A pest of potential economic importance to an area and not yet present in that area, or being of limited distribution and being officially controlled in that area. In the latter case, the area within which a quarantine pest is present and being controlled, is called a "quarantine area."

► Invasive Species
► Regulatory Entomology

Quasisocial Behavior

A level of sociality less than eusocial behavior. A type of presocial behavior. It involves individuals of the same generation sharing a nest and cooperating in brood care.

► Presocial
► Solitary
► Communal
► Subsocial
► Semisocial
► Eusocial Behavior

Quaternary Period

A geological period of the Cenozoic era, extending from about 2 million years ago to the present.

Queen

The primary reproductive in semisocial or eusocial insects.

Queensland Tick Typhus

This is a tick-borne disease found in Australia.

► Ticks

Queen Substance

A pheromone component produced by honey bee queens that regulates several aspects of hive function and mating.

Quiescence

A reversible state of inactivity initiated by adverse environmental conditions. Quiescence is also sometimes known as torpor.

► Diapause

Quiet-Calling Katydids

A subfamily of katydids (Meconematinae) in the order Orthoptera: Tettigoniidae.

► Grasshoppers
► Katydids and Crickets

R

Rabb, Robert Lamar

Bob Rabb is remembered as a pioneer in the field of Integrated Pest Management (IPM). He co-hosted perhaps the first international conference on IPM, in 1970. The proceedings of the conference were published as "Concepts in Pest Management" and this treatise remains as relevant today as it was at the time of publication. His interests in implementation of IPM and in applied ecology also resulted in publication (in 1979) of a book "Movement of highly mobile insects: concepts and methodology in research." Naturally, anyone interested in movement realizes that insects exist in places other than crop fields, so he conducted research on how the entire landscape influences pest abundance.

Bob Rabb was born August 6, 1919, in Lenoir, North Carolina, USA, and grew up in rural North Carolina where he learned to appreciate nature. He enrolled at North Carolina State University, with his formal education culminating in receipt of a Ph.D. from North Carolina State in 1953. Rabb also spent most of his career as a faculty member there, and was named W.N. Reynolds Professor of Entomology in 1981. He was also recognized by the Entomological Society of America, receiving the Geigy Award and the Founders' Memorial Award. He died on July 31, 2006.

Rabbit Fever

Also known as Tularemia, this is a serious infectious disease caused by the bacterium *Francisella tularensis*. The disease is endemic in North America, and parts of Europe and Asia. The primary vectors are ticks and deer flies, but occasionally the disease can also be spread through other arthropods. Animals such as rabbits and muskrats serve as reservoir hosts. The disease is named after Tulare County, California, where in 1911 the disease was studied in squirrel and human populations.

► Ticks

Race

A geographically or genetically distinct subgroup of a species.

Radiolabeling

The attachment of a radioactive atom to a molecule, incorporation of ^{32}P-dNTPs into DNA.

Radial Cell

A cell of the wing bordered anteriorly by a branch of the radius.

► Wings of Insects

Radial Sector

The lower of the two branches of the radius.

Radius

The third of the longitudinal wing veins, between the subcosta and the media. It is subdivided into up to five branches.

► Wings of Insects

Radoshkowsky, Octavius John

Octavius Radoshkowsky (Radochkoowsky, Radochkoffsky, Radoszkowskii, etc.) was born in Lomza, Poland on August 7, 1820. He was born into the Polish nobility and educated in Poland. His training also included the military, and he served in the Polish artillery, retiring as Lieutenant-General in 1879. Radoshkowsky had a general interest in entomology, and is considered a systematist and faunist. However, he favored the Hymenoptera, and is best known for his contributions to the Hymenoptera of the Russian Empire. Perhaps his most important contribution, however, is his role in founding and supporting the Russian Entomological Society. He was a founding member, and in his capacity of President he did much to ensure the stability of the Society by acquiring a residence and annual subsidy. He served as president from 1867 to 1880. Due to serious illness and family circumstances Radoshkowsky relocated from Russia to Poland. He died in Warsaw, Poland, on May 1, 1895.

Rain Beetles

Members of the family Pleocomidae (order Coleoptera).

► Beetles

Rallidentidae

A family of mayflies (order Ephemeroptera).

► Mayflies

Random Distribution

A distribution of organisms that lack pattern or order. The distribution is indistinguishable from a pattern based on chance.

Random Sampling

A method of allocating sampling units within a sampling universe in which each sample unit has an equal chance of being selected. Random sampling ensures an unbiased estimate, but is rarely used in the practice of arthropod sampling due to time and cost constraints.

► Sampling Arthropods

RAPD-PCR

RAPD is derived from the term "Random Amplified Polymorphic DNA." It is a type of PCR using single primers of arbitrary nucleotide sequence consisting of nine or ten nucleotides with a 50–80% G + C content, and no palindromic sequences. These 10mers can act as a primer for PCR and yield reproducible polymorphisms from random segments of genomic DNA.

Raphidiid Snakeflies

Some members of the family Raphidiidae (order Raphidioptera).

► Snakeflies

Raphidiidae

A family of insects in the order Raphidioptera. They commonly are known as raphidiid snakeflies.
► Snakeflies

Raphidioptera

An order of insects. They commonly are known as snakeflies.
► Snakeflies

Rapsmatidae

A family of insects in the order Neuroptera.
►Lacewings, Antlions, and Mantidflies

Raptorial

Suitable for grasping prey. This term usually is used to describe legs.

Rasorial

This describes appendages or structures adapted for, or used for, scratching. In insects, these are normally leg structures.

Raspberry Cane Borer, *Oberea bimaculara* (Olivier) (Coleoptera: Cerambycidea)

As the name suggests, this species of beetle damages the canes (stems) of raspberry.
► Small Fruit Pests and their Management

Raspberry Fruit Worm, *Byturus unicolor* (Say) (Coleoptera: Byturidae)

This fruit-feeding beetle is found in eastern North America.
► Small Fruit Pests and their Management

Raster

A complex of hairs, spines and bare areas on the ventral surface of the last abdominal segment of scarab beetle larvae.

Ratardidae

A family of moths (order Lepidoptera) also known as Oriental Parnassian moths.
► Oriental Parnassian Moths
► Butterflies and Moths

Ratemiidae

A family of sucking lice (order Phthiraptera).
► Chewing and Sucking Lice

Rearing of Insects

NORMAN C. LEPPLA
University of Florida, Gainesville, FL, USA

Insect rearing is not much different from other forms of animal husbandry and it has similar rewards for a person who is patient, persistent, observant, and reasonably well organized. It is generally safe for humans unless they are hypersensitive to insect proteins, react to the physical irritation of insects or their body parts, work with insects that sting or bite, or expose themselves to toxic substances used in the rearing procedures. Rearing methods can be a simple duplication of nature, such as holding insects and their food plants or animals in cages. In other cases, it can take years to develop a method to successfully rear a very specialized insect, often with breakthroughs based on discovering details about its life history. Methods can also be derived empirically by experimenting with a variety of materials and procedures, until success is achieved. Regardless, the satisfaction in rearing at least the immature stages of insects can be an exciting and fulfilling hobby or vocation.

Once insects have been held to the adult stage, having undergone incomplete (nymphs) or complete (larvae) metamorphosis, the challenge is to induce mating and oviposition of viable eggs. An insect species will mate only in an environment that has the necessary conditions, such as courtship cues, adequate temperature and humidity, appropriate light levels, and often food. Oviposition usually requires a specialized substrate that duplicates or mimics the insect's natural situation. Substrates typically protect the eggs from predators and parasites, and locate them in proximity to larval food. However, given no choice in captivity, some insects will mate and the females will scatter their eggs under completely artificial conditions. First instar larvae of these species travel considerable distances in search of suitable habitats and food.

Taking into consideration the wide range of life histories (e.g., terrestrial, aquatic, subterranean, plant or animal feeding, parasitic, predatory), insect rearing can be approached much the same as raising chickens, rodents or fish. Suitable founders must be collected or purchased, specialized facilities designed and constructed, equipment obtained and in most cases modified, materials and supplies tested, and site-specific rearing procedures established. Both immature and adult insects normally need food, usually with specific nutritional and physical characteristics, presented in certain kinds of containers. Once obtained, fertile eggs may require surface sterilization and incubation in carefully controlled environments. Colonies also must be protected from pathogens and predators, as well as environmental and procedural failures. The rearing processes and insect life history characteristics are checked every generation, e.g., rate of development, pupal weight or adult size, percent emergence and mating, and the number of viable eggs.

Selecting an Insect to Rear

Virtually any insect can be collected as an egg, larva or nymph and maintained through stages in metamorphoses until it becomes an adult. However, it is considerably more difficult to establish a colony that produces continuous generations. Knowledge is required about the species' habitat, natural food and behavior. Re-creation of soil and aquatic environments, symbiotic relationships, and specialized foods can make rearing difficult. Some insects undergo temperature- and photoperiod-dependent diapause or require host plant cues to terminate multi-year cycles. Feeding by trophallaxis may necessitate maintenance of an entire colony, as in termites, ants and other social insects. Because of these and other peculiar life history characteristics, the easiest insects to rear are relatively small, multivoltine (more than one generation per year), plant-feeding, terrestrial species with wide host ranges and few unusual environmental requirements. Commonly cultured insects include pests of common crops, stored products or landscape plants, as well as abundant species that are not pests. Examples include armyworms, loopers, hornworms, mealworms, weevils, mealybugs, aphids, ants, grasshoppers, and lady beetles.

There are published lists and specialized directories of arthropod cultures, e.g., Drosophila spp. strains. "Arthropod Species in Culture" listed colonies of the following taxonomic orders (species, colonies): Acari (41, 77), Anoplura (1, 1), Coleoptera (78, 266), Diptera (168, 301), Hemiptera (90, 206), Hymenoptera (119, 169), Lepidoptera (101, 308), Mallophaga (3, 3), Neuroptera (2, 2), Orthoptera (64, 203), Siphonaptera (2, 7), and Thysanura (4, 11). The most numerous colonies were the twospotted spider mite, *Tetranychus urticae* (24), confused flower beetle, *Tribolium confusum* (21), yellow fever mosquito, *Aedes aegypti* (21), housefly, *Musca domestica* (28), tobacco budworm, *Heliothis virescens* (25), and American cockroach, *Periplaneta americana* (26). "Suppliers of Beneficial Organisms in North America" is maintained by the California

Environmental Protection Agency (http://www.cdpr.ca.gov). This publication lists more than 130 species of beneficial organisms available from 142 suppliers. The species are classified as predatory mites (17 species, 325 suppliers), parasitic nematodes (6, 111), stored product pest parasites and predators (4, 13), aphid parasites and predators (17, 361), whitefly parasites and predators (9, 268), parasites and predators for greenhouse pests (23, 504), scale and mealybug parasites and predators (7, 149), insect egg parasites (12, 238), moth and butterfly larval parasites (6, 30), filth fly parasites (8, 143), other insect parasites (4, 9), general predators (21, 410) and weed controls (36, 50). The most popular species were the lacewings *Chrysoperla carnea* (65 suppliers) and *C. rufilabris* (54), mealybug destroyer, *Cryptolaemus montrouzieri* (52), whitefly parasite, *Encarsia formosa* (54), convergent lady beetle, *Hippodamia convergens* (56), predatory mite, *Phytoseiulus persimilis* (54), and a parasitoid of moth eggs, *Trichogramma pretiosum* (77). Many more species could be reared using the techniques developed for their close relatives.

Founding a Colony

Insect colonies are initiated from field-collected specimens or previously established colonies. Any developmental stage can be used, but surface-sterilized eggs are less likely to introduce a pathogen. Eggs are generally used to initiate a colony from another colony because they are durable and easy to ship. However, eggs may be difficult to find in nature, and subsequent larvae or nymphs often suffer high levels of mortality because they are parasitized or, if viable, are not yet laboratory adapted. Thus, it is generally advisable to collect pupae or large nymphs, hold them in individual containers for parasite and pathogen screening, combine the adults in mating cages with food and a suitable oviposition substrate, and collect and treat the eggs for use in establishing a colony. From either source, field or insectary, the degree of success achieved will depend on the quality of colonized insects and skill with which they are reared. Many species that can be colonized and reared for multiple generations are on average much larger, healthier (free of malnutrition, pathogens, parasites and predators), uniform in growth, and more active and fertile than those in nature.

Facilities and Equipment

Insect rearing facilities have evolved from so-called "insectary" buildings with ambient temperature and humidity, to highly controlled facilities that contain insects under high security. Insectaries provide adequate environments for rearing insects in semi-natural conditions on host plants or animals. However, pathogens, parasitoids and predators are not controlled and workers are exposed to potentially dangerous pathogens and allergens. Conversely, temperature, humidity, air quality and quantity, light quality and photoperiod, sanitation, and security are closely maintained in rearing facilities. Insects and supplies are carefully screened for contaminants before they are admitted, and human access and exposure are limited. All openings to a rearing facility are sealed or filtered to prevent insects from entering or leaving, particularly in quarantine facilities. These rearing facilities range from small rooms with single occupants to massive factories with hundreds of workers. Regardless, they must be well insulated and have highly filtered, re-circulated air to be cost efficient. A garage or out-building can easily be modified to serve as an insect rearing facility.

Equipment is required to provide suitable environments, handle the insects, move and store materials and supplies, observe specimens, assure sanitation, and prepare diets. The environment is maintained by air conditioners, fans, humidifiers and de-humidifiers, mechanical or electrostatic air filters, and incandescent and fluorescent lighting. Tables, chairs, a deep sink, and perhaps a dishwasher are also needed. A dedicated refrigerator is required for storing diet ingredients and a freezer can be used to chill insects for handling. A binocular microscope may be needed to determine sex, screen for parasites and predators, or determine species. Specialized techniques and a high-powered microscope would be required to identify insect pathogens. Laboratory carts with wheels can be very useful for moving insects, materials and supplies. A cooker and blender must be provided to work with gelled diets.

Materials and Supplies

Typical insect rearing materials include hardware cloth, screen, or Plexiglas® for making cages; wood or metal framing; shelves and supports, and oviposition substrates. Materials may also be needed to modify rearing containers, support diets, and build small devices for handling insects. Supplies for insect rearing are similar to those found in a family kitchen, including products for preparing and serving diets, protecting tables, and cleaning and sanitizing surfaces. Egg treatment is not much different than cleaning fresh vegetables with a mild bleach solution. Cotton and sponges are used to hold liquids and prevent feeding insects from drowning. All kinds of paper and plastic containers are used as purchased or modified for insect rearing (Fig. 1). The most specialized supplies are often dietary ingredients for larvae or nymphs. Diets may be natural, such as certain fruits and vegetables, or formulated from specific nutrients. Medical and veterinary pests are usually maintained on living hosts, although mosquitoes can be reared in trays containing water and food. Most materials and supplies for rearing insects are reasonably inexpensive and specialized diets can be purchased to avoid their preparation (Table 1 and 2).

Insect Rearing Procedures

Insect eggs are resilient and generally do not require special care unless handled. Newly emerged larvae or nymphs can remain on the plant or animal host until it is no longer suitable for their development. They can then be transferred to new hosts or simply held for pupation, or additional molts if they have incomplete metamorphosis. Eggs are often surface sterilized with 10% bleach solution or another germicidal chemical to eliminate microorganisms, particularly if they are field collected. This procedure requires individual eggs to be removed from bundles and substrates. The bleach solution dissolves the cement and outer layer of the chorion, thus freeing the eggs. However, this treatment renders them susceptible to desiccation or drowning, so they must be handled carefully. Surface sterilization is recommended if eggs are to be placed in containers of artificial diet (Fig. 2).

Larvae and nymphs are maintained in containers or cages that provide diet, surface area, appropriate environments, and protection from contamination. The diet must induce feeding, provide adequate nutrition and not deteriorate during the insect's development. As the insects grow, they require more food, space and separation from considerable amounts of frass (feces). Overcrowded larvae often become cannibalistic. The containers and cages buffer the developing insects from extremes in temperature and relative humidity, as does the rearing facility and holding room. Air circulation is important to balance moisture and minimize vertical stratification in holding areas.

Adult colonies are derived from pupae or nymphs that have been sexed, selected for desired characteristics, and screened for parasites, pathogens, and other contaminants. If closely related insects are being reared, a contaminant can be the wrong species. Food, water and a suitable oviposition substrate are usually provided in a container or cage and, as with the immatures, it is essential to control the environment. A considerable amount of testing may be required to provide the necessary conditions for mating and oviposition. Depending on the kind of insect, these conditions can involve space, lighting, attractants, sex ratios, airflow, host

cues, complex courtship behavior, and so forth. Production of viable eggs is usually the greatest problem to overcome in establishing a continuous colony of insects.

Food for Immature and Adult Insects

Insects that feed on plants and animals are often maintained on their natural hosts or associated tissues, such as leaves, fruit, meat or blood (Table 3). This requires that the hosts be reared continuously or tissues be collected and kept fresh. With insect life cycles extending from a few days to several years, providing host material can be the most time consuming effort in insect rearing. This is particularly true for predatory and parasitic insects because three trophic levels must be synchronized: the initial plant or animal, second level host and beneficial insect. Consequently, insects are often selected for rearing that feed on human and animal food as immatures and adults, or require only sugar water or nothing as adults. These include crickets, wax moths, cockroaches, stored product pests, certain beetles and grasshoppers, and a wide variety of flies. So, some cockroaches eat dry dog food, grasshoppers eat lettuce, plant bugs eat green beans, flies eat fruit, and so forth. Gelled (often agar-based) diets have been developed to provide water with the food and incorporate preservatives. These kinds of diets can be prepared using published formulas or purchased along with the insects from specialized companies. Diets must be fresh because the ingredients can deteriorate during prolonged storage.

Isolation and Sanitation

Insects and their diets attract a host of competitors, predators, parasites and pathogens. Even a very small colony can easily become infested with scavenger or predatory mites, ants, cockroaches,

flies and gnats. Most of these kinds of problems can be solved with cleanliness and barriers. Germicidal soaps and a 5% solution of commercial bleach will provide surface sterilization with minimal corrosion. Barriers include sealed walls, electrical outlets and plumbing, reach-in boxes, screened or solid cages, paper and plastic containers, and plastic bags. Food should be stored in a refrigerator or freezer. Rough surfaces, drop ceilings, porous materials and cracks are difficult to sanitize. Positive air pressure helps to keep contaminants from entering and rearing procedures should be accomplished from clean to dirty, with no backtracking. Normally, parasites that penetrate

Biodiversity	Heterogeneity, behavior

barriers can be eliminated by breaking their life cycles, possible because they develop more rapidly than their hosts. Potentially parasitized insects are isolated from the colony until they are determined to be clean. Pathogens can be more problematic because they are difficult to detect and identify. In practice, diseased insects are carefully discarded and the colony is screened until symptoms cease, often without determining the exact cause. Sanitation and surveillance are increased concomitantly. As in kitchens, some of the bacteria that contaminate insect diets are human pathogens.

Quality of Reared Insects

Care must be taken to assure the quality of artificially reared insects relative to their intended purpose. Yield, size, sex ratio, rate of development, egg production and mobility are typically monitored depending on the situation. It is also important to keep track of environmental conditions, e.g., temperature, relative humidity, light quality and photoperiod, sanitation, materials and supplies, and work performed. Often check sheets are used for monitoring insect production and quality control charts with averages and ranges suffice for life history and behavioral measurements. This kind of information is required to "troubleshoot" the rearing process and determine causes of failures to produce acceptable insects. Virtually all severe insect rearing problems result from failure to perform standard operating procedures or defective environmental controls. Once established, rearing operations become routine and individual procedures easy to forget.

As in animal husbandry, insect rearing expertise develops with experience and knowledge gained by trial and error, and by studying information developed by others. It is considered both an art and science, requiring a "brown thumb" analogous with the green thumb of the gardener. The fastest way to learn new techniques is to visit established insect rearing facilities, talk with colleagues individually and at conferences, participate in an organized course, and read technical publications. Facilities and contacts can be located by Land Grant University faculty members, perhaps at extension and research centers, and state department of agriculture and U.S. Department of Agriculture scientists. Currently, the only comprehensive insect rearing course in the United States is a weeklong, intensive workshop taught twice each year at Mississippi State University. Written information on insect rearing techniques is scattered mostly in the methods sections of scientific papers or accumulated in difficult to locate, out-of-print books. Although there are many others, the following journals have tended to publish papers on insect rearing: Annals of the Entomological Society of America, Entomologia Experimentalis et Applicata, Florida Entomologist, Journal of Insect Science, BioControl (formerly Entomophaga), and specialized publications, such as the Journal of the Lepidopterists' Society and Journal of Apicultural Research. Commercial suppliers of insects, diets and educational materials are an excellent source of information on rearing (see Table 2). It can also be advantageous to adapt methods from books on rearing agricultural pests, such as the boll weevil (Curculionidae), screwworm (Calliphoridae), corn earworm (Noctuidae), or tobacco hornworm (Sphingidae). It will require some searching but there is a considerable amount of invaluable information on insect rearing.

De Re' Aumur, René Antoine Ferchault

René Antoine Ferchault de Réaumur was born in 1683 at La Rochelle, France. He achieved success early in life, being elected to the Academy of Sciences at the age of 24, after publication of some important work on geometry. He worked principally as a naturalist, publishing articles on regeneration of lost appendages by crustaceans, fossils, luminescence by molluscs, the digestive systems in birds, and other topics. Not until 1734 did he begin publishing on insects, but by 1742 he had authored his "Memoires pour servir à l' histoire des insectes" in six volumes, and had begun a seventh volume, on beetles. In this treatise he gave a clear picture of insects and insect habits, and their relationship with nature. In addition to the natural history of insects, he attempted to develop a classification system based on behavior. Thus, he grouped insects, worms, molluscs, and reptiles together. Though this seems strange now, as we are conditioned to classification systems based on structure, classification was still in its formative stages and much more unusual systems had been proposed. This publication gave him prominence among naturalists, and his work remains a classic example of careful observation. However, Réaumur contributed to science and technology in many ways, including invention of a thermometer, the use of porcelain for thermometers, improved steel production and enhanced the economy of tin plate production.

Recapture Technique of Sampling

An absolute method of sampling that involves capture of insects, marking of captured insects, release of the marked insects, and then recapture of marked and unmarked insects from the natural population. After the recapture effort, the proportion of marked insects is used to estimate the initial population size.

► Sampling of Arthropods

Recombinant DNA Technology

All the techniques involved in the construction, study and use of recombinant DNA molecules. Often abbreviated rDNA, which can be confused with ribosomal DNA.

Recombination

A physical process that can lead to the exchange of segments of two DNA molecules and which can result in progeny from a cross between two different parents with combinations of alleles not displayed by either parent.

Recruitment Trail

An odor trail produced by an individual worker that is used to recruit nestmates to a location where other workers are needed: a food source, nest site, a breach in the nest wall, etc.

► Pheromones

Rectal Gill

A tracheal gill occurring in the anterior region of the rectum in naiads of Anisoptera (Odonata).

Rectal Myiasis

A form of myiasis that occurs in the intestine or anus. Fly larvae invade these areas and complete their development internally, in the rectum of the host. Among flies associated with this are rat-tailed maggot, *Eristalis tenax* (L.) (Syrphidae); latrine fly, *Fannia scalaris* (Fabricius) (Fanniidae); false stable fly, *Muscinia stabulans* (Fallen) (Muscidae); and lesser house fly, *Fannia canicularis* (L.) (Fanniidae).

► Myiasis

Rectal Pad

A section of the rectum containing enlarged cells that take up water and ions from the rectum.

Rectum

The posterior region of the hindgut leading to the anus (Fig. 3).

► Alimentary System

► Alimentary Canal and Digestion

Recurrent Vein

A crossvein, often extending obliquely, and usually associated with the costa and subcosta, though this varies among taxa.

► Wings of Insects

Red Bugs

Members of the family Pyrrhocoridae (order Hemiptera).

► Bugs

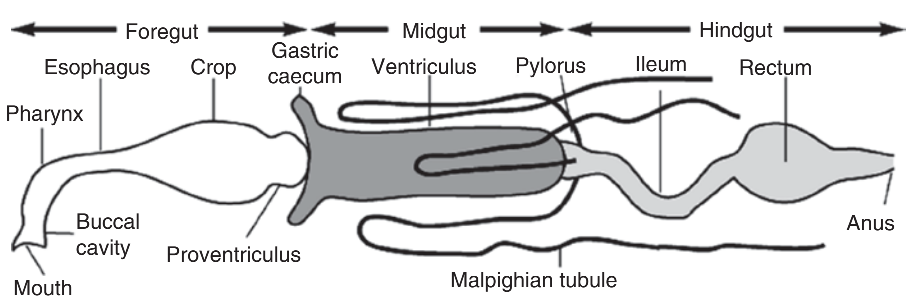
Red Flour Beetle, *Tribolium confusum* Jacquilin du Val (Coleoptera: Tenebrionidae)

This is a common flour pest, and is difficult to control.

► Stored Grain and Flour Insects

Redi, Francesco

Francesco Redi (Fig. 4) was born at Arezzo, Italy, on February 18, 1626. After earning a degree in medicine, he became a tutor for five years, but then moved to Florence where he became physician to the Grand Dukes Ferdinand II and Cosimo III. He conducted much experimentation aimed at improving medicine, but also was proficient at poetry and music. Among his scientific publications are "Observations on vipers," "Experiments on the generation of insects," and "Medical consulting." Among his literary contributions are the "Bacco in Toscana," and "Arianna inferma." He is best remembered for his work establishing that insects are not produced by spontaneous generation, but rather are derived from other insects. Perhaps more importantly, by working with the development of fly larvae on meat he demonstrated the value of experimentation, and the value of changing one variable at a time in elucidating biology. He died at Pisa, Italy, on March 1, 1698.



Rectum, Figure 3 Generalized insect alimentary system (adapted from Chapman, The insects: structure and function).

Red Imported Fire Ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae)

BASTIAAN M. DREES
Texas A&M University, College Station, TX, USA

The red imported fire ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae), is a social insect that produces hills or mounds in open areas where the colonies reside, although colonies occasionally occur indoors, near and within structures, such as utility housings or tree trunks. Fire ant mounds may reach 30–40 cm high and 30–50 cm in diameter with no holes or central entrance hole on the mound's surface. Inside, mounds have interconnecting galleries that may extend 30–40 cm deep, although some tunnels can penetrate to the water table. In response to solar radiation and ambient conditions, fire ants move within the mound seeking optimum temperature for the development of brood (eggs, larvae and pupae), a process called thermoregulation. Foraging worker ants enter and exit through tunnels radiating up to 5–10 m away from the mound. The disturbance of mounds results in a rapid defensive response by worker ants, which quickly run up vertical surfaces to bite and sting any objects encountered.

Two forms of imported fire ant colonies occur: the single queen (monogyne) and the multiple queen (polygyne) forms, the latter containing two or more inseminated, reproductively active queen ants. Worker ants in single queen colonies eliminate additional queens and respond defensively to neighboring colonies to maintain territories. Multiple queen colony worker ants do not display territorial behavior and, consequently, they can produce 3–10 times as many ant mounds in a given area of land and result in 500 mounds and 50 million ants per ha. Areas infested with the single queen form normally have 50–75 mounds per ha.

Description

A mature colony can contain over 200,000–400,000 sterile, female worker ants. These ants range in length from 1.5 to 5 mm and are dark reddish brown with black abdomens. Worker ants build up the colony, care for the queen and brood, defend the colony and forage for food. Their functions within the colony are determined by the size and needs of the colony, and by the age of the worker ant. The younger workers serve as nurse ants, which tend and move the queen and brood. Older workers serve as reserves to defend the colony and to construct and maintain the mound. The oldest worker ants become foragers.

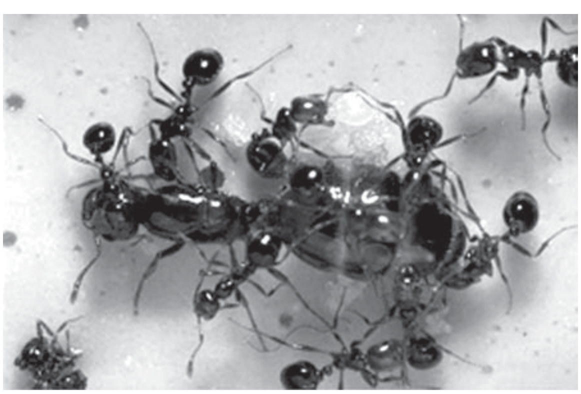
Developmental stages include eggs, larvae and pupae, referred to as brood. The eggs are spherical and creamy white. The larvae are legless, cream-colored and grub-like with distinct head capsules. Pupae resemble worker ants and are initially creamy white turning darker before the adult ants emerge (eclose).

Winged, reproductive, male ants develop from eggs that are not fertilized. Fertilized eggs can develop into either sterile, female worker ants, or winged, reproductive females depending upon the nutrition provided to the larval stages and the chemical signals (juvenile hormone level and pheromones) within the colony. Winged, female reproductives are reddish-brown, while males are shiny black with smaller heads. These ants stay in the colony until conditions exist for their nuptial flight. Queen ants (mated, female reproductives) are larger (9 mm) and have no wings (Fig. 5).

Spread

Spread occurs naturally (through mating flights, ground migration and floating colonies on water during floods) and artificially (by humans through shipment of infested articles like nursery potting media, sod, bales of hay, or soil). It is limited primarily by the availability of soil moisture and cold temperatures. Predictions suggest the ant is unable to survive where the minimum yearly temperatures are less than −12.3 to −17.8°C.

Mating flights occur mid-day (10:00 a.m. to 2:00 p.m.) during the first sunny days after a period of rainy weather when temperature are suitable (24°C) at any time of the year, but mainly in the spring and the fall. Winged male and female reproductives (also called sexuals or alates) couple in the air (90–300 m high). The males die after mating, but the females seeking a nesting site are attracted to shiny surfaces (e.g., water surfaces, shiny truck beds) and land within a mile (1.6 km) or two unless carried farther by the wind.



Red Imported Fire Ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae), Figure 5 Fire ant queen and workers.

Colony Formation

Newly mated females that survive the nuptial flight and that reach suitable nesting habitats (estimated to be about 1% due to predation and other mortality factors), remove their wings and burrow into the ground (Fig. 6). Sealed in a chamber that they dig, these females begin to lay eggs (10–20 per day) that

Red Imported Fire Ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae), Figure 6 Fire ant mound at base of tree.

hatch into larvae in 6–10 days, which are fed from energy produced from the breakdown of flight muscles, infertile (trophic) eggs, young larvae and oil reserves. The first worker ants emerging are uniformly small and are called minums or nanitics.

Life Cycle

Each queen ant can produce about 800 eggs per day. The eggs hatch in 8–10 days and the larvae develop through four stages (instars) over 12–15 days before pupating for a period of 9–16 days. Development requires 22–37 days, depending on the temperature. Most worker ants live 60–150 days with larger ants living longer, but during cooler weather, workers can survive for 8 months or more. Newly established colonies develop winged, reproductive ants after about 6–8 months and can produce 4,000–6,000 alates per year. Queen ants can live for more than 7 years.

Habitat and Food Source(s)

Ants communicate through vision (sight), vibration (sound), touch and chemicals (pheromones, including a queen pheromone that attract workers and may suppress dealation and reproduction, and a trail pheromone produced by Dufour's gland associated with the worker ant stinger). They forage when temperatures range from 22 to 36°C. Upon locating food resources, they develop a trail using a pheromone that directs other worker ants to the site. Fire ants are omnivores, consuming sugars (carbohydrates), certain amino acids, ions in solution and some oils containing polyunsaturated fatty acids. Although they primarily consume other arthropods and the honeydew produced by some types of sucking insects (Hemiptera), they will also consume seeds and other plant parts like developing or ripening fruit, and dead plant and animal tissues.

Worker ant mouthparts are for biting and sipping liquids. Worker ants consume only liquids and particles <0.9 μm, storing food in their crops and their postpharyngeal gland (oils only) until feeding it to other worker ants and ultimately, to larvae and queen(s) – a process called trophalaxis. Young larval stages (instars) are fed regurgitated liquid food only. However, the last (fourth) larval stage can ingest solid food particles. Worker ants place bits of solid food in a small depression (called a food basket or praesaepium) just in front of and beneath the larva's mouth (an area called the presternum). They digest the proteins externally (extraorally) by secreting enzymes and by chewing and swallowing smaller particles.

Pest Status

Like a weed species, the aggressive and abundant imported fire ant reduces biodiversity, particularly other ant species, in newly infested areas. These soil-dwelling ant colonies are most commonly found in urban, agricultural and non-agricultural areas and affect people, livestock, wildlife and the flora and fauna of infested lands. Although the exact economic costs of fire ant damage and control are unknown, estimates for the southeastern United States have been more than a half billion to several billion dollars per year. The cost of producing agricultural commodities, such as nursery and sod production, has increased in infested areas. There, quarantine regulations mandate treatment of materials to be shipped to non-infested areas.

Medical Importance

For most people, contact with the ants is merely an irritation and a nuisance, but for some people (particularly very young, old or indigent people), the ant's sting can result in medically serious problems or even (rarely) death. Imported fire ant workers are highly defensive and aggressive. When disturbed, they run up vertical objects quickly (8 cm/5 s) en masse (tens to hundreds) and seem to bite (with their mandibles) and sting (with their modified ovipositor) all at once. The venom injected produces a burning, fire-like sensation for which the ant gets its common name: fire ant. Each worker ant can sting repeatedly. Queen ants do not sting, but they do contain venom. Surveys have documented that more than 50% of the people living in infested areas are stung by the ant annually. Most people can tolerate multiple stings, but may have problems with secondary infections at the sites of the stings. However, about 0.6–6.0% of people stung are sensitive to the venom and can experience serious medical problems from even one sting.

The venom produces a fluid-filled pustule within a day or so (10–12 h) of being stung (Fig. 7). The venom consists of aliphatic substituted alkaloids that are cytotoxic (cell-killing), and a small amount of protein, which is responsible for allergic responses (swelling or edema, and anaphylactic shock characterized by swelling, sweating and shortness of breath that can lead to respiratory arrest and heart failure). The pustules persist for several weeks and may leave scars. Ruptured pustules can become infected.

The ants also affect people indirectly by modifying their behavior to avoid contact with the ant. There are also increased health and environmental risks associated with insecticide application or other attempts to control this pest.

Red Imported Fire Ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae), Figure 7 Pustules on hand resulting from fire ant stings.

Equipment Damage

The ants or entire colonies move into buildings or vehicles seeking favorable nesting sites, particularly during flooding and very hot, dry conditions. Fire ant foraging and nesting activities can result in failure of many types mechanical (e.g., hay harvesting machinery, sprinkler systems) and electrical equipment (e.g., air conditioner units, traffic box switching mechanisms).

Agricultural and Ecological Impact

In addition to being considered medically important pests of people, pets, livestock and wildlife, imported fire ants can also damage crops such as corn, sorghum, okra, potatoes, sunflowers and others by feeding on the seeds, seedlings and developing fruit. Predatory activities of fire ants suppress populations of ticks, chiggers, caterpillars and other insects. Predatory activity attributes to wildlife reductions in some areas. Many animals are also affected by these stinging ants, particularly those that cannot quickly move away from the threat (e.g., very young, old, or confined animals). Ants recruit to moist areas of the body (eyes, genitals), yolk of hatching birds and wounds, and begin stinging when disturbed. Stings result in injury such as blindness, swelling or death. Indirectly, animals avoid infested food, water and nesting areas. The ants can reduce food sources for some insect-eating (insectivorous) animals, such as some birds and lizards, and they may compete with seed-feeding (gramnivorous) animals for food, or by altering the distribution and composition of plant communities.

In addition to direct damage to plants, they also aggravate populations of other insect plant pests like some Hemiptera (aphids, scale insects, mealybugs) by protecting them from natural enemies as the ants consume the sugary honeydew produced by these pests. However, the ants primarily prey on arthropods, such as some species of ticks, many caterpillars and other insects often considered pests.

This behavior can provide benefits to producers of cotton, sugarcane and other commodities.

History of Spread

The fire ants comprise a group of 18–20 insects species native to the New World within the genus, *Solenopsis*, which contains about 200 species including "thief ants" (an ant species, most of which are incapable of stinging humans, nesting close to other ant nests and robbing them of stored food and brood). The black imported fire ant, *S. richteri* Forel, was accidentally introduced from the Paraguay River drainage area of South America to the U.S. port of Mobile, Alabama in 1918. The red imported fire ant, *S. invicta*, is believed to have been introduced from northern Argentina or southern Brazil to the same U.S. port around the early 1930s. *S. invicta* spread westward at about 198 km per year.

Several native fire ant species occurred in the U.S. before *S. invicta* and *S. richteri* Forel arrived: *S. xyloni* McCook, the southern fire ant; *S. geminata* (Fab.), the tropical fire ant; and, two desert-adapted species, *S. aurea* Wheeler and *S. amblychila* Wheeler. While *S. xyloni* and *S. geminata* have also been considered to be pest ants, they have been largely displaced in the southeastern U.S. by the red and black imported fire ants. Imported fire ants occur at higher densities than native fire ant species, leading to increased human contact and problems. In the U.S., *S. richeteri* occurs in northern areas of Alabama, Mississippi, Georgia and southern Tennessee, with a sexually reproductive hybrid population of *S. invicta* and *S. richteri* throughout the remainder of these states and part of Georgia.

Solenopsis invicta now occupies 128 million ha (316 million acres) in nine southeastern states (Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, Texas) in the U.S. with limited infestations in Arizona, Oklahoma, Tennessee, New Mexico and California. Infestations also occur in a number of island countries in the Carribean including Puerto Rico, the Bahamas, the British and U.S. Virgin Islands, Antigua and Trinidad. The species has recently been detected in New Zealand and Australia (Brisbane).

History of Control Efforts in the U.S

- 1929 – Imported fire ant first detected in the northern Mobile area and Spring Hill, Alabama
- February 1937 – First organized control program in Baldwin County, Alabama (1–3 ounces 48% calcium cyanide dust per mound); 2,000 acres or 800 ha treated
- 1948 – Mississippi spends $15,000 to treat ant mounds with chlordane dust; Alabama and Louisiana provide chlordane to farmers free or at cost
- 1957 – Arkansas conducts 12,000 acre eradication project in Union County, and the city of El Dorado applied heptachlor (2 lb/acre) by air; congress appropriates $2.4 million for USDA to begin a federal-state cooperative control and eradication program dedicated to the use of aerial and granular applications of heptachlor and dieldrin (2 lb a.i./acre)
- 1958 – Mandated treatments of regulated items initiated to comply with USDA imported fire ant quarantine regulations
- 1960 – Heptachlor rate lowered to 0.25 lb a.i./acre with two applications, 3 and 6 months apart
- Early 1960s – Growing concerns about the detrimental effects of treatments to wildlife, contamination of food and crops ended the program
- 1962 – Lofgren develops conventional bait formulation; mirex developed as an active ingredient: mirex (0.3%) dissolved in soybean oil (14.7%) on impregnated corn grits (85%)
- 1962–1978 – 140 Million acres treated with mirex bait by ground and aerial equipment, although many treatments consisted of three applications to the same area; thus, ~46.6 million acres were actually treated
- 1967 – Feasibility studies were initiated by USDA-ARS in Gainesville, Florida, to use mirex to eradicate imported fire ants

- Late-1960s to early 1970s – mirex residues found in environment, non-target organisms and to be toxic to estuarine organisms
- 1970–1971 – U.S. Department of Interior bans all mirex uses; EPA issues notice of cancellation of mirex
- 1977 – Mirex reported to be a potential carcinogen; EPA cancelled registrations December 31
- 1978 – Amdro® (hydamethylnon with oleic or linoleic acid added to increase oil solubility formulated in soybean oil (20%) on a pregelled defatted corn grit carrier) tested
- 1980 – Amdro registered by EPA for use on pastures, range grasses, lawns, turf and nonagricultural lands
- 1983 – Prodrone, the first insect growth regulator (IGR) is registered by the EPA
- 1985 – Logic® (fenoxycarb), another IGR, registered by the EPA
- 1986 – Ascend®/Affirm® (abamectin) registered by the EPA
- 1995–2000 – Biological control efforts initiated using importation and release of phorid flies (*Pseudacteon tricuspis* and others) and manipulation of a disease, *Thelohania solenopsae*
- 1998 – Distance®/Spectractide® Fire Ant Bait (pyriproxifen), another IGR, registered by the EPA
- 1998 – Extinguish™ (methoprene), another IGR, registered by the EPA for use in croplands in which other baits can not be applied
- 2000 – Justice®, Eliminator®, Strike® Fire Ant Baits and others containing spinosad (spinosyns A and B combined), a new insecticide class (spinosyn derived from bacterium, *Saccharopolyspora spinosa Mertz* and Yao) registered by EPA
- 2000 – Chipco® FireStar® and TopChoice® (fipronil bait and granular products, a phenyl pyrazole insecticide), approved by EPA

Red Imported Fire Ant Territorial Behavior

ALLAN T. SHOWLER
USDA-ARS SARC, Weslaco, TX, USA

The imported fire ant, Solenopsis invicta Buren, is a stinging social insect indigenous to parts of Brazil, Paraguay, and Argentina, and it was accidentally introduced to the United States in Alabama in 1929. The fire ant has since spread across the southern United States and Puerto Rico, and because of its venomous sting, it is widely viewed as being an exotic pest. Queens start colonies after nuptial flights that occur year round, but peak flight activity occurs between May and August. Colonies can produce 3,000–5,000 queens each year, and fire ant reproduction in a colony can be accomplished by a single queen or by multiple queens in polygynous colonies. Queens are morphologically distinct from other individuals in the colony, but workers range in length from 2 to 6 mm and definite subcastes among workers have not been identified.

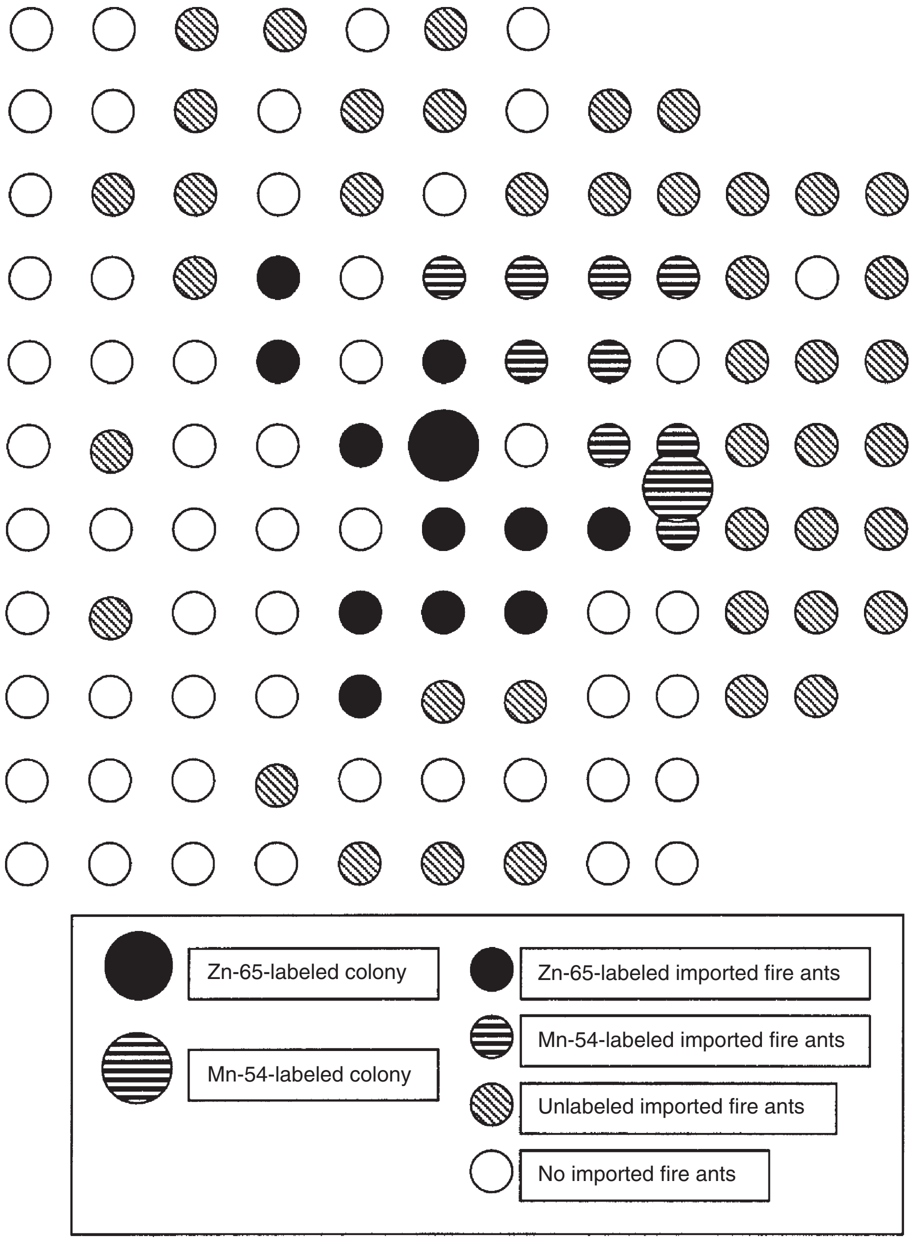
Fire ants establish colony mounds with subterranean galleries that can support populations of 50,000–230,000 workers. Mound densities of up to 2,500/ha, but usually <250 mounds/ha have been reported in pastures, cultivated areas, unattended woodlands, and disturbed habitats. Tunnels radiate 2–12 mm below ground level from each colony mound. One colony's tunnel system was exhumed and its tunnels were found to collectively extend 84 m. Tunnel exits occur intermittently and they facilitate access to foraging areas. Fire ants are omnivorous and they feed on a wide diversity of arthropods, molluscs, plant material, honeydew produced by hemipteran insects, and nectar. Mass foraging at specific sites is initiated by a trail pheromone secreted by a gland and extruded through the stinger of scout workers inside tunnel systems.

