrids and a judicious insecticide use scheme, which allowed the tomato industry in the Dominican Republic not only to subsist, but also to increase the area planted to 8,940 ha and yields to 30.4 t/ha.

Host Plant Resistance

In the 1980s, a major crop improvement project was launched by the PROFRIJOL network to incorporate genetic resistance to whitefly-transmitted viruses affecting common bean in Latin America. This was conducted under the coordination of the International Centre for Tropical Agriculture (CIAT), in Colombia. Despite the termination of this successful project due to the economic crises that have affected national and international agricultural research institutions in Latin America, some international projects (such as CRSP-USAID) continue to generate begomovirus-resistant common bean varieties in Central America from its main pilot site at the Pan-American Agricultural School (Zamorano) in Honduras.

REDCAHOR was another network created in the early 1990s to improve horticultural crops in Central America, but it was short lived. In past years, only some semi-commercial initiatives in Guatemala (University of San Carlos and University of Wisconsin), and the Tropical Whitefly IPM Project coordinated by CIAT, are developing tomato hybrids and varieties possessing resistance to whitefly-borne begomoviruses. The most advanced tomato breeding project in Latin America is now conducted by the Horticultural Research Institute "Liliana Dimitrova" in Havana, Cuba.

Physical Exclusion

Because young plants are more susceptible to damage by whiteflies and whitefly-transmitted viruses, seedlings must be protected in seedbeds before transplanting in the field (e.g., tomato and pepper seedlings). Seedlings are usually protected in insect-proof screenhouses or glasshouses, or at least with insect-proof fleece placed over the seedbeds. This practice has been increasingly accepted over the years, thanks to a few entrepreneurs who produce virus-free seedlings for sale. Also, some farmers use micro-tunnels to produce their own seedlings.

Among the many mesh sizes commercially available, it has been shown that a 50-mesh screen effectively stops *B. tabaci* adult entrance into protected structures, while allowing adequate airflow through the screening to favor seedling development. However, structures constructed with screens or plastics treated with an absorbing additive that blocks a portion of the ultraviolet light spectrum, and which hinders the ability of *B. tabaci* to locate plants, are still uncommon due to the high cost of this novel technology. In Israel and elsewhere, it has been shown that greenhouses protected with these ultraviolet-blocking materials have lower whitefly populations and less virus incidence, in comparison to similar materials that transmit more ultraviolet light.

Another approach that has gained acceptance, especially in Mexico and Guatemala, is the use of "floating" row covers to reduce the spread of whitefly-transmitted viruses. With this technology, field-sown or transplanted seedlings can be protected in their early stages of development by temporarily covering them with lightweight materials, such as spun-bonded polyester, and there is no need for any supporting structure.

The cover remains over the plants until it is necessary to remove it to allow bee pollination and other cultural practices.

Mulching

Mulches are used for certain crops in order to control weeds or to avoid contact of delicate fruits with the soil. However, some mulches have been shown to reduce the number of whiteflies, and incidence of whitefly-transmitted viruses in certain crops. Aluminum, silver or metallic mulches have proven to be most effective in reducing *B. tabaci* adults on plants. The most important factor is not the color of the mulch, but the intensity with which the light is reflected off the mulched soil. The main constraints to the adoption of this method of whitefly control include the high cost and the environmental impact of discarded plastics.

An environmentally-friendly and cost-effective alternative to mulching is the use of ground covers, which have been successfully tested in commercial tomato fields in Costa Rica. Instead of repelling whiteflies, they mask the young tomato plants from viruliferous whiteflies. Among several promising candidate plant species, coriander (*Coriandrum sativum*, Apiaceae) stood out, as farmers can harvest it 35 days after planting, after the critical period of tomato plant susceptibility is over. This technique warrants more attention, as it is particularly well suited for small farms.

Chemical Repellents

Any compound capable of keeping whiteflies away from susceptible plants reduces the possibility of virus inoculation and subsequent disease expression. Protection can be achieved either by feeding deterrent (acting after contact) or repellent (acting at a distance, as vapors) substances.

It has been shown that in proper doses, both cooking and mineral oils can deter *B. tabaci* without causing phytotoxicity, but these are not widely used by farmers. Moreover, in Costa Rica, after testing approximately 70 hydroalcoholic extracts from plants, deterrence of whiteflies was detected in the following ten species: worm-seed (*Chenopodium ambrosiodes*, Chenopodiaceae), sword bean (*Canavalia ensiformis*, Fabaceae), "chile muelo" (*Drymis granatensis*, Winteraceae), bitterwood (*Quassia amara*, Simaroubaceae), mother of cocoa (*Gliricidia sepium*, Fabaceae), neem (*Azadirachta indica*, Meliaceae), wild "tacaco" (*Sechium pittieri*, Cucurbitaceae), "sorosí" (*Momordica charantia*, Cucurbitaceae), fish bean (*Tephrosia vogelii*, Fabaceae), and wild sunflower (*Tithonia diversifolia*, Asteraceae). Some of them are currently receiving additional research.

Volatile substances of botanical origin, mainly alcohols and aldehydes, can repel whiteflies. Repellency has been shown to exist for cinnamaldehyde, perialdehyde, 1-hexanal and Z-3-hexen-1-ol. These compounds have been further tested by enclosing them in controlled-release dispensers to avoid phytotoxicity and increase their life span both in field crops and commercial greenhouses.

Concluding Remarks

Whereas the knowledge on whitefly-related crop production problems has significantly increased in the past two decades, *B. tabaci* and *T. vaporariorum* are still major pests and vectors of plant viruses that affect many industrial and food crops in Latin America. The main reason for the apparent difficulty in controlling these pests has been the economic crises that drastically reduced crop production-oriented research and crop improvement projects in Latin America. Technical assistance or, rather, the lack of it, is also another major cause of the continuous emergence of insecticide-resistant populations of *B. tabaci* and *T. vaporariorum* in Latin America. In the absence of resistant varieties and technical assistance, farmers do not have alternatives different from chemical control. Insecticide abuse soon leads to the elimination of the natural enemies of whiteflies, and emergence of insecticide-resistant whiteflies.

Also, a major factor that have contributed to the existing escalation in the number of whitefly biotypes and whitefly-borne viruses has been the diversification of the traditional cropping systems in Latin America. Promotion of mixed cropping systems that include both traditional and non-traditional export crops provides continuous food for whitefly pests year round. In addition to the continuous availability of plants suitable for whitefly survival, the plasticity of begomoviruses, and the ease with which they form genetic recombinants, are also notable factors driving the epidemics of old and new begomoviruses in many commercial crops grown for local consumption or export in Latin America. Consequently, technology generation and transfer efforts should be reconsidered and strengthened in Latin America, particularly in view of the challenge presented by the unavoidable integration of Latin American agricultural markets into a highly competitive globalized world.

White Grubs, *Phyllophaga*, and Others (Coleoptera: Scarabaeidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

The whitish, soil-dwelling larvae of scarab beetle species are called white grubs. Traditionally, white grubs were considered to be members of the genus *Phyllophaga*, but increasingly the larvae of other members of the family Scarabaeidae such as *Anomala*, *Aphodius, Ataenius*, *Cyclocephala*, *Exomala*, *Polyphylla*, *Popilla*, *Rhizotrogus*, and other are included in this general term because they have a very similar appearance and biology.

Life History

The life cycle of the various species ranges from 1 to 4 years, although in the *Phyllophaga* species it is 2–4 years, with the 3-year life cycle most frequent. Duration of the life cycle is often related to latitude.

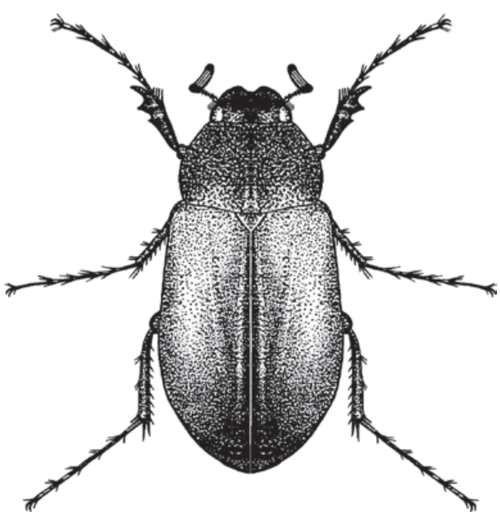
In southern areas, 2-year life cycles are common, whereas in the north three to 4 year cycles occur.

The general, 3-year life cycle starts with oviposition in the spring or early summer, followed by feeding and growth until autumn when cold weather induces a period of inactivity, and overwintering by second instar larvae. During the second year, feeding is resumed in the spring, the third instar is attained, and feeding continues until cold weather when another period of inactivity occurs. In the spring of the third year larval growth is completed, and pupation occurs during the summer. The adult remains in the soil until the following spring. Thus, the 3-year life cycle occurs during a 4-year calendar period (Fig. 50).

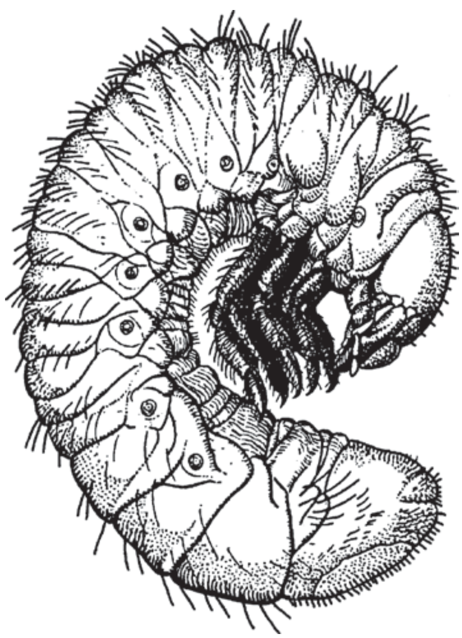
In the typical 2-year life cycle, oviposition occurs in the summer, eggs hatch in late summer, and young larvae commence feeding, quickly attaining the third larval instar, and then overwinter. They feed again throughout the second summer and overwinter as mature third instars. The following spring they feed briefly, pupate, and adults emerge, mate, and oviposit. Thus, in the 2-year cycle larvae develop more quickly, and the adult does not undergo a period of arrested development, as occurs in the 3-year cycle. The 2-year period of development occurs over three calendar years (Fig. 51).

Following is a description of common June beetle, *P. anxia*, perhaps the most abundant and damaging *Phyllophaga* in North America. It serves well to illustrate the biology of white grubs and June beetles. In Quebec, Canada, common June beetle displays the typical 3-year life cycle. Adults begin to fly in May and oviposit in June. First instar grubs are abundant in July and molt into second instars in August. The second instars overwinter, molting into third instars during June of the second year. Third instars overwinter at the end of the second year, developing into prepupae during June of the third year, and pupating in July. Adults are fully formed by September but remain in the soil until the following spring. As noted previously, the 3-year life cycle is spread over four calendar years.

About 10 days after mating, the female deposits its pearly white elongate-oval eggs about 2.4 mm long and 1.5 mm wide. The eggs absorb water, becoming enlarged in size, and eventually measure about 3 mm in length and 2 mm in width. Mean fecundity is about 55 eggs per female. Eggs hatch after about 20–30 days.



White Grubs, *Phyllophaga*, and Others (Coleoptera: Scarabaeidae), Figure 50 **Adult of *Phyllophaga* sp.**



White Grubs, *Phyllophaga*, and Others (Coleoptera: Scarabaeidae), Figure 51 **Larva of *Phyllophaga* sp., a common white grub.**

Young grubs often feed on decaying vegetation before turning to root feeding, but are not associated with manure. The grubs are pearly white, with a dark head and legs. They bear a thin covering of stout hairs, and when dug from the soil they assume a curved body posture or C-shape. Although the grubs feed at a depth of perhaps 5–15 cm during the summer months, they descend to about 30–100 cm during the winter months. Depth of burrowing is markedly affected by soil and moisture conditions and age of the grub. Survival of grubs is higher in light soils and with moderate moisture conditions; heavy rain is detrimental both to oviposition and survival of young grubs. Grubs pass through three instars over about a 24 month period that is spread over part of three calendar years. Larvae prepare a cell in the soil for pupation. This cell also serves as the overwintering site for the adult, which does not emerge from the soil until the following spring.

The body of adult *P. anxia* is oblong ovate in shape, dark brown in color, and measures 17–21 mm in length. The elytra are marked with numerous fine, shallow punctures. The underside of the thorax bears a dense coat of long hairs. The antennae are 10-segmented and elbowed and expanded at the tip. The basal segments of the legs are generally stout, the tibiae broadened and armed with teeth or stout spurs, but the tarsal segments are elongate and narrow.

Many predators, parasitoids, and pathogens of white grubs are documented. Larvae of robber flies (Diptera: Asilidae) and beeflies (Diptera: Bombyliidae) are frequently found in association with grubs. Among the parasitoids are such tachinids as *Cryptomeigenia theutis* (Walker), *Eutrixa exilis* (Coquillett), *Eutrixoides jonesii* Walton, and *Microphthalma* spp. (all Diptera: Tachinidae); the light flies, *Pyrgota* spp. (Diptera: Pyrgotidae); and the wasps *Pelecinus polyturator* (Drury) (Hymenoptera: Pelecinidae); and *Tiphia* spp. (Hymenoptera: Tiphiidae). Of the parasitoids, only *Tiphia* spp. are documented to be of considerable importance, sometimes accounting for up to 50% mortality among grubs. Mites (Acari: several families) are commonly associated with grubs and beetles; eggs and pupae generally are free of mites. However, few of these mite associates are thought to be parasitic or detrimental to white grubs. All the common groups of insect pathogens have been found associated with white grubs, especially *Metarhizium anisopliae* and *Beauveria bassiana* fungi. There is no evidence that these pathogens, and many of the other associates of white grubs, have significant impact on grub density.

Damage

Both larvae and adults can be damaging, but they usually have markedly different feeding preferences. Larvae are found in the soil, and normally feed on the roots of grasses. Adults, however, usually feed on the leaves and flowers of deciduous trees and shrubs, particularly ash, elm, hackberry, hickory, locust, oak, poplar, walnut, and willow, and sometimes pine. Root crops such as beet, potato, and turnip are among the crops most susceptible to injury by larvae, but corn and strawberry are sometimes damaged, and the seedlings of virtually all vegetables are susceptible if grub density is high. Crops other than grasses are not preferred oviposition sites, so damage usually occurs only when crops are planted into land that recently has been grass sod, pasture, or sometimes grass crops such as timothy, small grains, or sorghum. Tree seedlings, especially conifers, are damaged when planted into grass sod or pasture. Alfalfa and clover seem to be avoided even though both crops often contain some grass. Adults disperse widely, and trees adjacent to grassland, especially when few in number, are sometimes injured by defoliation.

White grubs have limited mobility; their distribution is largely a function of oviposition preference by females. Thus, although the roots and tubers of crops may be consumed, this is often due to conversion of grassland bearing partially grown grubs to crop production areas, and a decrease in the availability of their preferred host plants, grasses. Typically, larvae clip the roots of plants with fibrous roots systems, especially during the second year of larval life, resulting in the wilting and death of young plants. However, they may chew holes into larger roots and tubers, damage that may not be apparent until harvest.

Damage to trees by adults also occurs, particularly in more temperate areas. In such areas, the transition from cold, wet weather to warm, dry weather is abrupt, causing mass emergence of adults and defoliation of nearby trees. In contrast, in warmer areas, the gradual increase in temperatures causes a protracted emergence by adults and the defoliation of trees is less apparent. Adults prefer young foliage, feeding from the edge toward the center of the leaves. They feed at night and hide during the day, so the cause of damage is often overlooked.

Management

Estimates of grub density are often made by digging and examining 0.3 m^3 sections of sod and soil. Due to the highly aggregated distribution of grubs and eggs, however, extensive sampling is required to obtain a high degree of precision, often 50–100 samples. Light traps are used to monitor populations of June beetles because they are nocturnal; such traps collect mostly males. Flights normally occur between sunset and midnight, and then again at sunrise, and are initiated by a combination of temperature and photoperiod stimuli.

White grubs and June beetles are controlled with insecticides by application to soil or tree foliage, respectively. Soil applications predominate except perhaps for protection of foliage in fruit crops. Persistent insecticides are used in soil environments, applied preplanting or at planting. Insecticide resistance has developed in some regions.

Because of the attraction of June beetles to grasses, particularly short or mowed grass, there is considerable risk when crops are planted into land that supported grass during the previous year, or when crops are grown adjacent to grass pastures or sod. If clover is planted immediately following grass, the risk to subsequent crops is reduced, partly because grubs rarely injure clover, but also because June beetles prefer not to oviposit in clover fields. It is also important that crops be free of grass and other weeds during the flight of June beetles, or considerable oviposition may occur. However, if grubs are already in the soil, the presence of grass weeds can be advantageous because grubs will feed preferentially on the grass.

Plowing and disking are sometimes recommended for destruction of grubs because the soft bodies of larvae are easily damaged by tillage. Also, tillage exposes grubs to birds, which can often be seen following tractors and consuming large numbers of exposed insects.

There have been few attempts to implement biological suppression of white grubs, other than the use of domestic animals such as poultry and swine to consume larvae. The spore-forming bacteria *Bacillus popillae* and *Bacillus lentimorbus* will infect and kill white grubs, but this expensive treatment is usually reserved for use on turf, where the bacteria can recycle through generation after generation of grubs. Entomopathogenic nematodes (Nematoda: Steinernematidae and Heterorhabditidae) have been evaluated for white grub suppression. Grubs are susceptible to infection, and high levels of suppression have been attained by both injection and surface application, but the results have not been consistent.

Wiedemann, Christian Rudolph Wilhelm

Christian Wiedemann was born in Braunschweig, Germany, in 1770. He obtained a medical degree in Jena, Germany, in 1792, and beginning in 1805 obtained a series of positions at the University of Kiel. His medical publications included books on anatomy, resuscitation of asphyxiated and drowned persons, and midwifery. In addition to his medical work, Wiedemann became very interested in Diptera. From 1800 to 1806 he edited the "Archiv für Zoologie und Zootomie," and from 1817 to 1825 the "Zoologisches Magazin." About this time he began a thorough study of exotic Diptera in several collections, including a redescription of Fabricius' flies, which was published in both Latin and German. Wiedemann also published an "Analecta Entomologica," with new descriptions, and then the "Aussereuropäische zweiflügelige Inseckten." He had access to rich collections from throughout South America and the West Indies, and named many new species. He died in 1849 at Kiel, Germany.

Wigglesworth, (SIR) Vincent Brian

Vincent Wigglesworth was born at Kirkham, England, and educated at Cambridge University. He was employed by the London School of Hygiene and Tropical Medicine, the University of London, and Cambridge University. He also directed the unit of Insect Physiology at Cambridge from 1943–1967 and was named Quick professor of biology. He was knighted for his profound contributions to insect physiology. Wigglesworth was one of the foremost insect physiologists of the 20th century, and is best known for his work with Rhodnius prolixus, a blood-sucking bug. His research included work on the hormonal basis for growth and molting, the role of brain secretions in regulating growth, function of sense organs, respiration in eggs, the role of the cuticle in preventing water loss, diel periodicity, and others. Probably his most important contribution, however, was the early work documenting the presence and importance of hormones regulating insect growth and development. His most important publications were "The physiology of insect metamorphosis" (1954), "The control of growth and form" (1959), and "The principles of insect physiology" (6 editions, 1939 to 1965). Wigglesworth's insect physiology was the standard insect physiology text for decades. He died in 1994.

Williams, Carroll Milton

Carroll Williams was born on December 2, 1916, in Richmond, Virginia, USA. He received a bachelor's degree from the University of Richmond in 1937, and a Ph.D. from Harvard University in 1941. He also earned a M.D. from Harvard. Appointed to the faculty of biology at Harvard in 1946, he was named Bussey Professor of Biology in 1965. Williams chaired the Biology Department from 1959 to 1962 and the Cellular and Developmental Biology Department from 1972 to 1973. Williams was a pioneer in insect endocrinology. He was the first to extract and characterize juvenile hormone. He also discovered brain hormone, and with the collaboration of others, partially characterized ecdysone. Williams also popularized the idea of 'third generation pesticides,' using synthetic hormones or hormone analogs as a means of specifically regulating insect populations without harming other forms of life. Although 'third generation' pesticides have not supplanted the second, there have been significant inroads made toward the use of insect hormones for pest management. Williams received numerous awards and honors over the course of his career, including the George Leslie Award, the Boylston medal, the AAAS-Newcomb Cleveland prize, the Howard Taylor Ricketts Award, and the Entomological Society of America's Founders Memorial Award. He also was a member of the prestigious National Academy of Sciences. Williams died on October 1, 1991.

Williston, Samuel Wendell

Samuel Williston was born at Boston, Massachusetts, USA, on July 10, 1852. He is known as an authority on Diptera and paleontology. He was raised in Kansas, however, and attended Kansas State University and left before completing his degree to seek his fortune. After contracting malaria, he returned to collect and complete his degree in 1872. He then commenced the study of medicine, and became interested in fossils, attaining an M.S. degree from University of Kansas in 1875. He became an assistant paleontologist at Yale University, and then received his M.D. in 1880 and his Ph.D. in 1885. At Yale University, he specialized in anatomy, and remained there until 1890. Williston then moved back to the University of Kansas, where he held the rank of professor and dean of the Medical School. In 1902 he moved to the University of Chicago, where he remained until his death. Although Williston's career did not include entomology, it was his recreational pastime – not an uncommon situation with "entomologists" of the era. And even as a part-time entomologist he attained recognition as a dipterist, and a renowned authority of Syrphidae. In fact, he turned down an offer from C.V. Riley to become a professional entomologist. He was a prolific writer, authoring 283 publications, most in paleontology but 97 in entomology. Among his important publications were "Synopsis of North American Syrphidae" (1886), and "Manual of the families and genera of North American Diptera" (1896). Williston died at Chicago on August 30, 1918.

Wilt Disease

Infection of lepidopteran larvae by many nuclear polyhedrosis viruses; the expression of infection is a drooping or wilting of larvae, followed by death.

Window Flies

Members of the family Scenopinidae (order Diptera).

► Flies

Wing

The paired membranous structures used for flight in insects. One pair (called the primaries) is normally attached to the mesothorax, the other pair (called the secondaries) to the metathorax. Either or both pairs may be absent. Some wings are modified for purposes other than flight.

► Wings of Insects

Wing Coupling

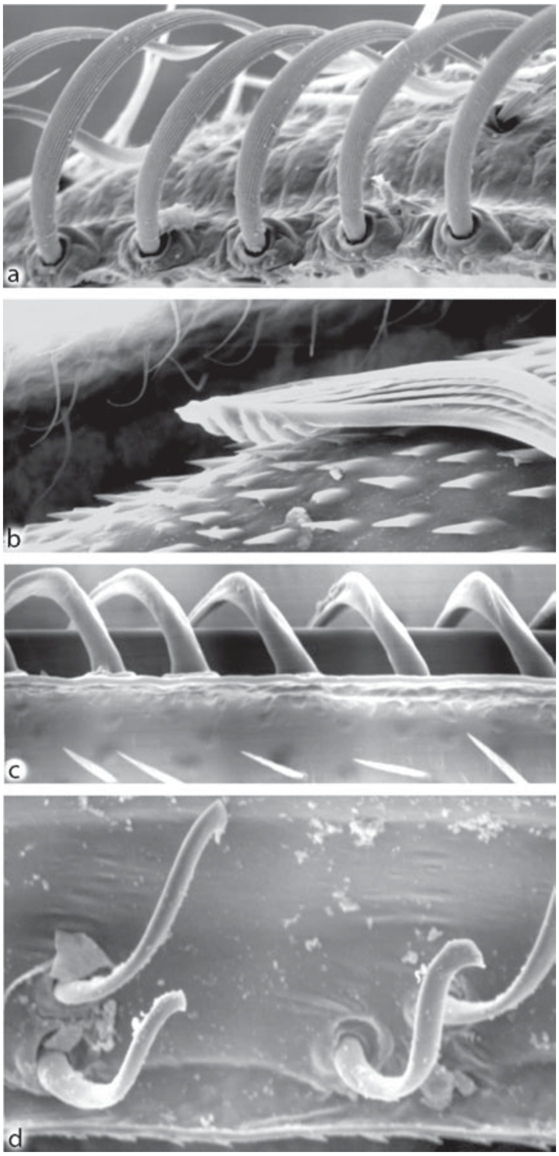
IAN STOCKS
Clemson University, Clemson, SC, USA

Although fossil remains suggest that early insects possessed lobes on the prothoracic segment suitable for gliding, we can infer that the first insects to use powered flight did so by using the mesothoracic (FW) and metathoracic wings (HW). Flight is energetically expensive, and many groups evolved mechanisms that enhanced flight efficiency and aerodynamic control. One solution is to ensure that relative FW and HW motion does not cause interference, thereby reducing flight efficiency and diminishing flight stability.

Many neopterous insects (those able to fold their wings posteriorly over their dorsum) have specialized structures that join the paired wings into a single aerofoil, thereby becoming functionally dipterous. In some neopterous groups, including Coleoptera, Neuroptera, Mecoptera, and some hemimetabolous orders, the paired wings operate principally by a phase shift in their motion. Some insects have solved the aerodynamic interference problem by modifying one pair so that it no longer has a role in generating lift (e.g., HW in Diptera, FW in Strepsiptera and Coleoptera) and does not function as a wing.

Insects with wings that are joined by specialized morphological adaptations occur in the "hemipteroid assemblage" (Psocoptera, Thysanoptera, Heteroptera, Coleorrhyncha, Hemiptera: "Auchenorrhynca," and Hemiptera: Sternorrhyncha), Hymenoptera, Lepidoptera, and Trichoptera. With the exception of Hymenoptera, and possibly some members of the "hemipteroid assemblage," wing-coupling is probably a derived (apomorphic) condition within each group. For example, in both Lepidoptera and Trichoptera, each of which has evolved a diversity of morphological adaptations for wing coupling, basal taxa in the order do not couple the wings (Fig. 52).

The terminology used to discuss wing coupling is used rather loosely in the literature, and typically connotes a greater concern for functional considerations than phylogenetic concerns, such as homology (Fig. 53). The term "hamulus" (pl. hamuli, literally "little hooks"), used primarily for the structures in Hymenoptera, is also used for similar structures in Trichoptera and Aphididae, even though they are substantially different in developmental origin and overall morphology. Similarly, "jugum" and its approximate cognate "fibula" are often used to designate the lobe-like expanded anal area at the basal-posterior margin of the wing. Such lobes occur in many mecopterans, lepidopterans, and trichopterans, and, depending on groups under consideration, may or may not be homologous structures. The term "frenulum-retinaculum" (Fig. 54) is used only in the Lepidoptera, referencing the frenular spine(s) and retinacular clasp on the HW and FW, respectively. However, as will be discussed below, even within this system there is considerable morphological variation. The terms "frenulum" and "frenular" have also been used rather loosely in the literature, but Braun argued to restrict the term "frenulum" to spines arising from the costal sclerite itself, with the term "costal spines" reserved for



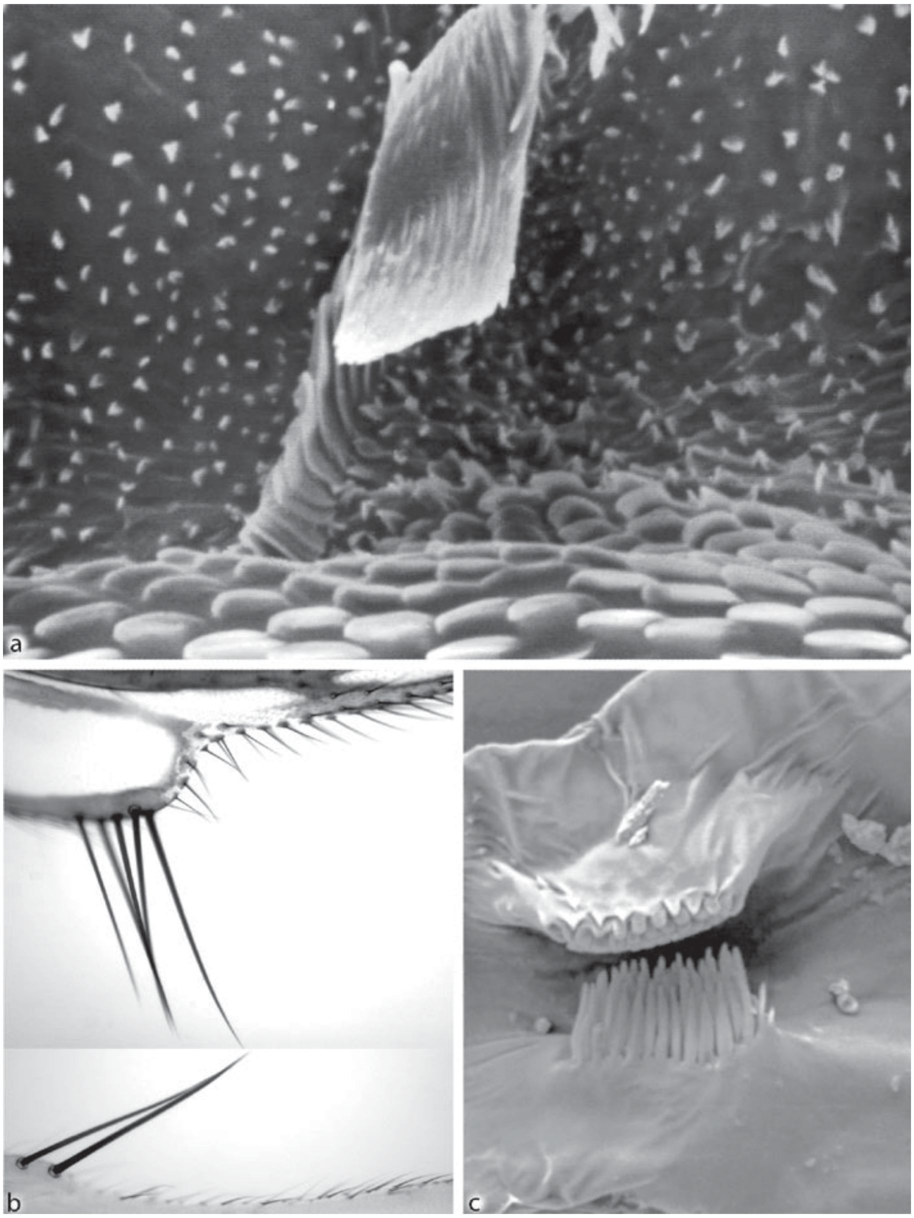
Wing Coupling, Figure 52 **Wing coupling mechanisms: (a) *Mystacides sepulchralis* hind wing hamuli (Leptoceridae: Trichoptera); (b) *Molanna ulmerina* hind wing hamulus engaged with FW posterior vein (Molannidae: Trichoptera); (c) *Vespula* sp. hind wing hamuli (Vespidae: Hymenoptera); (d) *Macrophya* sp. hind wing hamuli (Tenthredinidae: Hymenoptera).**

spines arising generally from the costal vein, both of which types may be used in wing coupling. Coupling due to an "amplexiform" arrangement of the wings, by which an expanded region of one wing overlaps part of the other wing, is most notable in certain Lepidoptera, but is also the means by which mayflies keep their wings together during the down stroke; subtle variations in the contour of the FW and HW, engendering an "amplexiform" overlap, might also enhance coupling in some trichopterans and possibly some psocopterans.

Little empirical evidence, such as videography, exists to support the conclusion that wing coupling is actually achieved by structural wing modifications. Indeed, high speed videography eventually demonstrated that micropterygid moths and rhyacophilid caddisflies *do not* couple their wings during flight. Conversely, high speed cinematography elucidated some of the flight mechanics of *Thrips physapus* (Thysanoptera) and *Piezodorus lituratus* (Heteroptera: Pentatomidae), including HW-FW coupling. In most instances where direct observation has not validated that wings are coupled, claims are based on the inference of a form-function relationship. Also, wing-coupling in many trichopterans and some hymenopterans might be used to enhance swimming through the water column in the search for submerged oviposition sites. Similarly, in some cases the wing modifications inferred to be wing-coupling devices might simply serve to change the position of the wings, such as by bringing the HW out of its resting position, or by securing one or both wings against the body wall.