Dyes ingested by fire ants helped to show that, between two different fire ant colonies, fire ants from the two colonies did not forage at the same places, and it was suggested that the fire ants exhibited intraspecific territorial behavior. Another study labeled one fire ant colony with radioactive Zn-65 ingested with molasses and spread throughout the colony by trophallaxis, and a nearby colony was similarly radiolabeled with Mn-54. The territories of both fire ant colonies were shown to be discrete and dynamic over 20 consecutive days (Fig. 8). Fire ant colonies in weedy and weed-free sugarcane habitats were labeled with the nonradioactive, stable-activable tracer element samarium. Instrumental neutron activation analyses of the samarium marker revealed that the tagged ants foraged at significantly more sampling stations in weed-free sugarcane habitats than in weedy sugarcane habitats. The smaller territorial size in weedy areas was a result of more dense prey populations, which permitted greater numbers of fire ant colonies per unit area than weed-free sugarcane habitats. It was suggested that a heavily infested area could be completely occupied by a contiguous patchwork of fire ant territories defended by different colonies.

There are nine traits that have contributed to the fire ant's rapid adaptation to the southeastern United States, including a large colony population size, a general omnivorous diet, mass foraging recruitment, massive aerial dissemination of reproductive females, the stinging mechanism. Three traits are related to territoriality: (i) tunneling behavior offers protection from trail disruption, (ii) utilizing foraging areas in water-saturated soil permits access to established territories in areas subject to flooding, and (iii) defending temporally dynamic territory boundaries that permit efficient use of foraging areas when specific sites have been depleted.

The fire ant's adaptability and competitiveness have enabled it to become widely established in the southeastern United States despite the presence of other, indigenous ant species. Transect studies have shown that 92–100% of baited sampling sites can be monopolized by fire ants. Since its introduction to the southeastern United States, the fire ant has been a significant competitive force upon the distribution of other formicid species, and species that had previously predominated were frequently displaced. The fire ant has become the dominant formicid species in the southeastern United States. Generally, fire ants can overpower indigenous ant species in combat. Even the Floridian poneroid ant, *Lasius neoniger* Emery, which uses mandibular and chemical defenses to eliminate 2.4 fire ants for every *L. neoniger* killed, eventually succumbs to attrition because of the sheer magnitude of fire ant colony populations. All attempts to control fire ants with mirex applications resulted in the suppression of other ant species, including the tropical fire ant, *Solenopsis geminata* (F.), and *S. xyloni* McCook. Some researchers have suggested that the use of toxins for fire ant eradication has instead contributed to its proliferation in the United States because of fire ant resurgences at the expense of other ant species.

After dominating its niche, the fire ant appears to reach an equilibrium with native ant species. Cohabitation of an area with the competitive fire ant is a result of (i) strategies by other species that exploit other resources in habitat-diverse environments, (ii) chemical repellency by some ant species (e.g., *Monomorium minimum* (Buckley)), (iii) high mobility (e.g., *Aphaenogaster rudis* Emery can



Red Imported Fire Ant Territorial Behavior, Figure 8 **Day 12 of 20 consecutive days of collecting imported fire ants on a 3 m × 3 m grid in a grassy field in southern Louisiana. Each point on the grid was a 35-ml plastic cup buried to the lip and baited at 1,000 h with raw animal fat for 1.5 h. Imported fire ants labeled with Zn-65 and Mn-45 were detected using an autogramma solid scintillation detector with a multichannel analyzer.**

move faster than the fire ant), or (iv) proximity to resources. The latter two strategies each contribute to the reduction of recruitment time to essential resources so that opportunities for foraging can be capitalized upon with greater success even within fire ant territories. One study demonstrated that three formicid species sympatric with the fire ant had similarly rapid recruitment times.

The territorial behavior of the fire ant, in combination with the other characteristics that enhance its competitiveness, has permitted this exotic ant to become widely established in the United States. In areas that can support high numbers of fire ants, territories abut each other, and they continuously shift over time to compensate for changes in prey availability (some of which might be caused by predation by the fire ant). The fire ant's offensive, defensive, and foraging capabilities in such conditions have displaced native ant species, but, on the other hand, the fire ant, because of the same characteristics, has emerged as the key predator of some economically important pests, including the boll weevil, *Anthonomus grandis grandis* Boheman, in parts of Texas, and the sugarcane borer, *Diatraea saccharalis* (F.), in Louisiana.

Redlegged Grasshopper, *Melanoplus femurrubrum* (Degeer) (Orthoptera: Acrididae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

The redlegged grasshopper is known from nearly all of the United States and southern Canada, and its distribution also extends south through most of Mexico. In portions of the southeastern USA, on the coastal plain from eastern North Carolina to southern Mississippi and Louisiana, and including all of Florida, it is replaced by a very similar form, *M. propinquus* Scudder, which appears to be a separate species. These are native insects.

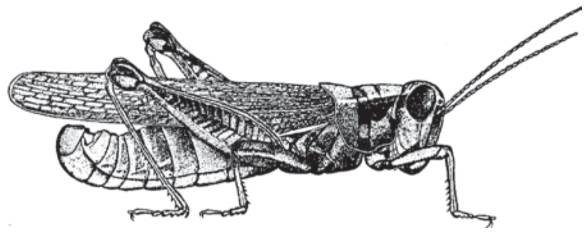
Life History

There is one generation per year throughout the range of these species, with the egg stage overwintering. Eggs hatch in late spring and adults are present from July until they are killed by heavy frost. The following information is derived from studies of *M. femurrubrum*, but likely applies equally well to *M. propinquus*.

The eggs are elongate-cylindrical in shape, and widest at the middle. They measure 4.1–4.6 mm in length and 0.9–1.5 mm in diameter. Their color is yellowish brown or creamy white. The eggs are deposited in structures called pods, which consist of two columns of eggs arranged in parallel rows. The pod, which is secreted by the female during oviposition, consists of frothy material secreted between, and covering, the eggs. The pod is a curved cylinder in form, and measures about 20–25 mm in length and 3–5 mm in diameter. It is buried in the soil, and normally contains 20–26 eggs per pod. The upper portion of the pod consists solely of froth, and the young grasshoppers chew their way through this material to escape from the soil. Eggs are often deposited among the roots of grasses and weeds, particularly along the edges of crop fields. The female can produce 300 eggs during its lifetime. These are not early-season grasshoppers. Hatching occurs about 3 weeks after hatching of twostriped grasshopper, *Melanoplus bivittatus* (Say), 2 weeks after migratory grasshopper, *Melanoplus sanguinipes* (Fabricius), and about the same time as differential grasshopper, *Melanoplus differentialis* (Thomas), with which redlegged grasshopper may co-occur. The period of hatching is extended, however, so nymphs can be found during most of the summer.

Development of the nymphal stage normally requires about 40 days, during which there usually are five to six instars. Throughout their development they are yellowish in color, but marked with a broad black stripe that extends across the face, eyes and prothorax, and onto the abdomen. They also bear a second, less discrete black stripe that is below, but parallel to, the aforementioned stripe, and that arches across the lateral lobe of the prothorax. The outer face of the femora are marked with a broad black stripe. The underside is yellowish. The hind tibiae are yellow or gray, and bear black spines. The overall body length of nymphs is 4–5.6, 6.2–7.2, 7.4–9.7, 10–15.5, and 16.5–22.5 mm for instars 1–5, respectively. Antennal segment numbers increase from 12–14 to 15–16, 17–19, 22–24, and 24–26 in the corresponding instars. In Virginia, total nymphal development times for grasshoppers displaying a total of six instars averaged 67, 42, 31, and 29 days when cultured at 26.5, 30, 35, and 38°C, respectively. Nymphs developing through seven instars required 5–10 additional days, depending on the rearing temperature. Mean instar development time was reported to be 3.6, 4.1, 4.7, 5.0, 5.8, and 7.9 days for instars 1–6 when cultured at 35°C, an optimal temperature. Nymphs change their behavior in response to temperature, with feeding commencing at 20–24°C, and nymphs moving to elevated perches to escape the heat when the air temperature or soil temperature gets high. Like most grasshoppers, they tend to remain inactive, even at high temperatures, in the absence of sunlight.

The adults are medium-sized grasshoppers, the males measuring 17–23 mm in length, and the females 18–27 mm (Fig. 9). They are reddish brown or grayish brown dorsally and yellow or yellowish green ventrally. The forewings lack distinct markings; the hind wings are colorless. The lateral lobe of the pronotum is usually marked with a distinct black area. The outer face of the hind femora is yellowish but bears an indistinct dark stripe. The hind tibiae are almost always



Redlegged Grasshopper, *Melanoplus femurrubrum* (Degeer) (Orthoptera: Acrididae), Figure 9 Adult male of redlegged grasshopper, *Melanoplus femurrubrum* (DeGeer).

deep red with black spines, and are the basis for the common name of these grasshoppers. In the male, the tip of the abdomen is rather bulbous, with the subgenital plate bearing a broad U-shaped depression apically. The cerci narrow rapidly from the base, with the distal third narrow and the tip either angled (*M. femurrubrum*) or rounded (*M. propinquus*).

The males, but not the females, of these two species are easily separated by the genitalia. In *M. femurrubrum*, the cerci are flattened at the tip, forming an acute angle dorsally. The cerci at the midpoint are relatively broad, about one-half the maximum width at the base. The furcula in this species diverge from the base and then converge distally, the space between the arms of the furcula forming a "U." In contrast, in *M. propinquus* the tips of the cerci are rounded, and the cerci are relatively narrow at the midpoint, about one-third the maximum width at the base. The furcula diverge more strongly, the space between the arms forming a "V."

Adults normally roost at night on the tops of tall grasses and weeds. Early in the morning they crawl down the plant and resume feeding when the air temperature warms, often moving along the soil in search of food. As is the case with nymphs, the adults ascend vegetation to escape high temperatures. In the evening they perch again on elevated roosts where they remain until they are warmed by sunlight in the morning. Females have a preoviposition period of 9–15 days before they commence egg laying. Redlegged grasshopper is a fairly strong flier and can fly 10 m if disturbed.

These species are polyphagous, feeding on a broad range of plants and apparently preferring a dietary mixture over a single food plant, and broadleaf plants over grasses. The preferred habitat is tall vegetation in pastures, fence rows, along irrigation ditches and roadways, and in fallow agricultural fields which have become weedy. The redlegged grasshoppers are known throughout North America for damage to crops, attacking alfalfa, barley, birdsfoot trefoil, clover, corn, lespedeza, oat, orchardgrass, soybean, timothy, tobacco, and vetch in addition to vegetables. Among the uncultivated plants eaten are aster, *Aster* spp.; Kentucky bluegrass, *Poa pratensis*; brown knapweed, *Centaurea jacea*; cinquefoil, *Potentilla argentea*; dandelion, *Taraxacum officinale*; fleabane, *Erigeron divergens*; goldenrod, *Solidago canadensis*; kochia, *Kochia scoparia*; Russian thistle, *Salsola kali*; smooth brome, *Bromus inermis*; sweet clover, *Melilotus officinalis*; wavyleaf thistle, *Cirsium undulatum*; western ragweed, *Ambrosia psilostachya*; and likely many others. The weeds fed upon most frequently in North Dakota alfalfa fields were reported to be kochia, *Kochia scoparia*; field bindweed, *Convolvulus arvensis*; awnless bromegrass, *Bromis inermis*; and foxtail, *Setaria* spp. On prairie, redlegged grasshopper ate primarily Kentucky bluegrass, *Poa pratensis*; western ragweed, *Ambrosia psilostachya*; golden aster, *Chrysopsis villosa*; tansy mustard, *Descurainia sophia*; and leadplant, *Amorpha canescens*.

Like most grasshoppers, redlegged grasshopper is favored by hot weather. Long-term periods of drought and hot weather favor population increase, especially in northern areas that normally are cooler. A certain amount of precipitation is necessary to provide adequate food for the grasshoppers, of course, but prolonged cool, wet weather, especially during the period of egg hatch, is detrimental for grasshopper survival. The late onset of winter can favor grasshopper population increase because it allows adults additional time to produce eggs.

Damage

Redlegged grasshopper is a defoliator, often removing all leaf tissue and leaving only plant stems. Lower densities leave plants ragged or tattered. Redlegged grasshopper is a common component of the grasshopper complex that affects plants growing along the margins of fields, though only causing extensive damage during periods of very high density. Redlegged grasshopper is capable of developing high densities and migratory tendencies during periods of drought, and may be found mixed into swarms of migratory grasshopper, *Melanoplus sanguinipes* (Fabricius).

Management

Liquid formulations of insecticides are commonly applied to foliage to protect against damage. Because grasshoppers rarely develop in crops, but instead invade from weedy areas, it is often the edges of crop fields that are most injured. Therefore, application of insecticide to the borders of crop fields is often adequate to protect an entire field. It is even better to apply insecticides to the developing grasshopper populations in weedy areas before they move to crops. This not only minimizes damage to crop plants, but often results in younger grasshoppers being targeted for elimination. Younger grasshoppers are more susceptible to insecticides, with large nymphs and adults sometimes difficult to kill.

Application of insecticide-treated bait is an effective alternative to foliar treatments for *Melanoplus* spp. because these grasshoppers spend considerable time on the soil where they come into contact with baits. Bait formulations are bulky and more difficult to apply than liquid products, so they are less often used, but have the advantage of limiting exposure of crops to insecticide residue and of minimizing mortality of beneficial insects such as predators and parasitoids due to insecticide exposure. Also, the total amount of insecticide active ingredient necessary to obtain control is usually considerably less when applied by bait because the grasshoppers actively seek out and ingest the toxin. Finally, for relatively expensive products that must be ingested to be effective, such as microbial insecticides, baits are the most effective delivery system.

The attractant used most commonly for grasshopper bait is flaky wheat bran, though other products such as rolled oats are sometimes suggested. No additives, other than insecticide (usually 5% active ingredient), are necessary because the wheat bran alone is quite attractive to *Melanoplus* grasshoppers. Other additives such as sawdust, water, vegetable or mineral oil, molasses, amyl acetate, salt, or sugar have been suggested, but provide little or no additional benefit over dry bran. The bait should be broadcast widely to maximize the likelihood of grasshopper contact, and should be applied while grasshoppers are in the late instars because adults ingest less bait.

Elimination of weeds within, and adjacent to, crops is the most important cultural practice, and can have material benefit in preventing damage to crop borders. However, during periods of weather when grasshoppers become numerous they may move long distances and invade crops.

Tillage is an effective practice for destruction of eggs. Deep tillage and burial are required, shallow tillage having little effect. All the crop-feeding *Melanoplus* species deposit some eggs in crop fields, especially during periods of abundance, but it is fence row, irrigation ditch, field edge, and roadside areas that tend to be the favorite oviposition sites, so tillage is not entirely satisfactory unless other steps are taken to eliminate grasshopper egg pods from these areas that cannot be tilled. Though providing suppressive effects, deep tillage is not consistent with the soil and water management practices in many areas, so may not be a good option.

Row covers, netting, and similar physical barriers can provide protection against grasshoppers. This approach obviously is limited to small plantings, and can interfere with pollination. Also, grasshoppers are capable of chewing through all except metal screening, so this approach does not guarantee complete protection.

The opportunities for biological control are limited. The microsporidian pathogen *Nosema locustae* is well studied as a microbial control agent of *Melanoplus* spp. and is available commercially. It is fairly stable, and easily disseminated to grasshoppers on bait. However, its usefulness is severely limited by the long period of time that is required to induce mortality and reduction in feeding and fecundity. Also, the level of mortality induced by consumption of *Nosema* is quite low, often imperceptible. It is best used over very large areas, not just on individual farms, and should be applied at least one year in advance of the development of potentially damaging populations.

Fungi have also been investigated for grasshopper suppression. A grasshopper strain of *Beauveria bassiana* has been effective in some trials, and *Metarhizium anisopliae* var. *acridum* has worked well for grasshopper and locust suppression in Africa and Australia, so it may prove useful for *Melanoplus* spp. Behavioral thermoregulation by grasshoppers, wherein they bask in the sun and raise their body temperatures, is potentially a limiting factor for use of fungi. Basking grasshoppers easily attain temperatures in excess of 35°C; such high temperatures decrease or even prevent disease development in infected grasshoppers. Inconsistent quality control in production of fungi also limits use of these organisms for grasshopper control.

Red Palm Mite, *Raoiella indica* Hirst (Acari: Prostigmata: Tenuipalpidae)

JORGE E. PEÑA[1], CATHARINE M. MANNION[1], F. WILLIAM HOWARD[2], MARJORIE A. HOY[3]
[1]University of Florida, Homestead, FL, USA
[2]University of Florida, Ft. Lauderdale, FL, USA
[3]University of Florida, Gainesville, FL, USA

The red palm mite, *Raoiella indica* is a serious pest of coconuts, date palms and other palm species, as well as a pest of bananas, in different parts of the world (Table 4). It is also known as the coconut mite, coconut red mite, red date palm mite, leaflet false spider mite, frond crimson mite, or scarlet mite. It has long been known from southern Asia and portions of the Middle East, including India, Philippines, Mauritius, Reunion, Malaysia, Israel and Egypt. Recently it became established in the Western Hemisphere in the Leeward Islands of the Caribbean and in Florida, where it is infesting palms, banana, ginger, bird of paradise and other plants within the Musaceae. Palms are the principal host. It has now moved to South America and likely will be widespread in most of the Neotropics before long.

Description of Stages

Adult female red palm mites are red, typically with dark patches on the body dorsolaterally, and about 0.32 mm long. Males are smaller than females and taper to a point posteriorly, giving them a triangular shape. Females are more oval. Dorsal setae are present on both sexes. The body of the red palm mite does not have a striae. The first pair of dorsocentral hysterosomal setae is longer than the others; the fourth pair of dorsosublateral setae is shorter than the first pair. All dorsal body setae are slightly clublike and serrate. The larvae are reddish and sluggish. The minute eggs (0.09 mm × 0.12 mm) are oblong smooth and red in patches of 100–300, and attached to the abaxial (lower) leaf surface by a slender stalk.

Life Cycle

Under laboratory conditions, at temperatures between 24 and 26°C and 60% RH, females completed their development in 24.5 days and males in 20.6 days; adult longevity was 50.9 days for females and 21.6 days for males. Fertilized females produced an average of 22 eggs and virgin females 18.4 eggs. In Mauritius, the preoviposition period is 3 days in summer and 7 days during the winter. Females lay an average of 2 eggs per day over an average oviposition period of 27 days for a total of about 50 eggs per female. The time for development of each life stage is: egg, 6.1–6.5 days; larva, 5.7–9.5 days; protonymph, 5.4–6.5 days; and deutonymph, 4.1–10.5 days. The time required to complete the life cycle is 21–33 days. Developmental ranges are influenced by temperature, RH and host plant.

Seasonality

These mites are generally abundant in Mauritius on coconut from September to March, except when heavy rains occur during November and January. Starting in April, there is normally a decline in populations, which continues through August. In the summer, the plants appear sickly and yellowish, a condition that may be the combined result of mite feeding and dry season conditions. Population increase is positively correlated with leaf moisture, crude protein and nitrogen levels in leaves in different coconut varieties.

Dispersal

Raoiella indica disperses by wind currents and transport of infested plants or leaves. One of the most common ways of dispersal is through human activity in tourist areas where persons will come in contact with ornamental palms.

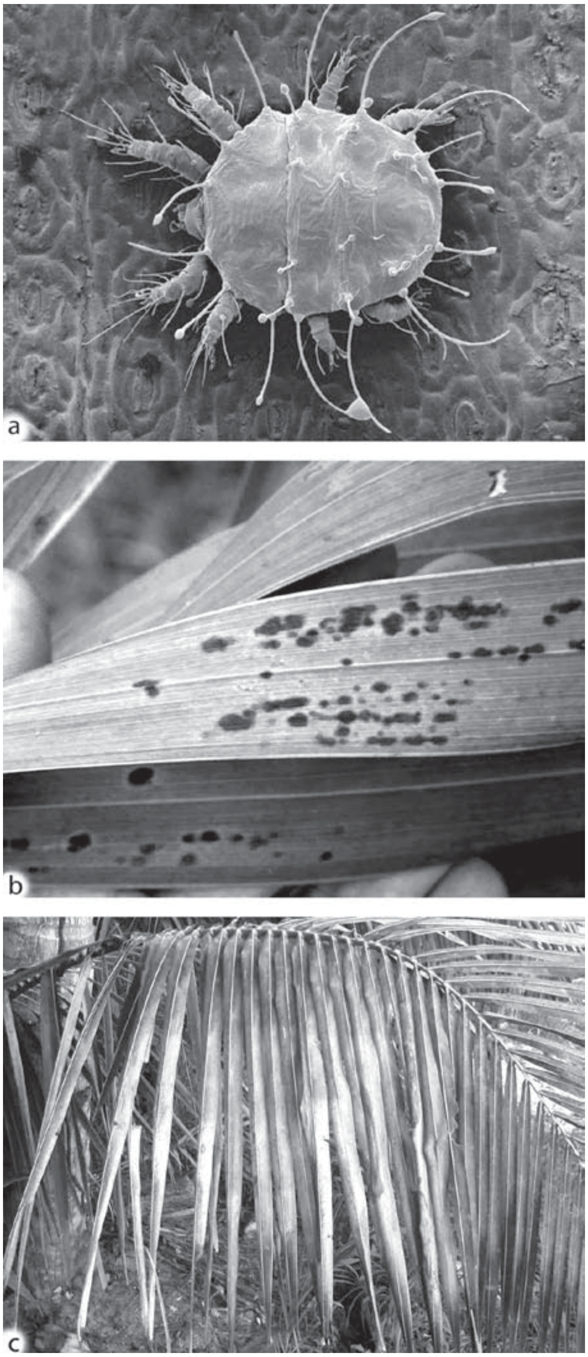
Damage

Raoiella indica lives on abaxial surfaces of coconut leaves. A higher number of mites tend to occur on the lower leaves. Mites are located in groups ranging in number from 20 to 300 individuals (eggs, larvae, protonymphs and deutonymphs). There is no data regarding within-plant distribution in other host plants. Young coconut palms are most severely injured, but mature plants also are damaged.

Extensive yellowing of lower leaves may be symptomatic of either red palm mite feeding, or any of several pests or diseases of palms and other arborescent monocots. For example, red palm mite damage has sometimes been misdiagnosed in the field as lethal yellowing, a highly prevalent disease of palms in southern Florida and various countries of the Caribbean Basin. Like the effects of red palm mite feeding, lethal yellowing infection results in extensive chlorosis of the lower leaves. However, in a very early stage of lethal yellowing disease, the emerging inflorescences become distorted and the male flowers, normally of an ivory, yellow, or orange color depending on variety, turn brown, and the coconuts of all stages of development drop from the tree. Of course, a key symptom that distinguishes red palm mite damage (Fig. 10) from lethal yellowing is the presence of dense populations of a red mite visible with the naked eye on the abaxial surfaces of older foliage. The exuviae (cuticle tissue discarded at molting) of red palm mites may be present as scaly patches on the leaf surface.

Chemical Control

Current knowledge of the effectiveness of chemical control of the red palm mite is based mostly on research in India and the Middle East. In the Middle East, insecticide applications are used in



Red Palm Mite, *Raoiella indica* Hirst (Acari: Prostigmata: Tenuipalpidae), Figure 10 **Red palm mite and damage: (a) Scanning electron microscope photograph of red palm mite (photo by Eric Erbe and Chris Pooley, USDA-ARS); (b) Spotting of coconut foliage caused by red palm mite (photo by J. E. Peña); (c) Bronzing of coconut foliage caused by red palm mite (photo by J. E. Peña).**

cases of high density of the mite when it is affecting date palm. In India, the application of neem oil sprays mixed with sulfur after a thorough cleaning of the coconut crown showed good results. The extract is sprayed from above, 5–6 times per year, and is possible with a sprayer-head attached to a long pole. The application of neem resulted in a yield increase of 25%. Parathion causes a decrease in mite density 14 days after application, followed by an increase of the mite population. Several systemic insecticides exhibited toxicity to the larvae, nymphs and adults. Phosphamidon was considered slightly superior to monocrotophos, dimethoate, formothion and demeton-methyl. However, these products are not registered to be used in coconuts or bananas everywhere.

Chemical control of other Tenuipalpidae in crops such as citrus have shown that in combination with petroleum oil, insecticides such as pyridaben, fenbutatin-oxide, dicofol or high rates of sulfur provided at least 35 days of control. Abamectin and emamectin can be used to control larvae, nymphs and adults of *Brevipalpus phoenicis*. However, abamectin was found to be slightly and moderately noxious to predacious mites, while emamectin was shown to be innocuous and slightly noxious to phytoseiids.

Natural Enemies

In India, during a survey for the indigenous predators, several predators were discovered preying on *R. indica*. The phytoseiid mite, *Amblyseius channabasavanni* and lady beetle, *Stethorus keralicus* Kapur (Coleoptera: Coccinellidae) were considered to be the most important predatory species. *S. kerlaicus* was observed feeding throughout the year on *R. indica* infesting coconut and areca palms in India. In the United Arab Emirates, there is natural control for the scarlet mite, but the natural enemies responsible for this control apparently are unknown. *A. channabasavanni* females effectively consume eggs and females of *R. indica*. Alternate food sources in the field include *Tetranychus fijiensis*, eggs and crawlers of scale insects and mealybugs that infest arecanut leaves. The field population of the predator is highest during May through June when *R. indica* populations are at their peak.

In Mauritius, the principal predator of *R. indica* in coconut plantations was *Typhlodromus caudatus* Chant (*Amblyseius caudatus* Berlese). The life cycle of this mite within a range of temperatures from 18 to 24.3°C required 15 to 6 days, respectively. Nymphs and adults of this phytoseiid can consume an average of 10.6 eggs per day and a total of 493 eggs during their active life cycle. In India, *Amblyseius longispinus* (=*Neoseiulus longispinus* Evans 1952) (Acari: Phytoseiidae) and *Stethorus parcempunctatus* and *Jauravia* sp. (Coleoptera: Coccinellidae) are important natural enemies in the area of Karnanka, while in the area of Kerala the prevalent predators are *A. channabasavannai* and *Stethorus tetranychi* Kapur. In India, *Amblyseius raoiellis* also is known to prey on *R. indica*. Nothing is known about the biology of this species. A related mite, *Amblyseius near raoiellis* has been collected in lime and mango in southern Florida fruits infested with *Brevipalpus phoenicis*. The predaceous mite *Neoseiulus longispinosus* (Evans), an old world species, was observed preying on *R. indica* in Saint Lucia. Other natural enemies reported preying on *R. indica* in the Caribbean are *Amblyseius largoensis* (Phytoseiidae), *Armascirus taurus* (Kraemer) (Cunaxidae) and *Telsimia ephippiger* Chapin (Coccinellidae: Coleoptera).

A small portion of *R. indica* mites have been observed to be infected by a fungus, possibly, *Hirsutella* spp. The tenuipalpid *Brevipalpus phoenicis* can be infected by some isolates of *Hirsutella thompsoni*.

Red Palm Weevil, *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae)

ABDULAZIZ M. AL-AJLAN
King Faisal University, Hofuf, Al-Hasa, Saudi Arabia

Date palm, *Phoenix dactylifera* L. (Palmales: Palmae), is one of the oldest fruit trees in the world and is mentioned in the Qur'an and the Bible. There are approximately 100 million date palms worldwide, of which 62 million can be found in the Arab region. The origin of the date palm is uncertain. Some claim that the date palm first originated in Babel, Iraq, while others believe that it originated in Dareen or Hofuf, Saudi Arabia, or Harqan, an island on the Arabian Gulf in Bahrain.

The date palm is a perennial and can live about 150 years. The female date palm normally begins to bear dates within an average of five years from the time of planting of the offshoot. The Middle East and North Africa are the major date palm producing areas of the world.

The red palm weevil, *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae), is the most dangerous and deadly pest of the date palm, as well as coconut, palm oil, sago and 13 other palm species.

Information on red palm weevil was first published in 1891 in India. This pest was first described as a serious pest of the coconut palm in 1906, while in 1917 it was described as a serious pest of the date palm in the Punjab, India. In 1918, red palm weevil caused serious damage to the date palm in Mesopotamia (Iraq), but no insect specimens were collected to confirm it. Red palm weevil entered and was discovered during the mid-1980s in the Arabian Gulf countries. However, it has become a most destructive pest of date palms in the Middle East.

Distribution of Red Palm Weevil

The red palm weevil occurs in the following countries: Bahrain, Bangladesh, Burma, Cambodia, China, Cyprus, Egypt, France, Greece, India, Indonesia, Iran, Iraq, Israel, Italy and Sicily, Japan, Jordan, Kuwait, Laos, Myanmar, Oman, Pakistan, Palestine, Philippines, Qatar, Saudi Arabia, Singapore, Spain, Sri Lanka, Syria, Taiwan, Thailand, Turkey, United Arab Emirates, Vietnam, and in Oceania: Papua New Guinea, Solomon Islands, Western Samoa.

Life Cycle

All stages (egg, larva, pupa and adult) are spent inside the palm itself and the life cycle cannot be completed elsewhere. The female deposits about 300 eggs in separate holes or injuries on the palm. Eggs hatch in 2–5 days into legless grubs, which bore into the interior of the palm, moving by peristaltic muscular contractions of the body and feeding on the soft succulent tissues, discarding all fibrous material. The larval period varies from 1 to 3 months. The grubs pupate in elongate oval, cylindrical cocoons made out of fibrous strands. At the end of the 14–21-day pupation period, the adult weevils emerge. Thus, the life cycle is about 4 months.

All kinds of palms are probably suitable for the development of the red palm weevil, which has been found on the following palms: coconut palm, date palm, nigbong palm, ornamental palm, palm oil, palmyra palm, royal palm, sago palm, sedang palm, sugar palm, talipot palm, and the wild date (toddy) palm.

Eggs

The eggs are creamy white in color, long and oval in shape. The average size of an egg is 2.6 mm long and 1.1 mm wide.

Larva (grub)

The full-grown larva is conical in shape and is a legless fleshy grub. It appears yellowish brown, while the newly hatched larva is yellowish white in color, with a brown head. The length of the full-grown larva is 50 mm and the width is 20 mm. The head is brown in color and bent downwards. Mouthparts are well developed and strongly chitinized, which enables the grub to burrow into the trunk. However, the grub requires a moist environment.

Cocoon

When about to pupate, the larva constructs a cocoon of fibers from the palm. The cocoon is oval in shape, with an average length of 60 mm and a width of 30 mm.

Pupa

The pupa is at first cream colored but later turns brown. The head is bent ventrally, the rostrum reaching the tibiae of the first pair of legs. The antennae and eyes are quite prominent. The elytra and wings are brought down ventrally, passing underneath the femora and tibiae of the second pair of legs, overlapping the third pair of legs and meeting in the middle of the abdomen. The average length of the pupa is 35 mm and the width is 15 mm.

Adult

The adult weevil is a reddish brown cylinder with a long prominent curved snout. It varies considerably in size and is about 35 mm in length and 12 mm in width. The head and rostrum comprise about one third of the total length (Fig. 11).

The mouthparts are elongated in the form of a slender snout or rostrum, which bears a small pair of biting jaws at the end and a pair of antennae near the base. The rostrum is reddish brown dorsally, and ventrally it is dark brown. In the male, the dorsal apical half of the snout is covered with a pad of short brownish hairs; the snout of the female is bare, more slender, curved and a little longer. The antennae consist of the scape and funicle. The eyes are black and separated on both sides of the base of the rostrum.

The pronotum is reddish brown in color and has a few black spots. These black spots are variable in shape, size and number. The elytra are dark red, strongly ribbed longitudinally, and do not cover the abdomen completely. The wings are brown in color and the weevils are capable of strong flight.

The male weevil has a tuft of soft reddish brown hairs along the dorsal aspect of the snout; this tuft is absent in the female. Also, the male produces an aggregation pheromone "ferrugineol" and/or "ferrolure" (4-methyl-5-nonanol), which is a synthetic lure used in the pheromone bucket traps.

Red Palm Weevil, *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae), Figure 11 **Red palm weevil, *Rhynchophorus ferrugineus*, life cycle: larvae, cocoon, pupa, adult.**

Economic Importance and Damage

Normally, the red palm weevil infests palms below the age of 20 years, where the stem of the young palm is soft, juicy and easily penetrated. The weevils are destructive pests to palms.

The larvae are responsible for damaging the palm, and once they have gained access, the death of the palm generally ensues. The larvae normally never come to the surface, since they begin life inside the palm. Therefore, neither the damage nor the larvae can be seen. However, the trunk of the palm can be infested in any part, including the crown.

The damage caused by only a few larvae is astonishing. Even one larva may cause considerable damage for a young palm (offshoot). It is difficult to assess the actual loss caused by this pest, but undoubtedly it affects the production of date palms.

Methods of Control

Integrated Pest Management (IPM)

Because the red palm weevil is difficult to control with just one method, several combinations of control methods should be applied as follows:

Plant Quarantine

The transport of offshoots as planting material from infested areas can contribute to the spread of the pest. Strict quarantine at international and national levels should be applied.

Cultural Control

Field sanitation and cultural practices are some of the important components to prevent weevil infestation.

- Clean the crowns of the palms periodically to prevent decaying of organic debris in leaf axils
- Avoid cuts and injuries
- When green leaves are cut, cut them at 120 cm away from the base
- Cutting of steps in palms for easy climbing is to be avoided, as this provides sites for egg laying by weevils
- As palms affected by leaf rot and bud rot diseases are more prone to weevil infestation, they are to be treated with suitable fungicides; after that, application of an insecticide to prevent egg laying by weevils is essential
- Destroy all dead palms harboring the pest by cutting and burning

Mechanical Control

Dead palms or palms beyond recovery should be split open to expose the different stages of the pest present inside. The debris, including the outer logs and the crowns, should be burned.

Trapping Weevils

Trapping and destroying the weevils is another method to control the pest population. Trapping also is used to detect the presence of the pest in the field and also to assess the population.

The aggregation pheromone lure of red palm weevil is used to attract the weevils to the bucket traps which contain pieces of palm stem as food and a solution of insecticide.

Biological Control

No effective biological agent has been found that can be employed for the biological control of the pest.

Chemical Control

The wounds produced on palms due to cultural practices as well as anther wounds are favorite sites of oviposition by the female weevils. Treatment of such wounds by soaking them with insecticides can be an effective way to prevent red palm weevil entry into palms.

Once infestation is detected in a palm, curative control must be applied. If the infestation is in the crown, remove the affected and damaged portions and apply insecticide suspension. In case of infestation in the trunk, the infested part should be cleaned and plugged with a mixture of mud and insecticide.

Several insecticides under laboratory and field conditions are tested in order to evaluate the best insecticide that will affect the different stages of the weevil.

Training and Education

The cooperation of the farmer is essential in order to successfully implement weevil management. For any large-scale pest management program to succeed, it is imperative that farmers cooperate and become involved at the operational level. This can be achieved by making farmers aware of the seriousness of the problem and training them in various IPM skills.

Reed, Walter

Reed was born on September 13, 1851, in Belroi, Virginia, USA. Initially, he studied classics at the University of Virginia, but soon became interested in medicine and graduated as a doctor of medicine in 1869 at the age of 18. He then obtained a second degree at Bellevue Medical College in New York and held several hospital posts as a physician. By 1875, however, he elected to join the military and was commissioned a first lieutenant in the Army Medical Corps.

Reed married in 1876 and transferred to Fort Lowell in Arizona. For 18 years he moved from station to station on the western frontier, but in 1889 he was appointed attending surgeon and examiner of recruits at Baltimore, Maryland. Here he gained access to Johns Hopkins Hospital, and was able to enroll in courses in pathology and bacteriology. In 1893, he was appointed a major in the Medical Corps. In 1898, he was appointed chairman of a committee to investigate the spread of typhoid fever in military camps, which he found to be caused by contact and by flies, and this success led to his interest in the problem of yellow fever.

Yellow fever, which likely was introduced along with slaves from Africa, plagued the port cities of the western hemisphere in the nineteenth century. It was called "yellow jack" and was the most dreaded and deadly disease of the time. The epidemiology of this disease was unknown, but generally it was thought that the disease was spread on articles of bedding and clothing. However, in 1881 the Cuban physician Carlos Juan Finlay began to promote the idea that the disease was spread by mosquitoes. The role of mosquitoes remained unproven, even though the Italian bacteriologist Guiseppe Sanarelli claimed in 1896 that he had identified the causative organism, which he called *Bacillus icteroides*.

With the commencement of the Spanish-American War, there was concern about the health of American troops during the summer months when yellow fever was prevalent in Cuba. In 1900, Reed was deployed to Cuba, where he worked with Finlay and others to identify the cause of yellow fever. They quickly discarded the idea that it was caused by bacteria, and it would not be shown for another 20 years that a virus was involved. Finlay persisted in his belief that the mosquito *Aedes aegypti* was the vector, but there was no direct proof of its involvement. The research team agonized over using human subjects to assess the role of mosquitoes in yellow fever transmission because it was so deadly, so they decided to test their theories on themselves before subjecting others to exposure. After allowing for an incubation period for the virus (mosquitoes had to ingest the virus within three days of the patient becoming inoculated, and then required another 12 days before they could transmit the disease), they were able to accomplish transmission by mosquitoes. Unfortunately, some of the research team became ill and died, as did subsequent volunteers. They also demonstrated that dirty bedding and foul air were not implicated in spread of the disease.

It fell to others, particularly William Gorgas, to implement sanitation practices that eliminated mosquitoes and alleviated the threat of yellow fever transmission, but history awards Reed most of the credit for identifying the importance of mosquitoes. In truth, the idea that mosquitoes were involved was not a novel idea and did not originate with Reed. However, it was the team led by Reed that eventually established the relationship of mosquitoes to yellow fever, and stimulated the sanitation practices that would eventually largely eliminate the threat of yellow fever. For example, in 1901 only 18 people in Havana succumbed to yellow fever, whereas thousands had died in earlier years.

Major Reed returned to the USA and to great acclaim. He was awarded honorary degrees from Harvard University and the University of Michigan. Perhaps most significantly, the medical facility now known as the Walter Reed Army Medical Center was named in his honor. Walter Reed died on November 23, 1902, at Washington, DC, only two years after his stunning discoveries in Cuba.

Reflex Bleeding (Autohemorrhage)

IAN STOCKS
Clemson University, Clemson, SC, USA

Insects are organic chemists without equal among the terrestrial metazoa. Chemicals used by insects may be acquired by *de novo* synthesis (autogenously), or exogenously by dietary sequestration of secondary compounds from plants, insect prey, or parental transfer; they may even be appropriated from endosymbionts. Not surprisingly, insect defensive chemical ecology is a field of both great breadth and depth, and its study incorporates anatomy, ethology, physiology, development, phylogeny, and predator-prey and plant-insect ecology, and has been the focus of several extensive review articles. The biosynthetic pathways by which many insects come to possess their vast chemical inventory are increasingly well known, and many powerful experimental tools and techniques are available for analyzing compounds and their synthesis, such as gas chromatography, HPLC, NMR, mass spectroscopy, PCR, and radioisotope label tracking.

The manner in which insects present their defensive compounds is also diverse. For a chemical defense to function well, the insect needs to present to a potential attacker either a toxic chemical or some evidence that they contain a toxin of some kind. Ideally, this will happen before the prey insect is wounded or killed. Frequently, chemical defenses co-occur with aposematic coloration, and insects so protected often make no attempt at being inconspicuous while feeding or mating. Insects that defend themselves by actively presenting the toxic compound either by a device or behavior are known as "phanerotoxic." Reflex bleeding, or autohemorrhage, combines both elements into one physiological and behavioral phenomenon. The insect presents hemolymph, through integumental ruptures or specialized cuticular structures, compounds that are either chemically or mechanically repellent to the attacker.

A wide diversity of defense mechanisms has fallen, perhaps overly loosely, under the term reflex bleeding. Charles Hollande, in the early 1900s, was one of the first to bring order to the accumulating evidence of secretion-based defenses in insects. Even though his work was thorough and well illustrated, a number of phenomena that didn't strictly involve hemolymph were treated as reflex bleeding. While Cuenot (1894) was the first to use the term "reflex bleeding/blood" (saignée [saignement] réflexe), Hollande was the first to apply the term "autohemorrhage" (Autohémorrhée). Part of the terminological problem is due simply to the vast diversity of behaviors and physiologies possessed by insects; a single term is not likely to capture the defense response of both a stonefly and a meloid beetle. In some cases, such as in some sawflies and chrysomelids, the basic phenomenon will involve only glanduliferous products, regions where glandular products may mix with hemolymph upon release, or a genuine release of hemolymph through a deliberately made tear in the cuticle.

Thus far, only four, or possibly five (a questionable example from Lepidoptera), orders of insects contain taxa known to engage in reflex bleeding as a defense mechanism. Why the phenomenon has not evolved more often is a puzzle in its own right, but may be due partly to the fact that a series of anatomical, behavioral, and physiological processes are involved, and "coordinating" them into one phenomenon may not have happened often. Also, using hemolymph as a defense mechanism is metabolically expensive, and it is possible that hemolymph-mediated chemical defense represents an "evolutionary stage." In many groups where reflex bleeding is known, related lineages rely entirely upon glanduliferous secretions, perhaps reflecting evolution away from a defense method that includes the extravagance of hemolymph. Overall, the phenomenon might be more widespread but unrecognized, as indicated by the recent observation of bleeding in Cercropidae: Homoptera by Peck, discussed below.

Reflex Bleeding in Plecoptera

Experimental work on adults of the stonefly species *Pteronarcys proteus* Newman (Pteronarcidae) and *Peltoperla maria* Needham and Smith (Peltoperlidae) revealed that these species bleed from the intersegmental membrane of the coxo-trochanteral and tibio-femoral joints when disturbed. The liberated fluid is yellow-orange, contains hemocytes, spreads quickly, and coagulates quickly after contact with an attacker. Cursory chemical assays performed on the hemolymph for known defensive volatile compounds failed to identify any, and the hemolymph was not found to be distasteful to either ants or the investigator. When harassed by ants in experimental conditions, the stoneflies exuded hemolymph from the nearest affected leg. Hemolymph contact with ant mouthparts and antennae elicited a "head-plowing" behavior, presumably in an attempt to rid the body of hemolymph, wherein the ants plowed their heads into the substrate. This behavior actually enhanced coagulation rate and increased the spread of hemolymph over the body.

Defense is apparently achieved by the mechanical properties of coagulating blood, and perhaps also by the mode of delivery. In *Pteronarcys*, the hemolymph can be expelled so forcibly that it makes an audible popping sound, spraying fluid up to twenty-five centimeters. Even though the fluid was not repellent to mice, they were noticeably "startled" by the popping sound. The anatomical or physiological basis for autohemorrhage was not clarified, but is presumed to be increased hemolymph pressure that causes the intersegmental membrane to rupture.

Reflex Bleeding in Homoptera: Cercopidae

Reflex bleeding was recently reported from forty-two species of neotropical froghoppers in the tribes Tomaspidini and Ischnorhinini, adults of which were able to exude hemolymph from their pretarsal pads. The species examined had identifiable lines of weakness in the membrane of the pretarsal pad, and rupture along the lines of weakness was apparently caused by increased hemolymph pressure generated by contraction of the abdomen. No hemolymph was sprayed from the wound, which instead formed a globule maintained by surface tension. Staged encounters with predatory taxa such as ants (*Solenopsis* sp.), beetles (*Paederus* sp.), spiders (Agelenidae sp.), and anole lizards (*Anolis* sp.) failed to demonstrate any chemical or mechanical benefit to the cercopid from the reflex blood, and in almost all cases the froghoppers were acceptable prey. Autohemorrhage in this instance might serve as a startle mechanism that is functionally linked to the cercopid's tremendous jumping ability.

Reflex Bleeding in Lepidoptera

A baculovirus-induced pathology in *Heliconius himera* (Nymphalidae) was recently described as "reflex bleeding." Typical baculovirus-mediated pathology causes the caterpillar to liquefy. Viral genes encoding chitinases and proteases that are transcribed by the host cause the integument ruptures, which releases infective occlusion bodies (OB's) into the environment and makes them available for consumption by another host. In this case, the virus caused a slow release of OB's from hemolymph, delivered through cuticular spines after slight mechanical disruption, and was thus considered a type of reflex bleeding. Whether this phenomenon shares any of the main properties of reflex bleeding is open for debate, because rupture in this case is defensively moot, with the moribund insect apparently receiving nothing of defensive value from rupture.