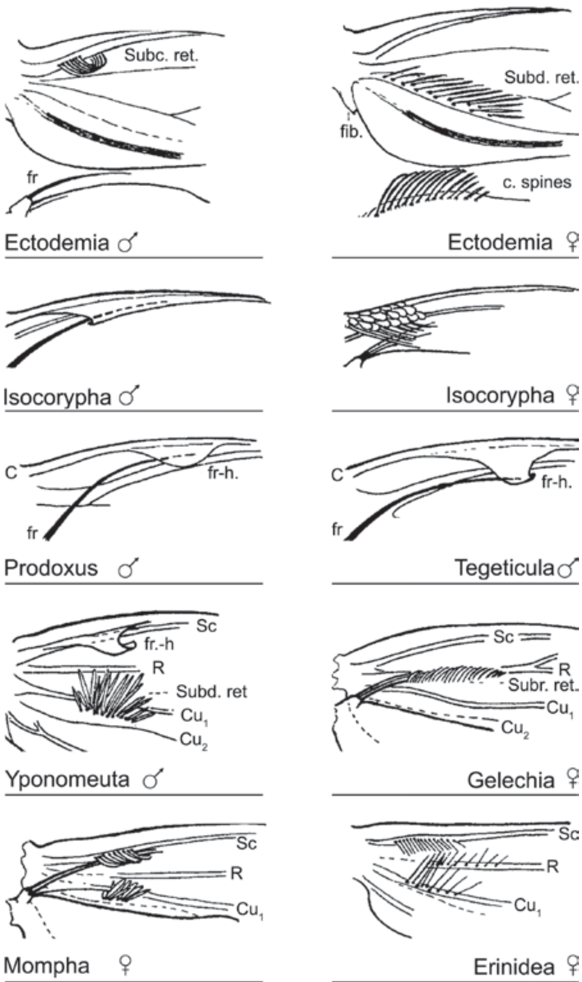
The "Hemipteroid Assemblage"

Discussion of wing-coupling structures in a group as extensive as the "hemipteroids" is problematic, but a great deal has been learned about the functional morphology of the various mechanisms and of the systemic value of these structures in less inclusive groups. Wing-coupling structures in certain psocopterans appear similar to those of some "homopterans," but this has not



Wing Coupling, Figure 53 **Additional wing coupling mechanisms: (a) *Cerastipsocus* sp. front wing (Psocidae: Psocomorpha); (b) *Panorp*a sp. front and hind wings (Panorpidae: Mecoptera); (c) *Sinea* sp. front wing (Reduviidae: Heteroptera).**

been studied in sufficient detail and could be a convergence. Those of thysanopterans appear to be unlike those of any other "hemipteroids," but this observation also could be due to insufficient taxon coverage. Within "Homoptera" (Hemiptera: "Auchenorrhyncha" and Sternorrhyncha) and Heteroptera, the wing coupling structures are phylogenetically useful at the family level. The placement of Coleorrhyncha is still unclear, but examination of the wing-coupling structure suggests a closer relationship to the Heteroptera than to any "homopteran" group.



Wing Coupling, Figure 54 The frenulum and its retinaculum in the Lepidoptera (modified from Braun, A. 1924. Annals of the Entomological Society of America 17: 234–257).

Psocoptera

Recent phylogenetic analyses do not treat Psocoptera as monophyletic, but the groups Psocomorpha and Trogiomorpha, which contain most of the common species of "psocopterans," do appear to be monophyletic. Almost no published information is available about wing coupling in psocopterans, but many taxa do have coupling mechanisms that bear an overall resemblance to a generalized homopteran-type of coupling. Two structures on the forewing, the "nodus" and "nodulus," are involved with FW-HW interaction, but only the nodulus engages the wings as a coupling mechanism. Two basic types of nodulus can be discerned, but a hook-shaped nodulus comprised of truncated spines that are basally fused appears to be an autapomorphy of Psocomorpha. In *Cerastipsocus* sp. (Psocomorpha, Psocidae), the coupling system is simply a clasp, or hook, comprised of a "tuft" of sclerotized, curved projections that arise from the terminus of the anal vein and posterior cubitus (first anal, 1A; CuP) on the posterior margin of the forewing. With wings mounted *in vitro*, the costal margin of the hind wing engages the groove formed by the clasp, and the margins of the wings assume a somewhat amplexiform configuration wherein the contours of the opposed FW-HW margins "overlap." Whether this position is assumed in flight is unknown.

Hemiptera: Auchenorrhyncha

Wing coupling structures have been documented in detail by scanning electron microscopy (SEM) in taxa from Fulgoromorpha (e.g., Cixiidae, Flatidae, Delphacidae), Cicadomorpha (Cicadidae), and "Jassidomorpha" (e.g., Cercopidae, Membracidae, and Cicadellidae). Sufficient morphological differences exist in the coupling mechanisms that three general types can be recognized, corresponding roughly with the above-mentioned groups. The basic wing-coupling apparatus (WCA) principally involves a "wing-coupling fold" along the posterior margin of the FW and a corresponding "wing-coupling lobe" on the anterior margin of the HW. Both structures are generally more strongly sclerotized and are often armed with a highly imbricated surface bearing serrations, denticles, or spatulate flanges sculpted onto the cuticle. In at least some "Jassidomorpha" and Fulgoromorpha, the HW costal margin is armed with a few stout "sensillae" which are articulated, innervated, peg-like "setae." They are presumed to function as coupling-hooks ("hamuli"), coupling-proprioceptive sensillae, or both.

Hemiptera: Sternorrhyncha

Species in the families Aphididae and Psyllidae possess HW structures that function as hamuli. Electron micrographs of the HW-coupling system of aphids reveal a single tight cluster of small spiral-shaped chitinous projections (of variable number, depending on species) from the membrane at the edge of the HW, which fit into a groove on the FW formed by a reflexed and more heavily sclerotized wing membrane. Although the "socket" from which the hamuli originate is apparently different from that of a typical socketed seta, they might be true setae and not highly modified and sculptured cuticular projections.

Psyllids, as represented by the blackberry psyllid, *Trioza tripunctata* (Fitch), have short but stout socketed spines that begin as a cluster on the humeral sclerite and the base of the costa, and several more that form a linear group on the costal margin after a short intervening space. A single, strongly curved hamulus occurs roughly at the halfway point on the margin. As with aphids, these hamuli engage with the FW in a groove formed by the posterior margin.

Heteroptera + Coleorrhyncha

Wing-coupling is widespread in Heteroptera and the mechanics of coupling are well understood, with significant detail provided by SEM imaging. A ventral "clip" (also referred to as "clasp") on the posterior margin of the FW engages a recurved and highly sclerotized costal margin (dorsal ridge). The clasp is a bipartite structure composed of pad and spinaculum, separated by a groove. Both the clasp and dorsal ridge may be ornamented with elaborate projections, flanges, serrations, or teeth that help secure the wing union.

The wing-coupling apparatus of *Peloridium hammoniorum* Breddin, a representative of the enigmatic Coleorrhyncha, bears closer affinity to those of heteropterans than those of "homopterans," but is distinctively different. In *P. hammoniorum*, the HW costal margin assumes a complex "S-shape" and is ornamented with coarse microsculpting. The profile formed by this shape presents an inner and outer groove, with the inner groove contacting the coupling apparatus of the forewing. The ventral surface of the forewing presents a bipartite clasp, with one part composed of about 20 sclerotized, spine-like projections that form a closely packed crown, and the second part composed of a sclerotized but flattened and round-tipped cluster of about four projections, which also are grouped closely.

Thysanoptera

Specialized fringes of setae ("cilia") on the wings of many thysanopterans (e.g., *Thrips physapus* L., Thripidae: Terebrantia) appear to be intimately involved with flight mechanics, and effectively double the wing surface area. Wing coupling is accomplished primarily by hooked setae on the HW that secure two long setae on the proximate, posterior region of the FW, but coupling could possibly be enhanced by other setae originating on the HW. Thysanoptera wings are in general lanceolate and possess fringes of long setae, but many taxa also have corrugated surfaces with wart-like swellings and rows of stout and curved macrotrichia. Thus, wing coupling might be more widespread than currently documented.

Endopterygota

Mecoptera

No species of mecopteran is known to be functionally dipterous, but structures of their wings suggest the possibility that wing coupling in at least Lepidoptera and some Trichoptera is derived from a mecopteran condition. In Panorpidae, for example, the posterior angle of the FW is enlarged into a lobe that bears a linear cluster of stout socketed setae (i.e., those derived from trichogen and tormogen cells, and often containing dendrites) known as frenular spines. The basal anterior region of the HW is also armed with such spines, and the FW spines and HW spines appear to interact during the wing beat. Such an interaction probably alters wing-beat frequency and/or blade angle, and possibly provides neurosensory feedback on relative wing position. Also, the wing margins are densely armed with short but stout socketed setae, and could be morphological precursors of the socketed setae, known as hamuli, in many Trichoptera and all Hymenoptera.

Hymenoptera

Hymenopterans from both suborders "Symphyta" (sawflies) and Apocrita (wasps and allies) couple their wings via hamuli, and the coupling mechanisms in many apocritan groups are so highly developed that each FW-HW pair assumes the profile and contour of a single, but flexible, wing blade. Even within Hymenoptera, the microstructure and number of the hamuli can vary significantly, but in all known cases the hamuli engage the posterior margin of the FW by hooking over a sclerotized "ridge" that forms a trough-like region. The sclerotized ridge is usually armed with microsculpted spurs that appear to provide further grip to the hamuli and prevent excessive sliding while the wing is in motion.

A comparative morphological analysis within a phylogenetic context revealed that there were three basic types of hamuli within the order: basal hamuli, which are found only in the symphytans Xyelidae, Pamphiliidae, and Xiphydriidae; secondary hamuli, which are either openly spaced or clustered, depending on group; and distal hamuli, which occur in all winged Hymenoptera. Several small studies have examined whether there is a relationship between certain flight parameters and the number and structure of the hamuli, but there is little conclusive evidence suggestive of a substantial pattern.

Trichoptera

Discussion of the biology and phylogeny of the Trichoptera invariably impinges on that of the Lepidoptera, which together form the higher taxon Amphiesmenoptera (lit. "dressed-up wings"). Indeed, Micropterygidae, the basal most taxon in Lepidoptera, was originally treated as a terrestrial branch of the Trichoptera. Current phylogenies are still unclear on the number of suborders within Trichoptera (or their topology), but typically the three suborders "Spicipalpia," Annulipalpia, and Integripalpia are discussed. Regardless of the eventual phylogenetic resolution, wing coupling in Trichoptera is a derived condition within each major group, with the basal taxa in each "suborder" functionally tetrapterous.

Several morphologically distinct coupling systems have evolved, but they all rely on modified socketed setae of one wing engaging with the partner wing in some manner. The most questionable type of coupling, which could be only an elaborated "frenular bristle"-based FW-HW interaction mode, is common in many Annulipalpia (e.g., Philopotamoidea), Integripalpia (e.g., Limnephiloidea), and "Spicipalpia" (e.g., Rhyacophilidae). In these groups, a cluster of stout setae at the proximate, anterior region of the HW interacts with a lobe on the proximate, posterior region of the FW, and this type of system co-occurs, depending on group, with coupling that is more properly of the hamular type.

The term "hamulus" is used broadly and denotes a functional role, and hamuli of striking overall structural similarity to those found in hymenopterans occur in members of several families of Trichoptera, many of which are believed to be accomplished fliers. In many of the integripalpian taxa, such as Leptoceroidea and Sericostomatoidea, hamuli are dispersed over part or most of the HW costal vein and couple with the wing vein that defines the posterior margin (posterior vein, circumferential vein) of the FW. Variations of this system, derived independently of those in integripalpian families, occur in the Hydropsychidae: Macronematinae (Annulipalpia). Hydropsychidae: Hydropsychinae have evolved a "reverse hamular-clip" system, wherein the costal vein of the HW "clips" into a structure on the ventral surface of the FW. A series of recurved spines originating on the FW anal vein oppose a patch of dense, acuminate, spine-like microacanthae (i.e., cuticular spines) located on the wing membrane between the anal vein and the posterior vein. Distally directed recumbent spines along the HW costal vein are "pinched" between the FW apparatus, and secure the wing. A similar system evolved in the Calamoceratidae (Integripalpia), which are also accomplished fliers, but in this case the "reverse-clip" is formed by two patches of socketed, denticulate setae, with one patch arising from the posterior vein and the other from a patch of wing membrane above the anal vein.

Lepidoptera

Wing venation and coupling mechanisms in Lepidoptera were used by some of the first lepidopteran systematists to subdivide the order. The shifting position of Micropterygidae between Lepidoptera and Trichoptera notwithstanding, the suborders Jugatae or Frenatae were created by Comstock to reflect the distinction between lepidopterans that used either a modified jugal lobe to "join" the wings (Hepialidae and "Micropterygidae," which in earlier classifications included taxa now placed in Agathaphagidae and Heterobathmiidae), or specialized frenular bristles on the HW that engaged a specialized retinacular clasp on the FW. As noted previously, micropterygids do not couple their wings, but hepialids *may* couple via a modified, thumb-like, jugum that hooks over the HW costal margin.

The true frenulum is sexually dimorphic; in males, several closely spaced spines become fused distally into a single spine, and recent phylogenies treat the presence of the single male frenular spine as a synapomorphy of the grade Heteroneura. The retinaculum, which serves as the FW "clasp," is also highly variable throughout the order, especially in females, and may be formed by modified spines, setae, scales, or flanges of wing membrane that protrude from the wing surface. The typical male retinaculum is a chitinous flange arising from either a vein or the interveinal membrane near the FW costa or subcosta.

Many Lepidoptera with large wing surface area, including the Papilionoidea (Butterflies), Hesperoidea (Skippers), and some bombycoids (e.g., giant silk moths), use "amplexiform" coupling, and rely on no specialized coupling structures. Instead, a greatly enlarged humeral angle (proximal anterior margin of the HW) rests below the FW posterior margin. These typically larger-bodied Lepidoptera generally have low wing-beat cycles, and use the greatly expanded wing surface area for primarily gliding flight.

A uniquely modified coupling system has evolved in the Sessiidae, a group that includes exceptionally good and typically day-active fliers. Like other moths, they have a frenular-retinacular coupling system, but they also are able to position the recurved posterior margin of the FW into an oppositely recurved groove on the anterior margin of the HW, thereby effectively sealing the margin along its entire length.

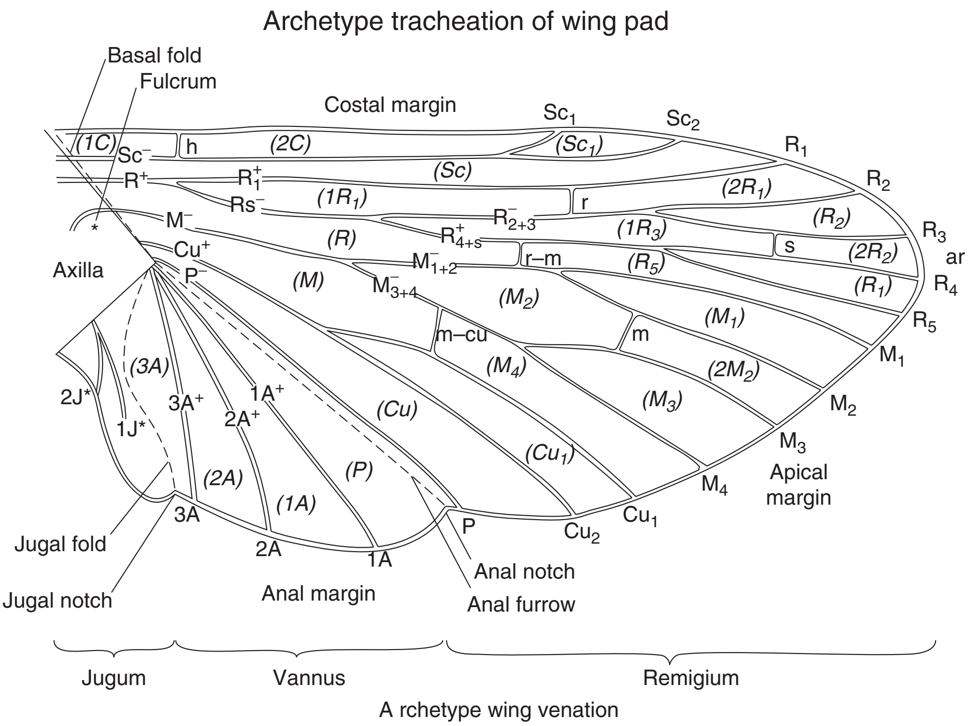
Wings of Insects

The ability to fly is one of the factors responsible for the biological and evolutionary success of insects. Typically, adult insects bear two pairs of wings that articulate with the thorax, though some have but one pair and others are wingless. Wings may be present in immature hemimetabolous insects, but they are incompletely developed (and called wing pads) until the adult stage is attained. Mayflies (Ephemeroptera) are exceptional in having a winged stage (the subimago) prior to reaching the adult stage, which also is winged.