Reflex Bleeding in Hymenoptera: Symphyta

Sawfly larvae are often protected by chemicals sequestered from their food, such as the terpenoids that diprionids and pergids regurgitate when harassed. This alone is an effective defense when multiplied by the dozens of nest-mates that may be feeding in an aggregation. However, only larvae from the tenthredinid subfamilies Allantinae, Blennocampinae, and Selandriinae are known to bleed reflexively when disturbed. *Athalia rosae* (L.) (turnip sawfly; Allantinae) is a well-studied model for the chemical, ecological, and anatomical attributes of reflex bleeding. Turnip sawflies and many other specialists sequester glucosinolates (e.g., sinalbin, siningrin, and glucobarbarin) from the cruciferous (Brassicaceae) plants on which they feed, and increase the concentration of these chemicals in their hemolymph well above that found in the leaves. The glucosinolates may be transferred unmodified through the pupal and into the imaginal stage. Experiments with *Myrmica rubra* worker ants and foraging yellowjacket *Vespula vulgaris* (L.) demonstrated that the reflex fluid significantly deterred predator foraging activity.

Experiments with species in the blennocampine tribe Phymatocerini led to the "easy bleeding-harmful hemolymph" hypotheses, which link the degree to which the integument is prone to rupture with the degree of hemolymph repellency, and remarkably good correlation was found between these variables. Scanning electron and light microscopy analysis showed that there was also a correlation between the density and distribution of "spider-like" microstructures and the propensity of the integument to rupture easily.

Reflex Bleeding in Coleoptera

Lampyridae

Lampyrids exude a sticky milky fluid from their elytra and pronotum when disturbed. There is clearly a mechanical-defensive role for the exudate, and staining and amino-acid analysis demonstrated that the fluid was identical in composition to the hemolymph. Lampyrids experimentally challenged by the ants *Pogonomyrmex badius* (Latreille) and *Crematogaster atkinsoni* (Wheeler) were able to reflex bleed repeatedly from regions proximate to the attacked area. The basis for the effectiveness appeared to be the coagulation mechanism, which developed quickly as the blood was smeared between the ants' mouthparts, legs, and antennae; affected ants immediately stopped their attack and engaged frantically in cleaning activities.

Light and electron microscopic examination of areas prone to bleeding, the elytral and pronotal margins and region around the antennal sockets, revealed that the bleeding sites are located in small, scattered, shallow depressions where the cuticle is very thin, and hydrostatic pressure seems to be responsible for forcing blood to rupture the integument. *Photinus pyralis* seems capable under experimental conditions of bleeding itself to death when repeatedly provoked. Further protection is provided by chemical constituents that impart a strong smell and repellent taste sufficient to deter many vertebrate predators. However, deterrence is not absolute and many invertebrate and some vertebrate predators will accept lampyrids as prey.

In a study of *Photinus* blood, steroid derivatives were found to be the major chemical repellent. These compounds, called lucibufagins, were shown by NMR and mass spectroscopic analysis to be similar to bufadienolides, previously known only from bufonid toads and some plants. Experimental manipulations with thrushes demonstrated that both whole *Photinus* specimens and extracts of lucibufagin applied to otherwise palatable *Tenebrio* larvae were rendered unacceptable. It is unlikely that *Photinus* synthesize lucibufagins *de novo*, because insects in general are unable to synthesize sterol rings, but instead modify existing cholesterol derivatives through additions to the backbone. *Photuris* sp. females are infamous "femmes fatales" that engage in aggressive mimicry with *Photinus* sp. males, which are able to synthesize lucibufagins. Male *Photinus* sp. respond to the flash signal of female *Photuris* sp., whereupon they are killed and eaten by the female. Females gain not only nutrients for egg provisioning, but also lucibufagins that enhance their defenses.

Lycidae

Lycids are related to lampyrids but do not appear to have the same mechanisms as lampyrids, even though they synthesize or sequester several toxic compounds. Many, such as *Metriorrhynchus rhipidius*, are aposematically colored species that feed openly in large aggregations on early summer flowers. Experiments suggest that lycids participate in an extensive Müllerian mimicry group, involving other families of beetles (e.g., Cerambycidae, Buprestidae, and Meloidae) and other insects (certain flies and moths). The basis for the mimicry is believed to revolve around offensive odorant and taste chemicals, such as substituted quinolines, dihydromatricariate, and 3-phenylpropanamide. The claim that lycids engage in reflex bleeding as part of the defense strategy is less clear than in other beetle families, because the liberated fluid was not unequivocally demonstrated to be hemolymph. The polyyne dihydromatricaria acid, a principal component of the fluid, is also produced by *Chauliognathus lecontei* Champion (Cantharidae), in which species it is released from dedicated defense glands and contains no hemolymph. Given that Cantharidae and Lycidae are thought to be closely related, it is open for debate whether the co-occurrence of dihydromatricaria is due to a genuine, and interesting, difference in delivery mechanism, or the result of a glandular secretion inadvertently contaminated during experimental analysis with hemolymph.

Chrysomelidae

Many of the chrysomelids examined to date contain a variety of compounds that are either toxic or repellent. Larval chrysomelids, which often feed in exposed locations, are particularly vulnerable to predators. Their defensive repertoire involves the sequestration and modification of cardiac glycosides (*Chrysolina*), steroid-derived cucurbitacins (Galerucinae), triterpene saponins (*Doryphorina*), and salicylaldehydes (larval *Chrysomelina*). They also autogenously synthesize pyrrolizidine alkaloid *N*-oxides (*Oreina* sp., *Platyphora* sp.), methylcyclopentanonid monoterpenes ("iridoids," *Chrysomelina*), and modified amino acid moieties of glucosides (adult *Chrysomelina*).

Defensive reflex bleeding by *Diabrotica undecimpunctata* Jac. (spotted cucumber beetle) larvae effectively deterred foraging *Solenopsis* sp. ants. Exudate, containing cucurbitacins, is produced from ruptures in the cervical and intersegmental membranes between the last two abdominal segments. The basis for defense, however, seems to be essentially mechanical. Attacking ants could become so entangled by the coagulating hemolymph that they perished, and experiments with mice demonstrated that they were non-toxic.

Larvae of the chrysomelid *Agelastica alni* (L.) (Galerucinae, Sermylini) reflexively bleeds a mixture of both hemolymph and exocrine glandular secretion. When molested, *Agelastica* larvae evert a cuticular sac-like structure that normally resides inside dorsolaterally located tubercles on abdominal segments 1–8. Examination of the exudate demonstrated that hemocytes were present. Examination of the structures at the blood release site showed that muscles and a glandular cell are associated with the cuticular sac.

The majority of chrysomelid species do not reflexively bleed but still sequester toxic or deterrent compounds in their hemolymph for permanent storage or as an intermediate step before delivery to specialized glands. Indeed, the line between hemolymph fluids that are reflexively bled or released under slight trauma can be thin, as illustrated previously by the "easy bleeding" Symphyta larvae. The phenomenon almost certainly is more widespread than currently recognized.

In chrysomelids, in particular, the distinction between purely glanduliferous secretions, reflex blood compounds, and other delivery modalities becomes complicated. Variation within the single subfamily Chrysomelinae is extensive, with reflex bleeding also known from buccal sites (e.g., *Timarcha* sp., in this species the fluid contains anthraquinones). Bleeding in this case appears to be partly contingent on the age of the adult insect and degree of membrane sclerotization.

Meloidae and Oedemeridae

Meloid beetles synthesize the primary defensive compound cantharidin (from Kantharos (Gr.) = beetle), and a tremendous amount of information on the biosynthetic and ecological aspects of cantharidin is available. Meloids share affinity with oedemerids and stenotrachelids, but oedemerids seem to be the only group other than meloids to synthesize cantharidin.

Use of "blister beetles" in folk medicine is ancient, and work with Meloidae began relatively early in the history of entomology. As early as 1810, pure cantharidin could be extracted from *Lytta vesicatoria* L. It was much later (1896) that reflex bleeding was first proposed as a putatively defensive phenomenon in *Meloe proscarabeus* L., which exudes an oily fluid from tibio-tarsal joints when disturbed.

Biosynthetic and ecological studies demonstrate that cantharidin synthesis forms a key component in an extensive ecological web of predator-prey interactions and courtship behavior. Cantharidin and cantharidin derivatives are synthesized endogenously by the condensation of three isoprenoid units to form the C_{15} sesquiterpene farnesol, followed by extensive degradation to yield the monoterpene anhydride. Cantharamides can also be extracted from meloids, wherein the anhydride oxygen is replaced by a basic amino-acid moiety. Palasonin, a cantharidin-like molecule, has also been isolated from meloids, clerids, and staphylinids, but previously had been known only from *Butea frondosa* Roxb. (Fabaceae). Palasonin is structurally similar to cantharidin, but experiments revealed that palasonin was not sequestered from the plant. The occurrence of cantharidin and palasonin in clerid and staphylinid beetles is believed to be due to the canthariphilous habits of many species in those families.

The bionomics of cantharidin synthesis of *Epicauta funebris* Horn (ebony blister beetle) from egg hatch through adulthood has been traced, and reveals that cantharidin has an important and complicated role in *E. funebris* biology. Triungulid larvae, which hatch from the egg with low cantharidin levels, gradually increase cantharidin concentrations 10^{-2} to 10 μg per individual over five instars. Cantharidin synthesis resumes only in imaginal males, wherein a so-called "cantharidin kidney" sequesters cantharidin in high quantities. Females, which quickly lose their endogenous supply of cantharidin, are "rearmed" during copulation as part of the males' spermatophore. Males replenish their supply after several days, and the females, depending on the species, may or may not pass significant amounts to the eggs.

Both larvae and adults are protected by cantharidin. Larvae store the chemical in the alimentary canal and regurgitate cantharidin in a milky, white fluid when disturbed. Adult males can store large quantities of cantharidin and synthesize several hundred milligrams per day. After 60–90 days they may possess >15 mg of cantharidin, or >20% of their dry body mass.

Reflexively bled cantharidin is broadly effective at deterring predators from an attack. *Pogonomyrmex occidentalis* (Cresson) ants quickly abandon an attack and the ants remove the beetle from the colony area while it is in a catalepsis. Ants and the predatory beetle *Calosoma prominens* (LeConte) engaged in cleansing behaviors in an attempt to remove the oil from their antennae and mandibles. Experiments with cantharidin extract revealed that cantharidin is a feeding deterrent at extremely low concentrations, making sugar water unpalatable to *Formica exsectoides* (Forel) ants at a concentration of 0.77×10^{-5} M.

Many species of insects actively seek cantharidin and incorporate it into one or more of their life-history traits, and some seem to use it as a proxy aggregation pheromone. However, most canthariphilous insects use cantharidin for their own protection or during and after courtship. Male *Schizotus pectinicornis* (L.) (Pyrochroidae) acquire dietary cantharidin in an unknown manner and transfer it to females during copulation. Females then transfer small amounts to the eggshells. *Neopyrochroa flabellata* (Fabricius) uses cantharidin during courtship, with males acquiring dietary cantharidin and advertising this fact to females during courtship displays. A frontal interocular cleft is used for cantharidin display, which, via secretion from a cephalic gland, is laced with previously ingested cantharidin. Females are able to gauge male quality by sampling from this cleft, and if they deem the male suitable, the female receives a large supply of cantharidin as part of his spermatophore. If they accept the mate, they distribute the cantharidin to their eggs, which become significantly protected from attack.

Coccinellidae

Coccinellid reflex bleeding, the ecological role that this behavior plays, and the pharmacological properties of the chemicals within the blood, are now well understood. The presence of hemocyte cells in reflex fluid has been documented in seven-spotted lady beetle, *Coccinella septempunctata* L., and the Mexican bean beetle, *Epilachna varivestis* Mulsant, and is presumably widespread in the family. Reflex bleeding in adults is restricted to the tibio-femoral joints (typically to the leg nearest the provocation) but continued attack will elicit autohemorrhage from other joints and prompt thanatosis. Many larvae possess extensively branched spines along their dorsum and can discharge blood from the tips of the spines when touched. For both larvae and adults, hemolymph functions as both a mechanical and chemical deterrent, and causes ants to frantically clean coagulating blood from their mouthparts, legs, and antennae. Larvae and adults were able to withstand a significant but undetermined amount of fluid loss and recover fully.

Epilachna varivestis hemolymph contains euphococcinine ($C_9H_{15}NO$), a homotropane alkaloid, which provides varying degrees of protection from attacking ants and spiders. Feeding tests with *Monomorium pharaonis* (L.) ants demonstrated that euphococcinine renders sugar solutions unpalatable at a concentration at 10^{-2} M, which is roughly equivalent to the concentration in reflex blood (−1.5 μg/mg body weight). *Hyperaspis trifurcata* Schaeffer larvae sequester unmodified carminic acid, which is produced by their prey, *Dactylopius* spp. (cochineal bugs) (Homoptera: Coccidae).

Coccinellids are also excellent alkaloid synthesizers, with an ever increasing list of alkaloid derivatives appearing in the literature. A curious example of chemical convergence between coccinellids and cantharids is that the coccinellid alkaloids precoccinelline (*C. septempunctata*) and hippodaminae (*Hippodamia convergens* Guérin-Méneville, convergent lady beetle) are also synthesized by *Chauliognathus pulchellus* (Macleay). The piperidine derivative 3-hydroxypiperidin-2-one appears to be an extremely potent component of *Harmonia axyridis* (multicolored Asian lady beetle) hemolymph, and is chemically similar to the venom of *Solenopsis invicta* (red imported fire ant).

A major group of defensive compounds are the lactone-derived class of "macrocyclic polyamines," a group so diverse within even one insect (*E. varivestis*) that it has been described as a type of "combinatorial chemistry." NMR experiments on pupal *E. varivestis* hemolymph revealed an entire class of previously unknown compounds that is based on cyclic oligomerization of five, six, or seven units of 10-(2-hydroxyethylamino) undecanoic acid. Synthesis of these molecules, named polyazamacrolides (PAML's), starts with L-alanine. The macrocyclic polyamines can reach massive ring sizes consisting of more than 98 members of the 5-, 6-, or

7-(2-hydroxyethylanino) alkanoic acids, each of which is incorporated randomly into the ring.

Evolution of Reflex Bleeding

Several considerations of evolutionary significance are raised by the phenomenon of reflex bleeding, whether the hemolymph released is laced with toxic compounds or not. As noted above, there may be an evolutionary "thin line" between integument that is disrupted easily by a probing predator and one that is predisposed to rupture by minimal force, perhaps provided by increased hemolymph pressure. An obviously maladaptive situation arises if the integument is so prone to rupture that any environmental insult results in a tear. Physical properties of the integument underlie the tendency to tear, but a hormonal or nervous interaction might allow the insect to limit rupture only to those circumstances where it would be beneficial.

Convergence seems to underlie the phenomenon of reflex bleeding from the leg. With the exception of the cercopids that bleed from the pretarsal pad membrane, the locus of rupture is the tibio-femoral joint (coccinellids, meloids, *Pteronarcys proteus*, *Peltoperla maria*). At least for coccinellids and meloids, reflex bleeding is linked with thanatosis, or feigning death. This behavior, with the legs pulled tightly in to the body, might have preceded integument rupture, in this case as one component in an exaptational suite of characters. A common thread in the published reports is the *expectation* that increased hemolymph pressure is responsible for tearing the leg intersegmental membrane, but such a mechanism is largely unverified. In the cases where morphological features suggestive of hemolymph-pressure mediated rupture do occur (e.g., Cercopidae), no other anatomical structures (such as accessory pulsatile organ or muscle) responsible for causing the increased pressure has been identified.

A second component, one nearly an *a priori* condition for reflex bleeding to be adaptive, is an efficient coagulation mechanism that reduces blood loss. Rapid coagulation is always associated with generalized reflex bleeding and is a non-trivial defense even in the absence of toxic compounds. Hemolymph-coagulating mechanisms in insects, coupled with integument repair (and wound repair in general) also may be involved in the exaptational puzzle that engendered the apparent repeated evolution of the phenomenon. The prophenol oxidase cascade is apparently a key physiological process. Another convergent phenomenon of an insect under attack is the ability to localize the hemorrhage to the region of insult, generalizing to more appendages or greater integument rupture only under relentless provocation. Because hemolymph is a metabolically expensive product and insects rely largely on hydrostatic integrity, minimizing fluid loss would be adaptive. At least in the case of the sawfly *Athalia rosae*, the larva can "suck" back the hemolymph that has bled.

An outstanding puzzle that also has received little attention in the literature is the mechanism employed by insects sequestering toxic chemicals to avoid autointoxication, especially those that circulate toxins in the hemolymph. For instance, cantharidin is a potent toxin that binds to protein phosphatase 2A, a metabolic constituent of all eukaryote cells. Presumably a mechanism prevents cantharidin from disrupting this system. A corollary to this question is similarly unanswered: what underlies the ability of a predator, or exploiter of the toxin as a resource, to avoid intoxication?

Perhaps most interesting is the evolution of an entire ecology involving the acquisition of the active compounds. Lampyrids, coccinellids, and especially meloids, participate in an extensive ecological economy where defensive compounds are the currency in demand. Insects with canthariphilous habits are known from four orders and six families, especially the beetle families Anthicidae and Pyrochroidae, and mirids in the genus *Hadronema* predominating. In many cases, cantharidin may serve as an aggregation pheromone, but why so many species would convergently use an obscure chemical with a restricted distribution in insects and no known plant origin is puzzling in its own right. Bryocorinae mirids are known to be "parasitic" on meloids, several species of which pierce the beetle's membranes and suck cantharidin-containing hemolymph. Other insects that are either predatory or parasitic on cantharidin-laden meloids are *Atrichopogon* midges (Ceratopogonidae) and *Pedilus* beetles (Pyrochroidae: Pedilinae).

Refuge (pl., refugia)

An area, usually untreated with insecticides, where insects can be preserved. This term usually is used in the context of preserving beneficial insects or pesticide susceptible insects.

Regeneration

Regrowth of a portion of the body (usually legs in arthropods) that has been lost through injury or autotomy (deliberate shedding of the body part).

Regenerative Cells

Cells found in the midgut that gradually grow and replace midgut cells that have been lost through age, wear, or other damage.

Regulated Area

An area into which, within which, and/or from which plants or animals, plant or animal products, or other regulated articles are subjected to regulatory measures in order to prevent introduction and/or spread of regulated pests.

Regulation of Sex Pheromone Production in Moths

ASHOK K. RAINA

U.S. Department of Agriculture, ARS, SRRC, FSTRU, New Orleans, LA, USA

Pheromones are chemicals secreted to the outside of the body to influence the behavior of other individuals, generally within the same species. Sex, aggregation and alarm are some of the common pheromones in insects. Sex pheromones are produced by individuals of one sex, to attract from a distance, members of the opposite sex for mating. On the other hand, contact sex pheromones present in some insects do not elucidate long range attraction, but help in keeping the pairs together thereby facilitating mating. Most species of moths are nocturnal in habit with all the essential activities confined to the dark period of the day. Communication between sexes is almost exclusively mediated through sex pheromones, usually released by the female.

It appears that attraction between sexes in moths had been observed as early as 1690. However, the first insect sex pheromone to be chemically identified was that of the female silkworm, *Bombyx mori*, in 1959. It took 20 years and 500,000 female abdomens to identify this pheromone. With introduction of analytical methods such as high pressure liquid chromatography, gas chromatography and combined gas chromatography and mass spectrometry, it is now possible to identify a pheromone from as few as 1–10 moths. Most moth pheromones consist of olefinic aldehydes, alcohols, or acetates with 10–20 carbon atoms and one or more sites of unsaturation. The pheromones may consist of a single compound, a specific blend of geometric isomers or a mixture of several components, produced in very small (nanogram) quantities in specialized glands or cells generally located on the telescoping ovipositor of the female. The act of releasing pheromones is commonly referred to as "calling."

Most lepidopteran sex pheromones are synthesized de novo from fatty acids corresponding in chain length, double bond position, and stereo chemistry to the type of pheromone produced. Biosynthesis of these acids takes place specifically in the pheromone gland rather than elsewhere in the insect. Typically, the starting material is an acetate that is converted to palmitic acid through fatty acid synthetase; however, preformed acids, such as oleic, linoleic, or linolenic acid, as well as amino acids, may be directly utilized by several species. Subsequent steps are controlled by two key enzyme systems: the microsomal β-oxidation, which results in limited chain shortening by two carbons, and a Δ 11 desaturase, which yields acids with unsaturation at the 11 to 12 position. In the corn earworm, *Helicoverpa zea*, Z-11-hexadecenal the major pheromone component (more than 90%), is produced by oxidation of the corresponding alcohol.

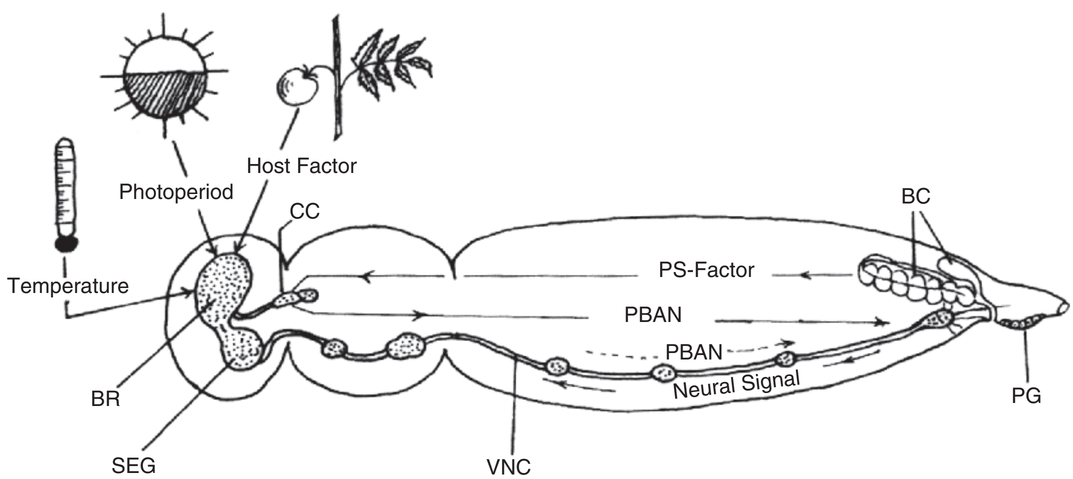
With sexual activity confined to a certain period of the 24-h day, there is no point in producing a pheromone when it is not needed. Therefore, photoperiod appears to be the major external factor regulating pheromone production in moths. This is particularly true of nocturnal species. However, as we will see later, there are other factors that can impact the regulation of pheromone production. We will use the corn earworm as a model to illustrate the intricacies of pheromone production. Corn earworm, like many moths is a nocturnal species. Sex pheromone is produced only during the night (average amount during peak production is ~100 ng), and females have negligible amounts of pheromone in their glands during the day. This diurnal periodicity of pheromone production is controlled by a peptide neurohormone. The hormone is produced in three groups of neurosecretory cells in the subesophageal ganglion and has been named the pheromone biosynthesis activating neuropeptide (PBAN). In the corn earworm and several other species of moths, PBAN is a 33 amino acid residue peptide. It is released into the hemolymph and activates pheromone production at the onset of scotophase. This was demonstrated by a simple bioassay which involved neck-ligating a female to stop pheromone production, followed by injection of either a homogenate of the brain-subesophageal ganglion, or synthetic PBAN into the abdomen of the ligated female. Pheromone titers were then determined by gas chromatography of the pheromone gland extract. One could also conduct the bioassay on a photophase female, without having to ligate it. However, in the gypsy moth the pheromonotropic signal is carried via the ventral nerve cord to the pheromone gland area to activate pheromone production.

The scenario presented for the corn earworm is not universal among moths. For example, species such as the black cutworm and oriental armyworm, which undertake seasonal migration, show delayed sexual maturation as well as delay in initiation of calling. It has been shown that juvenile hormone and PBAN are both involved in regulating pheromone production in these insects. The redbanded leafroller presents a rare case in which it is suggested that PBAN causes the release of a second factor from bursa copulatrix that stimulates pheromone production. In the cabbage looper, females maintain a high titer of pheromone during both day and night. The pheromone glands become competent to produce pheromone prior to adult eclosion and in response to reduction in ecdysone level. The subesophageal ganglion in this species contains PBAN-like pheromonotropic activity, but its exact role is not clear (Fig. 12).

Most neuropeptide hormones interact with surface receptors to activate second messengers which amplify the initial peptide-receptor signal. The second messengers may be small organic molecules such as cAMP, cGMP, ions such as calcium and hydrogen, or inositol phosphate. PBAN has been shown to increase intracellular cAMP levels, and calcium has been reported to be essential for mediating the pheromonotropic response. A G protein-coupled receptor from pheromone glands of *H. zea* was recently cloned. Genes encoding PBAN have been cloned from several insects. Besides PBAN, these genes carry sequences for four other peptides, including one for a diapause hormone.

The females of the corn earworm often mate on the first night after their emergence, and continue to mate throughout their short life, but only once each night. Pheromone production is terminated after mating and resumes during the following night. Continued production of pheromone after mating is a waste of resources and may cause disruption in egg laying, as the males will continue to be attracted to the female. A pheromonostatic peptide (PSP) which is transferred by the male to the female during mating, has been identified. Together with neural signals generated as a result of mating, PSP causes termination of pheromone production. In the corn earworm, pheromonostasis is temporary, and the female can produce pheromone on subsequent nights. However, termination of pheromone production is often permanent in species in which the female mates only once. An example of this is the gypsy moth. In this species, it is the presence of eupyrene sperm in the spermatheca of the female that is responsible for achieving pheromonostasis.

Another feature in the regulation of pheromone production is the role of host plants. First suggested almost 35 years ago, it was unequivocally demonstrated in 1988 in the corn earworm. Although the corn earworm is a polyphagous insect, it feeds primarily on fruiting parts of all of its hosts. The plant hormone ethylene, associated with fruit ripening, together with other volatile factors from host plants, were shown to induce pheromone production in females of wild or recently colonized corn earworms. This host-factor requirement is not



Regulation of Sex Pheromone Production in Moths, Figure 12 **Extrinsic and intrinsic factors regulating sex pheromone production in a female moth.**

very common among other species of moths, and in the corn earworm it was lost after prolonged laboratory rearing on artificial diet. In addition, temperature has been shown to play a modulating role in control of pheromone production. Thus, pheromone is not produced at very low or very high temperatures.

► Sex Attractant Pheromones
► Pheromones
► Juvenile Hormone

Regulations Affecting the Implementation of Regulatory Entomology Practices

CHRISTINA DEVORSHAK
USDA-APHIS-PPQ, Raleigh, NC, USA

Regulatory entomology is a specialized area within the scientific field of entomology dealing with laws, regulations and requirements aimed at protecting agriculture and the natural environment from pests. Such laws, regulations and requirements may be implemented at all levels of government including local, state, national and international levels. In the United States, the federal government agency that is primarily responsible for implementing such regulations and requirements is the United States Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) Plant Protection and Quarantine (PPQ). PPQ "safeguards agriculture and natural resources from the risks associated with the entry, establishment, or spread of animal and plant pests and noxious weeds to ensure an abundant, high-quality, and varied food supply.... Fulfilment of its safeguarding role ensures an abundant, high-quality, and varied food supply, strengthens the marketability of American agriculture in domestic and international commerce, and contributes to the preservation of the global environment." In addition, each state has a department of agriculture that includes a regulatory function.

Regulatory entomology had its start in the United States with the Federal Plant Quarantine Act (1912). The act provided the legal basis for implementing quarantines against non-native pests through preventing their introduction on plant material imported into the United States. The law was revised in 1957 (Federal Plant Pest Act). In 1971, APHIS was formed, integrating animal health and plant health protection into one agency. Noxious weeds were included in legislation under the Federal Noxious Weed Act (1974). Over almost 60 years, the legal and regulatory authority of the USDA remained largely unchanged in spite of new laws being added. It was eventually recognized that the legal and regulatory authority of APHIS and PPQ had to be revised and expanded to address new challenges in plant protection. In 2000, the Plant Protection Act was enacted by Congress, providing for a wider authority and greater enforcement of plant protection regulations. The Plant Protection Act consolidated and replaced 10 laws and acts in total, including the Federal Plant Pest Act and Federal Noxious Weed Act.

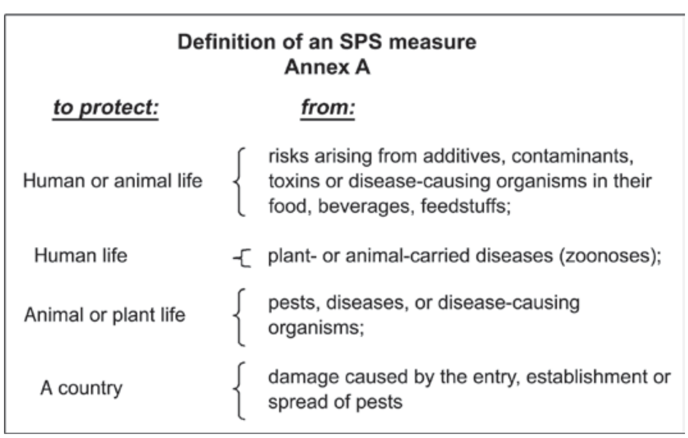
The need for the Plant Protection Act, and for increasing the role of regulatory entomology, is the result of ever increasing pressure on agriculture and the environment from threats arising from the unintentional introduction of plant pests. Increased movement of goods and people increase the risk of moving pests to new areas. Agricultural trade has increased steadily since the World Trade Organization (WTO) provided for a global, liberalized trade framework in the 1990s. As of 2000, the global value of agricultural trade exports was

~US$275 billion. Developed countries such as the United States, the European Community, Canada, Australia and Japan account for the majority of trade, while developing countries have had mixed results taking advantage of the liberalized trade environment. Nonetheless, there is a greater variety of products being transported from a wider range of countries. Along with increased trade, there is an increased possibility of moving pests.

The WTO and its agreements liberalized global trade, beginning in 1995. At the time the agreements were negotiated, it was also recognized that countries would need a means of implementing measures to protect their people, animals, plants and environments from the introduction and spread of pests and diseases. Members of the WTO therefore negotiated the Agreement on the Application of Sanitary and Phytosanitary Measures, or SPS Agreement as a subsidiary agreement of the WTO. It is a legally binding international agreement, and all Members of the WTO (including the United States) should follow its requirements. It sets out rights and obligations for Members of the WTO with respect to sanitary and phytosanitary measures that may be implemented for protecting human, animal or plant life and health. The SPS Agreement provides a framework to ensure that measures at the national level (e.g., laws, regulations or other requirements) are applied only to the extent necessary to protect health and that the measures are technically justified. In the same vein, the Agreement maintains that such measures should not be implemented arbitrarily or as disguised barriers to trade. Annex A of the SPS Agreement defines the scope of SPS measures (Fig. 13).

The SPS Agreement contains several key provisions that define rights, obligations and responsibilities of Members in designating SPS measures at the national level, several of which highlight the role and importance of scientific information. Article 2 (Basic Rights and Obligations) of the SPS Agreement states that “Members shall ensure that any sanitary or phytosanitary measure is applied only to the extent necessary to protect human, animal or plant life or health, is based on scientific principles and is not maintained without sufficient scientific evidence… .” This means that measures should be technically justified and based on available scientific information (see also Articles 3 and 5).

Article 5 (Assessment of Risk and Determination of the Appropriate Level of Sanitary or Phytosanitary Protection) addresses the application of risk assessment in determining appropriate SPS measures. Importantly, it states that risk assessments used for determining SPS measures should be based on methods developed by relevant international organizations and take into account available scientific evidence. It is also important to note that measures that deviate from standards, as



Regulations Affecting the Implementation of Regulatory Entomology Practices, Figure 13 **Definition of an SPS measure from Annex A of the SPS Agreement (WTO, 1994).**

defined in Article 3, should be based on risk assessment. Furthermore, Article 5 states that Members should implement measures only to achieve an appropriate level of protection, and that these measures should be the "least trade restrictive" possible. The Agreement allows for measures that are more stringent than those defined by standards, but these measures should be fully justified by a risk assessment.

Article 3 (Harmonization) of the SPS states that measures (laws, regulations and other requirements) should be based on international standards or that measures that deviate from standards should be technically justified. Members can use international standards as the basis for their national regulations and know that those measures cannot be challenged under the SPS Agreement. The Agreement identifies the internationally recognized standard-setting bodies as:

- The Codex Alimentarius Commission for food safety and human health
- The World Animal Health Organization (formerly Office Internationale des Epizooties or OIE) for animal health; and
- The International Plant Protection Convention for plant health

International standards developed by these organizations incorporate available scientific information and assess the risks associated with a given situation. As such, any measure based on a standard is by default considered to be scientifically and technically justified.

As stated above, the SPS Agreement identifies the International Plant Protection Convention (IPPC) as the international standard setting body for plant health. The IPPC is an international treaty with its own signatories, or Contracting Parties (member countries). It originally entered into force in 1952; it was amended in 1979 and the 1979 text entered into force in 1991. More recently, in 1997, the text was revised again largely to meet new expectations set forth in the SPS Agreement. The 1997 amendments created a Secretariat, the Commission on Phytosanitary Measures (CPM, comprised of all Contracting Parties, including the United States) and formalized standard-setting as part of the IPPC's mission.

The purpose of the IPPC is to secure common and effective action to prevent the spread of plant pests and to promote measures for their control. Although the IPPC has a clear relationship to the SPS Agreement and to trade, its scope is not limited to trade. The scope of the IPPC applies to protecting all plants including wild flora from plant pests. Plant pests include any organism that may affect plant health, including diseases and weeds. To achieve this goal of protecting plant health, the text of the IPPC sets forth rights, obligations and responsibilities of Contracting Parties, including pest risk analysis, harmonization, equivalence, minimal impact, regionalization, pest free areas and areas of low pest prevalence. According to the IPPC, Contracting Parties should make provision for a national plant protection organization (NPPO) that is responsible for performing certain key functions including:

- Phytosanitary certification
- Surveillance
- Implementation of appropriate phytosanitary measures
- Conducting quarantine treatments and certify exports
- Exchanging scientific and technical information
- Developing and observing standards
- Conducting eradication programs and other pest control programs, and
- Recognition of pest free areas and areas of low pest prevalence (IPPC, 1997a)

In the United States, the NPPO is APHIS-PPQ.

Contracting parties receive guidance on meeting these provisions through the use of international standards developed under the auspices of the IPPC. International Standards for Phytosanitary Measures (ISPMs) are developed under the guidance of the CPM. The CPM decides which ISPMs should be developed as part of the work program.

An expert panel is formed to draft the standard, ensuring that the best scientific expertise is incorporated into the standard. The Standards Committee (SC) reviews and revises the draft standard, which is then sent to all Members of the CPM for comment. After another review by the SC, the draft standard can be submitted to the CPM for adoption. To date there have been ~30 ISPMs adopted.

There are three general types of standards: reference, concept and specific. Reference standards include the ISPM No. 5 Glossary of Phytosanitary Terms and ISPM No. 1 Phytosanitary Principles fort the Protection of Plants and the Application of Phytosanitary Measures in International Trade. Concept standards include ISPMs such as ISPM No. 4 Requirements for the Establishment of Pest Free Areas and ISPM No. 6 Guidelines for Surveillance. The pest risk analysis standards (ISPMs No. 2 (revised) Framework for Pest Risk Analysis, and No. 11 Guidelines for Pest Risk Analysis for Quarantine Pests Including Analysis of Environmental Risks and Living Modified Organisms) are also concept standards.

Specific standards address specific pests or commodities. ISPM No. 15 Guidelines for Regulating Wood Packaging Material in International Trade is a specific standard; the only other specific standard at this time is ISPM No. 26 (2006) Establishment of Pest Free Areas for Fruit Flies (Tephritidae). Other pest or commodity specific standards are under various stages of development. Importantly, entomological expertise played a critical role in the development of ISPM Nos. 15 and 26; likewise, expert working groups for other pest specific standards are comprised largely of subject matter experts (e.g., fruit fly experts, forest entomologists, etc.). The role of entomological science is therefore essential to the development of international standards and, subsequently, national regulations.

Other ISPMs that rely heavily on entomological expertise include:

- ISPM No. 3 Guidelines for the Export, Shipment, Import and Release of Biological Control Agents and Other Beneficial Organisms
- ISPM No. 6 Guidelines for Surveillance
- ISPM No. 4 Requirements for the Establishment of Pest Free Areas
- ISPM No. 22 Requirements for the Establishment of Areas of Low Pest Prevalence
- ISPM No. 9 Guidelines for Pest Eradication Programmes
- ISPM No. 10 Guidelines for Pest Free Places of Production and Pest Free Production Sites
- ISPM No. 2 Guidelines for Pest Risk Analysis
- ISPM No. 11 Guidelines for Pest Risk Analysis for Quarantine Pests Including Analysis of Environmental Risks and Living Modified Organisms
- ISPM No. 14 The Use of Integrated Measures in a Systems Approach for Pest Risk Management

These standards are based on scientific (including entomological) and technical information and, as such, they provide scientific and technical guidance for the design and operation of key components of national regulatory plant protection programs. For example, ISPM No. 6 (Guidelines for Surveillance) provides valuable information on how surveillance programs for pests should be designed and executed, and covers basic sampling techniques. The PRA standards address how biological information on pests should be gathered and analyzed. Although the design of pest management programs does not necessarily include a risk assessment component, there is considerable overlap in the type of information needed to make accurate judgments. ISPM No. 14 provides extensive guidance on the integrated use of different types of pest risk management options to reduce pest risk. Finally, several standards discuss eradication, pest freedom and low pest prevalence from a regulatory standpoint. They provide both scientific and technical guidance as to how such programs may be developed, the types of information that should be gathered and analyzed, the requirements for certain procedures (e.g., surveillance) and how pest freedom can be officially recognized by other countries.

Other international agreements and protocols affect regulatory plant protection and regulatory entomology at the national level. The adoption of the Montreal Protocol, requiring the reduction in use or elimination of ozone depleting substances, may lead to reduced availability of methyl bromide, an important quarantine treatment, in the future. Although the use of methyl bromide for quarantine purposes is exempted from the Protocol, there is still a desire on the part of many countries to scale back their use of methyl bromide due to its ozone depleting effects. In the absence of suitable alternatives, the role of entomological expertise in finding pest management solutions (including the development of alternative quarantine treatments) has become increasingly important for regulators. Likewise, market forces and food safety standards are leading to acceptance of lower and lower levels of pesticide residues (maximum residue limits or MRLs) in food, with a concomitant reduction in the reliance on certain pesticides in the field.

Concurrently, it is becoming widely recognized that the operational standard of "Probit 9" for quarantine treatments is not a technically justifiable requirement for many, if not most, pests. Probit 9 security refers to the level of efficacy of a phytosanitary treatment and converts to 32 surviving individuals for every one million individuals treated. For more than 50 years, it has been assumed that this level of security was sufficiently protective, especially for fruit fly pests. However, as pest risk analysis continues to evolve, it has become evident that for many pests, Probit 9 may be too stringent a requirement; in some cases, Probit 9 may not afford enough security. In either case, NPPOs are re-evaluating the need for Probit 9 security and are seeking suitable alternatives (including pest management options) to long used point of origin-, in transit- or post-entry quarantine treatments. The need for entomological expertise in the regulatory arena is thus becoming ever more critical as NPPOs, including PPQ, seek new solutions to existing and newly arising pest problems.

It should also be understood that regulatory entomology is fundamentally different from other fields of entomology due to its legal and regulatory functions. In general, NPPOs are not concerned with common agricultural pests and their management within their respective territories, except in circumstances where those pests may readily move in agricultural trade. In a few instances, some established pests may be subject to regulatory measures or localized quarantines to prevent further spread (e.g., red imported fire ant, gypsy moth, Japanese beetle, pink hibiscus mealybug). NPPOs and regulatory entomologists are largely concerned with preventing the introduction and spread of quarantine pests (as defined by the IPPC, a pest of potential economic importance to the area endangered thereby and not yet present there, or present but not widely distributed and being officially controlled). In instances where a quarantine pest may become introduced, the NPPO may undertake an eradication, suppression or other quarantine program to either eradicate or prevent further spread of the pest.

Similarly, the role of scientific information in regulatory programs must be considered in relation to the role of *official* information. Scientific information, including taxonomic identity, geographic distribution and host range of pests can have serious impacts on regulatory processes, both domestically and internationally. Variability in scientific information as well as differing interpretations can lead to disagreements between NPPOs and cause serious disruptions to international trade. Official information would be information communicated between and among NPPOs regarding such issues as pest status in an area (distribution), issues related to biotypes or strains (taxonomic identity) and host status. Scientific information, for instance, may be used in developing a pest risk analysis (PRA); however, the PRA would be means of communicating official information between governments. It is thus important for there to be a clear connection between scientists and regulators while recognizing the respective roles of scientific and official information.

In short, regulatory entomology is concerned with preventing the introduction and spread of pests to new areas. This is accomplished through the implementation of laws (internationally and nationally), regulations and requirements at international, national and local/state levels. These laws, regulations and requirements are necessarily based on entomological science. Entomological expertise in regulatory plant protection is therefore essential; entomologists working in the regulatory arena provide a critical service in helping to protect both agricultural and natural resources.

Regulations Affecting Use of Pesticides in the USA

FRED FISHEL
University of Florida, Gainesville, FL, USA

The intent of regulations affecting pesticides and their use in the USA has evolved over the years. Beginning in 1906, the Federal Food, Drug, and Cosmetic Act required that canned, fresh, or frozen foods in interstate commerce be pure and wholesome. This law was also known as the Pure Food Law. There was no provision that specifically regarded pesticides. In 1910, the Federal Insecticide Act was signed, but it pertained to only fungicides and insecticides, and its main intent was consumer protection of farmers from falsely acclaimed pesticides. The original Pure Food Law was amended in 1938 to include coverage of pesticides on foods and pertained mainly to the arsenical class of pesticides. At that time, the first two arsenical pesticides were widely used – Paris Green and lead arsenate. The Pure Food Law contained provisions that required manufacturers to include coloring agents in pesticides that were originally white materials. The intent was to prevent the accidental use of foodstuffs that had a similar appearance, such as flour. Through the evolution of pesticide regulation, the intent of pesticide laws today include protection of pesticide applicators, the environment, consumers of treated products, pets, and domestic animals. Other countries have adopted similar regulations, though the policies may be more or less stringent.

Federal Insecticide, Fungicide and Rodenticide Act (FIFRA)

A more encompassing law, the original Federal Insecticide, Fungicide and Rodenticide Act, known as FIFRA, was passed in 1947. Its intent was for the United States Department of Agriculture to register all pesticides prior to their interstate commerce. This law remained in place until 1964, when it was amended to allow refusal of products that were determined to be unsafe or ineffective and their removal from the market.

Since pesticides have become an integral part of controlling pests, a succession of federal and state laws has addressed their changing role and regulation. In 1970, the United States Environmental Protection Agency (EPA) was formed and was charged with enforcing FIFRA, which was again amended in 1972. Pesticide laws and regulations were refocused with the basic goals of:

- Requiring EPA registration of all pesticides, each use of the pesticide, and product label approval
- Classifying all registered pesticides as either "general use" which can be used by anyone, or "restricted use" which requires licensing
- Establishing certification and licensing programs carried out by individual states that must meet at least minimal FIFRA requirements, although individual states are allowed to be more stringent. Licensed applicators are considered to be either "private" or "commercial" applicators
- Establishing tolerances for pesticide residues which may legally remain on raw agricultural products or in processed food
- Penalizing pesticide users for "use inconsistent with the labeling" of a pesticide
- Making it illegal to store or dispose of pesticides or containers other than as directed by regulations and penalizing for illegal handling of containers
- Providing civil penalties when there is an unintentional violation of a regulation. Fines can be $1,000 for private applicators and others, and as much as $5,000 for each offense by commercial applicators
- Providing criminal penalties when the law is knowingly violated. The maximum penalty for private applicators and others is $1,000 and/or 30 days in prison. Commercial applicators may be fined up to $25,000 or 1 year in prison, or both

Certification of Applicators

FIFRA distinguishes between commercial and private applicators. Private applicators use or supervise the use of pesticides on property owned or leased by them or their employee for the purpose of producing an agricultural commodity. Commercial applicators include all other certified applicators. The EPA has established rules and procedures to be followed by individual states for certifying both groups.

Private applicators may be required by states to demonstrate their competency to apply pesticides through a written or oral examination. This generally involves testing their ability to read and understand directions on pesticide labels and their general comprehension of safety and environmental problems potentially arising from pesticide use.

Restrictions on commercial applicators are more stringent, requiring persons seeking certification to demonstrate competency by taking a written examination and, if required by law, to attend certification programs and take performance tests. Topics covered by the examinations may include a person's ability to read and understand a pesticide label, knowledge of application equipment and techniques, knowledge of potential pesticide harmful effects on human health and the environment, and basic knowledge of pesticide laws.

The EPA regulations also divide commercial applicators into categories based on types and sites of pesticide use. For example, some categories are: agriculture, ornamental and turf, rights-of-way, and aquatic pest control. Persons seeking certification as commercial applicators must demonstrate knowledge of the use and handling of pesticides generally, and knowledge of the particular standards applicable to their respective area or areas. Individual states determine when certification must be renewed.

Recall of Suspended Pesticides

The 1988 amendments to FIFRA require the recall of pesticides if their registration is suspended, or if the EPA determines that a recall of the pesticide is necessary to protect health or the environment. If a pesticide is recalled, the registrant must take reasonable steps to inform users of the recall and must provide storage facilities to persons in possession of the pesticide and, if requested, transportation of the pesticide. Users of the recalled pesticide are entitled to an indemnity from the EPA for the price of the pesticide. An indemnity cannot be made unless there is a specific line item appropriation of funds made in advance by the U.S. Congress.