The wings are flattened regions of the integument, arising dorsolaterally between the nota and pleura of the meso- and metathoracic segments. They receive rigidity, in part, from the veins contained within the wings. The veins are thickened regions of the integument that remain separated, allowing blood (hemolymph) to be pumped through the veins. This is critical during expansion of the wings following emergence of the adults. The veins also contain trachea and nerves. Folds also are present in the wings, and take two forms: flexion lines, where bending occurs during flight, and folding lines, where the wing folds during periods of rest. The wings are normally transparent and membranous, though they may be iridescent, pigmented, or even thickened and opaque. A thickened, pigmented spot is found on the anterior edge of some insect wings, and is called the pterostigma or stigma. This region of greater mass reduces wing flutter during gliding, and enhances control of wing movement during wing beats. When at rest, the wings are held over the back, and in many insects involves folding. Longitudinal folding is most common, but transverse folding also occurs. The wings of Coleoptera and Dermaptera fold transversely so they can fit beneath the elytra.

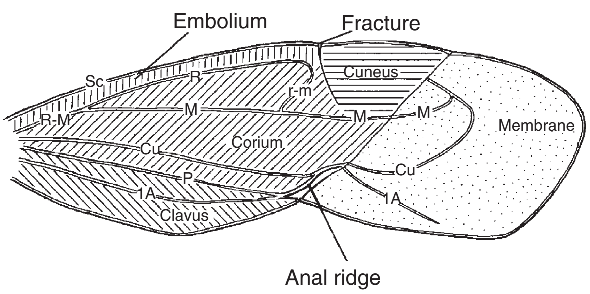
Areas of the Wing

Most of the wing veins are concentrated in the anterior region of the wings; this gives maximum efficiency and support during flight. The anterior edge is called the costal margin. The posterior region often bears separate lobes. The posterior region at the base of the front wing in Lepidoptera and Trichoptera is called the jugal lobe or jugum. Flies (Diptera) often have three separate lobes, the thoracic squama, alar squama, and the alula. The posterior wing edge is called the anal margin; the distal edge is the apical margin. The angle between the costal and apical margins is called the apical angle. The angle at the base of the anterior portion of the wing is the humeral angle. The anal area of the wing os the posterior region including



Wings of Insects, Figure 55 **Generalized wing venation showing wing regions and major veins.**

the anal veins. The costal area is the anterior region of the wing immediately behind the anterior edge. A fold in the wing often occurs in the cubito-anal area, and is called the anal furrow. A notch may also be present along the posterior edge, canned the anal notch (Figs. 55 and 56).

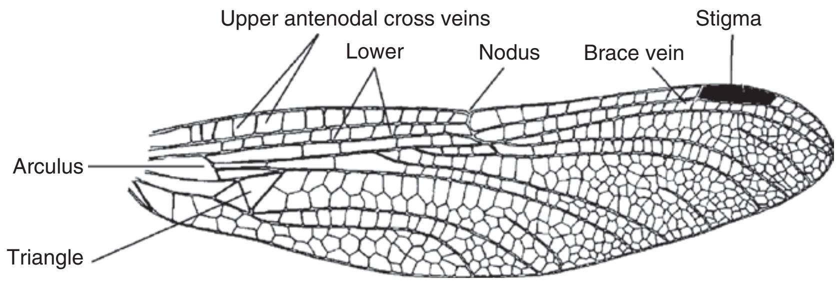


Wings of Insects, Figure 56 **A typical hemelytron, showing the thickened basal portion and the membranous distal (apical) portion of the front wing of a bug (Hemiptera).**

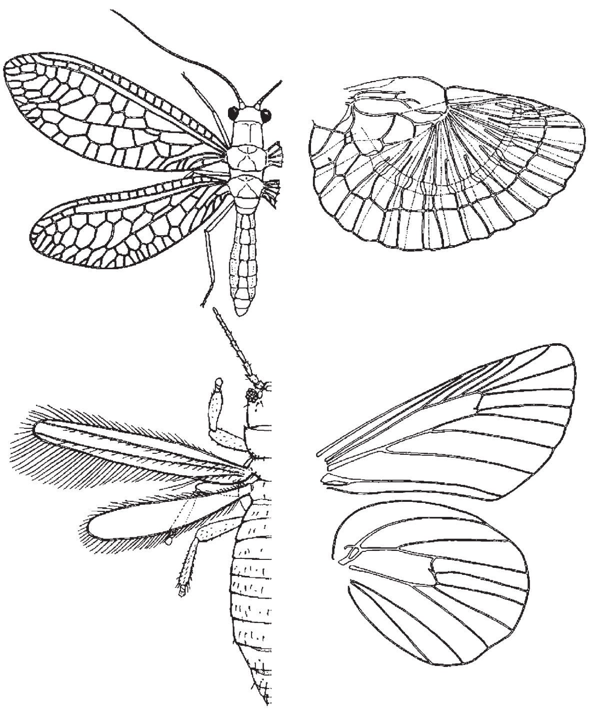
Wing Form

Wing form varies among the orders of insects. The front wings and hind wings are very similar in shape in the Odonata, Isoptera, Embiidina, and Mecoptera. In contrast, the hind wing is wider in Plecoptera, Mantodea, Blattodea, and Orthoptera. In some orders the hind wings are considerably smaller than the front wings, such as in Ephemeroptera and Hymenoptera. In Diptera, the hind wings (called halteres) are so reduced as to not aid directly in flight; in male Strepsiptera it is the front wings that are reduced to haltere-like structures. Wings also may be branched, a common condition in some Lepidoptera, or fringed, as in Thysanoptera, some Lepidoptera (e.g., Tinaeoidea), and some Hymenoptera (e.g., Mymaridae) (Fig. 57).

Wings may be shortened; when both pairs are reduced they are said to be brachypterous or micropterous. Wingless insects are called apterous. The size or occurrence of wings may



Wings of Insects, Figure 57 **The front wing of a dragonfly, showing net-winged venation and other characters found in Odonata.**



Wings of Insects, Figure 58 **Comparative wing structure showing diversity among insect wings: top left, lacewing wings (Neuroptera); top right, hind wing of an earwig (Dermaptera); bottom left, thrips wings (Thysanoptera); bottom right, skipper butterfly wings (Lepidoptera).**

vary seasonally or geographically within the same species; such polymorphism is common in Hemiptera, and to a lesser degree in Orthoptera (Fig. 58).

The front wings may be modified in form, and often are more sclerotized than the hind wings. The front wings of Coleoptera and Dermaptera are heavily sclerotized and called elytra; the wing venation is lost in these structures. In some beetles, particularly the Curculionidae, the front wings are fused together and cannot open. In Orthoptera, Mantodea, and Blattodea the front wings are thickened, but veins are evident; they are called tegmina. In the Hemiptera/Heteroptera, the basal portion of the front wings are thickened, but the apical region is membranous; these are called hemelytra.

Wing Coupling

The front and hind wings of insects are affected primarily by the distortions of the thorax, and do not move independently. Although not physically linked in Odonata and Orthoptera, many orders have anatomical coupling mechanisms that assist in synchronization of wing beat. Apparently the two-winged condition is more efficient than the four-winged condition, so they move together. The coupling takes the form of a jugal lobe at the base of the front wings, the humeral lobe at the base of the hind wings, and setae called frenular bristles. There are many variations among the different insect groups.

Wing Venation

In some primitive insects the pattern of insect veins is irregular. In most insects, however, the pattern of venation is dominated by a few longitudinal veins that radiate from the wing base to the broader wing tip. The principal longitudinal veins (and their standard abbreviation), ordered from leading to trailing edge, are: the costa (C), subcosta (Sc), radius (R), media (M) but often divided into anterior media (MA) and posterior media (MP), cubitus (similarly divided into CuA and CuB or Cu1 and Cu2), and anal veins (numbered 1A, 2A, 3A, etc.). These major veins may branch, with the given numerical subscripts. Cross veins connect the major veins transversely, and normally are named after the longitudinal veins they connect. The area enclosed by veins is called a cell, and wing cells are named after the anterior vein.

J. HOWARD FRANK
University of Florida, Gainesville, FL, USA

This insect, native to the Palearctic Region, was at one time placed in a family called Hydriomenidae. Wingless adult females, emerging in November from pupae in the soil, climb the trunks of deciduous trees. During their ascent, they mate with winged males. Eggs spend the winter in the treetops. Larvae, hatching from eggs in early spring when temperatures average about 13°C, feed on the first flush of leaves, whose tannin content is low. Timing of hatch is critical because larvae that hatch too soon face starvation. Larvae that hatch too late encounter increasing levels of tannins in the leaves, making digestion difficult. Fully grown larvae descend to the soil on silken threads in May, burrow into the soil, spin a cocoon, and pupate therein. The insect thus spends 6 months in the summer and autumn as a pupa in the soil.

Male moths have a wingspan of 28–33 mm with alternating pale buff and darker brown bands on the forewings and a similar but paler pattern on the hindwings (Fig. 59). They are active at night, fly well, and are attracted to artificial light and to pheromone of female winter moths. Wings of females are so reduced that they cannot fly. The adult stage is reached during early winter. Females lay an average of 150 eggs, which are deposited in crevices in bark of trees. The larvae are loopers, green with pale lines on the sides and a darker line dorsally.

Winter Moth, *Operophtera brumata* (L) (Lepidoptera: Geometridae) and its Biologicalcontrol, Figure 59 **Winter moth male (*left*) and female (*right*) lent by Dr L. Humble Lyle Buss.**

Trees attacked by the larvae include especially oaks (*Quercus* spp.), but also on several other genera of hardwoods, and a few conifers. Populations fluctuate from year to year, but seldom are important pests in their native range, in large part because of population regulation by natural enemies. Damage is reflected in varying annual increment of timber production.

At a study site near Oxford, England, it was determined that the principal biotic factor limiting population size of winter moth at low population levels was predation on the pupae. Predation by generalist predators of the genera *Philonthus* (Coleoptera: Staphylinidae) and *Abax* and *Pterostichus* (Carabidae) and the typical damage they caused to winter moth pupae (Fig. 60) was characterized visually in the laboratory in the mid-1960s. In the field, predation was quantified using serological methods, and later by burying pupae and then unearthing them for visual inspection. Both methods had defects. The serological method allowed specific identification of beetle predators, but was complicated by need to measure predator population sizes, to measure rates of digestion of prey proteins, and to assume that detection of prey protein in one individual predator indicated its killing of only one pupa. The burial method made specific identification of predators very difficult and, because of the unnatural burial of pupae, perhaps did not allow staphylinid beetles to follow tunnels made by prepupal hosts to their pupation sites. Also, burying pupae in disturbed soil may have made it easier for carabids to dig and find these prey. Therefore, the burial method may have over-emphasized the importance of Carabidae. Nevertheless, results from use of the two methods broadly agreed. Remarkably, the proportion of winter moth pupae killed by *Philonthus decorus* (Gravenhorst), assessed earlier by a serological method and later by a burial method, was identical at 42%; the major point of contention between the two studies was in the assessment of predation by shrews (*Sorex*) relative to that by Carabidae.

Long-term studies of winter moth at this site (Wytham Woods), beginning in 1949, contributed to methods for construction and analysis of insect life tables. In these methods, population density at the various stages during development is measured. Mortality occurring between two successive stages, reported as a k-value, is the difference between the logarithmic values of population density of the two successive stages. When two mortality factors, for example two parasitoids, act on one developmental stage, the separate mortalities caused by each can be treated as successive even when in reality they are simultaneous. When k-values for all stages have been calculated, total generational mortality (K) is their sum. For winter moth life tables using the data collected at Wytham Woods, k5 was the value assigned to predation on the pupae. It was the only one of the k-values shown to be positively density dependent. In this same study, k2 was the value assigned to mortality caused to the larvae by the parasitoid *Cyzenis albicans* (Fallén) (Diptera: Tachinidae); it was shown to be trivial and not density dependent, indicating that this parasitoid had no substantial effect.

Unusual defoliation of hardwoods was recognized in Nova Scotia, Canada, by 1935. By 1949, the culprit had been determined as winter moth, now damaging apple orchards, too. It had evidently arrived as an invasive species from Europe, and had become a very important pest. The Canadian Forest Service investigated and arranged for importation from continental Europe of parasitoids belonging to six species. Released in Nova Scotia, two of them became established: *Agrypon flaveolatum* (Gravenhorst) (Hymenoptera: Ichneumonidae) and *Cyzenis albicans*. In the main study area, adult densities dropped from >1,000 adults per tree in 1954 to <1 in 1963. This was a huge success for classical biological control.

In 1976, a native species, *Operophtera bruceata* (Hulst), seemed to be causing unusual problems near the city of Victoria, on Vancouver Island. In 1978 it was learned that outbreaking populations were mixed, including *Operophtera brumata*. Consequently, *Cyzenis albicans* and *Agrypon flaveolatum* were imported from eastern Canada and released in 1979–1980. Once again these biological control agents seemed to have suppressed winter moth populations.

Study of the declining winter moth population in British Columbia showed that k5, pupal predation, had become an important mortality factor. Moth pupae, buried and later unearthed, showed damage just as had been observed under laboratory conditions in England. The obvious conclusion was that the two parasitoids (*A. flaveolatum* and *C. albicans*) were effective control agents at high densities of the moth, but in fact the parasitoids were supplanted in importance by native generalist beetles at low densities. Data from Nova Scotia likewise showed the importance of pupal predation (k5).

The importance of the parasitoids was not demonstrated in England, where population densities were always low. In England, *C. albicans* was attacked by a hyperparasitoid; also, few of the eggs it deposited on leaves were ingested by winter moth larvae because of low host population density. Conditions were far more favorable for it in Canada, where it was released in dense host populations without the hyperparasitoid.

A possible explanation of the increased value of pupal predation following introduction of the biological control agents into eastern and then western Canada is interaction. Thus, dead winter moth pupae containing living pupae of *Cyzenis albicans* for 10 months may have provided an abundant food source for generalist beetle predators for 10 months, rather than the 6 months for which the food source represented by the healthy host pupae was available. This additional food source might have maintained predatory beetle populations at higher levels than in the absence of such prey. Alternatively, predatory beetles may prefer the food source offered by healthy prey pupae rather than the food source presented by parasitized pupae, thus concentrating attack on healthy pupae. The specific identity (nor even the generic identity) of the beetle predators has not yet been determined in either eastern or western Canada. There still are unanswered questions, and now winter moth has invaded the Pacific Northwest and New England of the USA.

Life History

As might be expected with different species occurring in many areas of the world, the biology is quite variable. The life cycle often requires 3 years, but sometimes takes only 1 year in warm climates, whereas it may extend up to 10 years in cold areas. In the case of *Melanotus communis*, egg deposition occurs in June, eggs hatch in July, and larvae require four additional summers to complete their development. A strong association of larvae with cool, moist soil is evident, although warmer soil will be tolerated if it is moist. The larval morphology is fairly typical of wireworms. They are yellow to yellow brown in color, shiny, and elongate. The head, thoracic plate, and anal plate are darker in color. Pupation occurs in the autumn, and then adults overwinter in the soil in pupal cells.

Most flight activity occurs in May and June. Adults fly throughout the evening hours. Females display a fairly high fecundity, some species producing 1,500 eggs. Adults are reddish brown to black, uniform or variable in color, elongate and flattened. Some species are small, less than 10 mm long, but commonly attain 15 mm in length. There often are numerous instars (ten or more), particularly among the species with long development times. Adults tend to be short-lived, usually perishing within a month of emergence from the soil.

The natural enemies of wireworms are not well known, and generally seem to be unimportant. In Florida, for example, *M. communis* is parasitized by the wasp *Pristocera armifera* (Say) (Hymenoptera: Bethylidae), but only about 4% of wireworm larvae are affected. Birds are often observed to follow tractors as soil is tilled, and to consume wireworms. However, they likely glean only a small proportion of larvae.

Damage

Wireworms feed belowground on seeds, roots, and other plant tissue. Nearly all crops can be damaged by wireworms, but corn, small grains, and tuber producing crops are especially damaged. Crops with harvested roots or tubers, such as carrots and potatoes, are most easily injured, as even surface scarring can result in loss. Grass sod and grass crops such as sorghum are highly attractive to click beetles, so crops planted immediately after grasses are most susceptible to injury. Most species prefer high moisture, and it is the heavier, wet portions of fields that are most likely to experience damage. Larvae tend to move toward the soil surface in the spring as the soil warms, where they feed until the soil warms; they then move deeper in the soil where it is cooler. Larvae again return to the upper layer of the soil in the autumn when the soil surface cools, and feed until it becomes cold, when they return to a position deep in the soil until the soil warms in the spring.