The Federal Food, Drug, and Cosmetic Act (FFDCA)

The FFDCA of 1938 has been amended several times in its history. It is administered by the Food and Drug Administration (FDA) of the Department of Health and Human Welfare. Whenever pesticides are applied, their residues will remain on treated surfaces for a time. The chemical properties, frequency of application, rate applied, and environmental factors determine how much residue will be present. Residues are undesirable when they expose people, domestic animals, or wildlife to unsafe levels of pesticides. Pesticide residues on agricultural commodities are regulated under both FIFRA and FFDCA. FIFRA regulates residues by forbidding the use of a pesticide in a manner inconsistent with its label, and by denying registration to pesticides found to cause unreasonable adverse effects to people or the environment. Because FFDCA prohibits the distribution of agricultural commodities that contain levels of pesticides that exceed federally determined maximum tolerances, it is interrelated with FIFRA. In order for EPA to register a pesticide under FIFRA, a tolerance must be established under FFDCA. Information on a tolerance is useful in determining to register a pesticide and, if so, how the label will be composed. This takes into account that if the label's directions are followed correctly, then the tolerance will not be exceeded. If a pesticide is used on a crop not listed on the label, the crop may be determined to be unfit and destroyed by the government.

Pesticide Record Keeping Requirements

The Food, Agriculture, Conservation and Trade Act of 1990 (FACT Act, Farm Bill) contains regulations that require certified applicators of restricted use pesticides to keep records of applications. Certified applicators are determined to include both commercial and private applicators. The USDA Agricultural Marketing Service is responsible for implementing the record keeping provisions of the FACT Act. FACT further requires that certified applicators adhere to individual state record keeping requirements. If there is no state record keeping regulations, then certified applicators must include the following items as outlined by FACT:

- The pesticide's product name
- The amount of pesticide applied
- The date that the pesticide was applied
- The location of the pesticide application
- The size of the treated area

FACT requires that all pesticide records be kept for at least two years after each application. Also, the application must be recorded within 14 days after the pesticide was applied.

Endangered Species Act (ESA)

The Endangered Species Act is a Federal law administered by the Fish and Wildlife Service (FWS) of the Department of the Interior. The ESA makes it illegal to kill, harm, or collect endangered or threatened wildlife or fish or to remove endangered or threatened plants from areas under Federal jurisdiction. It also requires other Federal agencies to ensure that any action they carry out or authorize is not likely to jeopardize the continued existence of any endangered or threatened species, or to destroy or adversely modify its critical habitat. As a result, EPA must ensure that no registered pesticide use is likely to jeopardize the survival of any endangered or threatened species.

The FWS has the authority to designate land and freshwater species as endangered or threatened and to identify their current habitat or range. The National Marine Fisheries Service has the same authority for marine species.

The FWS has the authority to prosecute persons, including pesticide users, who harm endangered or threatened species. In addition, EPA enforcement personnel have the authority to ensure that pesticide users observe labeling restrictions.

Occupational Safety and Health Act of 1970 (OSHA)

The OSHA of 1970 is administered by the Occupational Safety and Health Administration of the Department of Labor. This law:

- Requires any employer with eleven or more employees to keep records of all work-related deaths, injuries and illness and to make periodic reports. Minor injuries needing only first aid treatment need not be recorded. Records must be made if the injury involved medical treatment, loss of consciousness, restriction of work or motion, or transfer to another job
- Requires investigation of employee complaints that may be related to pesticide use, reentry or accidents

Written and administered by OSHA, the Hazard Communication Standard (HCS), provides protection for employees exposed to hazardous chemicals. Pesticides are considered hazardous chemicals. An employee is defined as a worker who may be exposed to hazardous chemicals under normal operating conditions or in foreseeable emergencies. Exposure or exposed means that an employee is subjected to a hazardous chemical in the course of employment through any route of entry (inhalation, ingestion, skin contact, or absorption), and includes potential (accidental or possible) exposure. This law requires:

- Employers to read the Standard and understand the provisions and responsibilities of an employer
- A list of the hazardous chemicals in the work place be made
- Employers to obtain material safety data sheets (MSDS) for all hazardous substances on their list
- All containers to be labeled
- A written communication program be developed and implemented
- That employee training be conducted based upon the chemical list, MSDS, and labeling information
- Employers must create a hazard communication file, and make it available to any employee upon request in a reasonable period of time

Superfund Amendments and Reauthorization Act of 1986 (SARA Title III)

SARA Title III is a Federal right-to-know law that affects those that produce or store hazardous chemicals. Pesticide producers, distributors, retailers, and some pesticide applicators are among those that must comply with this law. It is designed to inform communities regarding hazardous chemicals located in the vicinity and addresses the need for community emergency response plans in the event of an accident.

Title III has many sections, however, the areas that affect pesticide applicators, applicator businesses, or dealers are confined to:

- Emergency planning and notification: under certain conditions, the law requires notification of state and local officials about the location and amount of hazardous chemicals at a site. EPA has designed a Threshold Planning Quantity (TPQ) for a number of active ingredients, not the formulated product. When the product in storage is at or above the TPQ, the State Emergency Response Commission (SERC) must be notified in writing. Each facility is also required to designate a coordinator to work with the Local Emergency Planning Committee (LEPC). The state will notify the LEPC that the operation is covered under SARA. This is a one time notification.
- Emergency release reporting: describes the safety measures when an accidental release, such as a spill, of any extremely hazardous substance occurs. If all of the following occur:
  - The pesticide was spilled.
  - Is covered under SARA Title III.
  - The spill quantity was greater than the Reportable Quantity (RQ).
- The spill created off-site exposure.
- If those conditions exist, then one is required to notify the SERC, LEPC, and the National Response Center. If a pesticide is applied according to the label, the use is exempt from emergency release reporting.
  - Material Safety Data Sheet (MSDS) reporting: employers are required to obtain and keep material safety data sheets. They must submit copies of each MSDS, or a listing of MSDSs that must be maintained, to their local fire department, the LEPC, and the SERC. There is one exclusion: if a chemical is used solely for household, consumer, or agricultural purposes, notification is not required.
  - Annual inventory reporting: all regulated facilities must submit an annual inventory to their local fire department, LEPC, and SERC. The inventory must include:
    - All hazardous chemicals stored at the facility in quantities of 10,000 pounds or more, and
    - All extremely hazardous chemicals stored in quantities of 500 pounds, or 55 gallons, or more, or in a quantity that exceeds the TPQ, whichever is less

Agricultural producers are exempt from this section.

Resource Conservation and Recovery Act of 1976 (RCRA)

The EPA regulates wastes under the RCRA. EPA issues a list of materials that are considered hazardous. Under RCRA:

- Private applicators (farmers) who properly dispose of pesticide wastes, excess pesticides, and triple rinsed empty containers on their own property are generally exempt from the requirements of this law (states and tribes often have more strict laws)
- "Wastes" include unrinsed containers, excess pesticides and pesticide dilutions, and rinse and wash water that contain a listed chemical and cannot be used
- Those who accumulate wastes of acutely toxic pesticides totaling 2.2 pounds or more per month or wastes of any RCRA-regulated pesticides totaling 2,200 pounds per month are regulated. Such users must register as a generator of hazardous waste, obtain an identification number from EPA, state, or tribe and follow certain disposal requirements

The EPA RCRA telephone hotline can be contacted for determining if a pesticide is listed.

Food Quality Protection Act (FQPA)

The FQPA was signed into law in 1996 and was the first significant amendment to FIFRA since 1988. The following are some of the major provisions of FQPA:

- Periodic review of pesticide registrations. FQPA requires EPA to establish a system for periodic review of all pesticide registrations on a 15-year cycle using new food safety standards mandated under the act.
- Emergency suspension authority. EPA may suspend a pesticide registration immediately. A notice of intent to cancel must be issued within 90 days, or the emergency suspension would expire.
- Minor use pesticides. FQPA enhances incentives for the development and maintenance of minor use registrations through extensions for exclusive use of data, flexibility to waive certain data requirements, and requiring EPA to expedite review of minor-use applications.
- Time-limited tolerances. FQPA requires the establishment of a time-limited tolerance for pesticides that have received registration under Section 18 of FIFRA.

Worker Protection Standard (WPS)

In 1992, EPA announced its final rule revising its regulations regarding protection of workers from exposure to agricultural pesticides. It is directed toward the working conditions of the following two types of employees:

- Pesticide handlers. Those who handle agricultural pesticides, including mixing, loading, applying, cleaning or repairing equipment, flagging application equipment, etc.
- Agricultural workers. Those who perform tasks related to cultivation and harvesting.

The provisions are intended to accomplish the following:

- Eliminate or reduce exposure to pesticides. Exposure is limited by establishing restricted entry intervals (REIs) for all pesticide products used in the production of agricultural plants and for which REIs have not been set according to current standards.
- Mitigate exposures that occur.
- Inform employees about the hazards of pesticides.

Products affected by the WPS are, with some exceptions, those products registered for use in the production of agricultural plants. It includes any product registered for use in the production of agricultural plants on farms, forests, nurseries, and greenhouses. Facility owners and operators are ultimately responsible to ensure compliance within the WPS.

Safe Drinking Water Act (SDWA)

EPA establishes national drinking water standards, called Maximum Contaminant Levels (MCLs), for protecting the quality of drinking water for both underground and above ground sources. Public water systems may not deliver water exceeding the MCLs. Congress amended the law to require the development of a screening and testing program for chemicals, including pesticides, for possible endocrine disrupting effects. EPA has the same requirement within the FQPA.

Hazardous Materials Transportation Act (HMTA)

The HMTA was enacted over the concern for spills of unknown substances on public highways. It is under the jurisdiction of the Department of Transportation (DOT) since it is the agency responsible for the safe transportation of all materials on public highways. HMTA authorizes the Secretary of Transportation broad authority to designate any material shipped in commerce as hazardous if it poses an unreasonable risk to health, safety, and property. Hazardous materials can include radioactive materials, disease-causing agents, flammable and combustible liquids or solids, oxidizing or corrosive materials, compressed gases, poisons, and explosives. The list of materials does not include certain chemicals used in pesticides; however, pesticides fall within the materials characterized as hazardous under the regulations issued by DOT.

The regulations apply to common, contract, or private carriers of hazardous materials. A commercial pesticide applicator transporting pesticides for application under contract would constitute either a contractor or private carrier and be subject to the regulations. Under certain circumstances, a private applicator transporting pesticides may be subject to the regulations. Generally, the carriers subject to HMTA:

- Operate across state lines and transport materials listed in the Hazardous Material Table; or
- Transport materials above the reportable quantities for various chemicals listed in the Hazardous Substance Table; or
- Do not meet the above requirements, but operate in a state that requires compliance with DOT regulations

Most states have adopted the DOT requirements for intrastate commerce. It is important to note that one should always follow the DOT regulations if there are no state requirements and there is no interstate commerce.

To avoid liability, manufacturers and distributors of hazardous materials often provide the information needed to follow HMTA regulations. However, it is the responsibility of anyone handling hazardous chemicals to ensure that the information is correct. Anyone who falls under the jurisdiction of the DOT and HMTA should know how to use the Hazardous Materials Table and Hazardous Substance Table.

Private carriers transporting only within the borders of a single state are exempted from this requirement provided the transport vehicle has a gross vehicle weight of less than 10,000 pounds. If the vehicle is a tank truck, it must have a tank of less than 3,500 water gallons capacity to be exempted.

Pesticide Use in the USA

In terms of actual pounds of pesticides used in the USA, volumes have actually decreased, from 1.2 billion pounds in 1981 to 975 million pounds in 1997. At least partly responsible for this trend is technology in formulation manufacturing. Many of the newer generation pesticides are applied at much lower rates than older compounds, yet are just as or more effective in the achieved results.

Of the pesticides used in the USA, the majority sold was for agricultural purposes, followed by industrial, government and commercial use, and home and garden use accounted for the least amounts sold. By class, herbicides were sold in the largest amounts (Table 5).

A Global Perspective of Pesticide Regulation

During the 1960s, the Food and Agriculture Organization (FAO) and World Health Organization (WHO) created the Codex Alimentarius Commission for the purpose of developing international food standards. Its ultimate goal is health protection of consumers and ensuring fair food trade practices. A major impetus in its formation was the differing food safety standards among nations. Because of a lack of standardization, trade barriers were created. As a result of barriers, various trade associations pressured their governments into establishing food safety standards to facilitate safe trade practices. The standards developed encompass various factors affecting food safety; pesticide residues are but one aspect of its intent. Pesticide residue analysis methods have been developed by the Commission to ensure

Regulations Affecting Use of Pesticides in the USA, Table 5 Volumes of pesticide active ingredients used by sector (millions of pounds) in the USA

Sector	Herbicides[a]	Insecticides[b]	Fungicides[c]	Miscellaneous[d]	Total
Agriculture	470	82	53	165	770
Industry and government	49	30	20	30	129
Home and garden	49	17	8	2	76
Total	568	128	81	197	975

From Aspelin and Grube, 1998
[a]Includes plant growth regulators
[b]Includes miticides and contact nematicides
[c]Does not include wood preservatives
[d]Includes rodenticides, fumigants, and molluscicides, but does not include wood preservatives, disinfectants, and sulfur, which account for 1.6 billion pounds

standardization in the international community. For practically any commodity and every pesticide, maximum residue levels have been set by the Codex Alimentarius Commission.

Regulatory Entomology

LLOYD GARCIA
North Carolina Department of Agriculture and Consumer Sciences, Raleigh, NC, USA

Regulatory entomology entails the detection, management and study of non-native or geographically displaced insects in the public interest, principally by governmental agencies and institutions. This branch of entomology began in the 1800s, as governments around the world became aware of the detrimental effects to agriculture and to the public from the unrestricted movement of insect pests associated with trade goods. The United States government's first attempt to intervene in the control of a non-indigenous insect pest occurred in California in 1888. At this time, the vedalia beetle, *Rodolina cardinalis* (Mulsant), and a dipteran parasite, *Cryptochaetum iceryae* (Williston), were imported from Australia to control an accidentally introduced pest, the cottony cushion scale (*Icerya purchasi* Maskell). R. V. Riley, Entomologist to the U.S. Department of Agriculture, coordinated this classical biological control program. Following this successful control effort, interest in an expanded governmental role increased and, in 1904, the Bureau of Entomology was created within the U.S. Department of Agriculture. Other countries, and political subdivisions such as states and provinces, have similarly passed legislation to address the problem of invasion by exotic pests.

A principal role of regulatory entomologists is to prevent the entry of insects to new geographical areas where they may become established as pests. Border inspections of plants began in the U.S. in 1906 to intercept harmful organisms associated with trade goods (agricultural plants and plant products). Inspections have expanded in scope since then to keep pace with increases in trade and travel. In conjunction with border inspections, analyses of future pest status, termed Pest Risk Assessments, associated with the introduction of specific foreign insects are conducted to investigate the potential concerns subsequent to an introduction and to determine appropriate detection and control techniques. Introduction pathways are then examined and targeted for survey. Taxonomic support is critical to the correct targeting and implementation of mitigating measures.

The authority for the U.S. government to establish quarantines was legislated in the Plant Quarantine Act of 1912. Their purpose is to monitor and regulate the movement and spread, both interstate and internationally, of insect pests and trade goods that may harbor them. Regulatory entomologists are responsible for the implementation and enforcement of this act. Early quarantines for insects such as the gypsy moth and the Japanese beetle were effective in limiting the spread of these pests and formed the basis for future efforts. Control measures are also established as components of quarantine programs and can include insecticide treatments, foreign exploration for biological control agents and restrictions on the movement of regulated items such as nursery stock.

Regulatory entomologists also are responsible for determining if exports meet the insect pest requirements of state and foreign governments by certifying that products are free of injurious pests. To assist domestic producers, regulatory entomologists develop protocols designed to limit or prevent the movement of insect pests in or on trade goods. The protocols permit producers to fulfill quarantine regulatory requirements to control insects and to provide shippers with greater flexibility and efficiency in shipping pest-free products. Protocols can include various measures such as heat treatments, fumigation, isolation of production or transit areas, irradiation, insecticide applications, and/or changes in production and handling methods. With increased trade and speed of travel, the likelihood that insects will survive and become established in new geographic areas is increasing. It is the responsibility of regulatory entomologists to identify creative means to limit the number of introductions and to mitigate the impacts of newly established insect pests.

Regulatory Sequence

A DNA sequence involved in regulating the expression of a gene. A promoter or operator.

Rehn, James Abram Garfield

James Rehn was born at Philadelphia, Pennsylvania, USA, in 1881. As a child be became associated with the Academy of Natural Sciences, and then became a staff member and fell under the influence of prominent entomologists. By 1900 he was publishing on Orthoptera, which soon became his life's work. He made collecting trips to Africa and South America, as well as throughout the United States. He worked closely with Morgan Hebard on a great number of projects, and they both became renowned orthopterists. Rehn published over 300 papers on Orthoptera, and several books. Among his most important publications are "The grasshoppers and locusts of Australia" (in three volumes, begun in 1949) and "A monograph of the Orthoptera of North America (north of Mexico), Vol. 1" (with H. J. Grant, Jr.) (1961). He edited the "Transactions of the American Entomological Society" from 1917 to 1924, and served on many important committees of the American Entomological Society. Rehn received many honors, and served as president of the Entomological Society of America. He died on January 25, 1965.

Reitter, Edmund

Edmund Reitter was born at Mohelnice in Moravia (Czech Republic) on October 22, 1845. He initially worked as a farm manager, and was responsible for fish pond management on an estate. However, insects were his passion, and he moved to Vienna in 1879 and started a business selling insects. He moved to Mödling, near Vienna in 1881 and expanded his business to include entomological equipment and literature. Mödling became a favorite meeting place for entomologists, but Reitter's wife insisted that they move to Paskov, which was accomplished in 1891. Reitter's house again became a favorite meeting place for entomologists. Reitter is considered a genius among coleopterists because he had an uncanny ability to find useful diagnostic characters, even among species studied extensively by others. He was a prolific publisher, with over one thousand papers to his credit. He worked extensively across the various taxa of the Coleoptera. He also authored "Fauna Germanica" a 5-volume treatise that was the most important book on Coleoptera of Europe for decades. He is credited with describing a phenomenal 1,062 genera and 6,411 species! His personal collection contained 250,000 specimens, including 4,500 types; it is now housed in the Hungarian Natural history Museum. He died at Paskov, Moravia, on March 15, 1920.

Relapsing Fever

Several tick-transmitted spirochetes cause disease symptoms called "relapsing fever".

► Ticks

Relative Humidity

The percentage saturation of the air with water vapor.

Relative Methods of Sampling

Techniques used to sample insect populations that provide an estimate of abundance relative to other times or places (e.g., per trap or per unit time of visual search). Types of relative sampling include sex pheromone, blacklight and sticky traps, and amount of plant damage. (contrast with absolute methods of sampling).

► Sampling Arthropods

Releaser Pheromone

A pheromone that stimulated the nervous system to produce a quick behavioral response (contrast with primer pheromone).

► Pheromones

Remigium

The rigid anterior portion of the wing, which is directly affected by the wing muscles and is very important in flight.

Remington, Charles Lee

Charles Remington was an important force in modern American lepidopterology. He was born in Reedville, Virginia, USA, on January 19, 1922, but raised in St. Louis, Missouri, where his father was a prep school teacher with an interest in butterflies. He attended Principia College in Elsah, Illinois, where an emergence of periodical cicadas occurred, triggering a lifelong interest in insects. After military service in the Pacific region as a medical entomologist during World War II, he attended Harvard University. There, as a graduate student he co-founded the Lepidopterists' Society, which came to produce the "Journal of the Lepidopterists' Society." Remington graduated in 1948 and joined the faculty at Yale University, where he remained for his entire career.

Remington served as curator at the Peabody Museum of Natural History at Yale, where he began the Yale insect collection, which now numbers about 2.5 million specimens, and contains an unusually large number of extinct species and unusual (gynandromorph) specimens. He was well known for the breadth of his knowledge of entomology, not just his expertise in Lepidoptera. Remington's evolutionary research suggested that there were geographic regions where species tended to hybridize. In these areas, which he called suture zones, he suggested that species of all different sorts – plants, insects, mammals and so on – might be found hybridizing with close relatives. This evolutionary concept fell into disfavor for many years, but has recently been revived by others. Among other achievements was his involvement in the founding of "Zero Population Growth," an organization dedicated to controlling overpopulation. He died on May 31, 2007, in Hamden, Connecticut.

Remote Sensing

Examination of a site from a distance, typically from an airplane but also by satellite.

Removal Trapping for Population Estimation

An absolute method of insect sampling that involves repeated collection and removal of insects from an area. The rate of decline in abundance as the population is depleted is used to estimate the initial population size.

► Sampling of Arthropods

Reniform

Kidney- or bean-shaped. Noctuid (Lepidoptera) moths often bear a reniform spot in the center of the front wings.

Reoviruses (Cypoviruses)

The family Reoviridae contains members in nine genera that infect animals, plants and fungi.

The name of this group is derived from its association with respiratory enteric orphans. All reoviruses are characterized by a segmented dsRNA genome encapsidated within 50–70 mm icosahedral particles. Each of the dsRNA segments contains one or two open reading frames. Members of two genera, *Orbivirus* (referred to previously as arboviruses) and *Phytoreovirus*, cause disease in vertebrates and plants, respectively, but are capable of limited replication in their insect vector. In nature, the majority of reoviruses associated with animals cause asymptomatic diseases. Likewise, most of the non-occluded insect reoviruses (unassigned genera) are characterized as being weakly invasive and non-lethal.

A series of reoviruses have been detected in various *Drosophila melanogaster* cell lines and has been reported to contain 10–13 segments of dsRNA. These viruses may establish persistent infections and do not appear to adversely affect the host cell. In nature, the reovirus *Drosophila* S virus (DSV) has been isolated from malformed *D. simulins* populations. In *D. simulins*, this virus is maternally transmitted to the epidermal or mesodermal cells of progeny flies. The virus possesses reduced invasive powers; electron microscopy of infected tissues has revealed no evidence of cell lysis, release of the virus, or viral penetration. Infection of the cuticle epidermis results in the S-phenotype characterized by the loss of varying numbers of thoracic bristles. Interestingly, a reovirus of a terrestrial isopod, similar in several respects to DSV, is the causal agent of an inter-sex phenotype. Infection of female isopods by this reovirus induces external pseudohermaphroditism via inhibition of the feminizing endosymbionts affiliated with this isopod host. Other reoviruses related to DSV include the *D. melanogaster* F virus, *Ceratitis capitata* reovirus, and the housefly *Musca domestica* (HSV) reovirus. Unlike DSV, the HSV is virulent to its host, adult houseflies. The virus replicates in the cytoplasm of hemocytes and appears to undergo partially defective replication in the midgut tissue. In addition to dipteran hosts, reoviruses also have been detected in several hymenopteran parasitoids. The reovirus of the wasp *Diadromus pulchellus* (DpRV) has been well-characterized and is believed to be related to the *Orthoreoviruses*. The DpRV is considered to have a commensal relationship with its wasp host. This virus is distinct in that it produces ploidy-specific genotypes. In haploid male wasps, the DpRV contains 10 dsRNA segments, whereas in diploid female wasps the DpRV contains an additional 3.3 kb supernumerary dsRNA segment.

Members of the genus *Cypovirus* (cytoplasmic polyhedrosis viruses, CPVs) are the best-characterized insect reoviruses. CPVs have been isolated from over two hundred insect species and several non-insect invertebrates. The majority of CPVs have been isolated from the larval stages of Lepidoptera (moths, butterflies). CPVs, like the occluded baculoviruses and entomopoxviruses, are characterized by their ability to produce proteinaceous occlusion bodies. The size and shape of these occlusions may vary according to the viral isolate, the degree of maturation, and the type of host cell. For example, the silkworm *Bombyx mori* is host to a variety of different CPV strains that either produce cuboidal, hexagonal, or tetragonal shaped inclusions. In some cases, more than 10^4 viruses may be occluded within a single occlusion. Cypoviruses produce icosahedral virus particles (65 nm diameter) which encapsidate 10–12 dsRNA monocistronic segments (total size 14 to 15×10^6 Da), an RNA-dependent RNA polymerase, and various enzymes involved in the production of 5′ capped, methylated viral mRNAs. The electrophoretic patterns of extracted dsRNA segments have been used to cluster CPVs into twelve electrophenotype groups. Northern blots employing cDNA probes constructed from selected dsRNA segments have demonstrated no homology between the *Cypovirus* and non-occluded reoviruses. Furthermore, little homology was demonstrated among CPV isolates having similar dsRNA electrophenotypes.

In host insects, these viruses preferentially replicate in the midgut columnar epithelium and do not appear to spread to other tissues. However, it has been reported that a CPV of a chironomid is capable of replicating in the fat tissue. The occlusions, ingested by susceptible insects, are disrupted by the conditions in the alimentary tract and release the icosahedral virus particles. These non-enveloped particles contain surface projections that mediate attachment to the microvilli. Within the midgut columnar cells, the virus undergoes replication in a manner similar to that outlined for non-occluded reoviruses. As the name implies, the replication of the CPVs occurs in the cell cytoplasm. During the early phase of the disease, dissected midguts contain regions or zones of infected columnar cells. As the disease progresses, the virus spreads to adjacent cells in a fashion reminiscent of the expansion of viral plaques in cell monolayers. Additional infected cells may undergo extensive hypertrophy and become dislodged from the basement membranes. The sloughing of these cells into the lumen release inocula that can spread the infection to new regions in the midgut. In heavily infected hosts, the large numbers of progeny occlusion bodies generated in columnar cells produce milky colored midgut tissue. The occlusions produced in the midgut cells are released in the feces, aiding in the transmission of this disease. In nature, epizootics of CPV are uncommon. This disease causes problems in insect colonies, especially when insects are mass-reared. The cypovirus disease has several characteristics that make it ideally suited for spread within insectaries. Firstly, these viruses do not cause acute infections; their in vivo development is often described as a chronic, debilitating disease that may take weeks to kill infected hosts. During this period, the virus is continuously shed via the feces from infected insects. Secondly, slightly infected hosts may survive and produce chronically infected adults. During both mating and oviposition, the virus can be released from infected alimentary tracts and be passively transmitted to other adults or to the egg surface. At the population level, the presence of a cypovirus may result in reduced food intake, retarded development, and a gradual die-off, resulting in the collapse of the colony.

Repellents

Chemicals that cause insects to make an oriented movement away from the source of the chemicals.

Repellents of Biting Flies

EUGENE J. GERBERG[1], NORMAN G. GRATZ[2]
[1]University of Florida, Gainesville, FL, USA
[2]World Health Organization, Geneva, Switzerland

The first use of a repellent was probably by prehistoric humans, sitting in the smoke of a fire to avoid biting flies. This method is still used in many places by remote populations. Some individuals resorted to covering themselves with mud, or grease from the animals they killed, to reduce fly biting. Repellents against insects were first mentioned in classical Roman literature by Pliny, the Naturalist (23–79 AD). The Greek physician and pharmacologist, Dioscorides (40–90 AD) described the use of wormwood, *Artemisia absinthium*, to repel gnats and fleas. Most of the early repellents consisted of parts of plants or animals, and some were associated with religious beliefs. Native Americans rubbed cedar tree needles, *Juniperus virginiana*, on their bodies to repel insects. Some people wore herbs or plant extracts around their necks or rubbed them on their skins.

Oil of citronella was one of the most widely used early repellents. It was used for human application to repel adult gnats and mosquitoes since 1882, and was initially registered in the U.S. in 1948 as McKesson's Oil of Citronella. Citronella was the standard repellent for many years. Other essential oils that were used as repellents were anise, bay laurel, bergamot, cassia, cedarwood, eucalyptus and wintergreen.

In 1929, dimethyl phthalate was reported as a fly repellent. At Rutgers University, a number of compounds were synthesized, including ethyl hexandiol, and reproducible methods of evaluating repellents were developed. Indalone (dimethyl carbate) was reported as a repellent in 1937.

At the U.S. Department of Agriculture laboratory at Orlando, Florida, and later at Gainesville, Florida, thousands of compounds were tested for repellency. During World War II, the standard military repellent was 6-2-2, a mixture of 6 parts dimethyl phthalate, and 2 parts each of ethyl hexandiol and indalone.

After World War II, the standard military repellent was M-2020, which was a mixture of 40% dimethyl phthalate, 30% ethyl hexandiol and 30% dimethyl carbate. The standard clothing repellent was M-1960, a mixture of 30% benzyl benzoate, 30% n-butylacetanilide, 30% 2-butyl-2-ethyl-1,3 propanediol, and 10% Tween 80.

Diethyl toluamide (DEET) was developed in 1954. DEET was by far the best repellent developed, and is the repellent of choice for the military. Military forces may have to deploy in areas where vector-borne diseases are rampant, and other methods of protection cannot be employed. Pest mosquitoes may exist in such large numbers as to interfere with military operations. A long lasting repellent was required and a new extended duration repellent formulation was developed. However, these sorts of conditions normally do not occur in the backyard of suburbia, or on the sunny beaches of the coast. Therefore for normal civilian use, shorter duration repellents may be satisfactory.

In recent years there has been a tendency towards the use of "natural agents" or phytochemicals. Among the so called "natural" products, or better described as "herbal" products, are the following:

Citronella

Oil of citronella is the volatile oil obtained from the steam distillation of freshly cut or partially dried grass of the genus *Cymbopogon*. Oil of citronella is an essential oil made up of more than 80 compounds of closely related terpenic hydrocarbons, alcohol, and aldehydes.

Geraniol

Geraniol is a component of citronella. Geraniol coeur is a mixture of geraniol, nerol and citronellol.

Quwenling

Quwenling is derived from the waste distillation after extraction of lemon eucalyptus (*Eucalyptus maculata citriodon*) and used in China as a mosquito repellent. The principal active ingredient is p-methane-3,8-diol.

Neem

Neem is a compound found in the leaves, seeds and seed oil of the neem tree (*Azadirachta indica*). The neem tree is a tropical tree, native to East India and Myanmar.

Soy Bean Oil

Soy bean oil is composed of a lecithin base plus other derivatives from soy oil.

Oil of Palmarosa

The oil from *Cymbopogon m. martinii* var. *sofia* provides 12 h of protection against *An. culicifacies*, *An. annularis* and *An. subpictus*.

Castor Seed Oil

A distillation fraction of castor seed oil was reported as a mosquito repellent.

Thujic Acid

Diethylamide of thujic acid distilled from the wood of western red cedar, *Thuja plicata*, was reported as a repellent of *Aedes aegypti*.

Indian Privet

The steam distillate of leaves of Indian Privet (*Vitex negundo*) provided 1–3 h of protection against Aedes aegypti.

Lemon Oil

Lemon oil was similar to DEET in repellency against the sand fly *Lutzomyia youngi*.

Tarweed

An extract of tarweed (*Hemizonia fitchii*) containing 1,8-cineole (eucalyptol) repelled *Aedes aegypti*.

Eucalyptus *camaldulensis*

Various extracts from this plant, including eucamol, 4-isopropylbenzyl alcohol, *p*-methane 3,8-diol were reported to be repellents to *Aedes aegypti* and *Ae. albopictus*.

(+)-Eucamolol

Eucamolol and its 1-epimer showed significant repellent activity against *Aedes albopictus*.

There are numerous reports in the literature of repellency of phytochemicals, but most of these phytochemicals have not been developed commercially. Three repellents have recently come to the market, and may be the trend of the future.

Merck 3535

3-(N-butylacetamino)-propionate has shown strong repellent action against biting flies.

KBR 3023

KBR 3023 is a Bayer product, a piperidine derivative, 1-Piperidinecarboxylic acid, 2-(2-hyroxyethyo) 1-methylpropylester.

PMD

PMD is similar to Quwenling, but is derived by a different extraction process. The active ingredient is p-methane-3,8-diol with additional isopulegol and citronellol. The product provided 5 h of complete protection time against *Anopheles funestus* and *An. gambiae*.

Though Permethrin, a pyrethroid, is not technically a repellent, it is used in a manner similar to repellents, to protect a person against biting insects. It is used to impregnate uniforms, clothing and bed nets.

The future repellents may be systemic repellents, or compounds masking the attractiveness of humans. Compounds may be developed to shield or block the body from bites.

Development of new repellents with increased protection time and effectiveness will likely come from a better understanding of host-finding. Attraction compounds combined with an insecticide may be developed to apply to clothing.

Despite recommendations that repellents be used to prevent mosquito-borne disease transmission, there is very little scientific evidence that repellents can be used to reduce the transmission of vector-borne diseases. It should be recognized that people use repellents to prevent annoyance from mosquito bites, and it would be inappropriate to recommend the use of repellents to prevent disease transmission by biting vectors.

Replete

Individual ants whose crops are greatly distended with liquid food. Repletes serve as living reservoirs, and will regurgitate on demand to supply the colony with food.

Reproduction

JAMES L. NATION
University of Florida, Gainesville, FL, USA

As in nearly every other aspect of their lives, insects display great diversity in modes of reproduction. Most insects reproduce in the adult stage by laying eggs, but a few reproduce during an immature stage, a process known as paedogenesis. Some, such as aphids and certain flies, for example, give birth to live young. Although sexual reproduction by union of male and female gametes is typical, certain insects reproduce some or all of the time by laying unfertilized eggs (parthenogenesis).

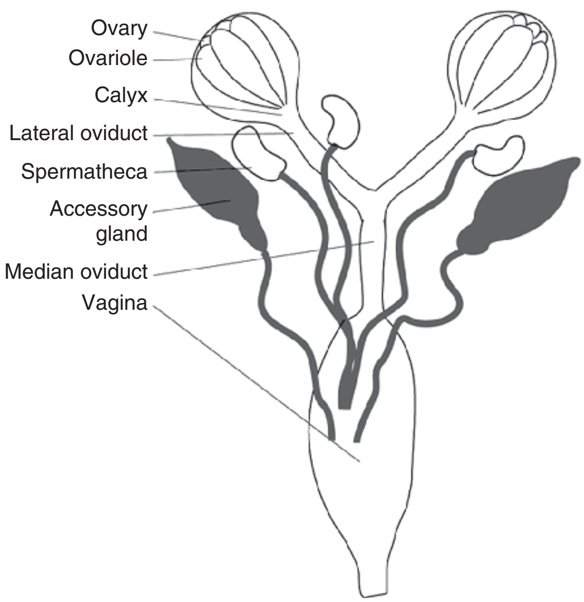
Oocytes accumulate yolk and cytoplasm and develop in egg chambers or follicles in the ovarioles within the ovary. Follicles are surrounded by a single layer of epithelial cells, the follicular epithelium. The presence or absence of nurse cells associated with ovarioles divides ovaries into two major groups; meroistic ovaries have nurse cells and panoistic ovaries do not. Nurse cells provide nutrients and gene products for the developing oocyte. In panoistic ovaries, similar components probably are provided by other cells, possibly the follicular epithelium. Insects typically produce eggs with a large amount of yolk relative to the cytoplasm, and the yolk is rich in proteins and lipids to be used in forming the new embryo and for energy, respectively. In most insects the yolk is formed from large glycolipoproteins called vitellogenins that are synthesized in fat body cells and transported to the ovaries by hemolymph. In contrast, small molecules called yolk proteins, to distinguish them from large vitellogenins, are incorporated into the yolk by the higher Diptera, such as tephritid fruit flies, drosophilid flies, house flies and related dipterans (but not in mosquitoes, which have vitellogenins). Two different sets of genes are required for the synthesis of yolk proteins and vitellogenins. Some parasitic insects produce small (20–200 μm), almost yolkless eggs that are deposited in a host (another insect) where the developing embryo absorbs nutrients from the host through a thin egg shell. In most insects several hormones regulate oogenesis, synthesis of yolk proteins, and additional aspects of reproduction such as pheromone production, mating, and oviposition. Not surprisingly, the complement of hormones is not the same for all groups of insects. When maturation of the oocyte is nearly complete, a vitelline membrane is secreted, followed by secretion of the egg shell, or chorion. After the chorion is secreted onto the egg, it is ready to pass down the oviduct and, in most insects, be fertilized by sperm released from the spermatheca. Hymenoptera and some coccids (Hemiptera) produce haploid males without fertilization and diploid females when the egg is fertilized. The ratio of sex chromosome to autosomes and/or the presence of sex-determining genes are two mechanisms known to determine gender in most insects.

The Ovary and Egg Production

The typical internal reproductive system of females consists of paired ovaries, lateral oviducts, a common oviduct, one or more spermatheca and accessory glands. These structures are located dorsally to the alimentary tract. Generally, several to many ovarioles make up an ovary. Each ovariole contains a string of egg chambers called follicles. The tsetse fly *Glossina* spp. has one ovariole, two other dipterans (*Melophagus* spp. and *Hippobosca* spp.) have two, *Drosophila melanogaster* has from 10 to 30, the blowfly *Calliphora erythrocephala* has about 100, the American cockroach *Periplaneta americana* has eight, and termite queens (Isoptera) may have up to 2,000. The nymphalid butterfly, *Phyciodes phaon*, commonly known as the phaon crescent, has four ovarioles in each ovary and about 50 immature oocytes that look like a string of pearls in each ovariole when the adult female emerges from the pupal stage. Just one ovary containing one ovariole occurs in some aphids, and Collembola have sac-like ovaries that do not contain ovarioles. Typically, oocytes in various stages of development occur in each ovariole in many insects, but generally, the most terminal set of oocytes is matured and laid before the other oocytes grow very large, and in some insects at least, the growth of secondary oocytes is under hormonal control. It makes sense that one set of eggs is matured and laid, making room in the abdomen for maturation of the next set (Fig. 14).

Nurse cells are associated with developing eggs in meroistic ovaries that occur in most of the Holometabola (except Siphonaptera), and in Hemiptera, Dermaptera, Psocoptera, Siphunculata, and Mallophaga among the Hemimetabola. Panoistic ovaries that do not have special nurse cells likely evolved first, and occur in present-day Thysanura, Odonata, Plecoptera, Blattodea, and Isoptera. Panoistic ovaries evolved secondarily in Ephemeroptera, Orthoptera, and Siphonaptera.

In meroistic ovaries, nurse cells may occur in the same follicle with the developing oocyte (*Drosophila*), in an adjacent follicle (Hymenoptera), or be located in the germarial region with long cytoplasmic strands projecting to the developing oocyte (some beetles and Hemiptera). Nurse cells



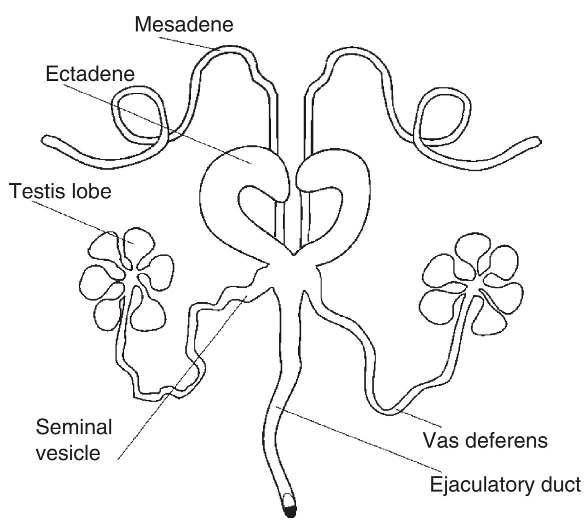
Reproduction, Figure 14 Diagram of a female reproductive system as found in *Rhagoletis* (Coleoptera) (adapted from Chapman, 1998, The insects: structure and function).

transfer nutrients and gene transcripts (mRNA) to developing eggs, and finally are used up in the process. Presumably follicular cells that surround all follicles provide nutrients and gene transcripts in those insects with panoistic ovaries.

Hormones control ovary growth, synthesis of yolk proteins and vitellogenins and their assimilation by the developing oocytes. Juvenile hormone seems to control all reproductive functions in some insects (Orthoptera, for instance), but in others juvenile hormone and ecdysone are important, and in still other groups juvenile hormone, ecdysone, and additional neuropeptide hormones are required. Juvenile hormone is synthesized by the corpora allata in adult insects, as in larvae, but ecdysone is synthesized by the ovaries in adult females. Near the termination of egg growth, the follicular epithelium secretes a thin protein sheet, the vitelline membrane, around the yolk and cytoplasm. Then the follicular epithelium secretes a laminar meshwork of cross-linked proteins, the egg shell or chorion. The follicular epithelial cells, now on the outside of the egg shell, die and are sloughed off the egg. The chorion contains no chitin, and with a few exceptions, it is not mineralized like the egg shell of birds. Sperm, which are released from the spermatheca as the egg passes down the common oviduct, traverse the chorion by passing through a small, usually twisted channel, the micropyle. More than one micropyle channel may be present. Although most Diptera have only one, the migratory locust *Locusta migratoria* has 35–43 openings.

The Male Internal System and Sperm Production

Typically, sperm are produced in paired testes in males, although in some Lepidoptera the testes are fused into a single structure. From the testes they pass into the short vas efferens that leads into the longer vas deferens and finally into the ejaculatory duct. Accessory glands are often, but not universally, part of the male system and when present they are attached by a duct to the vas deferens or to the ejaculatory duct (Fig. 15). Secretions from the accessory glands form the spermatophore in some insects, or if no spermatophore is formed, the secretions are added to the sperm prior to transfer to the female. Some of the secretory products provide nutrients and stimulate contractions in the reproductive tract of females, aiding movement of sperm into the spermathecae of the female. Each testis generally consists of a number of tubes or follicles in which spermatozoa are matured. Follicles may vary from one to more than 100 follicles, and may be incompletely separated from each other, as in Lepidoptera, or the testes may consist of several lobes, each with several follicles. In Diptera the testes consist of an elongated and undivided sac. Typically, sperm progress through several developmental stages. Sperm begin as diploid cells secreted by mitotic divisions of cells in the germarium. These initial diploid cells, called spermatogonia, further divide by mitosis into numerous diploid spermatocytes that become enclosed within a cyst or capsule of somatic cells (also diploid). Spermatocytes within a sac or cyst generally arise from the same spermatogonial cell



Reproduction, Figure 15 **Diagram of a male reproductive system as found in *Tenebrio* (Coleoptera) (adapted from Chapman, 1998, The insects: structure and function).**

and have synchronized development. Spermatocytes may undergo still more mitotic divisions; there are five to eight divisions in Acrididae and seven in *Melanoplus*, but eventually in a maturation zone they divide by meiosis and produce haploid spermatids. Spermatids undergo some further maturation in the transformation zone, and usually are bundled together by a thin membrane in this stage, or may be enclosed within a spermatophore. Insect spermatozoa tend to be long and have a slender head region, probably an evolutionary adaptation to navigate the micropyle.

Many males mature sperm during the pupal stage, while others may require several days as an adult to mature sperm. In contrast to the situation in most vertebrates, sperm can survive in the spermatheca of a female for weeks, months, or even years. Honeybee queens have been known to lay fertilized eggs after several years (8–9 years in one reported case), and queen ants were reported to contain viable sperm after 15 years.

During most of the twentieth century, various experiments failed to show hormonal control of spermatogenesis, but beginning in the 1970s ecdysteroids were found in the testes of flies, crickets, mosquitoes, and various lepidopterans, and experiments showed that they were synthesized there and stimulated spermatogenesis. Neuropeptides also may be involved in a cascade of reactions leading to ecdysteroid synthesis in testes; physiological levels (~10^{-13} to 10^{-15} M concentrations) of an ecdysiotropic peptide from gypsy moth brain stimulates synthesis of ecdysteroids in testes of larval and pupal gypsy moth males. These observations bring spermatogenesis in insects more in line with well known hormonal control of spermatogenesis in other animals.

An unusual situation evolved in male Lepidoptera. They produce both apyrene sperm without a nucleus and nucleated eupyrene sperm. Only the latter type can fertilize an egg. The two types of sperm are present in some of the earliest families of Lepidoptera that evolved, but one of the most primitive families, the Micropterigidae, do not produce apyrene sperm. Male Lepidoptera form a spermatophore in the female bursa copulatrix during mating, and both types of sperm are incorporated. As sperm pass down the ejaculatory duct, male silkmoths (*Bombyx mori*) secrete an enzyme, an endopeptidase called initiatorin, from cells in the ejaculatory duct. In the spermatophore, initiatorin begins to act upon the surface coat of both types of sperm, but the coat of the apyrene sperm is more quickly digested, releasing them. Motile apyrene sperm agitate the viscous contents of the spermatophore and aid liberation of the eupyrene sperm. Initiatorin also activates a carboxypeptidase that digests proteins in the seminal secretions and liberates arginine and other amino acids. Arginine is readily converted to glutamate, which sperm metabolize to provide energy for motility.