Management

Considerable effort has been made to develop baits for wireworm sampling. Growers are advised to assess the population densities of wireworm larvae prior to planting in the spring by baiting wireworms. Baiting is accomplished by burying whole wheat, corn, sorghum or other attractive food sources in the soil at a depth of 10–15 cm, and by counting the number of wireworm larvae attracted. Soaking the bait for 1 day increases its attractiveness. Baiting does not work well if the soil is less than 8°C, so a sheet of transparent plastic is sometimes placed over the section of soil containing bait; this warms the soil and increases the mobility of wireworm larvae, allowing a more accurate assessment. Larvae can also be separated from the soil by sifting; a screen with 6–7 meshes per cm is desirable. Soil sampling followed by screening is an accurate, but labor intensive, means to predict wireworm problems prior to planting. Spatial distribution of larvae is variable, but sometimes aggregated, requiring extensive sampling.

Adult populations can also be sampled. Pitfall traps and sticky traps are useful for sampling adult populations on the soil surface and in flight, respectively. Click beetle catches on sticky traps and in light traps are not completely equivalent, so both types of trap should be used in population studies. Pheromone traps are beginning to come into use for these insects.

Insecticide is often applied to prevent susceptible crops from being injured by wireworms. The most common approach to wireworm suppression is to apply persistent liquid or granular formulations at planting, and to incorporate the insecticide into the soil near the seeds or seedlings. Preplant applications generally, but not always, are more effective than postplant treatments. Sometimes insecticides are applied broadcast over the entire field, but more commonly they are applied in bands over or along the rows. For long-duration crops, the planting time application may be followed by a mid-season application. Insecticide also may be incorporated into the irrigation water. Effectiveness varies considerably among insecticides, and some insecticide resistance has been reported. Soils with high organic matter content sometimes interfere with insecticide efficacy.

Grasses are particularly attractive to many wireworms. A strong relationship between wireworms and previous growth of sod is usually apparent. Grass cover crops such as sorghum-sudan can be highly attractive, and it is important to have the fields free of such grasses during peak flights. Where crops can be flooded, 6 weeks of flooding or two 4-week periods of flooding separated by 2 weeks of drying can eliminate wireworms.

Wirth, Willis Wagner

Willis Wirth was born on October 17, 1916, near Dunbar, Nebraska. He studied biology at Peru (Nebraska) State Teachers College and received a B.S. degree from Iowa Sate University in 1940, a M.S. degree from Louisiana State University in 1947, and a Ph.D. from the University of California at Berkeley in 1950. He served as an officer in the U.S. Public Health Service during World War II, working on malaria control and quarantine. From 1949 to 1983, Wirth was a research entomologist with USDA, ARS at the National Museum of Natural History, Smithsonian Institution, in Washington, DC. He served on many special assignments over the years, working in Australia, Florida, Texas, New York, Panama, and several locations in Europe. Wirth became a renowned authority on biting midges, studying the taxonomy and public health implications of Ephydridae, Chironomidae, Canaceidae, Dolichopodidae, and Ceratopogonidae. Wirth provided committee service for the Entomological Society of America, and was an adjunct professor at the University of Maryland and the University of Florida. After retiring in 1984, Wirth moved to Gainesville, Florida, to take an active role in the Florida State Collection of Arthropods. He published over 400 papers, mostly on biting midges, and particularly on Ceratopogonidae. He died September 3, 1994, in Gainesville, Florida.

Wolcott, George N

PAULINE O. LAWRENCE
University of Florida, Gainesville, FL, USA

George Norton Wolcott (Fig. 63) was born in Utica, New York on July 12, 1889, to David Clinton Wolcott and his wife Marion Delia Benedict. He attended Utica Free Academy in Utica, New York, and upon graduation in 1905, attended New York State College of Agriculture (now Cornell University). He received the B.S. in either 1907 or 1909, and the M.S. in Agriculture in 1915. In 1925 Wolcott was awarded the Ph.D. in Entomology from Cornell University. He married Magdalen Hall in 1919 and the couple had three children: Ann, David, and Oliver. Although he initially (in 1910) worked as a

Wolcott, George N, Figure 63 George Wolcott.

Federal Agent in the Bureau of Entomology of the Department of Agriculture in Texas, his most significant contributions to agricultural entomology were made in Puerto Rico. There, he worked with the Sugar Producers Association from 1910 to 1912 and as Director of Entomology of the Insular Experiment Station, Rio Piedras, from 1914 to 1916 and again from 1932 to 1956, when he retired and returned to the mainland. Between 1919 and 1929 he held various positions as Entomologist, initially in Puerto Rico, then in the Dominican Republic, Haiti and Peru, returning each time to Puerto Rico, the place he seemed to love. One of his most notable undertakings was to control the lesser sugarcane borer, *Diatraea saccharalis* (F.) (Lepidoptera: Pyralidae) in Puerto Rico. He initiated the release of the egg parasitoid *Trichogramma minutum* Riley (Hymenoptera: Trichogrammatidae) for *D. saccharalis* egg population reduction and eliminated the burning of sugarcane fields to prevent the destruction of parasitoid populations. He was equally successful in control of *D. saccharalis* in Haiti. Dr. Wolcott also conducted extensive studies on several coleopteran pests of sugarcane, including the sugarcane rhinoceros beetle, *Strategus barbigerus* Chapin, the white grubs *Lachnosterna* sp. and *Phyllophaga* sp. (Coleoptera: Scarabaeidae), and the sugarcane root weevil (= sugarcane rootstock borer), *Diaprepes abbreviatus* L. (Coleoptera: Curculionidae). Wolcott promoted the use of beneficials, including parasitoids, in pest control programs and to that end, traveled extensively through the Caribbean and Latin America, collecting various parasitoids such as *Cryptomeigenia aurifacies* Walton and *Eutrixoides jonesii* Walton (Diptera: Tachinidae) and *Tiphia parallela* Smith (Hymenoptera: Scoliidae) for white grub control. One of Dr. Wolcott's contributions to entomology in Puerto Rico has also had a significant and longlasting beneficial impact on biocontrol in the southeastern United States. He introduced the wasp *Larra americana* Saussure (later identified as *L. bicolor* F.) (Hymenoptera: Sphecidae) into Puerto Rico from Brazil for the control of the mole cricket *Scapteriscus didactylus* (Latreille) (Orthoptera: Gryllotalpidae) ("La changa"), a pervasive agricultural pest in Puerto Rico. This single classical biological control effort by Dr. Wolcott laid the foundation for current biological control successes against mole cricket pests of turfgrass throughout the southeastern United States. More than 200 of Dr. Wolcott's publications and manuscripts continue to serve as important references for scientists who study pest problems in the Caribbean region. In particular, his "Insectae Borinquenses," a revised annotated check-list of Puerto Rican insects, is a classic. At one time some of his books had been adopted as texts by several agricultural colleges and institutes in the Caribbean. Dr. George N. Wolcott was not only a prolific writer and meticulous researcher, but he trained many in entomological techniques. He also revived the once defunct Entomological Society of Puerto Rico, founded by Dr. Van Dine, to further promote the exchange of ideas among entomologists and other agricultural scientists throughout the Caribbean Basin.

Wollaston, Thomas Vernon

Thomas Wollaston was born at Scotter, Lincolnshire, England, on March 9, 1822. He obtained a B.A. and M.A. from Jesus College, Cambridge. Suffering from ill health, he wintered at Madeira for several years and visited Cape Verde and St. Helena, setting the stage for his studies of island fauna. Among his important publications were:

"Insecta Maderiensia" (1854), a treatise on the variation in species (1856), a museum bulletin of the Coleoptera of the Canary Islands (1864), "Coleoptera Atlantidum" (1865), "Coleoptera Hesperidum" (1867), and "Coleoptera Sanctae-Helenae" (1877). On these islands he elucidated the endemic fauna, discovering numerous new species of beetles. He died January 4, 1878, at Teignmouth, England.

Wood-Attacking Insects

S. K. Gangwere[1], S. Sastry[2]

[1]Wayne State University, Detroit, MI, USA

[2]U.S. Department of Health and Human Services, Washington, DC, USA

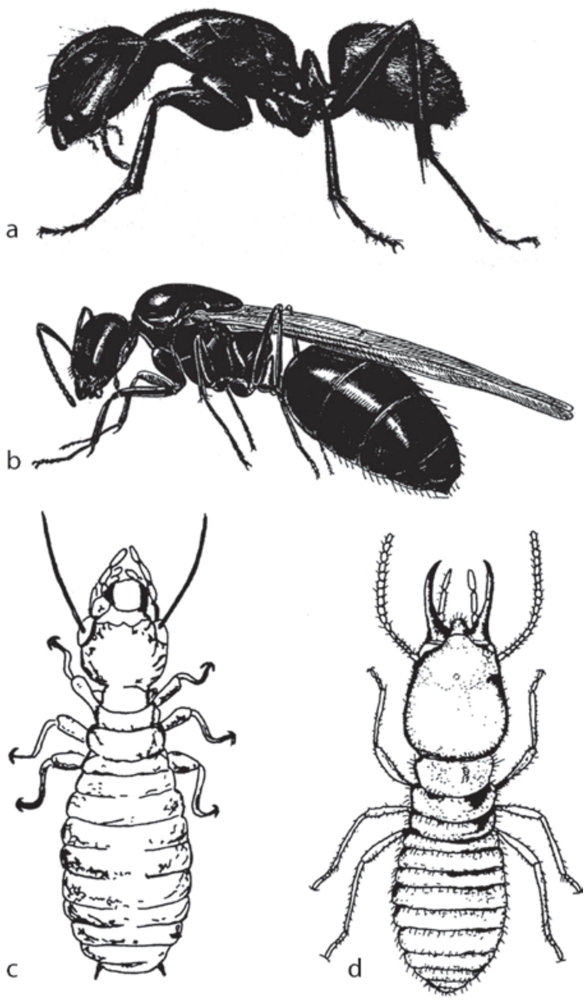
The relentless advance of western civilization has involved, among other things, deforestation concomitant with construction of centrally heated homes, businesses, and other facilities in place of the once-extensive woodlands. The termites, carpenter ants, beetles, and other insects that formerly dwelled within woodlands, of course, proceeded to invade the structural lumber used in today's construction. This lumber is obtained both from increasingly expensive hardwoods such as oak, hickory, ash, and maple, and from less desirable softwoods such as pine, hemlock, fir, redwood, and other evergreen trees. Both have a central, dark-colored, non-living heartwood and an outer light-colored, living sapwood, and both are susceptible to attack by wood-destroying insects, except for the heartwood of black locust, cypress, cedar, redwood, and certain other trees which is relatively resistant to attack.

Carpenter ants, termites, powderpost beetles, and the old house borer are among the many insects with destructive habits found in and around wooden buildings. They share little phylogenetic relationship other than joint inclusion in the overall class Insecta and a predilection to burrow in and chew wood. Carpenter ants, unlike termites, are true ants. Termites are insects whose ant-like appearance is responsible for the common name "white ant" often applied to them. Reproductive forms of ants and termites have membranous wings, lacking in non-reproductive forms, and both exhibit a highly developed social behavior. This is as opposed to powderpost beetles and the old house borer which are true beetles and not in the least ant-like in appearance. These beetles have thick forewings (elytra) covering membranous hindwings and can be distinguished from one another by, among other attributes, their antennae, which are relatively short in the powderpost beetles and relatively long in the borer.

Carpenter Ants

Among the commonly encountered carpenter ants are the black carpenter ant, *Camponotus p. pennsylvanicus* (De Geer), and the reddish brown carpenter ant, *C. ferrugineus* (F.), of the eastern United States; the red carpenter ant, *C. novaboracensis* (Fitch), of the northern states; *C. herculeanus* (L.) and the west coast carpenter ant, *C. modoc* (Wheeler), of the western states; the Florida carpenter ant, *C. abdominalis floridanus* (Buckley); and the Hawaiian carpenter ant, *C. variegatus* (F. Smith) (Fig. 64).

In their natural woodland habitat, carpenter ants play an important role as predators of defoliating caterpillars, aphids, and other insects. They also break down vulnerable, dying trees and logs and stumps resulting therefrom. Unfortunately, they have turned to colonization of structural wood as mankind has increasingly replaced woodland with heated buildings. Carpenter ants require wood with a relatively high moisture content, for which reason the "Minimum Property Standards and Building Codes" of HUD (U.S. Department of Housing and



Wood-Attacking Insects, Figure 64 **Wood-feeding insects: (a) a carpenter ant worker, (b) a carpenter ant queen, (c) a termite worker, (d) a termite soldier, specifically *Prorhinotermes simplex* (Hagen) (a is after USDA, b is after U.S. Bureau of Entomology, c is modified and redrawn from Duncan & Pickwell, d is modified and redrawn from U.S. National Museum).**

Urban Development) specify that only wood with a moisture content of less than 20% is appropriate for construction. One can predict with some certainty that a carpenter ant infestation in or around a specific structure stems from a preexisting or current moisture problem at that site.

Carpenter ants have an evenly rounded thorax separated from the apparent abdomen by a pedicel, or "waist" -like constriction that is lacking in termites. The pedicel in carpenter ants bears a single peg-like node. This node, together with the elbowed antennae, the circle of "hair" at the abdominal apex, and the large front and the small hind pair of strongly veined wings, helps identify them.

As the name carpenter suggests, these insects chew and tunnel within wood, but they do not actually eat it. At the outset they tunnel within moist, weathered wood, and then they may extend their activities into adjacent sound wood. They make nests in which to rear their young, whether in an infested house or in a nearby tree, post, or utility pole. They capture caterpillars, aphids, and other insects to feed their larvae which, like helpless fledglings, await the arrival of food.

Carpenter ant colonies consist of three kinds of individuals: numerous wingless, sterile female workers, a few winged reproductive males called drones, and usually only a single winged reproductive female called the queen. Workers resemble reproductive individuals except for their lack of wings. They either make chambers in wood in which to tend the eggs and larvae of the next generation, or they forage outside the nest. They may travel over 90 m in search of prey insects, animal remains, plant juices, and honeydew from aphids or scale insects to feed the queen and young back in the nest. They are prone to invade homes in early spring in absence of insect prey, foraging for sugars, meats, fats, and other food scraps found on kitchen counters, within dishwashers, in other food preparation and storage areas, and even search potted indoor plants for any infesting aphids or scale insects. These invaders may become so troublesome that they prompt a rash of calls to local pest control operators for help in eradicating them.

The relatively longer hours of daylight and the spring rains that follow are cues for adult carpenter ants to emerge from overwintering pupae. The winged reproductive female and male ants, like many other insects, are attracted to artificial light. They fly into brightened areas from tree stumps, logs, or other infested areas and gain access to the structural wood of buildings through the eaves, attic, sliding doors, or windows. Once established at these points, which are usually moist due to exposure to direct rainfall or condensation, they then may colonize adjacent areas of sound wood. They may also gain entry through sturdy tree roots penetrating a basement or garage wall, through tree branches in contact with the roof, or through firewood carelessly stacked against outside walls.

Numbers of winged swarmers appear and take flight in late spring, again causing alarm on the part of homeowners who fear that these troublesome insects are termites rather than ants. This triggers a second rash of calls to professional pest control operators. The winged ants in question consist of drones and of females destined to become queens. They mate, and the drones die soon afterward. Each inseminated queen breaks off her wings, burrows into wood with a favorable moisture content (usually 20% or more), settles within a hollow destined to become the new nest, and rears her first young. New workers emerge some weeks later from the initially laid eggs and soon take over all nest building, tending of young, and foraging, leaving the new queen to devote herself exclusively to egg laying. It takes more than 3–4 years to establish a productive colony, a single one of which may eventually have as many as 3,000 individual members.

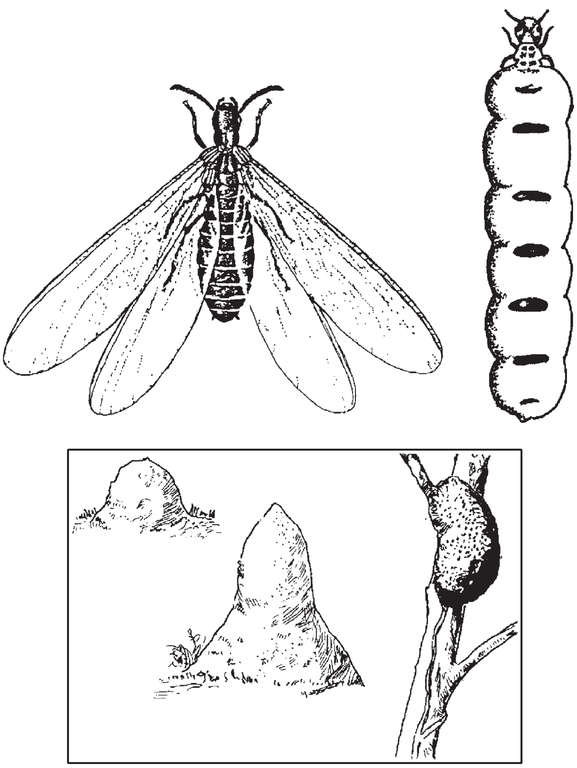
Carpenter ants overwinter in the pupal stage either in the nest, in soil, or at times under flower pots and other places of concealment. Their total life cycle takes about 50–70 days for completion.

As noted, carpenter ants do not eat wood, but they may severely damage it through their chewing. Workers make slit-like openings in the surface of the infested wood. They use these holes to eject loosened debris, leaving the chambers within with a clean, almost "sandpapered" appearance. This is opposed to the "dirty" appearance of termite tunnels. The ejected wood may be in the form of shavings or a fine sawdust depending on the nature and condition of the wood. Occasional cone-shaped mounds of sawdust piled up to 30 cm high on the floor beneath infested wood are evidence of carpenter ant activity. The ants damage windows, doors, flooring, attic joists, sill plates, fascia boards, eaves, beams, baseboards, decks, indoor swimming-pool boardwalks, wooden columns supporting porches, entrances, roofs, and fences. They also bite with their powerful mandibles, though this behavior is of negligible concern.

- Suggested remedial methods for use against carpenter ants include:
- Prevention of condensation on the building's wood components
- Keeping the roof intact and leakproof, especially at the chimney flashing, around vents, and where roof levels change
- Checking gutters and down spouts to see that they properly collect roof runoff and spill it onto ground-level splash blocks directed away from the house
- Installing window wells that slope away from the house and, if necessary, covering them with a plastic bubble
- Checking for leaks in plumbing, heating pipes, hot water heater, and clothes washer
- Ventilating and/or de-humidifying if dampness is a problem
- Using yellow exterior light installations where practical
- Trimming off tree branches touching the building
- Eliminating nearby tree stumps or logs with potential for carpenter ant activity
- Finally, locating the likely site of an infesting colony and its foraging runways and applying registered, EPA-approved insecticide formulations at that site after reading and carefully following the product label directions. Assuming the preceding is beyond the resources of the householder, as it often is, the control effort should be entrusted to a state-licensed, certified pest control operator.

Termites

Termites are small, reclusive, true wood-eaters belonging to insect order Isoptera. They lack the "wasp waist" of ants, from which they are further distinguished by their straight, bead-like rather than elbowed antennae and their usually colorless, dirty white appearance. Termites convert dead and decaying wood and plant derivatives into useful humus in nature, reducing and recycling the debris. Moreover, they serve as a much sought-after, wild food delicacy in some countries. They are of greatest concern, however, because of the extensive damage they cause to crops, trees, and buildings. They are a far more serious problem than are either carpenter ants or powderpost beetles (Fig. 65).



Wood-Attacking Insects, Figure 65 Wood-feeding insects: (a) a termite queen before having shed her wings, (b) a tropical termite queen visibly swollen with eggs, her abdominal tergites appearing as dark, segmentally repeated suffusions, (c) the above-ground termitaria or nests of three different species of tropical termite, with the far-right tree nest showing a pencil-like, Y-shaped tunnel leading to the ground (a is modified and redrawn from Elzinga, b is modified and redrawn from Skaife, c is modified and redrawn from Snodgrass).

Termites occur worldwide. About 2,200 species are known, mostly from tropical or subtropical regions, where some construct massive nests called termitaria, some up to 6 m high, composed of earth, saliva, and fecal materials. There are about 45 species in the United States, primarily in warmer regions. They are not nearly as well established in the colder, boreal parts of the country, but the advent of centrally heated buildings has provided an opportunity for them to occupy some of those areas too. Most of our local species either live in galleries within moist decaying logs or build nests in the ground.

Subterranean termites including *Reticulitermes* spp., damp wood termites including *Zootermopsis* spp., dry wood termites such as *Incisitermes* spp. and *Cryptotermes* spp., and the desert dry wood termite, *Marginitermes hubbardi* (Banks), are among the 30 native species known for their damage to plants and buildings. Notable for their destructiveness are *Reticulitermes flavipes* (Kollar) of the eastern, midwestern, and southern states, *Reticulitermes hesperus* Banks of the western states, and the Formosan subterranean termite, *Coptotermes formosanus* Shiraki, that has spread from the Orient into Honolulu and from there into many southern states.

Termites have three distinct castes: reproductives, workers, and soldiers. The juveniles or nymphs have the potential of developing, as needed, into functional reproductives, workers, or soldiers. Caste determination is determined not at the time of hatching, but is mediated through a pheromone exchange dependent on the specific requirements of the colony at a given time. This trophallaxis or mutual grooming, like that of ants, is the means by which wood particles and pheromonal secretions are spread throughout the colony, and the process is ultimately responsible for the colony's social organization. The fully winged original founders of the colony, the king and queen, are the primary reproductives. However, short-winged or wingless supplementary reproductives may be produced if the king or queen dies or if groups of termites become isolated from the parental colony. These supplementary reproductives may then take over colony formation.

A mature colony of termites produces large numbers of winged kings and queens, called swarmers or alates, in spring with the onset of rain showers, usually in May–June but in heated buildings as early as March–April. Incidentally, this timing coincides with that of the winged carpenter ants in and around homes. The alate termites fly about weakly before landing and shedding their wings. The female emits a pheromone which attracts the male, and they pair. Together they excavate a chamber within the soil beneath a rotting log or wood, and they remain underground in this "nuptial chamber" for life. The king mates with the queen, she lays eggs, and the royal pair then takes initial care of the hatched young, feeding them predigested nutrients. Later, when able to feed on wood, the nymphs and new workers assume all nest responsibilities except reproduction. The king and queen continue mating from time to time, and the queen's abdomen may become visibly distended with eggs. The delicate-bodied, colorless, wingless, blind, moisture- and darkness-requiring workers carry out all foraging, feeding, nest building, and other non-reproductive duties. They excavate passageways through the soil and reach structural wood directly if it is in contact with the soil, or they gain access to it indirectly through cracks in concrete slabs and foundations or by constructing earthen shelter tubes over concrete and masonry not in contact with soil. These tubes, which are reliable indicators of termite infestation, offer protection from desiccation and help the termites reach structural wood over foundations and other obstructions. They are constructed of a grayish, plaster-like sealant of saliva, excrement, soil particles, and bits of wood. They include: (i) narrow, branching, fragile exploratory tubes which are abandoned after contact with the above-surface wood or other cellulose material, (ii) lighter colored drop tubes suspended from floor joists or crawl spaces from wood to ground and composed exclusively of wood particles, and (iii) more substantially built working tubes used to facilitate the workers' movements from soil to wood.

Though termites eat wood, a dietetic feat that few other animals can perform, they lack the digestive enzymes required to break down and assimilate the nutrients of this cellulose-laden substance. How do they eat a food they cannot digest? The answer involves minute single-celled microorganisms housed within the termites' specialized alimentary canal that provide the required enzymes. The relationship between the two organisms is a mutualistic one in which the protozoans receive a dark, moist sheltering home and an abundance of masticated food both for their use and for that of the host termite that provides the food. Neither can live without the other. Newly hatched termites lack these intestinal protozoans and die if unable to become infected. Newly molted termites not only shed their skin but also cast the entire lining of the hind gut, including the protozoans lodged within. However, like the newly hatched termites, they quickly infect themselves through oral and anal food exchanges with their nest mates and become functional wood eaters themselves.

Termite foragers are delicate-bodied, colorless, wingless workers that require darkness and moisture. They construct pencil-like runways to bridge any masonry, sub floors, support piers, or metal supportive joists that they must traverse from their nest in the ground, where they find needed moisture, to the house above, whose wood they eat. These tunnels, like their above-ground galleries, are lined with a grayish, plaster-like sealant of saliva, excrement, and soil and so are reliable indicators of infestation except, of course, when concealed (as they sometimes are) within the foundation's hollow cinder blocks. Thus, one cannot rely upon discovery of a warning sawdust trail such as that left behind by carpenter ants or powderpost beetles. Damage may be far advanced, and the wood close to structural failure, before discovery of termite infestation.

Termite soldiers are characterized by an enlarged yellowish-brown, hard head with powerful jaws. The function of this wingless, blind caste is to defend the colony from enemies, particularly ants. Termite soldiers, kings, queens, and young nymphs are unable to feed themselves, so they must be fed, mouth-to-mouth, by other nymphs and workers.

Mark-release-recapture methods indicate that often it is not a single colony that is active in a given area, as previously thought, but sometimes several decentralized entities interconnected by a network of underground tunnels with different nesting and foraging sites. The foraging populations of six *Reticulitermes flavipes* entities have been estimated as ranging from 200,000 to 5 million termites. Once foragers initially locate food, they secrete a pheromone resulting in an increase both in numbers of individuals and in increased activity. The foraging territory may encompass up to one-third acre, and the foraging distance may exceed 70 m.

How can one determine whether an infestation is a carpenter ant or a termite one? Termite tunnels are obvious indicators of infestation. In absence of them, however, large numbers of accumulated, similar-sized, delicately veined wings in and around lighted places are indicative of termites. If, on the other hand, one finds dead ants with attached, strongly veined, dissimilar-sized wings, this is indicative of carpenter ant infestation.

Termites have been called hidden invaders because they can eat away the wood of a door or window without leaving the slightest hint of their presence. They leave a thin papery covering of wood over such wooden elements as they infest, which consequently may crumble under slight pressure. Usually 3–8 years of untreated termite infestation is sufficient to cause extensive damage to a house. The annual cost of termite treatment in the United States is estimated at about two billion dollars.

Periodical inspection is indicated if one is to avoid the consequences of extensive termite infestation. This inspection should include general areas such as entrance doors and frames, walls, ceilings, sagging or buckling floors, slightly raised wallpaper, baseboards, closets, areas around showers, tubs, and window frames. In basements, foundation walls, sill plates, window sills, wooden stairwell bases, and plumbing should be inspected, along with floor joists and plumbing running through the floor; in attics, areas around chimneys, vent pipes, and roof rafters should be examined; and at the exterior of the house, firewood, form boards, or wood debris stacked against the house, planters, railroad ties, landscape timbers, fence posts, trellises, crawl space access doors, and windows and openings near pipes should be inspected. One should also tap the wood elements of the house with the handle of a screwdriver. A hollow sound indicates a hidden problem. HUD's "Minimum Property Standards and Building Codes" approves use only of pressure-treated, dry (moisture content less than 20%) lumber for construction. The above procedures and standards notwithstanding, no wood is ever entirely safe from the ravages of termites. These insidious creatures gain entry into buildings whenever they find favorable conditions.

Remedial methods for termites involve correction of moisture problems as soon as detected and scrupulously avoiding the soil-wood contact of which termites avail themselves to enter a building. Specifically:

- Grading the building lot so as to drain water away from the foundation
- Maintaining the gutters, keeping them free of leaks, clear of debris, and with the down spouts discharging away from the foundation
- Embedding deck, fence, and other posts in cement
- Assuring proper attic ventilation
- Covering three-quarters of the crawl space by polyethylene sheet (leaving one-fourth open) and providing proper crawl space ventilation
- Applying immediate control treatment if termites are seen indoors or immediately outside the building
- Establishing an effective termite barrier between buildings (including garages) and the surrounding lot. This step may involve employment of termite-certified, licensed pest control operators who apply registered, EPA-approved termiticides per the label directions.

Real estate agencies in some states are required by law to have buildings inspected by licensed pest control operators for the incidence of termites and other wood-destroying organisms. A formal report of corrective measures, if indicated, is required before finalization of the real estate transaction. In some states, builders are required by law to treat lots against termite infestation before undertaking construction, and they must provide appropriate warranties to that effect.

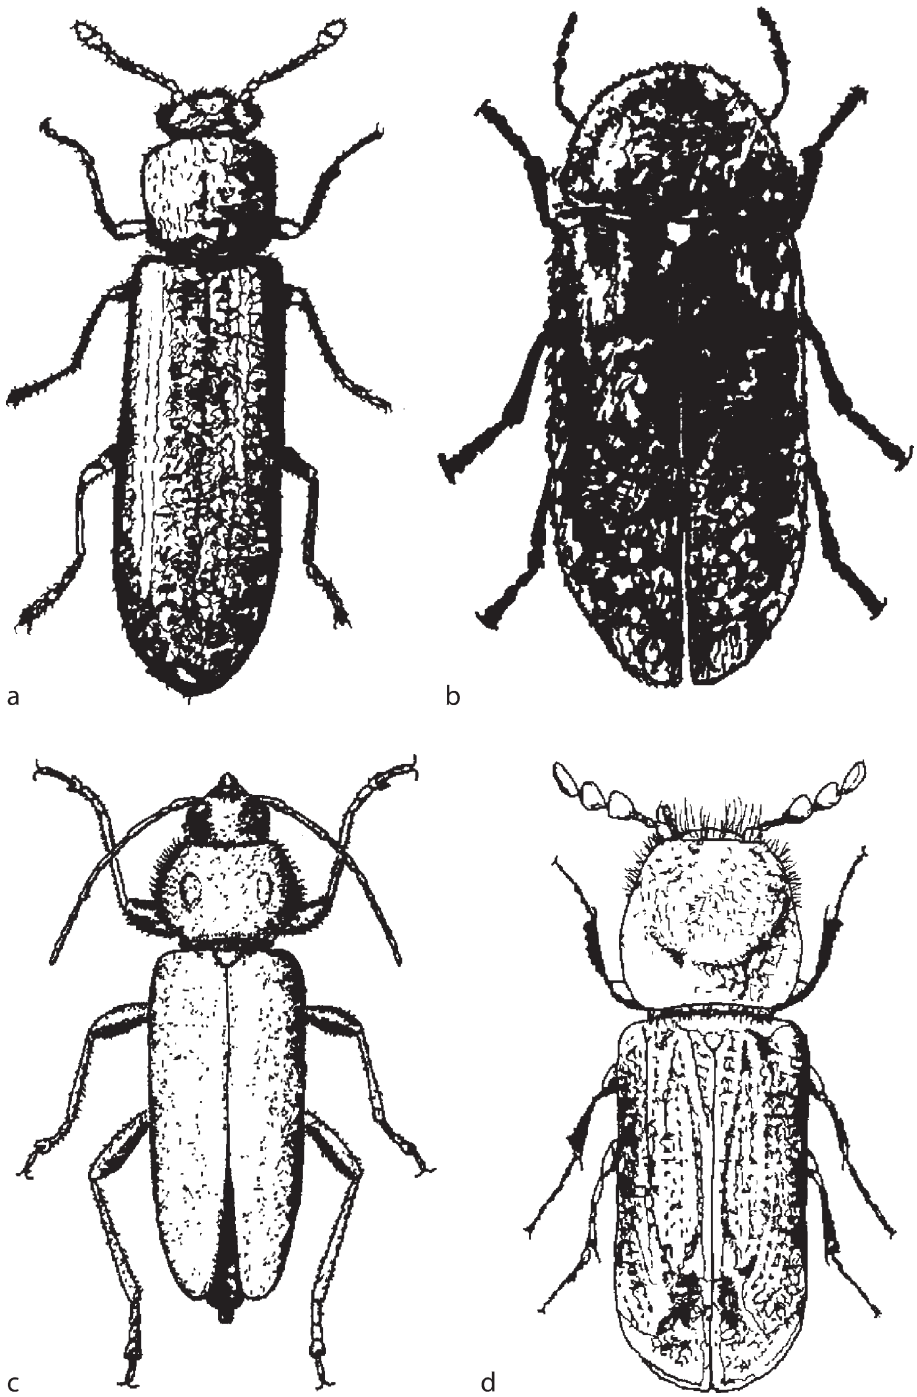
Powderpost Beetles

The related taxa of Coleoptera, the Anobiidae and Bostrichidae (some consider Lyctinae to be a separate family also), include species collectively termed powderpost beetles. All of them damage timber, reducing its inner tissues to powder and perforating it with "pinholes" or "shot holes," hence the common name. However, the nature of their frass (which is a mixture of sawdust and excrement) and the "shot holes" that they produce vary with the species. Powderpost beetles rank next to termites with respect to the overall damage done to buildings and to the dry seasoned timber that they infest and re-infest.