Pheromones in Reproduction

Many insects secrete pheromones, a special class of semiochemicals, to attract mates. Sometimes both sexes produce a pheromone that functions in some aspect of mating. Alternatively, only the female or the male may produce an attractant pheromone, commonly called a sex pheromone. The term "pheromone" is derived from two Greek words, pherein, meaning to carry, and *horman*, meaning to excite. The sex pheromone is usually composed of several chemical components secreted in a particular ratio or blend. Typically, glands at or near the surface of the body secrete the pheromone blend into the air. The total blend generally is considered to be the pheromone. The blend or ratio of components allows more information to be encoded, and allows greater discrimination among closely related species, which often use the same, or some of the same, components. Pheromones have been identified from more than 1,600 species of insects in 90+ families from 9 orders. Lists of Lepidoptera and the chemical nature of their sex pheromones are available on the Internet (Arn et al. 1999). Sex pheromones are sometimes used by predators and parasites to locate a potential host. The sex pheromone of

Dendroctonus frontalis, a bark beetle, not only attracts a potential mate, but may attract a clerid predator, *Thanasimus dubius*.

Most moths find each other and mate in low light intensity during some part of the evening or night. Perhaps because of activity at low-light intensity, their ability to detect chemicals in the air has evolved to a very high degree of sensitivity. In most Lepidoptera, the female produces the sex pheromone, and males fly to it. The antennae of many male Lepidoptera are plumose, with thousands of small hairs containing pheromone sensitive sensory neurons. The female silkworm moth contains about 1×10^{-8} g pheromone in her body. If this amount of pheromone were released instantly and uniformly distributed into slightly moving air, theoretically a male should be able to sense the pheromone about 4,560 m (2.8 miles) downwind. Any male within that active space, or wandering into its periphery, should be excited to fly upwind. The possibility of a male detecting a single female up to 4,500 m distant stretches the imagination. Several factors probably preclude this theoretical example from being achieved. First of all, females do not release their pheromone instantly, but do so slowly over some period of time each evening. Neither is there uniform distribution of pheromone in the air because of changes in wind current and direction, and buildings, trees, and other objects between the female and the male that disrupt the air flow and create turbulence. In addition, pheromones are adsorbed to the surface of plants and other objects, reducing the amount in the air. Nevertheless, the success of moths in locating each other under semi-dark conditions is impressive and attests to the effectiveness of pheromone in their success.

It is not always the female, however, that produces a sex pheromone. Some male Lepidoptera also produce pheromones, and in most bark beetles (family Scolytidae) both sexes typically produce pheromones. In true fruit flies (family Tephritidae), the male produces the attractant pheromone (with one known exception: the female olive fruit fly, *Bactrocera oleae*).

Sex pheromone synthesis and secretion seem to be under hormonal control in many, perhaps even most, insects, but few specific details have been elucidated. The most thoroughly studied examples of hormonal control of sex pheromone come from moths and cockroaches. A polypeptide hormone that controls the synthesis of the sex pheromone in moths has been named PBAN (Pheromone Biosynthesis Activating Neuropeptide). PBAN is now known from several different moths, and it may have slightly different roles in different moths. For example, in the redbanded leafroller, *Argyrotaenia velutinana*, PBAN regulates pheromone biosynthesis by increasing the supply of octadecanoyl and hexadecanoyl fatty acids needed for pheromone biosynthesis. In several moths, PBAN appears to regulate an enzyme, a Δ 11 desaturase, that is necessary to introduce a double bond into the pheromone precursors. In still others, it influences the reduction of fatty acids to the alcohol precursor of acetate pheromones.

Determination of Gender

At least three chromosomal systems, with variations, control sex in insects. Probably the earliest to evolve was one in which male sex chromosomes are XY and female XX. This system exists in many different groups today, including *D. melanogaster* and other Diptera. In some insects the Y chromosome has been lost, and those males are XO. Males in the orders Odonata, Orthoptera, and some groups in other orders are XO males. In Lepidoptera and Trichoptera, the female is the heterogametic sex, usually designated as ZW while males are ZZ. In the third system, found in Hymenoptera and some Hemiptera, females are diploid and males are haploid. If an egg is fertilized by a sperm, it becomes a female, and if no fertilization occurs, the egg develops into a haploid male. In honeybees and probably other Hymenoptera, the female can control the release of sperm from the spermatheca, and thus can control the sex of the individuals that will develop from the eggs she lays. In a few insects the sex of individuals is determined by prevailing temperature, as in subarctic mosquitoes, and in some gall midges by available nutrition.

Exactly how the different chromosomal patterns described above lead to sex determination is variable and poorly known for all except a few insects. The ratio of X chromosomes to autosomes (A) in determining sex of offspring has been characterized in *Drosophila melanogaster*. Although the Y chromosome carries genes for factors necessary for the production of motile sperm, it does not carry gender-determining genes in *Drosophila*. The ratio 2X:2A = 1 (one set of autosomes with an X from each parent) results in normal females, and the ratio of 3X:2A in aneuploids also results in female phenotype. A sex chromosome:autosome ratio of 0.5 (1X:2A, an autosome set from both parents, but an X from the female parent and a Y from the male parent) results in a normal male, and even a smaller ratio (1X:3A) produces a male phenotype. Intermediate ratios can result in mosaic intersexes in which the individual contains both male and female cells. Chromosomal ratios are ultimately expressed in specific gene actions. Since males have only one X chromosome, genes on it that control important functions or synthesis of critical molecules must be twice as active in males as in females, a process known as dosage compensation, but few details are known. Specific sex determining genes control the phenotype of some insects, including the housefly *Musca domestica*, the silkworm moth *Bombyx mori*, and some mosquitoes.

Reproductive Rate

The number of offspring produced per unit of time.

Reservoir

A site where organisms can survive, usually in relatively small numbers, and then invade or repopulate an area.

Resilience

An expression of the ability of some species to recover from disturbance. Persistence of a particular level or density despite perturbations (contrast with stability).

Resilin

JAMES L. NATION
Department of Entomology and Nematology, University of Florida, Gainesville, FL, USA

Resilin is a colorless, transparent structural protein of cuticle that has even better elastic properties than natural rubber. A rubber band elongates upon prolonged stretching, but experiments have shown that resilin retains about 97% of its original length even after extended periods of stretching. Resilin is not appreciably sclerotized, or else it could not retain its elasticity. Only small patches of resilin occur in the cuticle, and it mainly occurs at joints where wings or legs are hinged to the thorax. The prealar arm connecting the mesotergum to the first basalar sclerite of the thoracic wall in the wings of the migratory locust *Schistocerca gregaria* contains about 50 μg resilin and 15 μg chitin, and a similar hinge in large *Aeshna* spp. of dragonflies contains 5–7 μg resilin. A pad of resilin located near the coxal attachment to the pleural arch is compressed when a jumping flea crouches and prepares for a jump, and as the compressed resilin springs back to its original shape when the leap begins, it helps propel the flea into the air. Resilin is rich in the amino acids glycine and proline, as are some other structural proteins such as collagen, elastin, and silk fibroin. Resilin contains no hydroxyproline, hydroxylysine, tryptophan, or sulfur-containing amino acids, but does contain two unusual amino acids, dityrosine and trityrosine. These latter two amino acids may be involved in light cross-linking of resilin protein chains, enabling them to hold their shape. Studies of resilin biosynthesis are sparce, possibly because of the rather small areas in which it occurs and the difficulty of getting it out of the cuticle since it is insoluble in aqueous solvents. Resilin may be secreted by specialized epidermal cells.

Resistance of Solanaceous Vegetables to Insects

MENACHEM J. BERLINGER
ARO, Gilat Research Center, Beer Sheva, Israel

Tomato (*Lycopersicon esculentum*), potato (*Solanum tuberosum*) and pepper (*Capsicum annuum*) are “new world” crops. Tomato and potato originated in the northern regions of South America, and pepper in the tropical regions of Latin America. These crops are thought to be relatively new under cultivation, perhaps 200–300 years. Eggplants (*S. melongena*), however, originated in India and have been cultivated for hundreds of years. Wild eggplant species are not known.

The Pests and Their Geographical Origin

Almost all the pests are insects belonging to the following orders: Thysanoptera (thrips), Hemiptera (bugs, leaf-hoppers, whiteflies and aphids), Orthoptera (mole-crickets and grasshoppers), Coleoptera (beetles), Lepidoptera (moths and butterflies), and Diptera (flies). Out of the known pest species, only about one-fifth are major pests of primary importance. These may cause severe damage during almost every season and in many countries on different continents. All others are considered as minor pests, restricted to a rather limited area. Within this area, however, they might be severe pests of primary importance. Booklice or psocids (Psocoptera) and the wingless Collembola (springtails) are considered nuisance pests.

The pests affecting these crops either originated from South America, like the crop, and were accidentally reintroduced to the crop in other countries, or are local pests of other plants, which have adapted to the newly introduced crops. The greenhouse whitefly (*Trialeurodes vaporariorum*) and the potato tubermoth (*Phthorimaea operculella*) originated in Central America. The Colorado potato beetle (*Leptinotarsa decemlineata*) originated in North or Central America. The serpentine leafminer (*Liriomyza trifolii*) and the western flower thrips (*Frankliniella occidentalis*) originated in North America. Some other pests, such as the sweet potato (tobacco) whitefly (*Bemisia tabaci*) and the onion thrips (*Thrips tabaci*), are from Central Asia. The tomato fruitworm (*Keiferia lycopersicella*), the Egyptian cotton leafworm (*Spodoptera littoralis*), the beet armyworm (*Spodoptera exigua*), the *Phytometra* (*Plusia*) *chalcites*, the tomato fruitworm (*Helicoverpa zea*) and the African cotton bollworm (*Heliothis armigera*) seem to be local pests that have adapted to the newly introduced tomato, potato, pepper, and eggplants. Knowing the origin of the pests can assist with the search for resistant plants for breeding.

Mechanisms of Resistance

In solanaceous plants, resistance mechanisms are based on exterior and/or interior plant features. The most pronounced are the exterior mechanisms, based on physical means: trichomes or glandular-trichomes and their sticky exudate, which interferes with any small insect like thrips, whiteflies, aphids, leafminer flies or the younger stages of various larvae of other insects. These trichomes cover the plant's surface, leaves and twigs, and provide an exterior defense mechanism. The glandular hair exudate, when dislodged from cell walls, adheres to the legs and mouthparts of the insects and rapidly hardens, entrapping small insects or causing them to fall off the plant. Stuck insects rarely feed, quickly die, and thus are unable to transmit viruses. The interior mechanisms provide resistance that is based on secondary plant substances, which impose repellent, toxic, or hormonal effects, mainly on biting and chewing insects.

Trichomes occur in a multitude of forms in many wild tomatoes. In numerous species, there is a negative correlation between trichome density, and insect feeding and oviposition responses, and the nutrition of larvae. Specialized hooked trichomes may impale adults or larvae as well. Trichomes may also complement the chemical defense of a plant by possessing glands that exude terpenes, phenolics, alkaloids or other substances, which are olfactory or gustatory repellents. In essence, glandular trichomes afford an outer line of chemical defense by advertising the presence of "noxious" compounds. These features make them good sources for breeding resistance to virus transmission by insects. This is hereditary in the hybrids of the wild plants with cultivated varieties.

Resistant plants may possess both exterior and interior mechanisms, which then provide simultaneously resistance to a variety of pests. For example, *Lycopersicon* (*Solanum*) *pennellii* (e.g., LA 716) is resistant to a number of insect pests due to the accumulation of acylsugars exuded from type IV trichomes. Thus, it is resistant to *B. tabaci* adults, both causing direct damage and transmitting virus diseases. At the same time, it is also resistant to *S. littoralis*. The small larvae (L_I and L_{II}) become entangled in the sticky exudate of the leaf trichomes, like any small insect. Bigger larvae (L_{III}) generally overcome the stickiness, but they are then confronted with a juvenile hormone mimic in the leaves, which causes high larval mortality, adult morphological deformation, and male sterility. The survivors pupate earlier, and the emerging adults are smaller and less fertile than usual. The large larvae (L_{IV}) are not affected by these mechanisms.

The secondary plant chemicals, present in the ancestors of the domesticated cultivar, provided them with natural resistance to pests. Unfortunately, these chemicals may also be unpalatable or even toxic to people so such plant chemicals were deleted during the breeding process. In this way, the susceptibility to pests of the solanaceous crops was inadvertently increased during their domestication. As a result, the modern cultivars need to be continuously protected by the grower against pests. The reintroduction of resistance, or partial resistance, to pests into the modern cultivars is an invaluable component of integrated pest management programs.

Vector Resistance

Virus diseases are transmitted to these crops by various insect pests (e.g., aphids mainly to potatoes and pepper, and whiteflies and thrips mainly to tomatoes). Because viruses cannot be controlled, and infected plants cannot be cured, the only way (other than by eliminating vector insects) to combat viruses is by preventing their transmission, mainly by promoting resistance.

Hypothetically, two expressions of plant resistance are recognized: resistance, or tolerance, to the virus itself, distinguished as "virus resistance," and resistance to the virus-transmitter, distinguished as "vector resistance." These types of resistance are complementary and can be integrated into the same plant. The advantage of the combined vector-, and virus-resistance is due to the fact that plant resistance to insects is expected to be of greater durability than plant resistance to viruses, and the combination of the two resistance mechanisms will even prolong the durability of plant resistance to virus infection.

Breeding for Pest Resistance

Tomatoes are attacked by various pests, but within cultivated tomato varieties no sufficient pest resistance has been detected. Wild types such as *L. pimpinellifolium*, *L. peruvianum*, *L. chilense*, and *L. glandulosum* express some resistance to various pests. Nevertheless, adequate levels of resistance were detected mainly in accessions (ecotypes) of *L. pennellii*, *L. hirsutum* (also known as *L. hirsutum* f. *typicum*), and *L. hirsutum* f. *glabratum*. These sources of resistance had been intensively exploited. Some are resistant enough to prevent direct damage, and some, although virus-susceptible themselves, even prevent virus transmission. Glandular trichomes of these plants exude a sticky material and protect the plants by physically trapping and immobilizing of the pests. Others also exude chemicals that are toxic or repellent to the pests. The resistant accessions usually show resistance to various insects.

The potato pests are generally similar to those attacking tomatoes, but most of the sources of resistance had been chosen among wild *Solanum* species, some of which bear tubers. Some of the source plants, e.g., *S. berthaultii*, *S. polyadenium* and *S. tarijense*, possess glandular trichomes on the foliage that protect the plants by physically trapping and immobilizing the attacking insects. Other *Solanum* spp. possess a variable degree of secondary plant substances such as glycoalkaloids (e.g., tomatin, demissin, α- and β-solamarie, α- and β-chacinine, and α-solanine), which may have a toxic effect or inhibit feeding. *Solanum berthaultii* releases an aphid alarm pheromone that repels aphids such as *Myzus persicae*.

Aphids

The most severe aphid problem is the transmission of virus diseases in potato. Most of these aphid-borne viruses are non-persistent, or stylet-borne viruses. The agricultural means to prevent this virus transmission are very limited. One of the more efficient ways is the use of aphid vector-resistant plants. Naturally, most breeding efforts in potato have been devoted to aphid resistance. The potato crop is commonly infested by *Myzus persicae*, *Macrosiphum euphorbiae*, and *Aulacorthum solani*. Glandular hairs are quite effective in limiting aphid damage to the potato crop. They occur abundantly on *S. polyadenium*, *S. tarijense* and *S. berthaultii*. The sticky exudate, which is discharged from the trichome glands, precipitates on the aphid's limbs, impedes the aphid's movements and immobilizes it; the aphid finally starves to death. This trait of glandular trichomes is hereditary and expressed in the hybrid progenies of wild and cultivated plants. *Solanum polyadenium* and *S. berthaultii* are adequate sources for breeding potatoes resistant to aphids. The resistance of *S. chacoense*, *S. stolomfenerum* and *S. demissum*, to *M. persicae*, *A. solani* and *M. euphorbiae* depends on the species of the aphid and on the physiological condition of the leaves. This shortcoming must be considered while using them as sources of resistance.

Resistance in the wild tomato, *L. hirsutum* f. *glabratum* (PI 134417), is due primarily to the presence of the toxic factor that is exuded by the trichomes. A concentrated chloroform extract from the foliage is toxic to *Aphis craccivora*, *A. gossypii* and *M. persicae*.

Tomatoes, to which Mi-1, a *L. peruvianum* gene conferring resistance to the root-knot nematode (*Meloidogyne incognita*) was introgressed, also confer resistance to *M. euphorbiae*. Furthermore, tomatoes that bear the *Mi-1.2* gene, which also provides resistance to nematodes, express resistance to *M. euphorbiae* and to the Q-biotype of *B. tabaci* as well. The incidence of tomato yellow leaf curl virus, expressed in cumulative percent of infected plants, in tomato and in wild *Lycopersicon* spp. in the field. (The most resistant known accessions of the wild species were selected to demonstrate the potential of host plant resistance).

Whiteflies

High levels of resistance to the greenhouse (or glasshouse) whitefly, *T. vaporariorum*, are well known in *L. pennellii*, *L. hirsutum* and *L. hirsutum* f. *glabratum* accessions, whereas *L. chilense*, *L. minutum*, and *L. peruvianum* express moderate levels of resistance.

Tomato resistance to direct damage, and to the transmission of the tomato yellow leaf curl virus (TYLCV), by the cotton (or sweet potato) whitefly, *B. tabaci*, and resistance to *B. argentifollii*, is known in *L. pennellii*, and to some extent also in *L. hirsutum* and *L. hirsutum* f. *glabratum*, though they are susceptible to the virus itself. The incidence of natural virus infection seems generally to reflect the level of resistance of the plants to *B. tabaci* (Table 6).

Lycopersicon pennellii accessions LA 716 and PI 79659 are highly resistant to *Bemisia*, whereas the resistance of LA 1277 depends on light intensity and day length. The primary mechanism of resistance is the sticky exudate of the glandular trichomes. Whiteflies that land on these plants become entangled in this sticky exudate and die within a short time. In some accessions, the sticky exudate does not appear on the first three to four true leaves. These leaves are then unprotected and the whiteflies feed and develop on them readily. When artificially removed exudate is applied on cotton leaves, it protects them from whitefly attack for a long time. A toxic effect, browning and death of whiteflies, can be observed even when the sticky effect of the extracted exudate is neutralized by applying it on filter paper.

Among several *L. hirsutum* accessions, two are known to be rather resistant in respect to population build-up parameters, in comparison to the cultivated tomato: LA 1777 and IVT 771498; however, LA 1363 is rather susceptible. The main mechanisms of resistance are due to the physical interference of the glandular trichomes, and to toxic factors that occur in the trichomes and in the leaf tissues. Among

L. hirsutum f. *glabratum* (1*) PI 134418 (2*) PI 129157
L. hirsutum (3*) LA 1777 (4*) IVT 771498
L. pennellii (5*) LA 716 (6*) PI 79659

L. hirsutum f. *glabratum*, accessions PI 134418, PI 129157 and LA 407 are relatively resistant, and some others are not. In PI 365907, resistance depends on day length and light intensity and probably on some additional environmental factors. The main mechanism of resistance seems to be physical interference of the leaf trichomes and their exudate, which cause immobilization of the insects. It appeared that the exudate also has a repellent effect and, most likely, toxic factors that occur on the leaf surface or within the leaf are involved in plant resistance.

Leafhoppers

Total glycoalkaloid fractions, especially tomatine, provide resistance to the leafhopper in potatoes. *S. hougasii* and *S. bulbocastanum* are among the exploited sources of resistance. *S. berthaultii* (PI 218215) and *S. chacoense* (WRF 888) show less resistance than expected, probably because of their relatively low tomatine content.

Leafminer Flies

Lycopersicon pennellii accessions (LA 1735 and LA 716) possess a very high level of resistance to the leafminer *L. trifollii*. Adequate resistance is also found in *L. cheesmanii* (LA 1401) and in *L. hirsutum* f. *glabratum* (PI 126449). Larval antibiosis also occurs in F_1 hybrids. For breeding purposes, the resistance in *L. cheesmanii* has the most immediate value because it can be reciprocally hybridized with *L. esculentum*, and it produces orange fruit. Oviposition and adult feeding of *L. trifolii* on *L. pennellii* is significantly less than that on the cultivated tomato. This resistance is reduced when the foliage is rinsed with ethanol. Resistant attributes of *L. pennellii* can be transferred to *L. esculentum* through mechanical appression of *L. pennellii* foliage onto *L. esculentum* leaflets. Application of purified 2,3,4-tri-O-acylglucoses (the principal component of type IV glandular trichome exudate of *L. pennellii*) to *L. esculentum* significantly decreased feeding and oviposition on *L. esculentum*. Hence, the principal mechanism of resistance in *L. pennellii* to the leafminer is due to the secretion of acyiglucoses.

Lycopersicon hirsutum (PI 126445 and PI 127826) and *L. hirsutum* f. *glabratum* (PI 126449) possess a high level of resistance to the vegetable leafminer, *L. sativae* and *L. munda*.

Moths and Butterflies

Breeding resistance to moths and butterflies has been conducted mainly in tomatoes. The moths and butterflies belong mainly to three families. Members of the Gelechiidae are the tomato pinworm and the potato tuber moth. Both are oligophagous insects, which feed exclusively on Solanaceae under field conditions. High resistance expressed in delayed larval development, high mortality, and reduced leaf consumption to *K. lycopersicella* has been derived from *L. hirsutum* accessions (PI 126445, PI 127826 and LA 361) and from *L. hirsutum* f. *glabratum* accessions (PI 126449 and PI 134417). On these plants, basal cells of type VI trichomes and other epidermal cells as well as most of the palisade mesophyll are not consumed by *K. lycopersicella* larvae. It seems that these structures also contain deterrent chemicals. The resistance of other wild tomatoes – e.g., *L. peruvianum*, *L. peruvianum* var. *humifusum*, *L. cheesmanii* f. *minor* and *L. glandulosum* – varies in its intensity. *L. hirsutum* (LA 1777) is highly resistant to *P. operculella*.

Resistance to the tobacco hornworm, *Manduca sexta* (Sphingidae) is expressed in several of the *L. hirsutum* f. *glabratum* accessions (PI 134417 and LA 407).

Several of the moths that attack tomato crops belong to Noctuidae. Resistance of tomato cultivars to the tomato fruitworm *Heliothis zea* varies greatly, indicating that much of the variability can be used to develop less susceptible cultivars. Higher levels of resistance can be obtained from *L. hirsutum* (PI 127826) and *L. hirsutum* f. *glabratum* (PI 126449, PI 129157, PI 134417, PI 134418, PI 251304, PI 251305), whereas the resistance of

L. pimpinellifolium and *L. peruvianum* is insufficient. The antibiotic factor, which affects *H. zea*, appears to be inherited recessively. *H. armigera* larvae are strongly affected by feeding on leaves of the resistant *L. hirsutum* (LA 1777), *L. hirsutum* f. *glabratum* (LA 407), and *L. pennellii* (LA 716). Highest levels of resistance to *Phytometra chalcites* are found in *L. hirsutum* (LA 1777), *L. hirsutum* f. *glabratum* (LA 407 and LA 1625), and *L. pennellii* (LA 716). Resistance to *S. littoralis* larvae occurs in *L. hirsutum* (LA 1777), *L. hirsutum* f. *glabratum* (LA 407 and LA 1625), and *L. pennellii* (LA 1277). In conclusion, many sources of resistance are common to a various noctuid larvae, and their resistance is based mainly on toxic or antifeedant repellents.

Beetles

Tobacco flea beetle, *Epitrix hirtipennis*, adults are strongly repelled by *L. hirsutum* and *L. hirsutum* f. *glabratum* due to the exudate of their glandular trichomes. Removing this exudate by rinsing the leaves with 75% ethanol eliminates the resistance.

Colorado potato beetle, *Leptinotarsa decemlineata* resistance is due to the four-lobed glandular hairs on the leaves and stems of the wild potato *S. polyadenium*. Sticky material is discharged from these hairs on contact, trapping larvae or encasing their feet. Larvae with encased feet fall off the plants and die.

Feeding rates of *L. decemlineata* are negatively correlated with the occurrence of tomatine, a steroidal glycoalkaloid, in the tomato and in wild tomatoes such as *L. hirsutum*. High tomatine content in leaves virtually inhibits beetle feeding.

Resistance to Insecticides

One of the principal (but not only) reasons for difficulty with controlling insects and other arthropods. Resistance is usually metabolic, but can also have a behavioral or physical basis. Other causes of control failure commonly ascribed to resistance include incorrect mixing or formulation, incorrect application, weather-related interference, and the presence of microbes in the soil that biodegrade pesticides. Finally, the movement or emergence of insects post-application can sometimes give the appearance of resistance.

► Insecticide Application: The Dose Transfer Process

Resistant

Organisms that are tolerant of conditions that are deleterious to other strains of the same species. In entomology this term usually is applied to plant tolerance of pest damage, or arthropod tolerance of pesticides or pathogens.

Resource Concentration Hypothesis

The concept that the lack of diversity resulting from a homogeneous plant population limits community stability because herbivores have a ready food supply, favoring herbivore population increase.

Resource Partitioning

The differential use of resources by organisms.

Respiratory Horns

Elongate projections of the egg chorion that form a plastron on the egg, facilitating gas exchange but minimizing water loss. Respiratory horns are found on the eggs of several taxa, including Diptera, Hymenoptera, and some Hemiptera.

Respiratory Siphon

A tube found in larvae of certain insects, and used for breathing.

Respiratory Trumpet

Protuberances associated with the prothorax of the pupal stage in certain aquatic Diptera.

Restricted-Use Pesticide

This terminology was developed by the US Environmental Protection Agency to describe pesticides that are considered to be unsafe for use by the public without special training. Pesticides in this class cannot be purchased and used without license or permit. In contrast, less toxic or less hazardous materials are classified as "general-use pesticides" and can be purchased and used by anyone.

► Insecticides
► Regulations Affecting Use of Pesticides

Restriction Endonuclease

An enzyme that cuts DNA only at a limited number of specific nucleotide sequences. It is also known as a restriction enzyme.

Restriction Fragment Length Polymorphism (RFLP)

A polymorphism in an individual, population or species defined by restriction fragments of a distinctive length. Usually caused by gain or loss of a restriction site but could result from an insertion or deletion of DNA between two conserved restriction sites. Differences in DNA RFLPs are visualized by gel electrophoresis.

Resurgence of Pests

Increase in abundance of pests, rapidly and sometimes to higher than previous levels, following actions made to suppress them.

Reticulations

A netlike structure, usually referring to the pigmented pattern on eyes of Lepidoptera.

Reticulated Beetles

Members of the family Cupedidae (order Coleoptera).

► Beetles

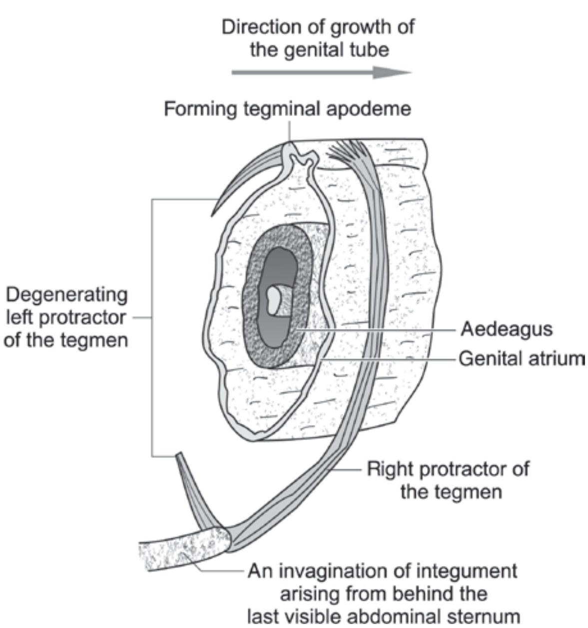
Retina

The light receptive apparatus of an eye.

Retournement and Deversement of the Aedeagus in Coleoptera

K. K. VERMA
Borsi, Durg, India

Seemingly coupled with the riding mode of copulation (that is the male riding on the back of the female, with both the participants of copulation facing the same direction) are two special features of the male copulatory apparatus in many Coleoptera, namely "retournement" and "deversement" (Fig. 16). Retournement refers to the turning or rotation of the aedeagus through 180° about its longitudinal axis during development (Fig. 17). Deversement refers to a sideway inclined asymmetric orientation of the deeply ventrally curved aedeagus, when in repose within the abdomen. Every time the intromittent organ is protruded for copulation, it returns to a symmetrical orientation, which is undone when the organ is withdrawn after coitus. In contrast retournement is an irreversible and permanent change in the orientation of the organ.

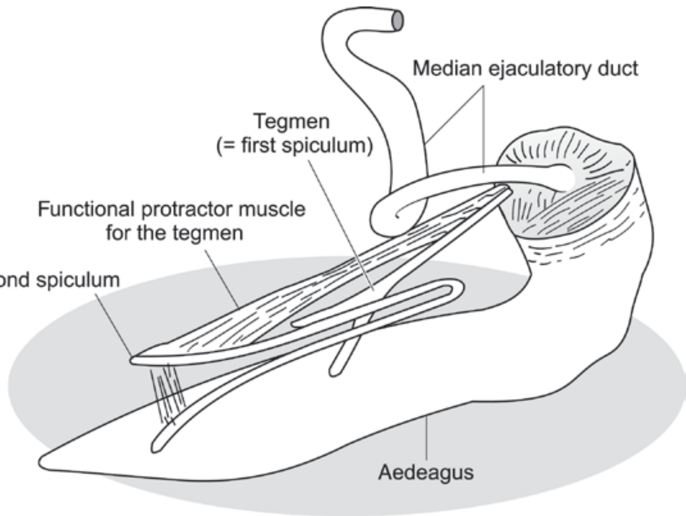


Retournement and Deversement of the Aedeagus in Coleoptera, Figure 16 Copulatory apparatus of *Aulacophora foveicollis*, ventrolateral view. Note the asymmetric origin of the protractor of the tegmen (=first spiculum) and the coiled course of the median ejaculatory duct (From Verma, 1994).

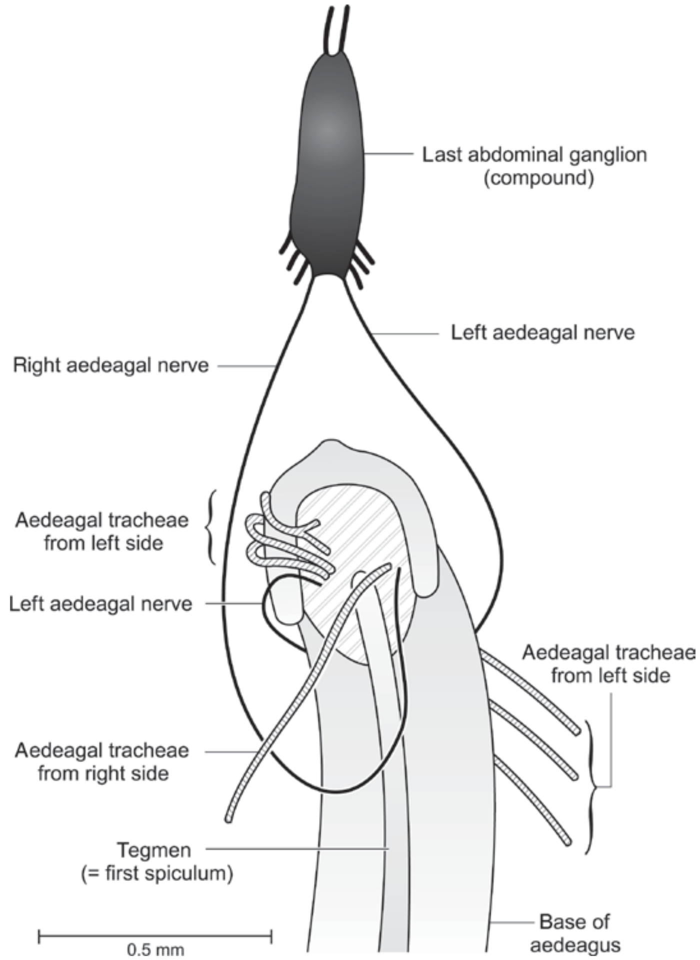
Heberdey has recorded retournement in the dytiscid *Hydroporus*. Jeannel has mentioned this phenomenon in some Silphidae, Staphylinidae and with probability also in Oedemeridae. Verma and his coworkers have noted retournement in many Chrysomelidae and in some other Phytophaga. In at least two chrysomelids, *Galerucella birmanica* and *Aspidomorpha miliaris*, the progress of retournement in development could be traced (Fig. 18). Retournement takes place in late pupal life in the former species, and soon after eclosion from the pupal skin in the latter. In two paropsine chrysomelids (*Chrysophtharta* species) from Tasmania, retournement could be inferred by comparing the orientation of the aedeagus in just-ecloded adults with that in reproductive males.

Retournement leaves behind certain anatomical effects, which help in inferring occurrence of the developmental turning of the copulatory organ. Such effects include: (i) the aedeagal nerve and tracheae, arising on the left side, enter the basal foramen of the aedeagus on the right side, and similarly the nerve and tracheae of right origin approach the foramen on the left side, (ii) the median ejaculatory duct, if not very long and winding, presents a coiled course, and (iii) the protractor muscle of the tegmen may present an asymmetry at its attachment on the tegmen and/or at its origin, as in the chrysomelids *Aulacophora* and *Colasposoma*, in the cerambycid *Aeolesthes*, and in the bruchid *Caryedon gonagra*.

Asymmetry of the protractor of the tegmen is due to involvement of this muscle in the mechanism of retournement during development. As has been observed in *Galerucella* and *Aspidomorpha*, this muscle is paired in development. The protractors arise on a pocket like invagination of the integument at the hind end of the abdomen behind the last visible sternum, or on



Retournement and Deversement of the Aedeagus in Coleoptera, Figure 17 **Diagram to illustrate mechanism of "retournement" of the aedeagus in Phytophaga (Coleoptera).**



Retournement and Deversement of the Aedeagus in Coleoptera, Figure 18 **Nervous and tracheal supply for the aedeagus in *Galerucella birmanica*, ventral view (From Verma, 1994).**

the second speculum, formed by sclerotization of the integumental pocket. (Note: the author of these lines chooses to refer to the apodemal part of the tegmen as the first speculum for reasons explained elsewhere.) Beyond the origin, the paired muscles extend forward and upward to find attachment on the dorsal surface of a longitudinal rod-like evagination of the genital atrium, which encloses the aedeagal rudiment. This outpocketing of the genital atrium is the forming apodemal part of the tegmen. Subsequently one muscle of the pair degenerates, and the surviving member exerts a downward unilateral pull on the genital tube (=aedeagus + the genital atrium). The pull is partly due to the genital tube growing in length anteriorly. As a result of this pull, the genital tube rotates, and the aedeagus turns through about 180°.

In most cases the right protractor of the tegmen survives, while the left one degenerates. Hence rotation of the aedeagus is clockwise, if looked at from behind. But occasionally the right one degenerates and the left one survives, and this results in anticlockwise retournement. The direction of retournement has been found connected with polymorphism in stored legume bruchids.

The mechanism of retournement also involves the role of a hormone, the juvenile hormone or JH. It has been found that in *Aspidomorpha miliaris*, if in a freshly ecloded adult male 22 h after the eclosion a ligature is put on the neck, connecting the head with the thorax, and thus availability of JH to the postcephalic body is denied, retournement fails to occur. If, however, the neck ligature is removed 30–32 h after the eclosion, anticlockwise retournement occurs, though in untreated males clockwise retournement is a rule in this species. This involvement of JH in the occurrence and direction of retournement has been experimentally inferred in a bruchid, too.

Diptera also show a phenomenon comparable to the retournement in Coleoptera. They show formation of “hypopygium inversum” and “hypopygium circumversum,” in development of which some terminal abdominal segments rotate through varying degrees, and this results in a rotation of the aedeagus. In beetles, however, retournement of the aedeagus is independent of the terminal segments of the abdomen, and these segments retain their bilateral symmetry undisturbed. Obviously, rotation of the male copulatory organ has evolved independently among Diptera and Coleoptera.

Jeannel has hypothesized that the riding mode of copulation, seen among Coleoptera, has evolved from the more primitive mode, the end-to-end method, in which the male and female, resting on the same substratum with their heads pointed in opposite directions, achieve intromission through their abdominal ends coming in contact. This primitive mode is seen among Hemiptera and also in some primitive Coleoptera. In the female the spermathecal opening is located in the sternal wall of the copulatory bursa. Hence, for successful sperm transfer in end-to-end copulation the ostium of the aedeagus, through which the internal sac is everted, is on the ventral face of the organ. When the primitive copulatory mode was replaced in evolution by the riding mode, the aedeagus has become ventrally curved to achieve intromission. When such a curved aedeagus enters the female bursa, its apical portion gets inverted; hence the ventrally placed ostium becomes dorsal, a position unsuitable for successful sperm transfer to the spermatheca. According to Jeannel this difficulty could be solved in some different ways, one of which is retournement. The retournement makes the ostium dorsal in the resting aedeagus, the apical part of which becomes inverted on intromission. Two other ways for achieving this end, as per Jeannel: (i) “l’inversion de l’aedeagus,” i.e., transposition in development of ventral features of the aedeagus to the dorsal surface and vice versa (e.g., in Carabidae and Psephalidae); and (ii) “la migration de l’orifice apical,” in which the apical region of the aedeagus is twisted, so that the ostium gets shifted to a dorsal position (e.g., in *Ptomaphagus* belonging to Catopidae). The terms “retournement” and “deversement” have been retained by authors, writing their communications in English, as they have been well defined, though they are French terms.

Jeannel has asked a question: Why a functional need, produced by the riding mode of copulation replacing the end-to-end mode, has not produced changes in the female organs? There is no satisfactory answer to this question as yet.

Deversement, or the laterally inclined orientation of the aedeagus in repose among internal organs, is obviously due to its ventral curvature and the need to accommodate the curved organ among other viscera. The asymmetry of the functional protractor muscle of the tegmen (vide supra) may also help in bringing the retracting aedeagus to an inclined orientation. The undoing of the deversement during protrusion of the organ for copulation seems to be due to the terminal part of the aedeagus being dorsoventrally depressed and the opening of the anogenital vestibule, bordered by the last visible abdominal tergum and sternum, being shaped like a horizontal slit.

Rey, Claudius

Claudius Rey, was born at Lyon, France, on September 8, 1817. He was a noted French entomologist who is remembered for his collaborations with Etienne Mulsant on Coleoptera and Hemiptera. Initially he was financially independent due to a family-owned printing business, which allowed him to direct most of his energies to the study of beetles. Though the business went bankrupt in 1847, his uncle offered him a job at a vineyard in southern France. While working at the vineyard he began a collaboration with Mulsant. Together they published almost continuously from 1850 until Rey’s death in 1895. He was an honorary member of the Entomological Society of France, and served as president of the Société Francaise d’ Entomologie from 1882 until his death.

RFLP

See restriction fragment length polymorphism.

Rhabdom

The site of the light-absorbing rhodopsin in an ommatidium. The rhabdom typically consists of several rhabdomeres and is situated in the center of the ommatidium.

Rhabdomere

The part of a retinular cell in an ommatidium that contains the light-sensitive rhodopsin. The rhabdomere membrane is formed into microvilli. The electrical impulses generated by light absorption are transmitted to the optic lobe of the brain.

Rhabdoviruses

The rhabdoviruses are a diverse group of more than 200 viruses which can cause disease in both plant and animal hosts. The animal rhabdoviruses are characterized by a bullet-shaped morphology, whereas certain plant rhabdoviruses have bacilliform morphology. The best-known rhabdovirus is the rabies virus, one of the many diseases studied by L. Pasteur in the 1880s. Many of the vertebrate viruses within the genera *Vesiculovirus* (vesicular stomatitis virus, VSV) and *Lyssavirus* (rabies-like viruses) are insect-transmitted and are capable of replicating in mosquitoes, blackflies, midges, sandflies and houseflies, as well as in select insect cell lines. The vesicular stomatitis virus, a relative of the rabies virus, has served as a model for studying the structure and function of rhabdoviruses. The animal rhabdoviruses are composed of a nucleocapsid protein (N) and a matrix protein (M) which form a helical structure encasing the (–) ssRNA. The resulting nucleocapsid or ribonucleic protein core is enveloped by a lipid-bilayer membrane. This envelope contains a viral glycoprotein (G) that anchors the membrane to the M-protein of the ribonucleic protein core. The M-protein (about 220 aa, pI = 9.07) is multifunctional, serving various structural roles as well as modulating viral transcription/replication and suppressing certain host cell functions. Extracted (–) ssRNA is non-infectious and requires encapsidated RNA transcriptase activity. RNA transcription is dependent upon three proteins, the N protein which complexes to the RNA to form a template, the L-protein which acts as the polymerase, and the polymerase-associated P (or Ns) protein responsible for RNA chain elongation.

The only well-characterized insect rhabdovirus is the Sigma virus of *Drosophila melanogaster*. This virus, discovered in 1937 by L' Heretier and Teissier, is characterized by its ability to induce CO_2 sensitivity (anoxia) and to be vertically transmitted to progeny flies via an extrachromosomal route. Unlike the polydnavirus, the Sigma virus does not integrate its genome into the host chromosome but undergoes limited replication in the cytoplasm of male and female gametes. Interestingly, the CO_2 anoxia, which is temperature dependent, also can be induced in fly and mosquito species that have been challenged with various lassa- and vesiculoviruses. The sensitivity to CO_2 is believed to be due to the presence of virus in the insect nerve ganglia and more specifically to the expression of the viral membrane proteins (G protein). The Sigma virus, unlike other rhabdoviruses, is not cytopathogenic and usually is considered to be harmless to *Drosophila*. This virus, unable to replicate in alternate hosts, undergoes a restrictive replication within *Drosophila* cells. In addition to the Sigma virus, several rhabdovirus-like particles have been detected in other invertebrates. In certain insects, such as the house cricket, *Acheta domestica*, the rhabdovirus VLP is polytropic, causing trembling symptoms and over 80% mortality. In other insects, such as the hymenopteran parasitoid *Biosteres longicaudatus*, a rhabdovirus VLP has been detected in venom apparatus. In this case, the virus does not appear to cause any pathology but may be involved in the suppression of the immune response of the host, the Caribbean fruit fly, *Anastrepha suspensa*. Like the polydnaviruses, this entomopoxvirus virus is associated with the lumen of the venom apparatus of the parasitoid.

Rhammatocerus schistocercoides, a Swarm-Forming Grasshopper from South America

MICHEL LECOQ[1], BONIFÁCIO MAGALHÃES[2]
[1]Centre de Coopération Internationale en Recherche Agronomique pour le Développement, Montpellier, France
[2]Embrapa Recursos Genéticos e Biotecnologia, Parque Estação Biológica, Brasília, Brazil

The grasshopper *Rhammatocerus schistocercoides* (Orthoptera: Acrididae: Gomphocerinae) causes severe damages in rice, soybeans, maize, sugar cane, and native pastures in Brazil. This species is mainly concentrated between the parallels 12° and 15° south and meridians 52°–61° west (Fig. 19). This area partially occupies the states of Rondonia, Mato Grosso, and Goiás, where since 1983 there have been severe outbreaks (mainly in 1984–1988 and 1992–1993). This insect also is present in Colombia and Venezuela, where it is reported as one of the main problems in the local agriculture.

***Rhammatocerus* schistocercoides, a Swarm-Forming Grasshopper from South America, Figure 19** Seventh (penultimate) instar of *Rhammatocerus schistocercoides*.

Biology

This is a univoltine species. Biological cycles in Brazil and Colombia are approximately the same, with one generation per year, nymphal development during the rainy season and adults during the dry season. In Brazil, females lay their eggs at the beginning of the rainy season, from September to late October. Nymphs (eight to nine instars) develop during the rainy season, from late October to mid-April. Adults appear in mid-April and remain in the immature state through most of the dry season (May–September). Breeding activity begins in late August, apparently regardless of the rains, followed by the first egg laying in late September. In Colombia, *R. schistocercoides* lays its eggs from February to March. Nymphs are present from March to August, and adults from August to March (Fig. 20).

Behavior

Rhammatocerus schistocercoides has a remarkable gregarious behavior, similar to the behavior of other gregarious acridians, e.g., the desert locust, *Schistocerca gregaria* (Forskål), and the migratory locust, *Locusta migratoria* (L.). To this date, no phase transformation has been demonstrated. Its gregarious behavior is very close to that of the Moroccan locust, *Dociostaurus maroccanus* Thunberg. Hopper bands are formed, spreading over a few hundred to a few thousand square meters, with densities frequently ranging from 5,000 to 10,000/m^2 for the first nymphal instars to 250–500/m^2 for the last instars. Hopper bands have a very standard shape, i.e., generally a frontal formation which is common in many gregarious species. They move from a few ten to a few hundred meters per day. Swarms are generally small-sized, of a few thousand square meters to a few hectares on the ground (Fig. 21). When flying, during the day, these swarms can be much larger, frequently one km or more in length. Density on the ground is around 500–1,500/m^2 and 2–3 insects/m^3 when flying. The height of flight is low and does not exceed 5–10 m. Swarms display a typical "rolling" behavior. Flight activity seems maximal during sexual maturation; it stops temporarily during oviposition. The direction of swarms is mainly determined by the wind. In general, the swarms present a low mobility and move only locally. Distance covered per day is low, even in good conditions, a few hundred meters to 2–3 km a day only.

***Rhammatocerus* schistocercoides, a Swarm-Forming Grasshopper from South America, Figure 20** **Adult of *R. schistocercoides*.**

Habitat

In Brazil, *R. schistocercoides* outbreaks occur in the "cerrado" area of Central Brazil (Mato Grosso) and in the "llanos" of Colombia and Venezuela. In Brazil, the vegetation of outbreak areas is mainly pure or bushy savannas (Fig. 22). Two main habitats have been recognized: breeding biotopes usually on sandy soils, and dry season dispersion/wandering biotopes on heavier sand-clay soils.

Recent studies revealed that *R. schistocercoides* outbreaks in Mato Grosso cannot be explained by the accelerated agricultural development that has occurred in the affected areas since the early 1980s. Evidence clearly indicates that *R. schistocercoides* outbreaks are a long-standing phenomenon, both

in terms of their extent and nature. In fact, the newly cropped and previously uninhabited areas have long been conventional outbreak areas for this species. Much evidence suggests that the outbreaks surely have been the result of irregular interannual rainfall, particularly marked during the dry season and at the onset of the rainy season, just when the grasshopper populations are achieving sexual maturation.

Rhyacophilidae

A family of caddisflies (order Trichoptera). They commonly are known as primitive caddisflies.

► Caddisflies

Rhypharochromidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Rhysodidae

A family of beetles (order Coleoptera). They commonly are known as wrinkled bark beetles.

► Beetles

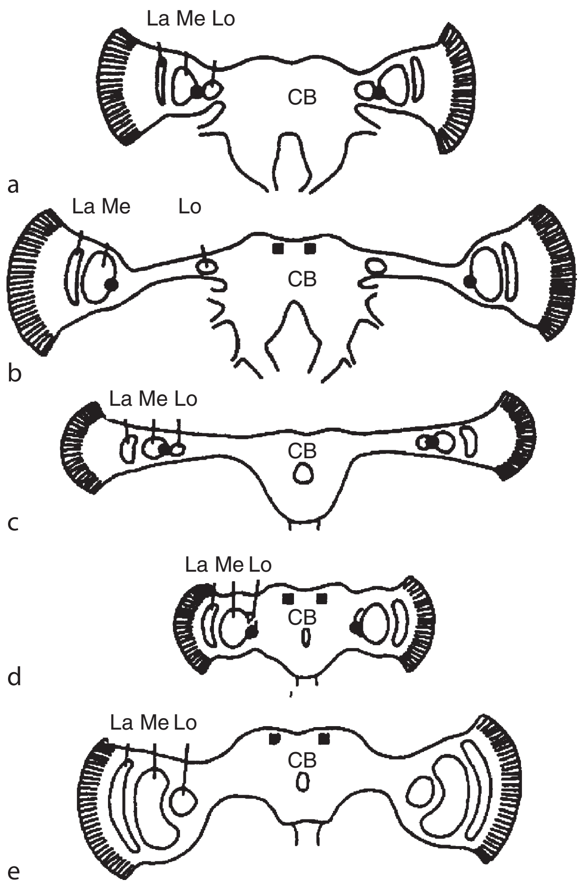
Rhythms of Insects

LAWRENCE K. CUTKOMP
University of Minnesota, St. Paul, MN, USA

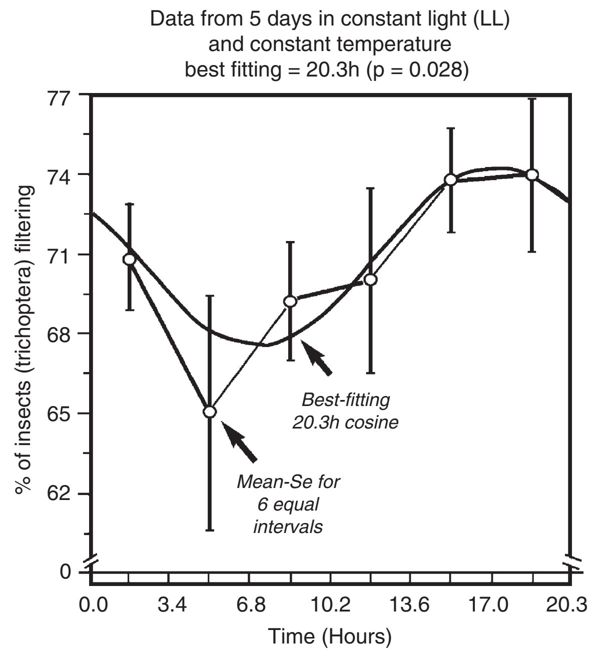
Chronobiology is an academic discipline that includes the rhythms of insects. There are several types of rhythms. The most common and prominent are "circadian rhythms," which oscillate with a period close to the astronomical (usually between 23 and 25 h, but an acceptable range is 20–28 h). Furthermore, such a rhythm is evident in every living organism studied. Other rhythms with different frequencies have been determined. The two other major groups are the "ultradian rhythms" (period of less than 20 h) and the "infradian" (greater than 28 h). They will be presented following the discussion of circadian rhythms. Plants and animals possess accurate time-measuring machinery termed "circadian clocks." The circadian system, studied extensively in insects, indicates that a central oscillator is located in the optic lobes serving as a pacemaker, but with neurons associated with neuroendocrine functions (Fig. 23). This information is based primarily on studies of *Drosophila*, especially the species *D. melanogaster*. Using larger insects, notably the cockroaches *Periplaneta americana* and *Leucophaea maderae*, it was shown that locomotion was controlled by the clocks in the optic lobes and was entrained solely through compound eyes.

Recent biochemical studies describe the organization of the circadian system. One component is termed the period protein (PER). This appears to colocalize with a peptide pigment dispersing hormone (PDH) in about half of the fruit fly's presumptive neurons. The period protein (PER) is also found in the pacemaker neurons of beetles and moths, but it may have different functions. In moths, the pacemakers are situated in the central brain and are associated with neuroendocrine functions. In other insects, the neurons associated with neuroendocrine functions appear to be closely coupled to optic lobe pacemakers. In some crickets and flies, central brain pacemakers are present in addition to optic lobe pacemakers.

Reliable documentation of a circadian rhythm utilizes the application of a statistically appropriate treatment using the cosine model. This permits one to verify the rhythm and detect possible masking effects when insects have been in unusual environments, or encounter interfering agents. An example illustrating this is shown in a comprehensive study with the caddis fly larvae, *Brachycentrus occidentalis* (Trichoptera), in



Rhythms of Insects, Figure 23 **Schematic of brains of (a) cockroach, (b) cricket, (c) beetle, (d) fly, (e) moth; Within optic lobes are lamina (La), medulla (Me) and lobula (Lo) which process and transfer visual signals from the compound eyes to the central brain (CB). Location of circadian pacemaker centers are indicated by filled circles in the optic lobes and by squares in the central brain (after Helfrich-Forster et al. (1998) Chronobiol Int 15:567–594).**



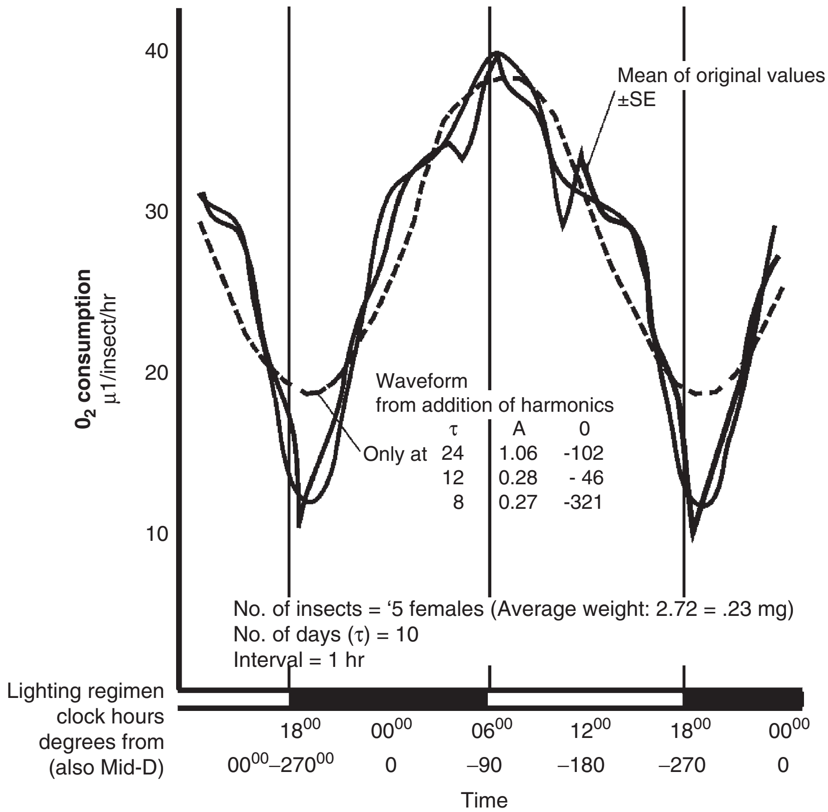
Rhythms of Insects, Figure 24 **Circadian waveform of filtering activity of caddis fly larvae (200 larvae) showing best fitting cosine (20.3 h) (after Sothern et al. (1998) Chronobiol Int 15:595–606).**

which an 8-h feeding schedule in water masked a circadian rhythm determined at 20.3 h (Fig. 24).

Examples of Behavioral Circadian Rhythms

Prominent circadian rhythms include locomotion and flight, foraging, biting habits (especially mosquitoes and other Diptera, cat fleas, among others). Other circadian rhythms include oviposition, hatching, pheromone emission, molting (eclosion in immatures), as well as spermatophore formation and the release of sperm, the secretion of ecdysteroids from prothoracic glands, and cuticle deposition. Oxygen consumption also shows a circadian rhythm as studied in the flour beetle, *Tribolium confusum*, using sterilized adults (Fig. 25). Circadian rhythms of oxygen consumption and heart rate have been discovered in the American cockroach. Additional biochemical rhythmic events, described as diurnal, were found with the neuroactive chemicals, acetylcholine and acetylcholinesterase in the cockroach, *Periplaneta americana*.

In summarizing the important role of circadian rhythms, it is evident that insects are best adapted to periodic environments in which the cycle of light and temperature is close to that of a solar day. Cycles with an unnatural period usually



Rhythms of Insects, Figure 25 **Oxygen consumption of flour beetles during a 24-h span using mean values of original data to show fit with a cosine function and a waveform using harmonics (after Chiba Y et al. (1973) J Insect Physiol 19:2163–2172).**

result in reduced longevity or impaired physiological function.

"Exogenous" rhythms are those that occur as a direct response to the environmental cycle of light and darkness and temperature. In the absence of these variables, the rhythm does not persist. In contrast, an "endogenous" rhythm is a periodic system that is a part of the temporal organization of the organism that is self-sustaining, i.e., it "free runs" in the absence of temporal cues such as the daily cycles of light and temperature.

Developmental Processes in Insects

Most insects, especially those living at higher latitudes, show seasonally appropriate cycles as indicated by activity, feeding and reproduction during the long days of summer. The winter is passed in a state of dormancy or diapause. Recent experimental studies designed to explain the circadian rhythms and photoperiodism in a diapausing insect have been conducted with the blow fly, *Calliphora vicina*. Both the locomotor activity rhythm and the rhythm system underlying photoperiodic timing are part of a circadian system and are dependent upon the environmental light cycle for entrainment and/or photoinduction. They appear to be brain-centered. Research on the blow fly indicates some differences, however. The locomotor activity in the adult fly shows an average circadian period of 22.5 h, whereas the photoperiod timing is much closer to 24 h. The suggestion made is that the locomotor activity is neural, while the photoperiod may have a humoral output, perhaps arising from the ovaries.

The conclusion is that circadian rhythms overall are an integral component of insect developmental processes, including diapause.

Studies carried out with the European corn borer, *Ostrinia nubilalis*, led to the conclusion that thermoperiodic and photoperiodic responses involved identical biological clock systems. Similar conclusions have been made with other insects, notably the cockroach, *Leucophaea maderae*, even though the latter insect does not undergo diapause (Fig. 24).

Spectrum of Rhythms

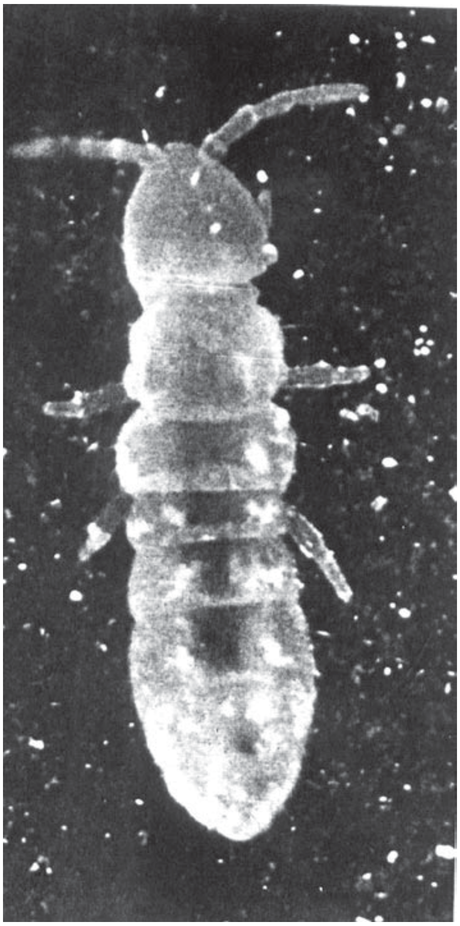
Rhythm frequencies include ultradian (0.5–20 h), circadian (20–28 h), and infradian (28 h to 6 days); those with low frequencies include circaseptan (about 7 days), circavigintan (about 20 days), circatrigintan (about 30 days), and circannual (about 1 year).

Circaseptan rhythm deserves a more complete discussion as it was discovered in a primitive insect (springtails, Order Collembola), namely *Folsomia candida*, and can be considered as a model for the study of infradian rhythmicity (Fig. 27). This insect is parthenogenetic. Insects were studied in the dark under humid conditions; daily counts of egg laying determined that egg deposition recurred at 7 days, the average number being 46.6, at a constant temperature of 15°C. With higher temperatures (not optimum), the interval between oviposition became circasemiseptan (about 3 days). The lengthening of the egg-laying interval also occurred with aging of the insects. The infradian rhythm of oviposition does not have any obvious environmental counterpart. A study of molting (ecdysis) determined that an infradian rhythm (about 3 days periodicity) occurred at 23°C.

Further studies with *Folsomia candida* determined that life spans could be varied by shifting from an optimal environmental temperature (20°C.) to a nonoptimal environmental temperature of 25°C. The temperatures were alternated every 12 h. The greatest longevity was found to be when the shift intervals were 7 days (circaseptan). A separate study with a Dipteran, the face fly, *Musca autumnalis*, revealed that shifts of the lighting regime every 2 or 9 days shifted at intervals of 7 days apart, had relatively short survival times, whereas some groups that were shifted at intermediate intervals did as well, or better, than the controls. One other documented circaseptan frequency response to the shifts of the lighting regimen of growth was found in an algal species, *Acetabularia mediterranea* (Fig. 26).

Lunar Rhythms

Lunar rhythms (circatrigintan) occur at about 30 days. Documented examples of lunar rhythms

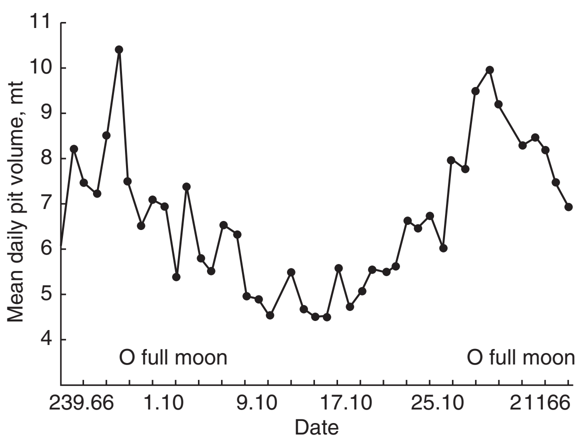


Rhythms of Insects, Figure 26 ***Folsomia candida*** **adult (Collembola: Isotomidae).**

have been found in a limited number of insects. Studies on the mayfly, *Povilla adusta* (Ephemeroptera), showed a periodicity of emergence from Lake Victoria in West Africa and in a crater lake, Barombi Mbo, with the emergence of adults occurring in greatest numbers after the full moon.

The ant-lion *Myrmeleon obscurus* (Myrmeleontidae), builds pits to capture prey. Using the volume of pits as a measure, it was found that maximum pit-building activity occurred at the full moon (about 28 days). This species also has a solar day activity (Fig. 27).

Experiments with a midge, *Clunio marinus* (Chironomidae), living in the intertidal zones of the Atlantic and the Pacific oceans have demonstrated semilunar rhythms. Adult emergence was governed by the superposition of a circadian rhythm that controlled pupal eclosion, and a semilunar rhythm that determined the beginning of pupation. The best documentation was done with the midge population from Normandy, France. The same species showed greater variation of the rhythm in other oceanic areas. In northern latitudes, the brightness of the moon may influence the behavior of the midge.



Rhythms of Insects, Figure 27 Daily pit volume of fifty ant lion (*Myrmeleon obscurus*) larvae subjected to normal daylight conditions and each larva fed one ant per day. Times of full moon shown by circles (after Youthed G J, Moran V C (1969) Insect Physiol 15:1259–1271).

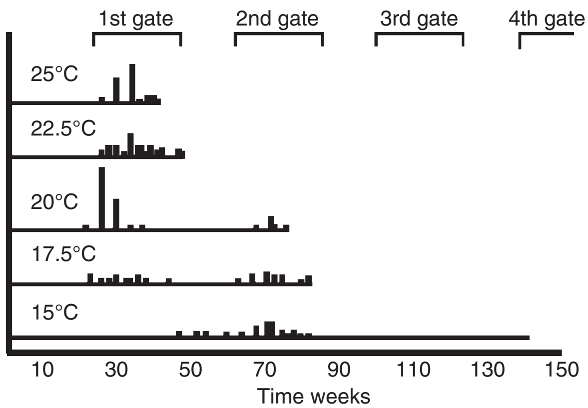
Circannual Rhythms

Circannual rhythms are uncommon. The best documented case is with a carpet beetle, *Anthrenus verbasci* (Dermestidae), which commonly has a life cycle of 2 years, termed "semi-voltine." It feeds on material of animal origin and is often found in house sparrow nests. The first winter is spent in diapause as a young larva, and the second winter as a full-grown larva. These larvae pupate and emerge the following spring. The period of the rhythm was between 41 and 44 weeks. When larvae were reared at cooler temperatures, 15–20°C, the larvae underwent two cycles of development and did not pupate until about 41 weeks after the first group reared at 25°C. This delay by the group reared at cooler temperatures indicated a phenomenon called "gated" rather than a continual or gradual sequence of pupation. This "gated" phenomenon had been previously shown by several workers investigating pupal eclosion in the fruit fly *Drosophila pseudoobscura*. Thus, the circannual rhythm in the carpet beetle was the result of the natural seasonal change, attributed primarily to day length (Fig. 28).

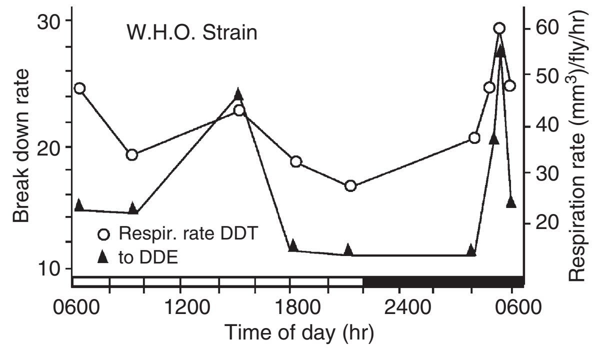
Some experiments with short-lived aphids (Hemiptera) showed that they appear to distinguish spring from autumn. Experiments with *Megoura viciae*, for example, indicated a non-rhythmic interval timer that prevents the aphids from responding prematurely to short days in the spring. No sexual forms were produced for as long as 90 days in a short photoperiod (at 15°C). After this duration, the photoperiod response was restored and reproducing oviparae were produced under the short-day treatment.

Interrelationships of Circadian Rhythms and Insecticide Sensitivity

A number of studies have explored the possibility that toxicity to an insecticide or toxin could be



Rhythms of Insects, Figure 28 **Circannual rhythm of pupation in *Anthrenus verbasci* (Oermestidae) using constant conditions of temperature, humidity and darkness. A black square represents the time of pupation to the nearest week, of an individual. Those at higher temperatures utilize the first gate; at lower temperatures an increasing number are required to wait (after Blake G M (1959) Nature (London) 183:126–127).**



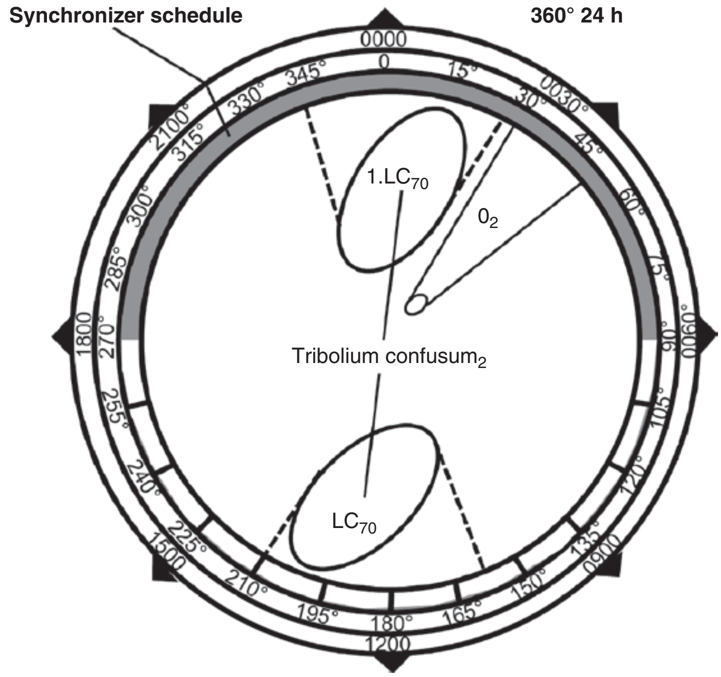
Rhythms of Insects, Figure 29 **The effect of time on the treatment of adult flies, *Musca domestica*, with DDT on rate of respiration (open circles) and conversion of DDT to its metabolite, DDE (after Shipp E, Otton J (1976) Ent Exp et Appl 19:235–242).**

related to a critical time in the insect rhythm, particularly with respect to lighting or photoperiod ("photophase" or daylight and "scotophase" or a dark period). In house flies, the respiratory rate correlated with the conversion of DDT (dichlorodiphenyltrichloroethane) to DDE (a metabolite). Both occurred in the mid-light period (Fig. 29). In a separate study, using the flour beetle, *Tribolium confusum*, measurements of their oxygen consumption were related to the sensitivity to a rapid acting organophosphate insecticide, dichlorvos. This species, normally feeding on flour, showed the greatest sensitivity in the middle of the dark period, while the peak in oxygen consumption occurred 2 h later (Fig. 30). Nocturnal species, such as German cockroaches and house crickets, showed the greatest sensitivity a few hours after the onset of a daily dark span. Several diurnal species, including the boll weevil, the pink bollworm and the two-spotted mite, showed the greatest sensitivity shortly after the onset of the light span.

The larvae and adults of the mosquito, *Aedes aegypti*, showed the greatest sensitivity to insecticides at the beginning of the dark period. Biting habits of mosquitoes reveal their greatest occurrence in the early evening, although a second period may occur before dawn, or late in the dark period. Noteworthy is the fact that both the larvae and the adults had maximum sensitivity to an insecticide at approximately the same time. The insecticides evaluated were dichlorvos on the adult mosquitoes and chlorpyrifos on the mosquito larvae.

Rhythmic events using locomotory activity in relation to sensitivity to an insecticide were studied in the American cockroach. The greatest sensitivity to dichlorvos occurred near the onset of the dark span, with locomotory activity occurring about 3 h later. In a separate study using house crickets, *Acheta domestica*, a positive relationship occurred with maximum locomotor activity and sensitivity to three anesthetics, namely ether, chloroform and carbon tetrachloride. The peaks occurred during early scotophase. The cricket can be considered to be nocturnal.

A study of the circadian rhythm of the nerve enzyme acetylcholine esterase showed synchronization with sensitivity to two insecticides,



Rhythms of Insects, Figure 30 **The lethal concentration (LC 70) of an insecticide, dichlorvos, expressed as a reciprocal to flour beetles, *T. confusum*, indicating a 2-h earlier lethal effect than peak oxygen consumption. The peak or acrophase of oxygen consumption occurred about 3 h after the middle of the daily dark span (after Vea HH et al. (1977) Chronobiologia 4:313–323).**

carbaryl and malathion. The test insect was the rice grasshopper, *Aiolopus thalassinus*, a diurnal species. The peak or acrophases of both rhythms occurred during the photophase at about the same time. A study conducted much earlier revealed a trimodel (8-h period) rhythm in the larvae of the mosquito, *Aedes aegypti*. The enzyme Mg^{2+} ATPase was measured in relation to its inhibition by the insecticide gamma chlordane.

Exceptions to the generalization that insecticide sensitivity has circadian rhythm peaks at or near the time of circadian peaks of insect metabolism were found in studies with a nocturnal insect, the cockroach, *Leucophaea madeira*, and the house fly, *Musca domestica*, a diurnal species. Similar peaks were found in sensitivity to pyrethrum, whereas peak activity and metabolism were distinctly different times in a 24-h period.

The practical application of the circadian sensitivity to toxins has had limited study. Perhaps it deserves greater attention to refine insecticide usage and insect sensitivity.

Ribbed-Cocoon Maker Moths (Lepidoptera: Bucculatricidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Ribbed-cocoon maker moths, family Bucculatricidae, total 247 species worldwide, with most species being Nearctic (103 sp.) or Palearctic (86 sp.). Most species are in the genus *Bucculatrix*. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults minute to small (5–16 mm wingspan), with rough-scaled oblique head and an eye-cap on the antennal bases; haustellum naked; labial palpi short and porrect; maxillary palpi minute, one-segmented or absent. Maculation variable and spotted, often with iridescent markings; venation reduced (especially on hindwings) and long fringes on hindwings. Adults are mostly diurnal. Larvae are leafminers, with some changing to external leaf skeletonizing in later instars, but a few are gall makers or stem miners. Pupation is in a white spindle-shaped cocoon with a ribbed surface, unique to the family. Numerous different host plants are known but many are in Compositae. Some species are economic.

Ribosomal RNA

Ribosomal RNA genes (rRNA genes) are found as tandem repeating units in the nucleolus organizer regions of eukaryotic chromosomes. Each unit is separated from the next by a nontranscribed spacer. Each unit contains three regions coding for the 28S, 18S, and 5.8S rRNAs.

Ribosome

A self-assembling cellular organelle comprised of proteins and RNA in which translation of mRNA occurs. Ribosomes consist of two subunits, each composed of RNA and proteins. In eukaryotes, ribosome subunits sediment as 40S and 60S particles.

Ricaniidae

A family of bugs (order Hemiptera, suborder Fulgoromorpha). All members of the suborder are referred to as planthoppers.

► Bugs

Rice Weevil, *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae)

This is one of the key pests of stored grain.

► Stored Grain and Flour Insects

Richardiid Flies

Members of the family Richardiidae (order Diptera).

► Flies

Richariidae

A family of flies (order Diptera). They commonly are known as richardiid flies.

► Flies

Richards, Owain Westmacott

O.W. Richards was born on December 31, 1901, and educated at Oxford University, Oxford, England. In 1927 he moved to Imperial College, and worked at the College Field Station at Slough on stored products pests until 1947. He remained at Imperial College until his retirement in 1967, and served as head of the Zoology and Applied Entomology Department for many years. Richards was principally interested in taxonomy, ecology and the theory of evolution. He had considerable expertise with various groups of flies, but was particularly interested in Aculeate Hymenoptera. His books entitled "Social insects" (1953) and "The social wasps of the Americas" (1978) reflect this latter interest. Over the course of his career, Richards published over 180 papers and six books, including two revisions (with Gareth Davies) of "Imms' general textbook of entomology" (1957, 1977). He served as president of the British Ecological Society and editor of its journal "Journal of Animal Ecology," and was considered one of the most distinguished entomologists of his generation. He died on November 10, 1984.

Ricinidae

A family of chewing lice (order Phthiraptera). They sometimes are called hummingbird lice.

► Chewing and Sucking Lice

Rickettsia

Bacteria-like, gram-negative organisms. Insect rickettsia are obligate intracellular pathogens with cell walls, but lack flagella. Some, such as *Wolbachia*, are seldom pathogenic, whereas others, such as *Rickettsiella*, are commonly insect pathogens.

Riffle Beetles (Coleoptera: Elmidae)

HARLEY P. BROWN
University of Oklahoma, Norman, OK, USA

The family Elmidae is divided into two subfamilies: Elminae and Larainae. The Elminae are far more abundant and diverse than the Larainae, with about 100 genera and over 1,000 species worldwide, of which 26 genera and about 100 species occur in the United States. This subfamily is represented in every American state but Hawaii and in every bordering province of Canada and state of Mexico.

Order: Coleoptera
Suborder: Polypleaga
Superfamily: Dryopiidea
Family: Elmidae

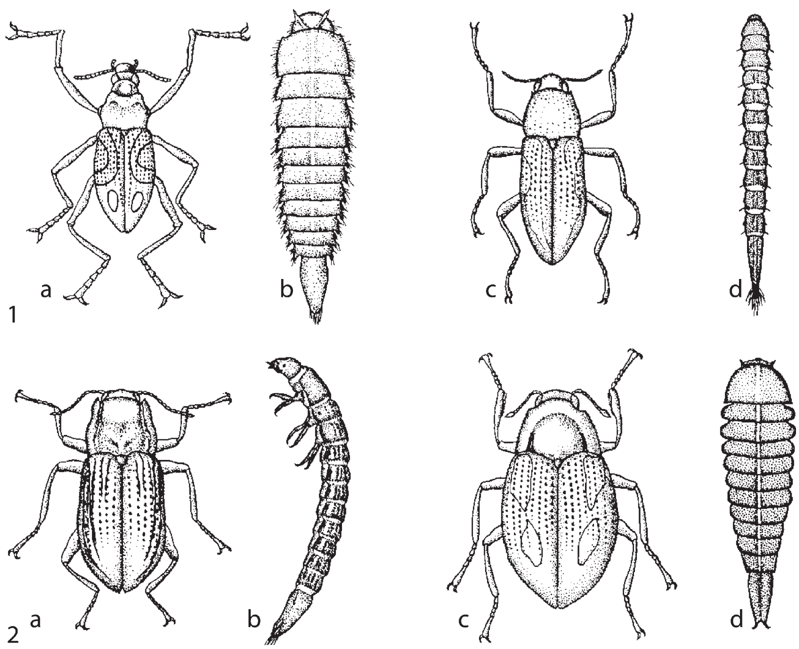
The Larainae, however, have only about 20 genera and 110 species world wide, with only two genera and no more than four species in the United States. Adult Laraines are usually found near or at the water's edge, sometimes partially submerged. When disturbed, they may fly rapidly. Some tropical species occur in swarms around cataracts or waterfall spray zones. (Big black adults of *Potamophilops* are conspicuous flying about in the spray of the world-famous Iguassu Falls shared by Brazil, Argentina, and Paraguay.) The bodies of Laraines are rather soft, and their lives as adults are much briefer than as larvae. In size, the adults range from about 3–9 mm.

Elmines are more completely aquatic, adults entering the water soon after pupation and usually never again emerging. They commonly share the habitat and food of their larvae and are rather long-lived (months or years). Although members of a few genera are quite sizable (e.g., some species of *Macrelmis* exceed 5 mm in length), most Elmines are small (1–3 mm) and some are tiny (under 1 mm) (Fig. 31).

Of the four genera illustrated, *Ancyronyx* is the most unusual. It is represented in the Western Hemisphere only by this one species. Its few known relatives occur in southeastern Asia. The other three genera are represented by a number of species in various regions of the U.S.A. *Microcylloepus*, though abundant in much of the U.S.A., is primarily Neotropical, with many species in South America. *Dubiraphia* is unusual among elmids in that the microhabitat of the larva is so different from that of the adult. *Optioservus* might well be termed the most typical elmid of American and Canadian brooks.

Ecology

Riffles are rippling streams, usually shallows across streambeds where water flows swiftly and is well aerated. In such habitats, elmids are the most typical and abundant beetles, but usually



Riffle Beetles (Coleoptera: Elmidae), Figure 31 **Riffle beetles: (i) *Ancyronyx variegates*: (a) adult, 2.1–2.6 mm long, conspicuously colored with black and yellow or orange, on or in waterlogged wood in streams of eastern North America; (b) larva, commonly with adults. (ii) *Dubiraphia vittata*: (a) adult, 1.8–2.5 mm long, brown or tan, with a broad yellowish longitudinal stripe on each elytron, clings to submerged plants in streams of eastern North America; (b) larva, usually in sediment on the bottom of streams. (iii) *Microcylloepus pusillus*: (a) adult, 1.65–2.2 mm long, reddish brown to black, often with reddish lengthwise stripe or spot on each elytron, common on many different substrates in streams of central and eastern North America; (b) larva, side view, often with adults. (iv) *Optioservus ovalis*: (a) adult, 2.4–2.6 mm long, plump, brown to black with two elongate yellowish or reddish spots on each elytron, in gravel or among mossy stones in spring-fed streams of eastern states; (b) larva, often with adults.**

quite inconspicuous. They are mostly bottom dwellers or clinging to submerged wood or debris, and do not swim or come up for fresh air.

The respiratory mechanism of adult Elmines is noteworthy because it enables them to remain permanently underwater without having to come up for fresh air. The key feature, termed a plastron, consists of a thin layer or film of air held by a dense coating of hydrofuge pubescence, or tomentum, on various parts of the legs and body. The plastron is in contact with the air reservoir beneath the elytra, into which the spiracles open. There is normally plenty of dissolved oxygen in the water of stream riffles, and oxygen can readily diffuse into the plastron, and then into the tracheal system and to all body tissues.

Since wetting agents such as soap and detergents destroy plastrons, riffle beetles do not thrive downstream from sites where people bathe and do their laundry. Other types of pollution such as sewage promote excessive bacterial growth and consequent oxygen depletion, and industrial wastes often include toxic substances. Because some species require water of great purity, whereas other species are tolerant of one or another type or quantity of pollutant, riffle beetles are useful as indicators of water quality.

In streams with high mineral content, all sorts of objects may become coated: wood, pebbles, boulders, and riffle beetles. Some elderly Elmines get covered by thick encrustations that outweigh the beetles. Other things than mineral armor often occur on riffle beetles: diatoms and sessile protozoans such as *Vorticella* are common.

Elmids range in color from tan to black, but many exhibit patterns of longitudinal or diagonal stripes or transverse bands, yellow to red. Some have prominent spots and patterns. Such aposematic coloration is probably related to the fact that elmids are not prey for most predators.

All known elmid larvae are aquatic, creeping on, or burrowing in, the substrate – some in mud, sand or gravel, some on, or under rocks, and others on, or in waterlogged wood, leaf-packs or detritus. Their respiratory mechanism employs a three-branched tuft of tracheal gill filaments that may be extruded from a cavity in the last abdominal segment, or withdrawn and covered by a trap-door-like operculum. They feed chiefly on diatoms and decaying plant materials.

When ready to pupate, mature larvae leave the water to find a suitable place in moist sand, humus, moss, or in a crevice, or beneath a rock, or under loose bark. Some larvae are able to just crawl out of the water in search of pupation sites. Drifting enables mature larvae to get from midstream to snags or boulders that they use to crawl out. Others, in streams with fluctuating water levels, simply wait in shallow water until the level drops so they can pupate in situ. In temperate regions, pupation occurs from late spring through summer, but in humid tropics, it may occur throughout the year. Pupation usually requires a week or two, though a bit longer for larger species.

Most kinds of insects use membranous wings as an important means of dispersal. Beetles are no exception, but their front wings (elytra) are relatively stiff and protective. However, the membranous hind wings are neatly folded beneath the elytra, and can pop out and unfold to serve in flight. Among Elminae, many of the newly emerged adults fly before they enter the water. Other adults never fly because their hind wings do not develop adequately. Usually, neither alates (fliers), nor non-fliers ever leave the water once they have entered it. At relatively low elevations, collecting at lights, or the use of light traps may yield hundreds of elmids. Collectors prefer light-collected specimens because they require so much less cleaning than those taken from streams.

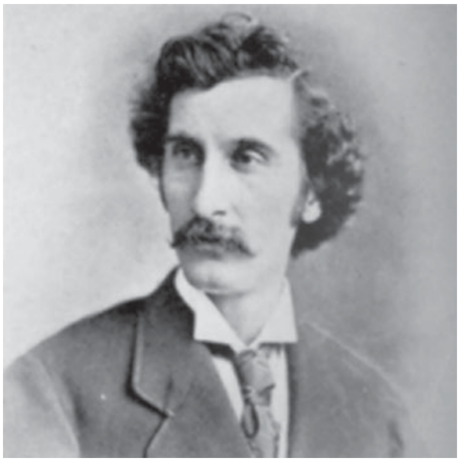
Riley, Charles Valentine

C. V. Riley was born at Chelsea, England, on September 18, 1843. One of the foremost American economic entomologists, he was educated in England, France, and Germany, but at the age of 17 moved to a farm in Illinois, USA (Fig. 32). He soon developed an interest in entomology and in 1864 moved to Chicago and began his career in entomology as a reporter for the "Prairie Farmer." In 1868 he was appointed State Entomologist for Missouri. Over the next 9 years he devoted much of his energy to the production of the annual reports on "Noxious, beneficial and other insects of Missouri" for the years 1868–1877. These were landmark publications in the field of economic entomology, and firmly established his reputation. Interestingly, it is not so much the information content of the reports that made such a positive impression at the time, but their appearance. Unlike earlier reports, Riley's were printed in large type and were quite readable, and they had excellent illustrations. Also, he endeavored to keep the reports readable by farmers by keeping the language within the understanding of the readers. During this period Riley also lectured weekly at the University of Missouri. He and B. D. Walsh started the "American Entomologist" in 1868, and Riley became sole editor for volumes 2–3. Between 1870 and 1872 Riley lectured at Kansas State University. In 1887 the US Entomological Commission was organized, and consisted of Riley, A. S. Packard, and Cyrus Thomas. He was involved in production of 4 of the 5 reports, and also several bulletins issued between 1877 and 1881. Soon after Riley was appointed to the Entomological commission, the "locust" plague affecting much of the central and western United States collapsed. Though it was nature, not the Entomological Commission, that caused the disappearance of the grasshoppers, Riley and the Commission received accolades. In 1887, Riley was appointed Entomologist by the United States Department of Agriculture, which led to creation of the Division of Entomology and then the Bureau of Entomology. Riley was adept at identifying qualified entomologists, and soon had a nationwide effort organized. It is largely due to Riley's efforts that the United States Department of Agriculture had such a prominent entomological component, and it is due to his organizational ability that federal entomology was so successful. He founded the entomological collections of the US National Museum with a donation of his own collection of 115,000 specimens. Riley promoted the idea of state experiment stations, which eventually had a profound effect on American agriculture by



Riley, Charles Valentine, Figure 32 **C. V. Riley.**

introducing scientific discipline to the farming process. He also promoted the idea of a federal branch of economic ornithology, which brought great attention to the importance of birds as friends of farmers, and which evolved into the Bureau of Biological Survey and eventually into the Fish and Wildlife Service. Riley also was involved in the formation of the Entomological Society of Washington, in 1884, and the Association of Economic Entomologists, in 1889. Riley edited a six-volume series called "Insect life" between 1888 and 1894. Riley played a prominent role in the introduction of natural enemies of cottony cushion scale from Australia into California, and the eventual solution of the grape phylloxera problem on grapes in France. Over the course of his extremely productive career, Riley authored nearly 3,000 papers, and he was a member of nearly all the American and European entomological societies. He died at Washington, DC, on September 14, 1895, after a bicycle accident.

Ring Gland

A composite structure encircling the esophagus, and found in some Diptera, that contains both ecdysone-secreting and juvenile hormone-secreting cells.

Ring-Legged Earwigs

Some of the earwigs in the family Carcinophoridae (order Dermaptera).

► Earwigs

Riodinidae

A family of butterflies (order Lepidoptera). They commonly are known as metalmark butterflies.

► Metalmark Butterflies and Moths

Ripicolous

Use to refer to organisms associated with riverbanks.

RNA

Ribonucleic acid, one of the two forms of nucleic acids.

RNA Interference (RNAi)

RNA interference is known by other names such as gene silencing, post-transcriptional gene silencing, transgene silencing, and quelling. In RNAi, the expression of genes is inhibited. The RNAi pathway, which occurs in most eukaryotic organisms, is thought to have evolved to prevent the invasion of exogenous genetic elements such as those of viruses; thus, it is effectively an immune response, but perhaps also is involved in genome maintenance. Transposable elements, for example, introduce a lot of "chaos" into genomes because they replicate like viruses and produce foreign proteins.

DNA in the cell nucleus produces messenger RNA (mRNA), which is exported from the nucleus to the cell cytoplasm. In the cytoplasm, ribosomes translate the mRNA, creating proteins as directed by the nuclear DNA. When foreign double-stranded RNA (dsRNA) from a virus is detected in the cytoplasm, the cell's immune system is initiated, starting with activation of an enzyme called "dicer." Dicer severs the foreign dsRNA into short units of 20–25 bp called "small interfering RNAs" (siRNAs). Then, proteins in the cytoplasm called the RNA-Induced Silencing Complex (RISC) cleave the siRNAs, leaving only single strands. RISC incorporates a single strand, then searches for matching sequences in the cell. If it locates a long strand of foreign RNA containing a matching sequence it binds to it, preventing it from being used as a translation template, and effectively eliminating its capacity to damage the cell.

It is possible to introduce synthetic double-stranded RNA into cells, much like an invading virus might do naturally. In doing this, the RNAi process can be induced, tricking the cell into attacking selected genes, repressing expression or function of the gene or a region of the gene. The process is highly specific, allowing highly targeted activities. RNAi is transferable in plants, moving from one region to another, and can be transferred by grafting. RNAi activities can be induced in nematodes by feeding them bacteria carrying the dsRNA. Delivery of dsRNA to other organism is more complicated, but in some cases it has proved possible to provide delivery to insects through feeding as well as by injection. This presents the possibility that plants could be engineered with insect-specific resistance, and that other insects could be affected by feeding them baits containing dsRNA. The effects of RNAi are heritable in plants, but heritability in insects and mammals is uncertain.

RNA Polymerase

An enzyme capable of synthesizing an RNA copy of a DNA template.

Roach Stoneflies

Members of the stonefly family Peitoperlidae (order Plecoptera).

► Stoneflies

Robber Flies (Diptera: Asilidae)

KENNETH W. MCCRAVY
Western Illinois University, Macomb, IL, USA

The Asilidae are a family of voracious predatory dipterans commonly known as robber flies. Distinctive features of robber flies include a hollowed-out region between the eyes, bearded facial appearance, large, strong legs for grabbing and subduing prey, and a tube-like proboscis that houses a needle-like structure (Fig. 34). This latter structure is used to stab prey and inject proteolytic saliva. Robber flies range in length from about 0.5–3 cm. They often are dull gray or brown, and generally lack bright coloration or striking patterns. However, striking metallic coloration is found in the southern Asian and South Pacific genus *Maira*, as well as in *Lampria* of the New World tropics. In addition, some robber flies are impressive bee mimics, a feature that may allow these flies to get closer to the bees they prey on, or may serve to protect these flies against vertebrate predators that have learned to associate bee color and shape with stinging ability.

The Asilidae includes roughly 7,000 known species worldwide. Based on the fossil record, the group dates back at least 35 million years. Robber flies are found on all continents except Antarctica, with the Eurasian and Australian regions having the greatest diversity. Robber flies are generally most abundant and diverse in dry and sandy areas, and in arid and semiarid regions. Apparently, relatively few species prefer woodlands, and those that do often tend to concentrate along the forest/grassland edges, perhaps because of the clearer field of view associated with these locations. Robber flies are generally quite diverse in grasslands, but shrubby grasslands tend to have the greatest robber fly diversity. This may be because the shrubs provide perching sites which are critical for finding prey and potential mates. Habitats with clay soils are generally associated with low robber fly numbers. These soils seem to provide poor habitat for the soil-dwelling larvae, probably because the texture of these soils makes movement difficult. These soils also provide relatively little vegetation for adult perches.