Ten of the 66 known species of Lyctinae, or "true powderpost beetles," occur in the United States, of which the *brown lyctus beetle Lyctus brunneus* Stephens and the European lyctus beetle *L. linearis Goeze* are ones of major concern. They infest seasoned hardwood with at least a 3% starch content. They attack the seasoned sapwood of such trees as ash, hickory, oak, elm, pecan, maple, poplar, cherry, sycamore, and walnut, as well as lumber, wood paneling, window and door frames, hardwood floors, furniture, tool handles, pallets, imported hardwood products, and even bamboo. They rarely infest lumber older than 5 years, and they never attack painted or varnished wood. They produce a powdery frass that, unlike that of the other powderpost beetles, is so fine as to resemble talcum powder. Development from egg to adult takes from 2–4 years, except in the south of the U. S. where two generations per year may occur. As the adult lyctines emerge from their holes they eject their powdery frass which often trickles out like raindrops. The adult is a small (usually under 5–6 mm long), flattened, reddish-brown or black beetle with a prominent head constricted behind the eyes. Each antenna has a long basal segment and a 2-segmented club (Fig. 66).

Bostrichids other than Lyctinae, or "false powderpost beetles," are of less consequence than powderpost beetles because the hardwoods that they infest are not commonly used for interior floors, woodwork, and trims, and they do not re-infest seasoned wood. Most false powderpost beetles are larger (some up to 52 mm long) than other powderpost beetles. They are usually black, elongate, and subcylindrical, with the head usually deflexed and covered by the hood-like thorax. Each antenna has a 3–4 segmented club. Their frass is coarse, meal-like, and tightly packed. Among important bostrichids are the black polycaon, *Polycaon stouti* (LeConte), cylindrical beetles up to 25 mm long whose prominent head, unlike that of the other bostrichids, is visible from above, not being concealed beneath the thorax, and the lead cable borer, *Scobicia declivis* LeConte, a reddish-brown beetle, 5–6 mm long, that normally bores in oak, maple, and other trees but may bore through the lead covering of aerial telephone cables.

There are nearly 260 species of anobiids in the United States, of which the furniture beetle, *Anobium punctatum* (DeGeer), and the deathwatch beetles *Xestobium rufovillosum* (De Geer), *Hemicoelus* spp., and the commonly encountered *Euvrilletta peltata* (Harris) are the most important. The furniture beetle is a reddish-brown cylindrical beetle 4–6 mm long. It lays its eggs either on the wood surface or inside emergence holes in finished wood. The eggs hatch in 6–10 days, and the larvae tunnel into wood. The larval stage typically lasts 2–5 years in processed wood, but in nature in dead tree branches the



Wood-Attacking Insects, Figure 66 **Wood-feeding insects: (a) a lyctine powderpost beetle, (b) an anobiid powderpost beetle, specifically the death-watch beetle *Xestobium rufovillosum* (De Geer), (c) the old house borer *Hylotrupes bajulus* (L.), (d) a bostrichid powderpost beetle, specifically the lead-cable borer *Scobicia declivis* Le Conte (a is modified and redrawn from USDA, b is modified and redrawn from Ohio Biological Survey, c is modified and redrawn from Bennett, Owens, & Corrigan, d is modified and redrawn from Mallis).**

life cycle is sometimes completed within a single year, probably because fungal and/or bacterial attack on the tree branch may make more nutrients available. The deathwatch beetle *Xestobium rufovillosum* is an insect that derives its name from its habit of tapping the head or jaws against wood. This ticking sound, actually a mating signal, becomes audible during periods of prolonged quiet, as during a wake or in the night, hence the common name. The emerging adults are slender, 6 mm long, dark beetles with lengthened, but not clubbed, antennae. They attack building timbers in poorly ventilated areas often previously damaged by moisture or fungi. *Euvrilletta peltata* is a reddish or brownish powderpost beetle covered by yellow hairs. It attacks both seasoned and unseasoned wood and is a serious pest of crawl space timbers in southeastern U.S.

Old House Borer

Over 1,200 species of the long-horned beetle family Cerambycidae are known from the United States, yet of that total only the old house borer, *Hylotrupes bajulus* (L.), of the Atlantic seaboard states causes significant damage to structural wood. Other long-horned species occasionally found in structural lumber emerge from the timbers and infest outside trees, but the old house borer attacks both seasoned and unseasoned lumber and re-infests previously attacked wood. This unfortunate habit may be responsible for its "old house" appellation, though it infests new homes too, particularly when infested lumber is used in construction. Its creamy white, peg-shaped larvae hollow out extensive galleries in the seasoned softwoods of the sills, floor joists, studs, door jams, flooring, siding, and rafters of old buildings. It attacks conifers, pines, spruce, fir, and hemlock but not hardwoods. The adult is a slightly flattened, dark, gray-black to brown-black beetle up to 25 mm long with yellowish gray hair on its body. Two raised, black glossy knobs on the prothorax help to distinguish it.

- Remedial measures suitable both for wood-damaging powderpost beetles and for the old house borer include:
- Selecting quality, kiln-dried, pressure-treated wood for construction
- Making periodic inspections for infestation
- Applying varnishes or paints to lumber

Notwithstanding these precautions, these insects may gain entry into the household and then usually can be eradicated only by fumigation carried out by trained professional help.

Other Wood-Damaging Insects

Some other wood-destroying insects, though economically insignificant compared to carpenter ants, termites, powderpost beetles, and the old house borer, deserve mention. Among the wood-damaging Coleoptera of minor importance are the golden buprestid, *Buprestis aurulenta* L., which attacks fire, lightning, or disease-damaged wood in the western states; the wharf borer, *Nacerdes melanura* (L.), whose larvae bore into the heartwood and sapwood of the seasoned softwoods used in fresh-water and marine wharf pilings; the parthenogenetic and paedogenetic telephone pole beetle, *Micromalthus debilis* LeConte, whose larvae attack oak and chestnut logs, wooden panels, as well as telephone poles; the curculionid *Hexarthrum ulkei* (Horn) whose larvae occasionally infest wooden buildings in eastern U.S., excavating small, irregular tunnels filled with a fine frass composed of distinct ovoid fragments; the spider beetle *Sphaericus gibboides* Boieldieu, which damages stored animal and vegetable products and tunnels in the wood of kitchen cabinets made of Douglas fir to pupate; the ambrosia beetle *Gnathotrichus sulcatus* (Le Conte) that bores complex tunnels into freshly cut wood and feeds on a fungus growing on the tunnel walls; and the wide-headed beetle *Platypus wilsoni* Swaine that infests fire, lightning, and disease-damaged hardwood and coniferous trees. Among the wood-damaging Hymenoptera of minor concern are the large carpenter bee *Xylocopa v. virginica* (L.), known for its characteristic round entry holes of about one-half inch in diameter in doors, porches, window sills, wooden beams, and fences from which pour a fine stream of sawdust; the horntail *Tremex columba* (L.), sometimes accidentally transported in firewood and poor grades of lumber used for construction; and the leaf-cutting bee *Megachile relativa* Cresson, which does not directly damage the sidings of homes but attracts woodpeckers that, in the act of predation on the bees, themselves cause serious destruction.

Yellow-Faced Bees

Members of the family Colletidae (order Hymenoptera, superfamily Apoidae).
► Bees
► Wasps, Ants, Bees, and Sawflies

Yellow Fever

WALTER J. TABACHNICK
University of Florida, Vero Beach, FL, USA

The mosquito borne yellow fever virus causes severe disease in humans. Yellow fever was first described as a disease in the early part of the seventeenth century. The disease was one of the most devastating and important diseases in Africa and the Americas during the next 300 years. There were yellow fever outbreaks in many port cities in the Americas that involved thousands of human cases. The specter of yellow fever was much feared throughout Africa and the Americas due to the havoc caused by the disease and the accompanying economic disruption. The last major yellow fever epidemic in the United States occurred in New Orleans in 1905. There were about 4,000 human cases of yellow fever and nearly 500 people died from yellow fever during this epidemic.

The history of yellow fever epidemics provides numerous examples why this disease inspired dread and fear in Africa, the U.S., Central America, the Caribbean and South America. Examples of the numbers of deaths during outbreaks are startling: 6,000 dead in Barbados in 1647; 3,500 deaths in Philadelphia; 1,500 in New York City in 1798; 29,000 deaths in Haiti in 1802; 20,000 deaths in over 100 American towns in 1878. Yellow fever has re-emerged with an upsurge of human cases in the latter half of the twentieth century. There were 100,000 cases and 30,000 deaths in Ethiopia in 1960–1962; 17,500 cases with 1,700 deaths in Upper Volta in 1983; Cameroon 20,000 cases with 1,000 deaths in 1990. The World Health Organization officially reported 18,735 yellow fever cases with 4,522 deaths for the period 1987–1991.

Insect Vectors

Several different mosquito species can be involved with the transmission of yellow fever depending on the geographic region and habitat. The most important mosquito species involved worldwide in the transmission of yellow fever to humans is *Aedes aegypti*, also known as "the yellow fever mosquito." The association between yellow fever transmission to humans by *Aedes aegypti* was a major breakthrough in understanding this dread disease. Major Walter Reed, U.S. Army, was the leader of the scientists who were able to show the role of *Aedes aegypti* in their work while stationed in Cuba in 1901. The subspecies *Aedes aegypti aegypti* is widely distributed throughout the tropics and subtropics of the world. This form is able to breed in a variety of artificial containers, i.e., flower pots, tires, water jars, many commonly found around human habitats. *Aedes aegypti aegypti* also has a distinct preference for humans as a source of blood that makes this species particularly efficient in circulating a pathogen from infected humans to uninfected humans. As a result, this highly urbanized mosquito species has the capability of sustaining the urban epidemics of yellow fever that have occurred during the last 300 years. The control of *Aedes aegypti aegypti* populations is considered of primary importance in reducing the risk of urban areas to yellow fever.

There are other mosquitoes that can be involved in yellow fever virus transmission. In tropical regions of the Western Hemisphere, mosquitoes in the genus Hemagogus transmit yellow fever virus to monkeys in the forest canopy. This is called the jungle yellow fever cycle in the Americas. The danger occurs when these canopy mosquitoes infect humans when trees are felled for clearing, and the infected human returns to an urban environment where *Aedes aegypti aegypti* can become infected, resulting in an urban epidemic. In tropical Africa, the mosquito *Aedes africanus* transmits yellow fever virus between forest dwelling canopy monkeys; *Aedes bromeliae*, *Aedes vittatus* and *Aedes furcifer-taylori* transmit the virus to monkeys in the savanna and gallery forest regions of Central Africa. The epidemic danger to humans is when infected humans bring the virus to urban centers inhabited by *Aedes aegypti*.

The Virus

Yellow fever virus is a member of the group of viruses called Flavivirus. The virus has been found in the tropical regions of the Americas and Africa, and there have been historical yellow fever incursions for brief outbreaks in parts of Europe. The yellow fever virus has never been demonstrated in Asia, Australia or the Pacific despite the presence of *Aedes aegypti* in these regions. The reason for this is unknown and the subject of much speculation. Although Walter Reed showed *Aedes aegypti* transmits the agent of yellow fever in 1901, and that the agent was smaller than bacteria, it was not until 1927 that yellow fever was shown to be a virus.

The Disease

Yellow fever symptoms may range from clinically inapparent to fatal. Studies have shown that in some regions of Latin America as much as 90% of the population have been infected with yellow fever virus and have no clinical symptoms of disease. Once an infected mosquito bites a human, the incubation period is generally 3–6 days. Mild cases appear similar to many other common illnesses that produce a fever. However, when clinical disease occurs, the onset of the disease is very sudden. There is high fever (102°–104°F), headache, malaise, back pain, chills, prostration, nausea, slow pulse and vomiting. Yellow fever virus can be found in the blood of the patient for about 4 days after infection, and as a result the patient is capable of infecting mosquitoes during this time. Some individuals show a rapid recovery at this point and the symptoms stop. This phase can last from 3 to 4 days. More severe cases also have their symptoms subside for a brief remission but symptoms return in a day or so with fever, vomiting, abdominal pain, prostration, dehydration, jaundice due to liver involvement, internal bleeding, bleeding of the nose, mouth, gums or in their urine, kidney or liver failure. The internal bleeding results in blood in the vomit, called "black vomit" due to the color, and dark stools. No virus is in the blood at this point so the patient is not infectious to mosquitoes. There is no cure; treatment is supportive to try to reduce the severity of these symptoms. This is the diphasic part of yellow fever. Twenty to fifty percent of people who enter the second phase die from yellow fever. Death usually occurs between the 7th and 10th day of the illness. Some very severe atypical cases of yellow fever may die as early as 3 days after the onset of symptoms. Mortality from yellow fever is about 10% of clinical cases but has reached as high as 50% of those people developing symptoms.

Dr. Max Theiler developed a vaccine against yellow fever, called the 17D vaccine, in the 1930s. In 1951, Dr. Theiler received a Nobel Prize for his work. This vaccine is still widely used and provides excellent protection against yellow fever for 10 years post-vaccination. There are studies showing that protection may be as long lived as 30–35 years after being vaccinated in some people.

Monkeys also can be infected with yellow fever virus. In most tropical regions of the world monkeys serve as the wild host, maintaining the virus in the absence of human involvement. Many monkey species experience yellow fever disease and suffer deaths. One of the early signs of yellow fever in a region may be the discovery of dead monkeys.

Impact and Problems

Yellow fever remains a serious and dread disease in many parts of the world despite advances in understanding mosquito transmission, advances in mosquito control, advances in understanding human risk and the development of a very effective and safe vaccine. The continued appearance of yellow fever epidemics in Africa, and the appearance of yellow fever cases in the Americas are all cause for concern that this dread disease remains very dangerous. In addition, the historical absence of yellow fever in Asia despite the presence of *Aedes aegypti* is also cause for concern since Asian populations would be extremely susceptible due to lack of any native immunity to the yellow fever virus. Asian populations may be extremely vulnerable to yellow fever with potentially catastrophic consequences.

The ability to interrupt a yellow fever outbreak will depend on being able to bring to bear a diverse array of tools including an efficient and effective mosquito control program and a massive vaccination program. Both are extremely difficult to accomplish in many regions of the world where the risk of a yellow fever outbreak may be greatest. Successful mosquito control against *Aedes aegypti* has reduced the number of yellow fever cases in many cities. However, mosquito control resources may be non-existent and delivery of vaccine insufficient. In the 1990s, the worldwide annual production of yellow fever vaccine was about 15 million doses with demands on vaccine extremely unpredictable. A vaccination program that is geared to regions in advance of an expected epidemic is cost effective, but it is unlikely to be successful because of the time delay in identifying the epidemic and because it takes 5–7 days for the vaccine to provide any protection after inoculation. On the other hand, a campaign to vaccinate the entire population in the absence of yellow fever would be extremely costly and require a long-term commitment to vaccinate anyone entering the population through birth or immigration. The challenges of yellow fever remain formidable.

Yellowstriped Armyworm, *Spodoptera ornithogalli* (Guenée) (Lepidoptera: Noctuidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

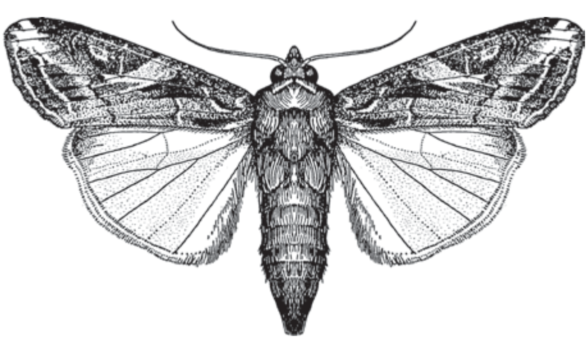
The distribution of this insect includes most of North America, Central and South America, and many Caribbean islands. As a pest, however, its occurrence is limited principally to the southeastern USA. A very similar species called western yellowstriped armyworm, *Spodoptera praefica* (Grote), largely replaces *S. ornithogalli* in the western USA.

Life History

Generally there are three or four generations annually, with broods of adults present in March-May, May-June, July-August, and August-November. Some of the latter brood overwinter as pupae rather than emerging as adults. Although eggs, larvae and adults of yellowstriped armyworm may be present in autumn or early winter, they cannot withstand cold weather, and perish. Development time, from egg to adult, is about 40 days.

The eggs are greenish to pinkish brown in color and bear 45–58 small ridges. In shape, the egg is a slightly flattened sphere, measuring 0.46–0.52 mm in diameter and 0.38–0.40 mm in height. Females typically deposit clusters of 200–500 eggs, usually on the underside of leaves. Total fecundity was determined to be over 3,000 eggs under laboratory conditions. The eggs are covered with scales from the body of the adults. Duration of the egg stage is 3–5 days at warm temperatures (Fig. 1).