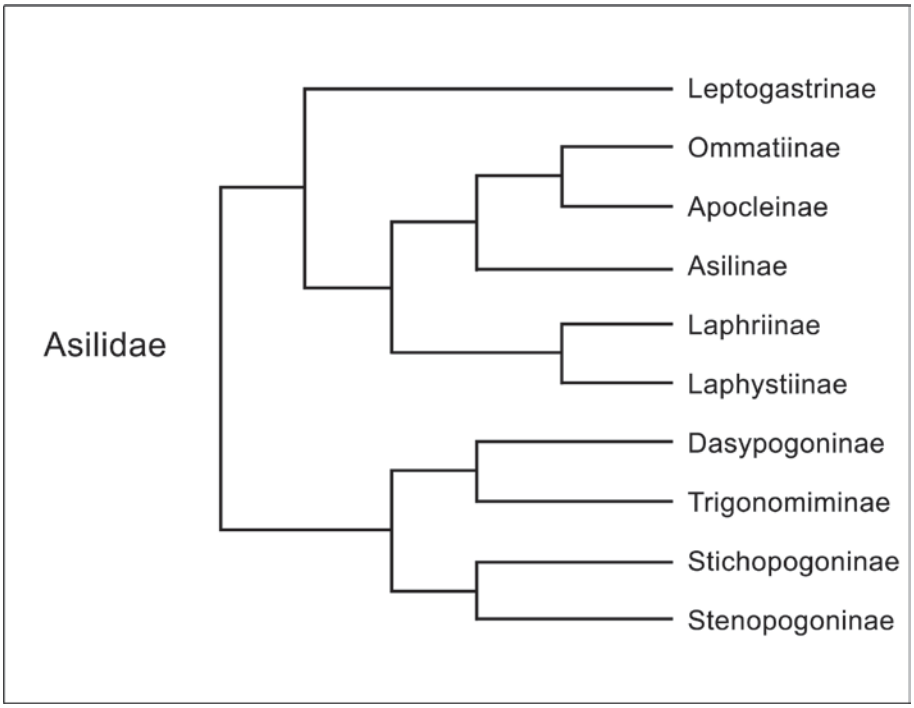
Classification and Relationships

The following is intended to put the robber fly family Asilidae into taxonomic perspective:

Order: Diptera (true flies)
  Suborder: Brachycera (short-horned flies)
    Superfamily: Asiloidea (robber flies and closely related families)
      Family: Asilidae (robber flies)

Some other common families that are close relatives of robber flies, and are also contained in the Superfamily Asiloidea, include the Bombyliidae (bee flies), Mydidae (mydas flies), and Therevidae (stiletto flies).

Recent classifications generally organize the Family Asilidae into 5–12 subfamilies. A hypothetical phylogeny of the subfamilies of Asilidae is shown (Fig. 33). The Leptogastrinae are commonly referred to as "grass flies." This is a relatively small subfamily, but does contain the widespread genus *Leptogaster*. *Leptogaster* is quite diverse in southern Asia, the South Pacific, and North America, but less so in Europe. The "Asilinae group" contains a trio of closely related families, the Ommatiinae, Apocleinae, and Asilinae. The first two subfamilies are sometimes included as tribes within the Asilinae. The Ommatiinae includes the widespread genus *Ommatius*, which appears to reach its greatest abundance in Asia, Africa, and Australia. In the subfamily Asilinae, the genus *Asilus* has been the subject of much uncertainty regarding the taxonomic status of many species. The subfamilies Laphriinae and Laphystiinae ("Laphriinae group") are likewise considered to be closely related. Both are widespread. The former includes the dominant northern hemisphere genus *Laphria*, as well as the primarily neotropical genus *Atomosia*. The Laphystiinae appear to achieve their greatest diversity in the Holarctic and African regions.



Robber Flies (Diptera: Asilidae), Figure 33 **Hypothetical phylogeny of the Asilidae (from the Geller-Grimm and Dikow website: http://www.geller-grimm.de/asilidae.htm).**

(Photo credits: (a) courtesy of Edward L. Manigault, Clemson University Donated Collection; (b–e) courtesy of Whitney Cranshaw, Colorado State University; (f) courtesy of David Cappaert, Michigan State University.)

The "Dasypogoninae group" includes the remaining four subfamilies. The subfamily Dasypogoninae is a diverse and widespread subfamily that includes the large New World genus *Diogmites* as well as the tribe Megapodini, which is confined to the Neotropical region. The Stichopogoninae includes pale colored flies that are often associated with sandy areas or mud flats. The Stenopogoninae is a large subfamily that includes the very diverse genera *Stenopogon*, *Cyrtopogon*, and *Microstylum*. The first two genera are very well represented in the northern hemisphere, whereas *Microstylum* is particularly diverse in South Africa.

Recent molecular evidence suggests that the family Asilidae is monophyletic, with the Leptogastrinae as the basal group. The monophyly of the

Asilinae group is likewise supported, but the Laphriinae and Dasypogoninae groups are each paraphyletic.

Reproduction and Immatures

Robber flies exhibit a variety of mating behaviors. In many species, the male simply chases down a female, captures her in midair and copulates with her. But in some species, more complex courtship behaviors have evolved. These may involve relatively simple behaviors by the male such as primitive dances and hovering performed for the female. But in many species, more complex courtship rituals have evolved. In *Nannocyrtopogon neoculatus*, for instance, the male places his foretarsi underneath those of the female, almost as if the two were "holding hands." The male then rhythmically lifts the female's legs. Males of some species have even evolved elaborate structures, such as very long or strikingly colored bristles, that serve as display signals for the female. Mating in robber flies can take place tail-to-tail, or male over female with both facing the same direction. In some species, mating actually takes place in the air, whereas in others mating occurs on vegetation.

In many robber fly species, egg-laying involves simply randomly dropping the eggs. However, other species oviposit in soil or vegetation. In these latter species, the abdomen of females generally has an elongated terminal segment or blade-like structure that serves as an ovipositor, allowing placement of the egg in crevices and holes of plant tissue or under loose soil. Likewise, egg shape often reflects the female's egg-laying habits. Random-dropper eggs are generally spherical. But eggs of ovipositioning species are usually more elongate, probably so they will be more likely to stay put in the particular location the female has chosen. As in most insects, parental care is lacking. Once laid, the eggs and larvae that hatch from them are on their own.

Robber fly larvae are maggot-like, and live in soil, decaying wood or old stumps, or beneath bark. The larval stage can last from one to several years, depending on the species. It was once thought that robber fly larvae were primarily phytophagous. However, it is now well established that, like the adults, larval robber flies are predaceous, although some scavenging may occur as well. Robber fly larvae generally feed on other immature insects, such as the eggs and immature stages of beetles, grasshoppers, and flies. Larvae of some species may provide biological control of pest species. Larvae of the robber fly *Promachus yesonicus*, for instance, commonly feed on beetle larvae. This fly has been shown to be a potentially effective biological control agent of white grubs that attack the roots of various crops in China. In field experiments, the addition of *P. yesonicus* larvae reduced grub populations by up to 99% and reduced damage to wheat seedlings by up to 96%.

Robber fly pupae are generally somewhat elongate, usually with strong thorny structures on the head and/or abdomen. Pupation generally takes place in the soil. When the adult is ready to emerge, it uses muscular contractions to work its way to the surface, then breaks through the pupal case.

Predatory Habits of Adults

It was once thought that robber fly adults were bloodsuckers that fed on cattle and other large mammals. However, it is now known that adult robber flies are rapacious predators of other arthropods. Unlike many predators which specialize on relatively defenseless prey, many robber flies will attack formidable opponents such as bees and wasps, and larger species of robber flies can overcome large dragonflies and horse flies.

Some robber flies are fairly specific in their predatory habits, but most are probably opportunistic generalists. There is some evidence that interspecific competition for prey among overlapping robber fly species may be reduced by behavioral differences. For instance, three species of robber flies in the genus *Efferia* coexist in the same habitat (oak brush savannah), but perch at different heights in the vegetation, feed on different sized prey, and are active at different times of the day. Little is known regarding potential biological control impacts of adult robber flies. Studies of the grassland robber fly *Proctacanthus milbertii* estimated that these flies kill from 0.5 to 2% of the adult grasshopper population per day. However, experimental removal of robber flies from a Montana grassland resulted in increased parasitism of grasshoppers by parasitic flies. Effects of robber fly predation on pest populations probably vary depending on species, habitat, prey availability, and other factors.

Robber flies are generally daytime predators. When prey is detected, the robber fly quickly darts out, grabbing the prey with its powerful legs, well equipped with large spines for holding the prey. Once the prey is captured, the robber fly quickly subdues it by stabbing it with its short, stout beak in the neck region, between the thorax and abdomen, at the end of the abdomen, or even through an eye. Although robber flies generally dispatch their prey with little problem, struggles sometimes occur. It has been suggested that the bristles which give robber flies their fierce, bearded appearance may serve to protect the eyes when the prey does struggle. After stabbing the prey, the robber fly injects neurotoxic saliva which immobilizes the prey. The saliva also contains proteolytic enzymes that begin the process of external digestion, liquefying the tissues. The contents of the prey are then sucked out.

Robber flies typically establish a perch in open, sunny locations, where they command a good view of passing prey. The robber fly's well-developed eyes and correspondingly acute vision allow it to detect even subtle movements. The eyes are so large that most of the head appears to be composed of these two compound eyes separated only by a deep depression. It has been suggested that robber flies have stereoscopic vision. This is a useful adaptation for predators that need to locate moving prey in a complex spatial environment and accurately determine distance to the prey. The robber fly's mobile head allows it to increase its field of view.

Robber flies generally capture their prey in flight. The three pairs of large, powerful legs are often used to form a net or basket. The prey is seized primarily with the front and middle legs, with support from the remaining legs. The legs have large, strong bristles to help in seizing and holding prey. However, not all robber flies capture their prey in flight. *Stenopogon coyote* has been observed leaving their perches to attack grasshoppers on the ground. Members of the subfamily Leptogastrinae are also notable exceptions to the "perch and intercept" behaviors of most robber flies. Leptogastrines are slender, elegant flies that superficially resemble damselflies, and are known by the common name "grass flies." Instead of perching and waiting for moving prey, these flies make "patrol flights" in search of stationary prey on vegetation. When a potential victim is located, the fly pounces, seizing the prey with its two front pairs of legs.

Among the perching robber flies, some species are particular in the type of perch they use, and will change position with changing microclimate. Studies of robber flies in the genus *Efferia* have shown that the flies tend to perch on the ground early in the day when temperatures are low. The body is held low to the ground, and is oriented with the axis perpendicular to the sun. This position maximizes heat absorption from the ground and the sun. As surface temperatures increase, the flies move to perches above the ground. At the highest temperatures, the flies perch with the body axis toward the sun, reducing heat absorption by minimizing the surface area exposed to the sun. The behavior of an assemblage of desert grassland robber flies has also been found to correlate with climatic conditions. Species active during late winter to late spring tend to perch on shrubs, and thus avoid hot soil surfaces. They also thermoregulate by moving between the soil surface and the vegetation. But species active from autumn through early winter include primarily ground perching species. Behavioral thermoregulation is probably of great importance in robber fly predatory success. Insect muscle performance, and therefore flight speed and quickness of take-off, is to a great extent dependent on body temperature.

The robber flies are an important group of insects that are exquisitely well adapted for their predatory lifestyle. Their distinctive appearance and interesting behaviors make them fascinating subjects for study by both professional and amateur entomologists.

Robineau-Desvoidy, Jean Baptiste

Jean Baptiste Robineau-Desvoidy was born at St. Sauveur in Puisaye, Department of Yonne, France, on January 1, 1799. He studied in Paris and obtained his doctorate in 1822, and then returned to his native town where he divided his time between medical duties and the study of natural history. Robineau-Desvoidy lived in a marshy area, a generally unhealthy environment. His death in 1857 at the age of 57 is attributed to this environment. At his death, a colleague took on the posthumous publication of Robineau-Desvoidy's work, "Diptères des environs de Paris." He published a large and important work in 1830 that was controversial and not well received. His basic thesis was that the classification of the adults could be based on the mode of life of the immature stage. As an indication of the disapproval by some of his colleagues, Macquart, in his "Histoire Naturelle des Diptères" ignores Robineau-Desvoidy. However, in his 1830 publication "Essai sur les Diptères" Robineau-Desvoidy described many exotic Diptera from South America and the West Indies.

Robust

Within statistics and sampling, the quality of being widely applicable. For example, a sampling plan is robust if it can be used to precisely estimate the density of an arthropod under many different environmental conditions.

► Sampling Arthropods

Robust Marsh-Loving Beetles

Members of the family Lutrochidae (order Coleoptera).

► Beetles

Rock Crawlers (Grylloblattodea)

Rock crawlers are a small order of primitive orthopteroid insects known only from Siberia, Japan, and North America. The order name is based on the Latin words *gryllus* (cricket) and *blatta* (cockroach). Sometimes this order is called Notoptera. The number of described species numbers about 20 in a single family, Grylloblattidae.

Characteristics

Rock crawlers are elongate, wingless insects. As the name "Grylloblattodea" implies, they resemble crickets and cockroaches, though the similarity with *Timema* walkingsticks also is apparent. As with other orthopteroids, the mouthparts are of the chewing type. Rock crawlers measure 14–30 mm in length, and are elongate and cylindrical. Eyes are small or absent. The head is large, consistent with orthopteroids. The antennae are filiform, moderate in length, and shorter than many crickets and cockroaches. The legs are unspecialized, and the tarsi have five segments ending with a pair of claws. The body segments are clearly differentiated, and the abdomen consists of ten segments. The tip of the abdomen bears a pair of segmented cerci, and in the case of the female, the ovipositor is of nearly equivalent length. The nymphs resemble the adults except for size. There are nine nymphal instars.

Biology

Rock crawlers are found among rocks, often in association with glaciers. Some dwell in caves. They are nocturnal, and apparently feed principally upon organic matter such as dead insects found on snow fields and glaciers. The adult deposits eggs singly in the soil or among moss, and the egg requires an incubation period of about a year. A protracted period of time, probably 5 years, is required to attain maturity. Rock crawlers are rarely observed, and their biology is poorly known.

Rocky Mountain Spotted Fever

LEWIS B. COONS, MARJORIE ROTHSCHILD
The University of Memphis, Memphis, TN, USA

Rocky Mountain spotted fever (RMSF) is caused by the bacterium *Rickettsia rickettsii*, a member of the spotted fever group of Rickettsiae, and transmitted by several species of ticks belonging to the family Ixodidae. Rickettsiae are intracellular parasites of eukaryotic cells. RMSF is a zoonosis that is cycled in small rodents, rabbits, dogs and other domestic mammals. Humans are accidental hosts and are not part of the natural transmission cycle. The maintenance and persistence of RMSF in domestic and wild animals is complicated. Serological tests have shown that antibodies to *R. rickettsii* exist in many species of ground feeding birds and at least 31 species of mammals. Not all these animals are of equal importance in maintaining the disease in nature. Meadow voles and chipmunks can develop high rickettsemias sufficient to infect more than 50% of ticks feeding on them. Dogs show symptoms of RMSF and often have a high seropositivity in areas where RMSF occurs. They have a low level of rickettsemia which is transitory in nature, and consequently dogs are not believed to be important as a reservoir potential of RMSF. However, dogs are important in bringing infected ticks into contact with humans.

RMSF occurs in most of the continental states of the USA, some parts of Canada, in Mexico, and in some parts of Central America, Brazil and Colombia. The disease is endemic in most of these areas. RMSF, also known as tick-borne typhus, has several local names, including the black measles in the Rocky Mountain region, Mexican spotted fever or fiebre manchada in Mexico, tobia fever in Colombia, and Sao Paulo fever or fiebre maculosa in Brazil. Six species of ixodid ticks are known to harbor and transmit *R. rickettsii* in nature, the Rocky Mountain wood tick *Dermacentor andersoni*, the American dog tick *Dermacentor variabilis*, the lone star tick *Amblyomma americanum*, the brown dog tick, *Rhipicephalus sanguineus*, the cayenne tick *Amblyomma cajennense*, and the rabbit tick, *Haemaphysalis leporispalustris*. The principal vectors of RMSF to humans are the Rocky Mountain wood tick in the western USA and Canada, the American dog tick in the rest of the USA, the brown dog tick in Mexico, and the Cayenne tick in Central and South America. Several species of Ixodes from the eastern and southern states of the USA as well as *Dermacentor occidentalis* and *Ixodes pacificus* in California are known to have natural infections of *R. rickettsii*, but their role in the transmission of RMSF is not understood. It is not yet clear what role the lone star tick plays in transmission of RMSF, although it can transmit the disease to humans. The rabbit tick rarely bites man, but it is important in maintaining the rickettsia in animal populations because it is the only vector of *R. rickettsii* found in all regions of the continental USA where the disease occurs. RMSF accounts for over 95% of the reported human rickettsial disease in the United States. Almost all human infections occur through tick bites although infection can occur through the fingers during tick removal, and laboratory workers handling infected ticks or *R. rickettsii* are at special risk.

History of Rocky Mountain Spotted Fever

RMSF has an important history among the annals of arthropod-borne diseases studied by scientists. It was first described as a disease in 1896 in the Snake River Valley of Idaho, although RMSF is known to have infected pioneers in the Rocky Mountain region since at least 1872. The disease was serious and often fatal. It had a mortality rate of over 90% in the Bitter Root Valley of Montana. The United States Public Health Service sent a physician and scientist, Dr. Howard Taylor Ricketts, to Hamilton, Montana, in the center of the Bitter Root Valley. Here, he started a laboratory in the most primitive of conditions where he carried out classic experiments in vector biology. First he established that the unknown pathogen of RMSF could be transmitted directly to guinea pigs which showed symptoms of the disease after inoculation. Other workers had previously theorized that a tick was the natural transmitter of the disease, but it was Ricketts who experimentally established their role as vectors of RMSF. In his laboratory, he fed a male tick on the ear of a guinea pig previously inoculated with the pathogen and then fed this tick on two other healthy guinea pigs which came down with the disease. Healthy guinea pigs did not contract the disease when placed in close contact with infected guinea pigs, eliminating the possibility of the aerosol route of infection. Ricketts then used infected field-collected ticks to transmit the disease to a guinea pig in his laboratory. He established that any stage of a tick can transmit the pathogen and that the pathogen is transferred from stage to stage in a given tick (transstadial transfer) and to eggs of the infected females (transovarial transmission). It was subsequently found by other scientists that the pathogen was a bacterium which was named *Rickettsia rickettsii* in his honor. Ricketts died in Mexico in 1910 from typhus, a non-tick borne rickettsial disease, shortly after completing his pioneering studies on RMSF.

The laboratory Dr. Ricketts started in Hamilton, Montana, is now the Rocky Mountain Laboratory which is part of the United States National Institute of Allergy and Infectious Diseases of the National Institutes of Health. The laboratory has grown considerably and today is an internationally renowned center for the study of infectious diseases, including RMSF.

Epidemiology

A dramatic shift in the geographical distribution of human cases of RMSF has occurred in the USA. Before the 1930s, most human cases were in the Rocky Mountain region although the disease occurred sporadically throughout the continental USA. Thereafter, human cases of RMSF declined in the Rocky Mountain region, but increased greatly in the southeastern and south-central states. Over 97% of all human cases of RMSF now occur outside the Rocky Mountain region, with some 48% of all cases reported from Oklahoma, Tennessee, North and South Carolina. Why this disease underwent a dramatic decline in the Rocky Mountain region is not known. Its increase in other regions coincides with the expansion of humans from urban areas into suburban and rural areas where people have a greater chance of being bitten by infected ticks. Associated with the change in the distribution of RMSF is a change in who is likely to be infected. In the Rocky Mountain States most infected persons were males who worked farms and ranches and frequented the woods to hunt, but in the southwestern and eastern USA, females and children as well as males contract the disease. The frequency of reported cases of RMSF in the USA is greatest among males, Caucasians and children. Two thirds of the reported cases occur in children less than 15 years old. The number of RMSF cases reported in the USA has varied from about 250–1200 cases per year over the last 50 years. RMSF occurs throughout the year but over 90% of cases occur in the spring and early fall, from April to September with the peak number occurring in June and July.

Ticks can acquire *R. rickettsii* by feeding on a rickettsemic host, or through transovarial or transstadial transmission, and by venereal transmission between ticks. Ticks thus function both as a reservoir and vector of *R. rickettsii*. Venereal transmission is not deemed important in the transmission of *R. rickettsii*. Ticks feeding on an infected host must ingest a "threshold" number of *R. rickettsii* to become infected. After ingestion, rickettsiae disperse out of the midgut, usually within 5 days, to the cells of all tissues and organs of the tick including the ovaries and salivary glands. Feeding has been shown to be a stimulus for rapid multiplication of the pathogen within cells of the infected tick, increasing the chance of passage into an animal host. This rapid multiplication, known as the reactivation phenomenon, greatly increases the chances of transstadial transmission to the next life stage and transovarial transmission to eggs. Transovarial transmission can be as high as 100% of offspring, and offspring are capable of continuing the transmission through as many as 12 generations of ticks. However, in later generations, many infected ticks die soon after completion of feeding, and those ticks that survive lay a smaller clutch of eggs. Transovarial transmission is more effective in females that acquire the pathogen transstadially since *R. rickettsii* cannot penetrate tick eggs after the vitelline membrane develops. *R. rickettsii* are pathogenic to ticks, especially the more virulent strains. The actual percentage of ticks infected with *R. rickettsii* usually varies from 2 to 10% in areas of endemic RMSF but may be less than 1%.

Rocky Mountain Spotted Fever, Figure 35
Photograph of a patient with Rocky Mountain spotted fever showing the entire body and extremities covered with the rash typical of RMSF (from Sonenshine, 1993, used with permission of Oxford University Press).

Symptomology

In humans, RMSF has a variable incubation period depending on the severity of the infection. In mild cases, the incubation period is about 3–14 days, in severe infections 2–5 days. Three symptoms are common in RMSF: a sudden onset of fever, a severe frontal headache, and a rash. Often these three symptoms are accompanied by muscle and joint aches. Patients may also experience vertigo, ringing in the ears and later photophobia. The rash is present in most but not all cases of the disease, but only a little over half of patients have a rash on the palms or soles. Much less common is the additional report of a tick bite. Temperatures can rise to over 40°C. The rash usually appears between the 2nd and 6th day after onset of symptoms, and begins on the wrists and ankles and less commonly on the back then spreads to all parts of the body including the face (Fig. 35). The rash starts as small surface spots that later become raised bumps. The spots may form large discolored areas similar to a bruise, which may leave a slight scar after healing. The rash is the result of blood leakage from injured endothelium of small blood vessels. The rash is often delayed in adults for up to 7 days.

Acute cases of RMSF can result in severe damage to vital organs. The heart may suffer from muscle damage, or the patient may become deaf, or develop impaired vision, or partial paralysis. Gangrene can also occur during the disease causing loss of toes or fingers. In fatal cases, death from RMSF usually occurs 9–15 days following onset of symptoms. Death is commonly the result of encephalitis, but may also be caused by renal failure. Strains of *R. rickettsii* with different virulence occur, and several different strains can occur in the same area. Mortality rates have declined from 20 to 30% in the 1940s to anywhere from 3 to 10% presently, no doubt due to the advent of antibiotics effective against the disease and a more educated public. If untreated, recovery from RMSF is slow. Physicians are also now more skilled in early diagnosis of RMSF. Mortality from RMSF is greater when there is a delay in treatment with antibiotics, or when older people are infected, or when people with genetic deficiency of glucose 6-phosphate dehydrogenase are infected. This deficiency can result in a greater hemolysis during the course of the disease.

Treatment

It is important not to delay treatment if RMSF is suspected, and the initial diagnosis and treatment should be made on clinical grounds and must not wait for the result of laboratory tests. Most people who die from the disease have not received prompt treatment after the onset of symptoms. Tetracycline and chloramphenicol are the only antibiotics approved for treatment. The disease can be confused with meningococcemia and human ehrlichiosis. Mortality of untreated RMSF varies from 20 to 80% with an average of 25%. Commercial vaccines have been withdrawn as ineffectual.

Prevention

RMSF is best controlled by avoiding tick-infested areas, or by wearing clothing that covers the ankles and wrists and wrapping the ankles with tape when in tick infested areas. The clothing should be light colored in order to see any crawling ticks. Use of a repellent or acaricide increases protection. Daily examination of the body, especially in areas where ticks are likely to be embedded, should be a routine preventive measure. Proper removal of ticks is important, especially because transmission of the disease can occur during tick removal. For proper examination of the body for ticks and a description of how to properly remove them see the entry on "Ticks." Save the tick for species determination by a physician or scientist. Put it in a plastic bag for storage. Removal of ticks early in feeding lessens the chance of transmission of *R. rickettsii*. Education about symptoms of RMSF is very important.

Rocky Mountain Wood Tick, *Dermacentor andersoni* Stiles (Acari: Ixodidae)

TIM LYSYK
Agriculture and Agri-Food Canada, Lethbridge, AB, Canada

The Rocky Mountain Wood Tick, *Dermacentor andersoni* Stiles, is distributed in western Canada east of the Coast Mountains in British Columbia, through Alberta, and Saskatchewan to 105° longitude and north to the 53rd parallel. The tick occurs in the northwestern United States including western Washington, Oregon and eastern California, Nevada, Colorado, Wyoming, Idaho and Montana. The southern limit of its range is northern New Mexico and Arizona, and the eastern limit includes western portions of North Dakota, South Dakota, and Nebraska. Preferred tick habitat in mountainous areas includes rocky slopes, clearing, outcrops and ecotones between grasslands and forest. South-facing slopes are preferred at higher elevations and in northern parts of its range. In drier, prairie habitats, the tick tends to localize in river bottoms and coulees. The presence of shrubby vegetation such as Saskatoon (*Amalanchier*) and rose (*Rosa*) are positive indicators of tick habitat, while the presence of aspen (*Populus*) is a negative indicator of tick habitat.

Rocky Mountain wood tick is a three-host tick and completes its life cycle in 1–3 years depending on latitude, elevation, and local environmental conditions. Longer life cycles occur in cooler areas such as higher elevations and more northerly latitudes. Adult ticks are brown with grey patterns and are ~3–4 mm long and 2–4 mm broad. Wood ticks have a rectangular basis capitulum and short, broad palps. The spiracle has a dorsal prolongation and numerous small goblets that distinguish it from the related species *Dermacentor albipictus* and *D. variabilis*. Adult ticks feed on various moderate to large hosts including cattle, sheep, horses, dogs, porcupines, goats, deer and humans. Adults are active in the early spring and quest when temperatures are above 10°C. In the interior of British Columbia, adults are active from mid-March through mid-May, with peak activity in early April. Ticks in prairie regions are active somewhat later, with peak activity in May through June. Adults seek hosts by climbing grasses or low shrubs and waiting for a host to approach. The adults sense carbon dioxide emanations from a potential host, become active, and attach to the host as it passes. Ticks will crawl on the host until they find a suitable site for attachment and feeding. Montane ticks tend to attach and feed on the upper surfaces of cattle near the withers while prairie ticks tend to attach to the undersides of cattle. This may be to avoid excessive exposure to increased solar radiation and host temperatures due to the later periods of activity in prairie regions. Both sexes feed on blood, although male ticks take smaller meals and may redistribute themselves on the host. Ticks that do not find a host in the spring may enter a behavioral diapause, and a small proportion of these can successfully overwinter to seek a host the following spring. Feeding females gain weight slowly during the first few days of feeding, but greatly increase the rate of engorgement after mating. Females require 7–10 days to become fully engorged, and can increase their weight from 4 to 700 mg (Fig. 36). Once engorgement is complete, the females detach, fall to the ground, and seek sheltered areas to oviposit.

The preoviposition period is dependent on temperature, ranging from 5 days at 25°C to

Rocky Mountain Wood Tick, *Dermacentor andersoni* Stiles (Acari: Ixodidae), Figure 36 Wood ticks, unfed and well fed.

20–40 days at 15°C. Females produce from 5,000 to 10,000 eggs over a period of several weeks, and die once oviposition is completed. Eggs hatch in about 4 weeks, depending on temperature. The larvae are six-legged and will attach to smaller mammals such as mice, ground squirrels, and chipmunks. Larval engorgement requires 5–10 days, and the fully engorged larvae drop from the host. Molting to the nymphal stage requires 1–4 weeks depending on temperature. Larvae are most abundant on hosts during July to August in the interior of British Columbia. Newly molted nymphs may attach to a small mammal host, engorge in 5–10 days, drop from the host, and molt to adults in 2–4 weeks depending on temperature. Nymphs that are unable to find a host may overwinter, and seek hosts the next spring. Nymphal activity thus occurs over a broader period time than do larvae, from April though August in the interior of British Columbia. Nymphs that are active early in the season are likely those that overwintered, while nymphs active later in the season likely originate from larvae produced the current year. Adults that are produced in the fall do not seek hosts but enter a behavioral diapause that must be terminated by chilling before they will resume normal feeding.

Feeding activity of adult wood ticks on cattle probably does not result in appreciable economic losses due to reduced weight gains of cattle. Adult activity occurs early enough in the season for compensatory weight gain to occur.

However, feeding ticks can cause paralysis in cattle in the interior of British Columbia south through Idaho. Paralysis can also affect sheep and humans, as well as dogs and horses. The economic effect of paralysis is difficult to estimate, but results from animal death, underuse of native pasture, and increased costs for surveillance. Currently, tick paralysis is prevented by early season application of synthetic acaricides such as Lindane. However, the availability of such compounds is increasingly limited. Other potential methods for managing ticks based on rangeland management practices have been proposed but not fully investigated.

Rocky Mountain wood ticks can vector several of diseases of humans and livestock. These include anaplasmosis in cattle, and Rocky Mountain spotted fever, Tularemia, and Colorado tick fever to humans. Disease prevention is achieved by removing ticks before feeding, and requires careful inspection after engaging in outdoor pursuits during the season of adult activity. Precautions to prevent ticks from attaching include wearing long pants outdoors, and pulling socks up over the pant legs. Repellents can also be used.

Rodent Trypanosomiasis: A Comparison Between *Trypanosoma lewisi* and *Trypanosoma musculi*

Clarence M. Lee[1], Earlene Armstrong[2]
[1]Howard University, Washington, DC, USA
[2]University of Maryland, College Park, MD, USA

Trypanosoma lewisi and *Trypanosoma musculi* are protozoans that belong to the Phylum Sarcomastigophora and Subphylum Mastigophora. The Mastigophora, commonly known as flagellates, typically possess one or more flagella. Although they reproduce asexually by binary fission, sexual reproduction is known to occur. Both *T. musculi* and *T. lewisi* are assigned to the class Zoomastigophorea, family Trypanosomatidae, and order Kinetoplastida because they have flagella, typically with a paraxial rod and an axoneme. In addition, they contain a single mitochondrial kinetoplast located near the flagellar kinetosomes and a Golgi apparatus located close to the flagellar depression.

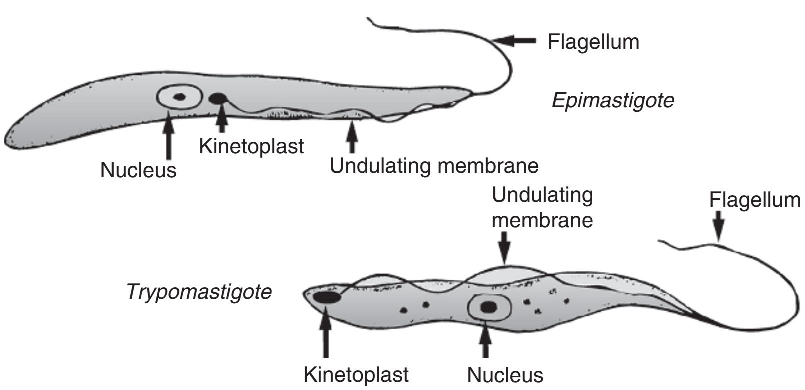
T. lewisi, a cosmopolitan parasite in the blood of rats (*Rattus* sp.), is transmitted by several species of rat fleas (*Ceratophyllus fasciatus*, *Nosopsyllus fasciatus*, and *Xenopsylla cheopis*). On the other hand, *T. musculi*, also a cosmopolitan blood parasite, is found in mice and is transmitted primarily by the rat flea, *Nosopsyllus fasciatus*. Both trypanosomes are highly specific for their vertebrate hosts where they live extracellularly, primarily in the bloodstream.

Fleas become infected with these trypanosomes upon ingesting a blood meal from an infected rodent. In the fleas, however, the trypanosomes are present in the alimentary tract, where they undergo morphological changes and then move posteriorly towards the rectum and anus. The trypanosomes are then voided in the feces of the insect vector ("posterior station transmission") and can be ingested by the rodent during grooming. Within the rodent, the trypanosomes now enter the bloodstream by way of the oral mucous membranes. Once in the bloodstream, they undergo further development and are now infective to the adult flea during a blood meal. Rosettes, which usually consist of eight daughter cells, have been found in both *T. lewisi* and *T. musculi* during in vitro cultivation. Rodents stressed by starvation, low temperature, multiple infections, or intraspecies fighting do not show an increase in the prevalence of the rosette forms.

Although *T. lewisi* was believed to be primarily monomorphic in appearance with lengths varying from 21 to 36.5 μm and an average of 30.6 μm, two additional forms (type II and III) have been observed. Type II is a morphological variation of the original type and it has a total length of 35.3–39.3 μm. The posterior end of this form is extremely elongated. The distance between the posterior end and the kinetoplast (P-K) is 11.9–15.0 μm. The average length of type III of *T. lewisi* is 26.7 μm (19.8–30.9 μm) and the distance between the posterior end and the kinetoplast is 2.9–6.3 μm. The size of *T. musculi* varied from 23 to 30 μm, with an average of 26.5 μm. This parasite has a diameter of 3–5 μm. Electron microscopic studies have shown that the kinetoplast of *T. lewisi* appears as a mass of DNA-containing fibrils, about 25 Å in diameter, lying in parallel array and situated within an enlarged portion of the mitochondrion. There are no studies on the kinetoplastic DNA replication of *T. musculi*.

The two developmental stages of *T. musculi* and *T. lewisi* differ by the position of the kinetoplast. In the epimastigote form, the kinetoplast is anterior to the nucleus, whereas in the trypomastigote form, the kinetoplast is posterior to the nucleus. Epimastigotes have been characterized as dividing, sausage shaped and juvenile forms while trypomastigotes are sometimes referred to as the adult, leaf-shaped stage. During the conversion of the epimastigote stage to the trypomastigote stage, there is a shift in the kinetoplast. The epimastigote form requires iron for its cytochrome oxidase system. When the epimastigote changes to the trypomastigote form, the trypanosomes are believed to utilize the iron from the host (Fig. 37).

Both *T. musculi* and *T. lewisi* parasites produce a self-limiting infection comprising of a growth phase, a plateau phase, and an elimination phase during a 2–4 week period. In *T. musculi* and *T. lewisi*, upon infection of their specific hosts, there is a latent period which is determined by the size of the parasitic inoculum. Following the latent period, there is a phase of rapidly increasing parasitemia in



Rodent Trypanosomiasis: A Comparison Between *Trypanosoma lewisi* and *Trypanosoma musculi*, Figure 37 **Epimastigote and trypomastigote forms of mouse trypanosomes.**

the infected blood that becomes stabilized after 6–7 days in *T. musculi* and 4–5 days in *T. lewisi*. This period is followed by a plateau phase in *T. musculi* that lasts about 7–10 days. The onset of the plateau phase with the elimination from the blood of all reproductive forms of the parasites is called the first crisis. The antibody ablastin is responsible for this elimination in *T. lewisi*-infected rats. A trypanocidal antibody is responsible for the elimination of reproductive trypanosomes in *T. musculi*-infected mice. A second crisis, at the end of the plateau phase, produces an abrupt fall in the parasitemia, and the parasites disappear from the blood within a few days. An IgM antibody is involved during this second crisis in *T. lewisi* and *T. musculi* infections. *T. lewisi* neither divides in the peritoneal cavity after the first crisis nor remains in the vasa recta of the kidneys after blood recovery from the infection. As opposed to *T. lewisi*, *T. musculi*-infected mice showed both continuous parasitic division in the peritoneal cavity and persistence of dividing forms in the vasa recta of the kidneys of the immune mice. These mice with chronic or latent infections are immune to re-infection and do not experience relapses, although isolated kidney forms and homogenates of kidneys from these animals are infective when inoculated into naive mice.

Trypanosoma musculi and *T. lewisi* infections, although referred to as non-pathogenic, can produce profound changes in the size, cellularity, and histoarchitecture of spleen, liver, lymph nodes, and thymus of the respective hosts. There are obvious pathological changes associated with the elimination of these parasites. They involve splenomegaly, marked enlargement of the lymph nodes, hepatomegaly to a lesser degree, and immunodepression, that are clinical features of the pathogenic trypanosomes in man and animal host.

Life Cycle and Control of Rodent Fleas

Fleas are holometabolous insects with an egg, several larval instars, and a pupal stage. Eggs of adult fleas are typically laid in the rodent's nest or bedding, where they hatch within a few days into larvae. The larvae feed on a variety of organic material in the nest or bedding materials of the host. Food of the larvae also may include feces of the adults which contain partially digested blood. The larvae eventually change into a pupa and then either a female or adult male emerges. Both sexes feed on blood.

Because rodent trypanosomiasis generally produces a benign infection in rats and mice, the *T. lewisi*-rat flea system (also *T. musculi*-mouse-flea system) has been used as a laboratory model for studying more virulent trypanosomes that are pathogenic to man and domestic animals. However, it is imperative that flea control strategies (e.g., improved garbage sanitation near homes where rodent populations may build up, as well as interrupting the flea development cycle, or chemicals) be used to reduce the threat or possibility of fleas vectoring the etiological agents of more serious man and animal diseases (e.g., plague, murine typhus, Q fever, etc.).

Rosen, David

David Rosen was born on April 20, 1936, in Tel-Aviv, Israel. He received his education at the Hebrew University of Jerusalem (M.S., 1959; Ph.D., 1965). His thesis research, entitled "Parasites of the Coccoidea, Aphidoidea and Aleurodidea of citrus in Israel" earned him the Jacobsen Prize in 1965. He obtained a postdoctoral appointment with Paul DeBach at the University of California at Riverside, and together they published "Species of Aphytis of the world" (1979). For this important project they received a gold medal from the Filippo Silvestri Foundation in 1980. In 1991 they published a second edition of "Biological Control by natural enemies." David also edited two volumes of "Armored scale insects: their biology, natural enemies and control" (1990), and coedited two volumes of "Pest management in the subtropics" (1994, 1996). Rosen was a powerful voice for practical implementation of biological control, and had a productive career emphasizing population dynamics of pests, particularly biological control of pests, and including the systematics of parasitoids. He served as chairman of the Department of Entomology at Hebrew University of Jerusalem, and was named Vegevani Chair of Agriculture in 1990. He served on the editorial board of several journals, and was well-known and highly respected in international biological control circles. Rosen's career included publication of 140 technical papers, 33 book chapters, and 8 books. He died on January 8, 1997.

Ross, Herbert Holdsworth

Herbert Ross was born in 1908 at Leeds, England, educated in British Columbia, Canada, and received his Ph.D. from the University of Illinois in 1933. Ross began work with the Illinois Natural History Survey in 1927 and was named head of the survey and identification section in 1935. He also held the rank of professor of entomology at the University of Illinois. Ross retired from the University of Illinois in 1969 but then worked for the University of Georgia until 1976. Herbert Ross was an authority on caddisflies (Trichoptera) and published over 200 technical publications, as well as several books. He is best known for a popular introductory text, "A textbook of entomology" (1948 and followed by several editions), but also authored "Understanding evolution" (1966), "Evolution and classification of the mountain caddisflies" (1956), and "Synthesis of evolutionary theory" (1962). Herbert Ross died November 2, 1978, at Athens, Georgia.

Rostrum

In weevils, the snout-like prolongation of the head containing the mouthparts distally. In Hemiptera, this sometimes refers to the beak or piercing-sucking mouthparts.

Rosy Apple Aphid, *Dysaphis plantaginea* (Passerini) (Hemiptera: Aphididae)

This is likely the most important of the apple-attacking aphids.

► Apple Pests and their Management

Rotation

In agriculture, purposeful alternation of crops grown on the same plot of land. In pest control, purposeful alternation of insecticides used to control a pest population.

Rotenone

This insecticide is derived from the roots of *Derris* and *Lonchocarpus*.

Rothschild, Miriam

Born into a famous and wealthy banking family on August 5, 1908, Miriam Rothschild might well have pursued a leisurely, less scholarly lifestyle more typical of her class and gender during that era. Instead, she followed the lead of her father, Charles, who was a naturalist as well as a financier. Her father had obtained the world's best collection of fleas and had studied the role of fleas in the transmission of bubonic plague. So Miriam spent many years preparing a six-volume illustrated catalogue of the Rothschild Collection of Fleas, earning her the honorary title of "Queen of Fleas."

Miriam Rothschild was married, and raised six children, but also pursued her scientific enterprises actively, publishing more that 300 papers in scientific journals. She was awarded eight honorary doctorates from institutions in three countries. In addition to the aforementioned taxonomic interests, she studied flea behavior, producing now-classic studies on the synchronization of the sexual cycle of the rabbit flea and its host. Later in life she became fascinated with chemical ecology, particularly the role of secondary plant compounds on caterpillar feeding behavior. Rothschild's interests also extended to butterflies, snails, trematodes, and birds, and she became a well-known naturalist in Britain, and elsewhere, as her public appearances on radio and television were broadcast. In 1991, she published the book "Butterfly Cooing Like a Dove," which helped to popularize insects. Eventually she turned her attention to wildflower habitat preservation and became an ardent conservationist. She died February 20, 2005.

Roubal, Jan

Jan Roubal was born at Chudenice, Czech Republic, on August 10, 1880. He was educated at the university in Prague, and in 1905 left the university as a high school teacher. He continued as a gymnasium teacher and director until he retired in 1940, when he directed his entire energy to the study of entomology. Roubal is reputed to have had an encyclopedic knowledge of Coleoptera. This, combined with an outgoing and unselfish personality, made him an important and influential coleopterist in middle Europe. He preferred the Staphylinidae, and influenced many others to work with this large group. He published over 300 papers, mostly on beetles but also on Hemiptera/Heteroptera. His "Katalog Coleoper (brouků) Slovenska a Parkarpatska" was published in three volumes (1930–1941) and set a new standard for catalogs because it contained extensive habitat data and comments. Roubal died at Prague on October 23, 1971.

Round Fungus Beetles

Members of the family Leiodidae (order Coleoptera).

► Beetles

Roundheaded Pine Beetle, *Dendroctonus adjunctus* Blandford (Coleoptera: Curculionidae, Scolytinae)

JOSE F. NEGRON
USDA Forest Service, Ft. Collins, CO, USA

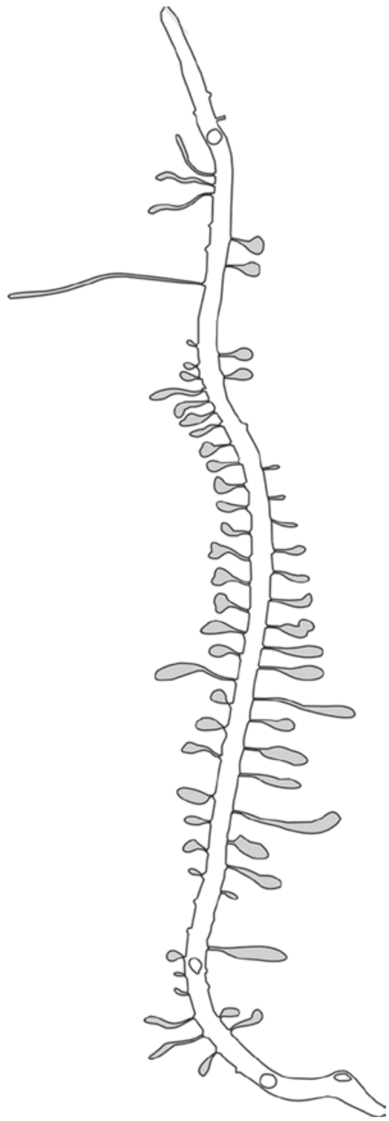
The roundheaded pine beetle, *Dendroctonus adjunctus*, is an important bark beetle that attacks and kills various species of pines from Nevada, Utah, and Colorado south to Guatemala. In the Southwestern United States its primary host is ponderosa pine, *Pinus ponderosa*. It often occurs in trees in conjunction with the western pine beetle, *Dendroctonus brevicomis*, and pine engravers of the genus *Ips*. Like other tree-killing bark beetles, the roundheaded pine beetle causes tree mortality by feeding and developing in the phloem of the tree. Utilization of the phloem for habitat and nourishment results in girdling of the tree so that translocation of nutrients is impeded. The insect also inoculates attacked trees with blue-stain fungi *Ophiostoma adjuncti* and *Leptographium pyrinum*, but the ecological role of these in helping the insect kill the tree or providing nutritional benefits to the insect is unclear.

Patterns of tree mortality range from a single tree to groups of tens to hundreds of trees. Occasionally, only a portion of the tree is attacked, commonly referred to as a strip attack, and the tree usually survives. Initial symptoms of attack include an accumulation of brown-reddish boring dust at the base of the tree and in bark crevices. As the insect enters the tree, resin canals, which are the primary defensive mechanism of the tree, are severed and resin exuded. The resin then solidifies on the outer surface of the bark forming a pitch tube. As the tree dies, the foliage changes in color from green to a light yellow and then bright orange within the first year of attack.

In the Southwest, the roundheaded pine beetle has generally a 1-year life cycle. The primary emergence and dispersal flight of the insect occurs in late October and early November, with some variation observed among geographical locations. Soon after emergence females seek suitable hosts for attack. Colonization of new hosts involves a complex chemical communication system of pheromones and host chemicals.