Larvae initially are gregarious in behavior, but as they mature they disperse, sometimes spinning strands of silk upon which they are blown by the wind. There usually are 6 instars, although 7 instars have been reported. Head capsule widths are about 0.28, 0.45, 0.8–1.0, 1.4–1.6, 2.0–2.2, and 2.8–3.0 mm, respectively, for instars 1–6. The larva grows from about 2.0 to 35 mm in



Yellowstriped Armyworm, *Spodoptera ornithogalli* (Guenée) (Lepidoptera: Noctuidae), Figure 1 **Adult yellowstriped armyworm, *Spodoptera ornithogalli* (Guenée).**

length over the course of development. Duration of the larval stage is 14–20 days, with the first three instars requiring about 2 days each and the last three instars requiring about 3 days each. Coloration is variable, but mature larvae tend to bear a broad brownish band dorsally, with a faint white line at the center. More pronounced are black triangular markings along each side, with a distinct yellow or white line below. A dark line runs laterally through the area of the spiracles, and below this is a pink or orange band. Dark subdorsal spots are found on the mesothorax of yellowstriped armyworm, and the triangular shape of these spots aids in distinguishing this insect from sweetpotato armyworm, *Spodoptera dolichos*, and velvet armyworm, *S. latifascia*, in southeastern USA. The head is brown but has extensive blackish markings (Fig. 2).

Larvae pupate in the soil within a cell containing a thin lining of silk. The reddish brown pupa measures about 18 mm in length. Duration of the pupal stage is 9–22 days, normally averaging 12–18 days.

The moths measure 34–41 mm in wing span. The forewings are brownish gray with a complicated pattern of light and dark markings. Irregular whitish bands normally occur diagonally near the center of the wings, with additional white coloration distally near the margin. The hind wings of yellowstriped armyworm are opalescent white, with a narrow brown margin; the sexes are dimorphic. Under laboratory conditions average longevity of adults is 17 days, with most egg production completed by the tenth day.

These species are very general feeders, reportedly damaging many crops, including alfalfa, blackberry, cotton, clover, grape, lentil, peach, rape, raspberry, sorghum, soybean, sugarbeet, sweetclover, sunflower, tobacco, wheat, and several vegetable and flower crops. Some of the weed species known to be suitable hosts are castorbean, *Ricinus communis*; dock, *Rumex* sp.; gumweed, *Grindelia* sp.; horse nettle, *Solanum carolinense*; horseweed, *Erigeron canadensis*; jimsonweed, *Datura* sp.; lambsquarters, *Chenopodium album*;

Yellowstriped Armyworm, *Spodoptera ornithogalli* (Guenée) (Lepidoptera: Noctuidae), Figure 2
Mature larva of yellowstriped armyworm, *Spodoptera ornithogalli* (Guenée).

morningglory, *Ipomoea* sp.; plantain, *Plantago lanceolata*; prickly lettuce, *Lactuca scariola*; and redroot pigweed, *Amaranthus retroflexus*.

Several wasp parasitoids affect *S. ornithogalli* including *Rogas laphygmae* Viereck, *R. terminalis* (Cresson), *Zele mellea* (Cresson), *Chelonus insularis* Cresson and *Apanteles griffini* Viereck (all Hymenoptera: Braconidae). Also, *Euplectrus plathypenae* Howard (Hymenoptera: Eulophidae) attacks larvae and causes a cessation of feeding within 2 days. Thus, this parasitoid is particularly valuable at minimizing damage. Numerous flies have been found to parasitize these armyworms including *Archytas* spp., *Choeteprosopa hedemanni* Brauer and Bergenstamm, *Euphorocera omissa* (Reinhard), *E. tachinomoides* Townsend, *Lespesia aletiae* (Riley), *L. archippivora* (Riley), *Omotoma fumiferanae* (Tothill), *Winthemia quadripustulata* (Fabricius), and *W. rufopicta* (Bigot) (all Diptera: Tachinidae). A nuclear polyhedrosis virus is highly pathogenic to larvae, and survivors that do not succumb exhibit reduced fecundity. Undoubtedly predators are important, but their effect has not been quantified.

Damage

Larvae damage plants principally by consumption of foliage. The small, gregarious larvae tend to skeletonize foliage but as the larvae grow and disperse they consume irregular patches of foliage or entire leaves. However, they will also feed on the fruits of tomato, cotton, and other plants. Larval consumption of soybean was estimated to total 115 sq cm; this is an intermediate value relative to some other lepidopterous defoliators.

Management

Insecticides are applied to foliage to prevent injury by larvae. The microbial insecticide *Bacillus thuringiensis* can be applied to kill armyworms, but should be applied when the larvae are young as they become difficult to control as they mature. Larvae will consume bran bait containing insecticide.

Proximity of crops to rangeland containing weed hosts, or to alfalfa, may be important factors predisposing other crops to injury. At high densities, especially if alfalfa hay is mowed, larvae will sometime disperse simultaneously and invade nearby fields. Physical barriers such as trenches can be used to deter such dispersal.

Yellow-White Butterflies (Lepidoptera: Pieridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Yellow-white butterflies, family Pieridae (including jezebels, orangetips, sulphurs, whites, and alfalfa and cabbage butterflies), total about 1,275 species worldwide, most being Indo-Australian (ca. 515 sp.). Four subfamilies are recognized: Pseudopontiinae (a single African species), Dismorphiinae, Pierinae, and Coliadinae. The family is in the superfamily Papilionoidea (series Papilioniformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults small to large (23–100 mm wingspan); antennae often with weak clubs. Wings mostly triangular or rounded; hindwings usually small and rounded, but sometimes larger than forewings and somewhat pointed (Dismorphiinae); body usually slender but sometimes robust. Maculation usually variously yellow or white, with darker spots or patches of various shape (rarely without markings); rarely hyaline; sometimes very colorful, and many with special UV coloration ve different from what is evident under white light. Pierinae are mostly white species and Coliadinae have more of the colorful and yellow species; many pierid colorations are from pterin or flavone deposits. Adults diurnal. Larvae leaf feeding (one species feeds gregariously in Mexico). Various plants are utilized, including Capparidaceae, Leguminosae, Loranthaceae, and Santalaceae, among others, but

Yellow-White Butterflies (Lepidoptera: Pieridae), Figure 3 **Example of yellow-white butterflies (Pieridae), Anthocharis sara Lucas from California, USA.**

especially Cruciferae. Some economic species are known, particularly on cabbages and other crucifers (Fig. 3).

Young, Jr., David A

David Young was born May 26, 1915, at Wilkinsburg, Pennsylvania, USA. He obtained a B.A. degree from the University of Louisville in 1939 and then taught science in the public school system from 1939 to 1941. In 1942 he was awarded a M.S. from Cornell University. Serving in the military during World War II, he returned to serve as an instructor at the University of Louisville from 1946 to 1948. He also studied at the University of Kansas, and was awarded a Ph.D. in 1950. Young then joined the United States National Museum and was employed by the Insect Identification and Foreign Parasite Introduction Section of USDA from 1950 to 1957. Young joined the faculty of North Carolina State University in 1957, where he retired in 1980 but continued his writing until 1986. Young was an internationally acclaimed leafhopper specialist. He described 807 new species, 207 new genera, and a new tribe. Among other publications, he authored the monumental "Taxonomic study of the Cicadellinae (Hemiptera: Cicadellidae)," which was published in three parts and treated 292 genera from throughout the world. He died on June 8, 1991.

Yucca Moths (Lepidoptera: Prodoxidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Yucca moths, family Prodoxidae, total 65 species, mostly western Nearctic, but now also including some genera (Lamproniinae) from other regions that previously were placed in Incurvariidae. The family is in the superfamily Incurvarioidea, in the section Incurvariina, of division Monotrysia, infraorder Heteroneura. There are two subfamilies: Prodoxinae and Lamproniinae. Adults small (5–33 mm wingspan), with rough head scaling; haustellum reduced, scaled; labial palpi porrect; maxillary palpi folded, five-segmented (rarely four-segmented). Maculation often is white with various darker markings, or more colorful and iridescent. Adults are diurnal. Larvae are seed, flower stalk, or stem borers; rarely gall makers. Host plants are various yucca plants (Agavaceae) for the well-known yucca pollinators of North America, while other species (Lamproniinae) are on hardwood trees and bushes.

Z

Zachvatkin (Jasykov), Aleksei Alekseevich

YURI A. ZACHVATKIN
K.A. Timiryazev Agricultural Academy, Moscow, Russia

A.A. Jasykov (Yazykov in the modern English transcription) was born on December 1, 1905, in Ekaterinburg. He spent his childhood with his parents in Montreux, Switzerland. His father came from an old noble family. According to the traditions of the Russian nobility, he received a home education with tutors in sciences and culture. Just before the beginning of World War I, the family returned to Moscow where his private home education was continued. His early interest in natural history brought him in 1920 to the State University of Moscow where he worked first in the university herbarium and then in the Zoological Museum of the university. There he specialized in entomology, particularly in the taxonomy of Cicadinae (Hemiptera: Cicadidae). After the October revolution of 1917, he could no longer officially enter the university because he was from a noble family. However, the university professors allowed him to attend some courses. His only formal education was at a painting studio in Moscow. From 1926 through 1931 he worked as a technical assistant in the Central Asian Institute of Plant Protection. Participating in numerous expeditions, he showed his great and numerous talents in research. He published several papers concerning the systematics of the Cicadinae and the parasites of the Acridinae (Orthoptera: Acrididae). He also discovered specific features of hypermetamorphosis in the Meloidae and Bombyliidae. Restoring his lost documents, he took the surname of his stepfather. The last work by Jasykov was published in 1931, and from 1932 all his papers were signed as Zachvatkin. For a short time he worked in the All-Union Institute of Plant Protection in Leningrad, and in 1933 he was invited to the Entomological Laboratory of the Research Institute of Zoology of the State University of Moscow. Soon he began to study the Tyroglyphidae (Acarina), an important group of stored products pests, and to develop measures for damage prevention. In 1935 he received a Ph.D. degree, and in 1939 a Doctor of Biological Sciences degree. In 1941 he was appointed a professor of the Department of Entomology of the university. In addition to his applied research, he conducted fundamental research in acarology. The discovery of primitive segmented mites (Endeostigmata) and the differences in tagmosis and in the development of the fourth legs of mites from various groups allowed him to distinguish three independent groups of Acarina: Acariformes, Parasitiformes and Opilioacarina. This concept was strongly supported by V.N. Beklemishev, the leading specialist in comparative anatomy and morphology of invertebrates. Being a noted authority in general embryology and in the embryology of arthropods, he developed a theory of the origin of multicellular organisms and of the evolution of ontogenesis in lower invertebrates. He also created a new concept of the origin of Holometabola and Hemimetabola.

Many of his ideas were later confirmed in the works of his followers. He was twice awarded the Stalin Prize. In 1948, when Soviet biology was suppressed by Lysenkoism, he was forced to accept the position of the Deputy Dean of the Faculty of Biology and Pedology of the university. He became very depressed by his constant battles with Lysenko's henchmen and he passed away in Moscow on December 14, 1950. His main publications include "Tyroglyphoid mites (Tyroglyphoidea)" (1941) and "Comparative embryology of lower invertebrates" (1949). Many manuscripts and lectures were included in his posthumous book "Collected scientific works" prepared by his pupils and friends and published in 1953.

Zeller, Philipp Christoph

Philipp Zeller was born at Steinheim-on-the-Mur, Würtemberg, Germany, on April 8, 1808. He began collecting insects as a boy, and though he received a degree from the University of Berlin, he obtained no formal instruction in entomology. He began working at the gymnasium at Frankfort on the Oder in 1830, and devoted his leisure time to study of insects, especially the Lepidoptera, eventually becoming known as an authority on Microlepidoptera, including Pyralidae and Tineidae. He began publishing in 1833, and was named Professor by the King of Prussia in 1852. Among his important publications were "North American Micro-Lepidoptera" (1872, 1873, 1875) and "Natural history of the Tineina" (with H.T. Stainton) (1855). He named many of the economically important Microlepidoptera from around the world. Zeller died at Grunhof, Germany, on March 27, 1883.

Zetterstedt, Johann Wilhelm

Johann Zetterstedt was born on May 20, 1785, near Mjölby, Sweden. Interested in biology from his youngest days, Zetterstedt entered Lund University in 1805, and received a doctoral degree in 1808. He was named docent in botany in 1812, but there was no salary attached to this position, so he supported himself with private lessons. In 1822, he was awarded a position at the University, and worked there until his retirement in 1853. In 1869 he received an honorary degree. Zetterstedt's list of publications is not very long, but includes some important works, including "Fauna insectorum Lapponica" (1828), "Insecta Lapponica descripta" (six issues between 1838 and 1840), and the monumental "Diptera Scandinaviae disposita et descripta" (14 volumes between 1842 and 1860). He died December 23, 1874, at Lund, Sweden.

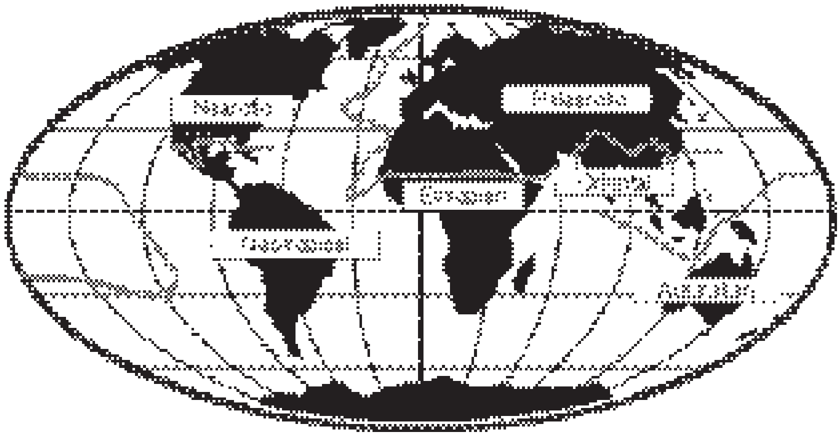
Zoogeographic Realms

Dissimilar distributions of existing animals (normally illustrated by vertebrates), usually isolated geographically and defined by continents (Fig. 1), but sometimes separated by mountain ranges or other physiographic features. The principal realms are:



Zoogeographic Realms, Figure 1 **The traditional zoogeographic realms.**

Australian Realm

Australia and nearby islands, with a preponderance of marsupials, large flightless birds, and parrots, as well as an absence of mammals. This is sometimes called the Austalasian realm.

Oriental Realm

India and southeast Asia south through Indonesia, with tree shrews, orangutan, and gibbon.

Ethiopian Realm

Africa, though northernmost Africa is more similar to Europe (Palearctic realm), with antelopes, giraffes, elephants, rhinoceros, gorillas, dogs, and cats. This is sometimes called the African or Afrotropical realm.

Neotropical Realm

South and Central America including the Caribbean Islands, with sloths, armadillos, anteaters, tapirs, toucans, and hummingbirds.

Holarctic Realm

(Nearctic and Palearctic realms) – the Holarctic realm includes most of the northern hemisphere, but is often subdivided into the Nearctic realm (North America south to central Mexico) and the Palearctic realm (Europe and Asia except for southeast Asia). The faunas of the Nearctic and Palearctic are really quite similar, with such animals as vireos, wood warblers, deer, bison and wolves.

Some authors, however, subdivide the realms further, treating separately the African island of Madagascar (Malagasy realm) and the contact area of the Australian and Oriental realms, particularly the Indonesia-Papua New Guinea area (Indo-Australian realm). The zoogeographic realms are sometimes called the biogeographic realms but this is not particularly desirable because plant distribution does not entirely conform to the regions formed by animal distribution.

► Floristic Kingdoms

Zoogeography

The distribution of animal groups in space.

► Zoogeographical Realms

Zoonosis (pl. zoonoses)

Diseases of animals that may be transmitted to humans, often by arthropods.

Zoophagous

Feeding on animals or animal products.

Zopheridae

A family of beetles (order Coleoptera). They commonly are known as ironclad beetles.

► Beetles

Zoraptera

An order of insects. They commonly are known as angel insects or zorapterans.

► Angel Insects

Zorapterans

Members of the insect order Zoraptera.

► Angel Insects

Zorotypidae

A family of angel insects (order Zoraptera).

► Angel Insects

Zygaenidae

A family of moths (order Lepidoptera). They commonly are known as smoky moths and burnet moths.

► Burnet Moths

► Butterflies and Moths

Zygote

A fertilized egg formed as the result of the union of the male and female gametes.