Once the adult beetles enter the tree, a small chamber is excavated and then the main egg gallery begins either to the right or left of the chamber for the first 2.5–5 cm. The egg gallery then turns vertically moving upward with the grain of the wood and gently meandering to the right or left (Fig. 39). The gallery is constructed by the female and packed with frass by the male behind. Galleries as long as 122 cm have been observed but they are normally about 31 cm and located in the inner bark but do score the wood. Ventilation holes are excavated about every 4–8 cm. Females oviposit single eggs in niches alternately on both sides of the gallery. Egg niches are about 1.5 mm across and about 1 mm deep and are covered with frass and other debris. Egg niches are about 4–8 mm apart. Oviposition begins after the tree is invaded, ceases through the winter, and then resumes in the spring, usually March, and continues into April.

The eggs are pearly white, oblong, and about 1 mm in length and 0.6 mm in width. Some eggs may begin hatching in the fall, but the majority will hatch in the spring. The eggs and egg-laying adults are the primary overwintering stage. The larvae are legless, grublike, mostly translucent but with light reddish-brown coloration. Each larva constructs its own larval gallery, which are most commonly 4–15 mm in length. There are four larval instars. Average head capsule width for instars 1–4 is 0.5, 0.7, 1.0, and 1.2 mm, respectively. Average body length for the fourth instar is about 6.3 mm. Larval development through the third instar is rather fast and rather slow in the fourth instar. Pupation occurs at the end of the larval gallery usually between June and August. Average length of the pupae is 5.2 mm. The beetles will usually complete development and become adults by the middle of August but will remain on the tree until the flight period begins again in the fall.



Roundheaded Pine Beetle, *Dendroctonus adjunctus* Blandford (Coleoptera: Curculionidae, Scolytinae), Figure 39 **Roundheaded pine beetle egg gallery (drawing by Joyce VanDeWater).**

Newly emerged adult beetles are shiny black with a reddish tint in the elytra; parent adults are shiny black. Males exhibit heavy pigmentation along the angular rear margin of the seventh abdominal tergite while females have a transverse elevated ridge on the anterior area of the pronotum, which is lacking in the males. Adult beetles vary widely in total length from 2.9 to 6.9 mm but the majority are 4.5–6.0 mm. Females tend to be slightly larger than the males.

The roundheaded pine beetle can kill trees in all crown and diameter classes. Studies have indicated average diameter at breast height of beetle-killed of 29 cm in the Sacramento Mountains of south-central New Mexico, 43 cm in the Pinaleno Mountains of Arizona, 48 cm in the Pine Valley Mountain of Utah with dominant, co-dominant, and intermediate trees being killed. In these areas, tree mortality was more common in areas with high stocking and poor tree growth. In an outbreak in Nevada, tree mortality was most common in trees at least 50 cm in diameter at breast height.

Various natural enemies attack the roundheaded pine beetle but little is known about their ecology and impact. The most important appears to be the red-bellied clerid, *Enoclerus sphegeus*. The roundheaded pine beetle is probably the only species in the genus in North America that overwinters mostly in the egg stage and that has a flight period predominantly in the fall.

Rove Beetle Dermatitis

A term used by some authors for dermatitis linearis.

► Dermatitis Linearis

Row Cover

A covering, usually consisting of spun-bonded polyester, that is placed over crops to protect them from adverse weather or pests.

Royal Cell

In honey bees, a large wax cell constructed by workers and used to rear the queen larvae. In some termites, a cell in which the queen is housed.

Royal Jelly

A high-quality food produced by the hypopharyngeal gland of worker honey bees that, if fed to larvae throughout their development, can cause them to develop into queens. Royal jelly also is known as "bee milk."

Royal Moths

Some members of the family Saturniidae (order Lepidoptera).

► Emperor Moths
► Butterflies and Moths

Royal Palm Bugs

Members of the family Thaumastocoridae (order Hemiptera).

► Bugs

R-Strategists

Species with life history characteristics making them well suited for exploiting transient environments ("r" is an expression denoting the intrinsic rate of increase). r-selected species represent an extreme on a continuum of life history characteristics, with K-selected species at the other end of the continuum. r-selected species can also be said to conform to the "ruderal strategy" (Table 7).

Ruderal

A type of organism, especially plants, found in sites associated with humans and human disturbance. This term is also used with respect to insects that display the characteristics of r-Strategists.

► r-Strategists

Rudimentary

Poorly developed, very small in size, or embryonic.

Rufous

Pale red in color.

Rugose

Wrinkled or roughened.

Runoff

The liquid spray material that drips off the target after a heavy pesticide application is made. The surface water that leaves a field after irrigation.

Rupicolous

This describes organisms that dwell among rocks and stones.

Russian Wheat Aphid, *Diuraphis noxia* (Mordvilko) (Hemiptera: Aphididae)

An Asian pest of wheat, this species has become very important in southern Africa and North America.

► Wheat Pests and their Management

R-Strategists, Table 7 A comparison of the characteristics of r-selected and K-selected species

	r-Selected	K-selected
Habitat type	Unstable, not permanent	More stable
Reproduction	Rapid under favorable conditions; many offspring produced	Usually slower; fewer offspring produced
Development	Rapid; often multivoltine	Slower; often univoltine
Mortality	Often density independent and catastrophic	Often density dependent and more gradual
Population size	Extremely variable in time	Less variable in time
Dispersal capacity and mode	High and random	Lower and oriented
Brood care	Absent	Sometimes present
Body size	Often quite small	Often larger
Competition	Variable, but often low	Often very keen
Ultimate effect	High productivity	Efficient use of resources

Rust Diseases

Rust diseases of plants do not require insects to be pathogenic, but benefit from transport by insects.

► Transmission of Plant Diseases by Insects

Rust Flies

Members of the family Psilidae (order Diptera).

► Flies

Rusty Grain Beetle, *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Laemophloeidae)

This is an important grain-infesting beetle in colder climates.

► Stored Grain and Flour Insects

Ryania

An extract of *Ryania speciosa* (Flacurtiaceae) plants that is used as a botanical insecticide. The active ingredients are alkaloids, and extracted from the roots and stems. There are several active ingredients, the most important of which is ryanodine. It is regarded as a slow-acting stomach poison, and is more stable than some other botanical insecticides.

► Botanical Insecticides

Rove Beetles (Coleoptera: Staphylinidae)

J. HOWARD FRANK[1], M. C. THOMAS[2]
[1]University of Florida, Gainsville, FL, USA
[2]Florida State Collection of Arthropods, Gainsville, FL, USA

The family Staphylinidae belongs to the suborder Polyphaga of the order Coleoptera (beetles). The superfamily Staphylinoidea includes the small families Hydraenidae, Ptiliidae, Agyrtidae, Leiodidae, Scydmaenidae, and Silphidae, and the huge family Staphylinidae.

Order: Coleoptera
Suborder: Polyphaga
Superfamily: Staphylinoidea
Family: Staphylinidae

Four phyletic lines are now (Lawrence and Newton 1995) included in Staphylinidae:

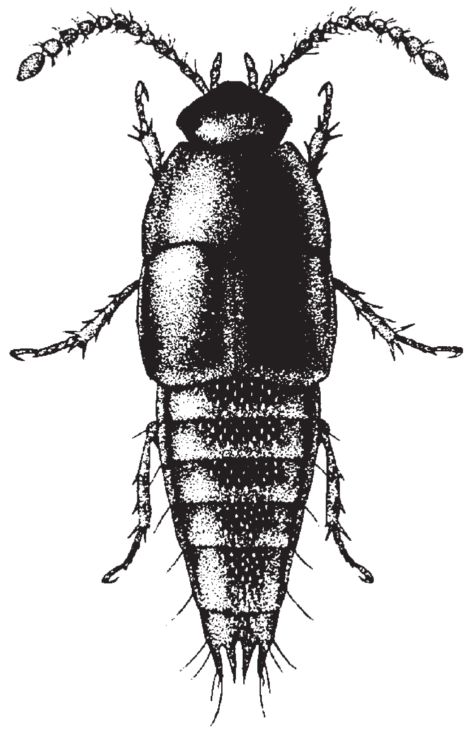
1. Subfamilies Glypholomatinae, Microsilphinae, Omaliinae, Empelinae, Proteininae, Micropeplinae, Neophoninae, Dasycerinae, Protopselaphinae, and Pselaphinae
2. Subfamilies Phloeocharinae, Olisthaerinae, Tachyporinae, Trichophyinae, Habrocerinae, and Aleocharinae
3. Subfamilies Trigonurinae, Apateticinae, Scaphidiinae, Piestinae, Osoriinae, and Oxytelinae
4. Subfamilies Oxyporinae, Megalopsidiinae, Steninae, Euaesthetinae, Solieriinae, Leptotyphlinae, Pseudopsinae, Paederinae, and Staphylininae

The former taxa Brathinidae (now just part of subfamily Omaliinae), Dasyceridae (now subfamily Dasycerinae), Empelidae (now subfamily Empelinae), Glypholomatini (formerly a tribe of Silphidae), Microsilphinae (formerly a subfamily of Silphidae), Pselaphidae (now subfamily Pselaphinae), and Scaphidiidae (now subfamily Scaphidiinae) of earlier authors are here included within the family Staphylinidae. As now constituted, this is one of the largest families of beetles, with over 45,000 species known worldwide and probably over 75% of tropical species still undescribed. In the future, systematists may, however, choose to split the family into the four phyletic lines to form four families.

Adults

The length of adult Staphylinidae ranges from less than 1 mm to almost 30 mm. Most are under 7 mm long. Most have short elytra, exposing several abdominal segments – but it would be an error to imagine that all have short elytra, or that all beetles with short elytra are Staphylinidae. Typically, they are slender with short elytra and abdominal musculature that renders them very flexible, thus able to enter narrow crevices. Those that have short elytra trade flexibility for exposure, rendering them subject to desiccation and dependent upon humid habitats. Typically, abdominal segments are bounded by tergites, one or two sets of paratergites, and sternites, with membranous connections, but in some genera (e.g., of Paederinae and Osoriinae, and partially so in Steninae) the tergites-paratergites-sternites are fused into rings around each segment, probably limiting water loss. The length of adults, which is nevertheless normally used to express size, is an inaccurate determinant of size because abdominal segments typically can be telescoped – making the body appear longer when under moist conditions and alive, but shorter when dried and dead. Eyelessness has evolved in some soil-inhabiting (Leptotyphlinae) and cave-inhabiting species, and winglessness in species occupying environments including mountains, the soil, caves, and seashores (Figs. 40–43).

Non-entomologists sometimes confuse Staphylinidae with Dermaptera. However, the non-opposable valvulae (appendages of the ninth abdominal segment) are not the opposable forcipes of Dermaptera, and the radial wing-folding pattern of Dermaptera is unlike that of Staphylinidae.



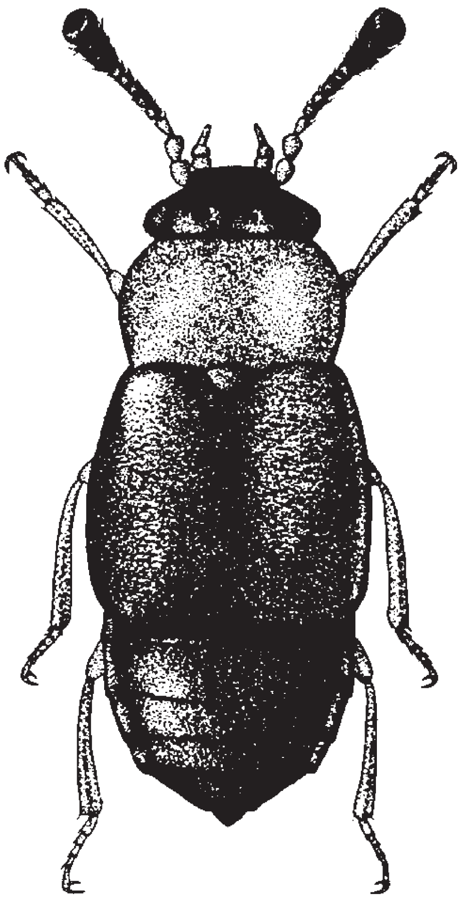
Rove Beetles (Coleoptera: Staphylinidae), Figure 40 Adult *Coproprorus rutilus*, subfamily Tachyporinae, 3.8 mm long, West Indies.

Immature Stages

Staphylinid eggs typically are white, spherical, spheroidal, or pyriform. Eggs of some genera within the Staphylininae (e.g., *Philonthus*) have pronounced surface sculpture, allowing identification at least to the species-group level. Larvae are campodeiform (sometimes called staphyliniform). In some subfamilies (Paederinae, Staphylininae, and to a lesser extent in their immediate relatives) the head is relatively more heavily sclerotized and there is a distinct "neck" (nuchal constriction of the head). Prepupae of Aleocharinae, Steninae, and one genus (*Astenus*) of Paederinae spin a silken cocoon in which they pupate. Pupae are obtect, pigmented, and sclerotized in the subfamily Staphylininae, but exarate, white, and unsclerotized in all the other subfamilies. In general, the immature stages develop rapidly, in a few days to a few weeks, and the adults are long-lived.

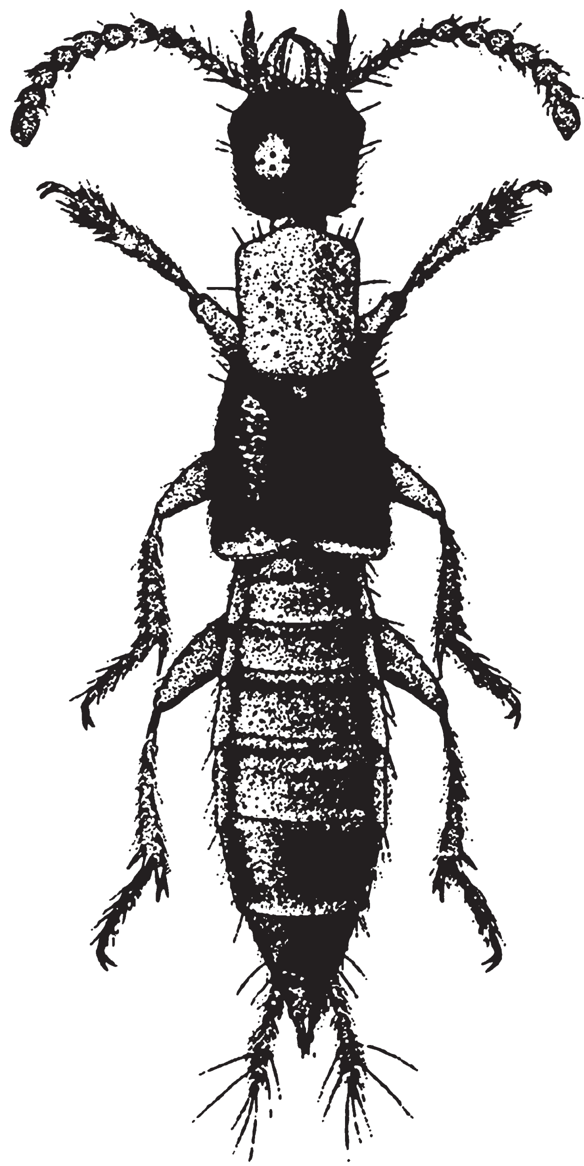
Habitats

Staphylinidae occupy almost all moist environments throughout the world. Because none of them is truly aquatic, they do not live in open waters; although winged adults may be skimmed from the sea surface far from land, their presence is due to misadventure but attests to their dispersive ability. They live in leaf litter of woodland and forest floors and grasslands. They concentrate in



Rove Beetles (Coleoptera: Staphylinidae), Figure 41 **Adult *Proteinus thomasi*, subfamily Proteininae, 1.5 mm long, North America.**

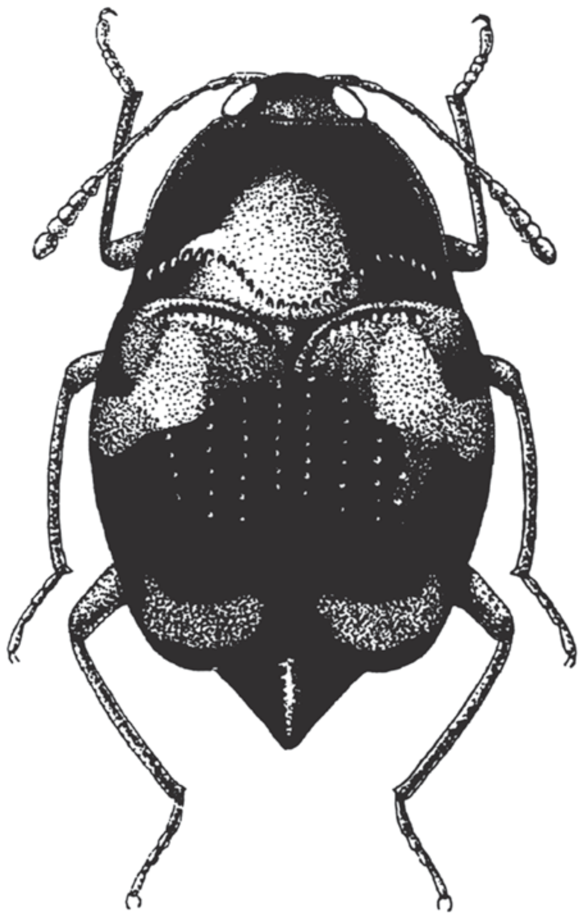
fallen decomposing fruits, subcortical cavities of fallen trees, drifted plant materials on banks of rivers and lakes, and dung, carrion, and nests of vertebrate animals. Several hundred species live only on seashores. Large numbers of species are specialized to existence in nests of social insects. Many inhabit caves, underground burrows of vertebrate animals, and smaller soil cavities, even of burrows that they (a few of them) excavate. Many live in mushrooms. Adults and even larvae of a few are associated with living flowers. Others climb on plants, especially at night, and hunt for prey. A few seem to live with terrestrial snails, although their role is not understood. Their distribution in arid environments is restricted to moist microhabitats.



Rove Beetles (Coleoptera: Staphylinidae), Figure 42 **Adult *Neobisnius occidentoides*, subfamily Staphylininae, 4 mm long, North America.**

Food

A little about the feeding habits of Staphylinidae has been deduced from casual observations by many observers, and from dissections of alimentary canals and from feeding trials and examination of mouthparts by a few. Archetypal



Rove Beetles (Coleoptera: Staphylinidae), Figure 43 Adult *Scaphisoma quadriguttatum*, subfamily Scaphidiinae, 4.3 mm long, North America.

staphylinids probably were saprophagous. Saprophagy is still a major feeding mode in Piestinae, Osoriinae, and Proteininae, perhaps with some adaptation to mycophagy. Mycophagy has evolved in Oxyporinae, Scaphidiinae, some Tachyporinae, and a few Aleocharinae. Phytophagy has evolved in some Oxytelinae, to the point where the diet of adults and larvae of *Bledius* consists of diatoms, and at least one species of *Apocellus* has been accused of damaging flowers, one species of *Carpelimus* has (probably wrongly) been accused of damaging cucumbers, and one species of *Osorius* (Osoriinae) has been accused of damaging turf grass. Saprophagy has evolved toward carnivory in other subfamilies (many Tachyporinae, most Aleocharinae, Pselaphinae, Euaesthetinae, Steninae, Paederinae, and Staphylininae), representing the bulk of species in the family, so that it may be said that most Staphylinidae – tens of thousands of species – are facultative predators. Some have specialized, for example *Oligota* (Aleocharinae) as predators of mites, *Erichsonius* (Staphylininae) as predators of soil-inhabiting nematodes, *Odontolinus* (Staphylininae) as predators of mosquito larvae in water-filled flower bracts of *Heliconia* (Heliconiaceae), and *Eulissus* (Staphylininae) on adult dung-inhabiting scarab beetles. One line of Aleocharinae (*Aleochara*) has evolved to become parasitoids in fly puparia.

Presocial or Subsocial Behavior

This behavior is known in *Bledius* and *Platystethus* (Oxytelinae) and *Eumicrota* (Aleocharinae). Adults construct chambers in which they deposit and guard their eggs, *Bledius* in sandy or muddy shores, *Platystethus* in the dung of ungulates, and *Eumicrota* in mushrooms. Another dimension of social behavior has arisen in interactions with termites and ants – thousands of species of Aleocharinae, and numerous species of several other subfamilies, are inquilines in the nests of these social insects, with attendant structural and behavioral adaptation. *Emus* (Staphylininae) invades bee nests in Europe, and a species of *Euvira* (Aleocharinae) develops in communal nests of a butterfly in Central America.

Obligate Relationships with Higher Plants

Among those species attracted to flowers, *Pelecomalium testaceum* (Omaliinae) pollinates *Lysichiton americanum* (Araceae) in the mountains of the Pacific coast of the USA and Canada. It is conceivable that *Polyobus* spp. do the same for

Espeletia (Asteraceae) in the northern Andes of South America. *Charoxus* spp. (Aleocharinae) also have an obligate relationship with plants – the adults are attracted in the Neotropical region to the syconia of *Ficus* spp. (Moraceae) within which they oviposit, but the adults and larvae feed on pollinating wasps (Agaonidae) of those fig flowers.

Relationships with Fungi

There are three forms of relationships with fungi. Adults and larvae of many species eat fungi. Others find prey items (fly larvae and other organisms) in fungi. A major association with fungi is that adults of many species are infected by Laboulbeniales (Ascomycetes), and some other fungi, many of which specialize at the level of host genus, tribe, or subfamily.

Relationships with Decomposing Plants, Dung, and Carrion

The frequent presence of many staphylinids at decaying plant materials raises the question of whether they arrived there by random movement – and then remained there – or whether they are attracted in much the same way that adults of their prey (fly larvae, etc.) arrived there. Thus, adults and larvae of *Cafius* (Staphylininae) inhabit decaying brown algae (Fucales) on sea beaches and eat fly larvae; adults and larvae of some *Philonthus* (Staphylininae) occur in the dung of ungulates and eat fly eggs and larvae; adults of some *Eulissus* (Staphylininae) are found in the dung of ungulates and there maim and then eat adult scarab beetles; adults and larvae of some *Belonuchus* and *Philothalpus* (Staphylininae) are found in decaying fruits, and eat fly larvae; adults of some *Platydracus* (Staphylininae) are found in carrion and eat fly larvae and adults.

Nests of Vertebrates

Some staphylinid species have specialized to live in the nests of vertebrates, especially tortoises, birds, and rodents. Their prey seems to be mainly the larvae of fleas and flies. Thus, in central Asia, where sylvatic plague is endemic, some are credited with suppressing flea populations – and thus help to suppress transmission of plague. Adults of *Amblyopinus* and its close relatives (tribe Amblyopini, subfamily Staphylininae) occur in the fur of some rodents in Central and South America. For years they were suspected of being parasites of these rodents, and taking blood from them. Now, however, they are believed to be phoretic on the rodents, thus being transported from nest to nest. They oviposit in the nests, and larvae feed as predators there of other arthropods.

Secretions and Glands

Glandular systems of Staphylinidae are mainly implicated in the production of defensive secretions, of which there is a remarkable array. However, glands of some species that are inquilines in nests of social insects produce substances that appease rather than repel the nest-builders. Further, glands of adult *Stenus* (Steninae) produce a surfactant, stenusin, that enables these beetles to skim over the surface of fresh water into which they have fallen, to regain dry land.

Pederin is a powerful toxin and DNA inhibitor circulating in the hemolymph of all devel opmental stages of some species of *Paederus* (Paederinae) and close allies in the subtribe Paederina. It is produced by endosymbionts in some, but not all, adult females. Is transferred to eggs at oviposition, and thus to larvae and pupae. Males may obtain it by eating eggs. It is a defensive secretion active against spiders, but seems to have no insecticidal effect. It is a contender for the title of most powerful animal toxin.

Pheromones

A female sex pheromone has been identified in *Aleochara curtula*, but pheromones in 45,000 other species remain unidentified.

Prey Capture and Pre-Oral Digestion

The mandibles are the mouthparts typically associated with prey capture by predatory adults and larvae. However, adult *Stenus* (Steninae) use a prey-catching apparatus in which the labium (with its palpi) can be protruded by hemolymph pressure to grip small prey such as Collembola. Oxyporinae, Steininae, Euaesthetinae, Paederinae and Staphylininae have pre-oral digestion. They use mandibles to hold their food, secrete digestive fluids, and imbibe partially-digested food. A consequence is that their digestive systems contain much liquid and few solids, so visual identification of food is difficult. Drops of anal secretions of Neotropical *Leistotrophus* (Staphylininae) adults placed on leaves attract their prey.

Natural Enemies

Scattered evidence – needing analysis – suggests that spiders, various insects (including Reduviidae, Carabidae, Asilidae, Formicidae, etc.) amphibia, reptiles, birds, and bats, include Staphylinidae among their diets. Among the parasites, fungi play a major role, and hymenopterous parasitoids, nematodes, and nemata, a relatively minor role. Non-target effects of chemical pesticides and habitat destruction kill many Staphylinidae.

Biological Control

Biological control practitioners have observed predation by various non-specialist Staphylinidae on fly larvae and other invertebrates and have imported various Staphylinidae into Italy, Hawaii, mainland USA, and Easter Island, to capitalize on the perceived benefits – without evident success. Species of *Belonuchus*, *Creophilus*, *Ocypus*, *Philonthus*, *Philothalpus*, and *Thyreocephalus* (Staphylininae) and *Paederus* (Paederinae) have been moved. Other attempts have involved more specialist *Oligota* (Aleocharinae) against tetranychid mites in East Africa, and *Aleochara* against horn fly in mainland USA, but again with little success. Current attempts in Europe involve conservation of native staphylinids, including *Tachyporus* (Tachyporinae) as predators of cereal aphids, and *Aleochara* as predators of root maggots (including augmentative use).

Fossils

Pleistocene fossil Staphylinidae have been reported from northeastern North America from peat bogs, and from Europe. They seem to be of extant species and help to show former distribution of some of these species. Oligocene fossils are amber from the Baltic, the Dominican Republic, and elsewhere, and from shales in the USA (Colorado), France, Germany, and elsewhere. Most of these are recognizably members of modern genera. Deposits from the mid-Cretaceous to lower Jurassic in Eurasia have also yielded fossils. Most of these resemble members of modern subfamilies. The oldest recorded staphylinid, more than 200 million years old, is from the upper Triassic of the USA (Virginia). Species-level identification of present-day staphylinids normally requires dissection, at least of the genitalia – when this cannot be done with fossil specimens they have limited value.

Importance to Humans

The importance of staphylinid predation on pests has been demonstrated repeatedly in the literature. They suppress populations of pest insects and mites in numerous crops (agricultural, horticultural and forest entomology), and of biting flies and fleas (medical and veterinary entomology). Their presence in carrion gives them a role in forensic entomology. With one exception (*Paederus* and its close allies) they have trivial importance as pests; but although contact of humans with *Paederus* may cause dermatitis on human skin, the toxin pederin may be harnessed for its therapeutic effects, and some *Paederus* species are valuable predators of crop pests. Finally, Staphylinidae form a substantial part of the world's biodiversity.

S

Sabrosky, Curtis

Curtis Sabrosky was born on April 3, 1910, at Sturgis, Michigan, USA. He graduated from Kalamazoo College in 1931, and obtained a M.S. from Kansas State University in 1933. He taught at Michigan State University from 1936 to 1944, and after military service joined the United States Department of Agriculture at the Systematic Entomology Laboratory. He served in this capacity for 35 years, until retiring in 1980. Widely recognized as an authority on Diptera, Sabrosky published on several families, but considered Chloropidae to be his favorite. He worked diligently on the International Code of Zoological Nomenclature, and served as the president of the Society of Systematic Zoology and the president of the Entomological Society of America. He died on October 5, 1997.

Sackbearer Moths (Lepidoptera: Mimallonidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Sackbearer moths, family Mimallonidae, total 254 species, all New World and primarily Neotropical (250 sp.). The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia (some researchers maintain the family in its own monobasic superfamily, Mimallonoidea). Adults medium size (22–60 mm wingspan), with head scaling roughened; haustellum short or vestigial; labial palpi short (rarely 2-segmented); maxillary palpi vestigial; antennae bipectinate; body robust. Wings broad (Fig. 1) and triangular, usually with a falcate of acute forewing; hindwing rounded. Maculation mostly somber shades of brown or gray, to nearly black, but some more colorful, and with various markings or striae. Adults are nocturnal. Larvae are leaf feeders, with cases having openings that can be plugged by the head and a plate-like structure on the posterior of the body. Host plants are recorded in a number of plant families, including Anacardiaceae,

Sackbearer Moths (Lepidoptera: Mimallonidae), Figure 1 **Example of sackbearer moths (Mimallonidae), *Mimallo amilia* (Cramer) from Peru.**

Combretaceae, Fagaceae, Melastomaceae, Myrtaceae, and Rubiaceae, among others. A few can be economic.

Sacbrood

A disease of honey bee larvae caused by a nonoccluded RNA virus.

► Sacbrood Disease

Sacbrood Disease

This is a viral disease of honey bees, and is characterized by the diseased-infected larva being encased in a tough fluid-filled sac formed from the larval cuticle. The presence of dead or dying brood is the first symptom of infection. The brood dies soon after being capped but before changing to pupae. Affected capped cells often contain a small puncture, usually about the size of a pinhead. If a large proportion of brood becomes affected, the colony is weakened. Bees appear reluctant to remove dead material from the cells and the queen is forced to deposit eggs elsewhere in the hive. The dead larvae are discolored, usually dark, with the head curled and darkened. Older larvae typically are affected, and the disease can persist in dead insects for several months. Acquisition of the virus is via ingestion. The spread of sacbrood in a hive is believed to be caused by feeding young larvae contaminated pollen, nectar or water. Nurse bees become infected with the virus while cleaning out cells containing infected larvae. The spread of sacbrood from hive to hive is due to the exchange of contaminated equipment or bees, or robbing. Sacbrood disease may appear at any time during the year, but more often during the brood rearing season. Colonies showing symptoms of sacbrood disease will often recover if moved to environments with good nutrition. Requeening the hive also is recommended. Apparently the virus affects the ability of the larva to molt. It is found on several continents, but not much is known about it.

Sac Spiders (Class Arachnida, Order Araneae, Families Tengellidae, Zorocratidae, Miturgidae, Anyphaenidae, Clubionidae, Liocranidae, and Corinnidae)

DAVID B. RICHMAN
New Mexico State University, Las Cruces, NM, USA

The sac spiders are a varied group that at one time was included mostly in one family, the Clubionidae. Now, after some extensive taxonomic analysis, the nominate family is down to two genera in the United States, *Clubiona* and *Elaver* (formerly *Clubionoides*); all the rest have been transferred to new families. In retrospect it is obvious that these disparate groups should have family status. In the case of the Tengellidae and Miturgidae, the genera are more closely related to the three-clawed spiders than the two-clawed spider families into which the other "clubionoid" families fall. The characters used to separate the original family Clubionidae (including Anyphaenidae and the other clubionoid families) from the related Gnaphosidae (ground spiders) included conical, contiguous spinnerets (Gnaphosids, except for the ant-like genus *Micaria*, have cylindrical spinnerets that are usually separated by at least one spinneret diameter), endites (lateral mouthparts) lacking a depression (*Micaria* is often said to lack a depression, but Platnick considers it to have a small median one), and eyes homogeneous in size and shape (the eyes of most gnaphosids are heterogeneous in size and shape).

The Tengellidae, Zorocratidae and Miturgidae are unusual because of their current placement within the three-clawed spiders, although many (but not all) are actually two-clawed. The loss of the third claw (used primarily for web walking) apparently started to occur among non-web builders fairly early and appears to have occurred more than once.

Based on genitalic characters these spiders are not closely related to the other "clubionoid" families and Griswold has suggested that the tengellids actually are a sister group of the lycosoids. He also implies that the tengellids may turn out to be only a subfamily of the Miturgidae.

The North American genera now placed in the Tengellidae include *Lauricius* and at least four other genera. At least 50 species may be in this family, with about half of them described. *Lauricius hooki* is a flattened, crab spider-like, and fast moving representative of the family that is commonly found clinging to the underside of rocks in the southwestern USA. Another North American genus in this family is *Liocranoides*. The cribellate genus *Zorocrates* is now given a separate family, the Zorocratidae, along with the Madagascar genus *Uduba*. *Zorocrates karli* is a wolf spider-like species commonly found in desert scrub in the southwestern USA.

The Miturgidae, as now defined, include several common and also less-known genera. Some (such as *Calamistrula* in Africa) are cribellate and these, plus a few others (such as *Griswoldia*) are three-clawed. All of the members of the North American fauna are ecribellate and two-clawed. Several miturgids, such as *Syspira*, resemble wolf spiders. The common sac spider genus *Cheiracanthium* was recently removed from the remains of the Clubionidae and placed in this family. This spider is one of the most studied of the sac spiders in regard to economic impact in agricultural crops. They are predators of a number of pest species and, like several of the anyphaenids, are known to recognize and eat insect eggs.

The rest of the "clubionoids" are all two-clawed spiders, apparently more or less related to each other. The first family to be separated from the Clubionidae in most publications was the Anyphaenidae. The members of this family have tracheal spiracles that are from one third to over half the distance from the spinnerets to the epigastric furrow (in most spiders this spiracle is just anterior to the base of the anterior spinnerets). Another characteristic of the family is the possession of claw tufts of flattened hairs. These are classic sac-building spiders that are probably important members of the natural enemies complex in agroecosystems, especially in tree crops, such as citrus and pecans. They are known to feed on insect eggs and also at extrafloral nectaries, as well as on moving insect prey, including aphids and other pests. The most numerous anyphaenids in the United States are in the genera *Anyphaena* and *Hibana* (formally *Aysha*).

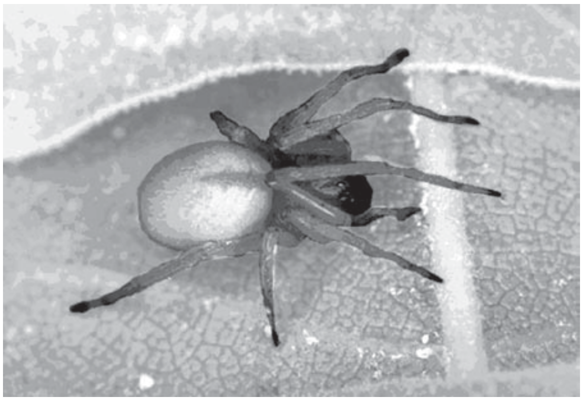
As noted earlier, the Clubionidae s.s. are now represented in the United States by only two genera, *Clubiona* and *Elaver*. These common sac spiders are found under rocks and bark, and in sacs inside folded leaves. They have prominent claw tufts on their tarsi.

The Liocranidae are two-clawed, like most of the "clubionoid" families. This family has been drastically altered recently. Many of those currently recognized as liocranids were referred to as phrurolithines in the literature, but these have now been transferred to the Corinnidae, leaving only a handful of genera, including *Neoanagraphis* and *Agroeca* in North America.

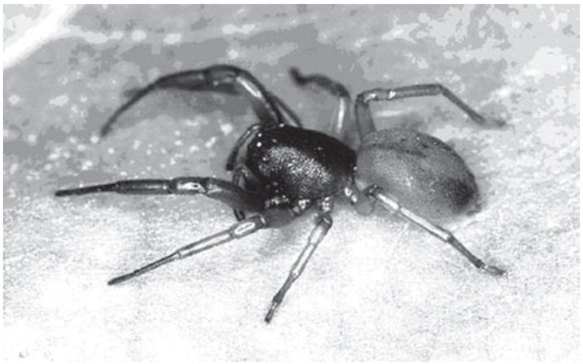
The Corinnidae are now the largest of the clubionoid families in the world, with nearly a thousand species, and contains some ant or velvet ant-like species, as well as many common typical "sac" spiders in the genera *Trachelas* and *Meriola*. One of the most abundant genera is *Castianeira*. These typically run over the ground much like large ants or female mutillid wasps. Other North American genera in this family are *Mazax* and *Corinna*, with the latter not occurring north of Mexico. All of the phrurolithines (now transferred from Liocranidae) have multiple macrosetae (spines) on the ventral first tibiae. Phrurolithines are abundant in leaf litter at high elevations in the southwestern USA.

It is sometimes rather disconcerting to the non-specialist to see so many drastic changes in classification in a common group of organisms. Unfortunately, classification schemes are imperfect because they are based on the data at hand. Whales were once classified with the fishes because it was obvious that, like fishes, they were aquatic, had fins, and were good to eat. The characters of warm-bloodedness, presence of air-breathing lungs, suckling of young, and complicated social interactions resulting from a very unfish-like nervous system were overlooked. Similarly, any "sac" spider with the eyes in two rows was dumped into the Clubionidae (or even earlier the Drassidae, which also included anyphaenids and gnaphosids). It must be kept in mind that, while more stable than the multitude of common names and classifications, scientific names and classifications are approximations that become (we hope) more accurate as information is added.

Despite the taxonomic muddle of the sac spiders, these creatures are well worth investigating. The probable important roles of sac spiders in the natural enemies complex in agricultural cropping systems is among the best documented of the spiders, although much remains to be done. *Cheiracanthium*, *Hibana*, *Anyphaena* and *Trachelas* are all probably of interest in this regard, as other genera may prove to be in future studies. Several species of *Cheiracanthium*, for example, are common in Egyptian cotton fields, and may be important in controlling various cotton pests. *Hibana velox* has been observed eating the eggs of the sugar cane root stalk borer weevil, *Diaprepes abbreviatus*, and *Cheiracanthium inclusum* is known to feed on the eggs of soybean looper, *Pseudoplusia includens* (Figs. 2 and 3).



Sac Spiders (Class Arachnida, Order Araneae, Families Tengellidae, Zorocratidae, Miturgidae, Anyphaenidae, Clubionidae, Liocranidae, and Corinnidae), Figure 2 ***Cheiracanthium inclusum*** **female from New Mexico. Photo by D. Richman.**



Sac Spiders (Class Arachnida, Order Araneae, Families Tengellidae, Zorocratidae, Miturgidae, Anyphaenidae, Clubionidae, Liocranidae, and Corinnidae), Figure 3 ***Trachelas mexicana*** **female from New Mexico. Photo by D. Richman.**

The life cycle of the miturgid *Cheiracanthium inclusum* (as noted earlier, this species is usually placed in the Clubionidae in the literature) is perhaps the best known of all the sac spiders, primarily because of its agriculture importance. As may be presumed for many, if not most, other sac spiders the cycle is annual, with adults being prominent in the late summer. Adults of the anyphaenid *Hibana incursa*, a common spider in pecan groves in the southwestern USA, are also found only for a short time in late summer, with immature spiders found throughout the year. During winter they usually are found in silken sacs under bark or in pecan nut hulls. They invade understory plants in the spring, before the pecans leaf out, apparently seeking prey insects such as aphids.

Of the spiders in these families, only a few are known to have venom that can cause notable effects in humans. All of these are in the genus *Cheiracanthium* and include both *C. inclusum* and the European species, *C. mildei*. The latter apparently was introduced into the United States a number of years ago. Mild necrotic arachnidism has been reported for both species. North Africa has even larger species of *Cheiracanthium*, but almost nothing is known about their venoms.

Saddle

A chitinous plate on the anal siphon of mosquito larvae.

Saddle-Case Makers

Members of the family Glossosomatidae (order Trichoptera).

► Caddisflies

Sagittal

This has two different meanings, depending on use: (i) sagittal or sagittate describes things that are arrowhead-shaped or elongate triangular; (ii) sagittal is also used to designate something situated along the longitudinal plane (“sagittal plane”) of the body. The sagittal plane is the longitudinal, vertical axis that divides a bilateral symmetrical animal in half, resulting in right and left halves.

Sahlberg, Carl Reinhold

Carl Sahlberg was born at Eura, Finland, on January 22, 1779. He entered the Academy in Turku in 1795, and in 1802 obtained the degree of “magister,” followed by being appointed the docent of natural history in 1804. In 1810 he obtained a medical license. In 1816 he was named the professor of natural history and economy. After a devastating fire, the University was transferred to Helsinki, and in 1828 he was named professor of zoology and botany. He retired in 1841. Sahlberg did not publish extensively, though the two-volume series “Dissertatio entomologica Fennica enumerans” is noteworthy. He died on October 18, 1860, at Uusinkartano, Finland.

Sailer, Reece I

Reece Sailer was born on November 8, 1915, near Roseville, Illinois, USA. He studied biology at Western Illinois State College from 1934 to 1936, but transferred to the University of Kansas where he obtained his bachelor’s degree in entomology in 1938, followed by a Ph.D. in 1942. He worked for a short time as assistant state entomologist in

Kansas, then moved to the United States Department of Agriculture, Bureau of Entomology and Plant Quarantine. His principal duties involved identification and research on Hemiptera. A special interest was stink bugs. He also was involved in an extensive and comprehensive assessment of forest fauna treated with DDT, a study that anticipated the eventual problems associated with this popular and widely used insecticide. In 1957 he became Assistant Chief of the Insect Identification Branch. Throughout the 1950s he taught insect ecology at the University of Maryland. He developed a strong interest in biological control, and in 1960 he moved to France to serve as Director of the USDA European Parasite Laboratory. During this time period the laboratory introduced parasitoids of alfalfa weevil, cereal leaf beetle, and European elm bark beetle, as well as predators of balsam woolly adelgid and face fly. In 1966 he returned to Beltsville, Maryland, as Chief of the Insect Identification and Parasite Identification Branch. He retired in 1973 and accepted a graduate research professorship at the University of Florida where he taught biological control and conducted research on citrus whitefly, mole crickets, and other invading pests. Sailer was author of over 100 publications and received numerous honors for his dedicated and effective research and service, including being elected president of the Entomological Society of America. He died on September 8, 1986, while vacationing in Delaware.

Saldidae

A family of bugs (order Hemiptera). They sometimes are called shore bugs.

► Bugs

Saliva

This generally is a liquid secretion of the salivary glands (= labial glands), but sometimes apparently originating from the crop, into the buccal cavity (mouth) of the insect. The saliva consists of water, salts, proteins, and enzymes, though sometimes it contains plant growth regulators or is contaminated with plant disease organisms such as viruses. Although digestion is an important aspect of saliva, it also serves to lubricate the mouthparts and aids in swallowing. In piercing-sucking insects that penetrate plants, saliva also may harden to form tubes or "sheaths" that hold the mouthparts (stylets) firmly in place and help prevent leakage while the insect sucks up liquids from the phloem or xylem. The saliva also hinders the plants' response to injury and feeding, to the benefit of the insect. Piercing-sucking insects normally have a salivary canal for secretion of saliva plus a food canal for food uptake, but thrips (Thysanoptera) have only a single canal, the food canal, that is used both for secretion of saliva and uptake of food.

► Alimentary Canal and Digestion
► Plant Viruses and Insects
► Transmission of Plant Diseases by Insects

Salivary Glands

Glands (sometimes called labial glands) that produce saliva. They are found in the head, but may be large and extend into the abdomen in some insects. The glands are connected by ducts to the insect's mouth. Some salivary glands are modified for production of silk. Some persistent plant viruses pass into the salivary glands and then are secreted into plants when the insects feed. A few viruses (persistent propagative viruses) replicate in the salivary glands.

► Saliva
► Silk
► Alimentary Canal And Digestion

Salpingidae

A family of beetles (order Coleoptera). They commonly are known as narrow-waisted bark beetles.

► Beetles

Sample

A collection of sample units from a sampling universe. (contrast with census).

► Sampling Arthropods

Sample Size

The number of sample units collected from the sample universe for a given sampling effort. Ideally, sample size is based on prior information about dispersion and the desired level of precision or accuracy. Sometimes referred to as average sample size, abbreviated ASN.

Sample Unit

A proportion of the habitable sample universe from which counts of individuals are taken. The sample unit is based on a specific sampling method, should be representative of the behavior and size of the organism, and should strike a balance between cost and variability. Examples include whole leaves, branches or plants, a set number of sweeps along a row, a sticky trap set at canopy height, 10-min timed count, a 1 m^2 quadrat, etc.

Sample Universe

The physical area that contains the population of interest. Typical examples include a single crop field, an orchard, a section of stream, the cows in a pasture or barn, etc. Synonymous with the management unit in agricultural production systems.

Sampling Arthropods

STEVEN E. NARANJO
USDA-ARS, Western Cotton Research Laboratory,Phoenix, AZ, USA

Sampling is a fundamental component of any experimentally based research program in the discipline of entomology, whether conducted in the laboratory, greenhouse or field. It also is an essential element for describing, measuring and quantifying arthropod population dynamics, whether the goal is to understand the population or community ecology of a given species or group of species, or to develop decision aids for integrated pest management (IPM). Although a population census may be highly desirable for many reasons, rarely does one have the time and resources to exhaustively count every insect, spider or mite within a defined area even if that area is relatively small, say, a small greenhouse or field plot. Instead we must resort to drawing a sample from the population and using the information gained from this sample to estimate variables such as population density or size and to draw inferences that can be applied to the entire population. Fortunately, there is a large body of theory and practical knowledge to guide our efforts in sampling. This short review will attempt to provide a broadly-based, non- mathematical overview of sampling, from discussion of the goals of sampling, to the basic tools for gathering data, to the basic components and mechanics of developing a useful sampling plan.

Samples and sampling are terms with which most entomologists are intuitively familiar. However, as with any field of study, there is a specific vocabulary associated with the study of sampling that may not be as well understood. Thus, brief definitions of some of the more commonly used terms in sampling are provided (Table 1).

Goals of Sampling

The first, and perhaps most important, element in the development of a useful sampling plan or

Sampling Arthropods, Table 1 **Definitions of some common terms associated with arthropod sampling**

Absolute method	A sampling method that allows the estimation of numbers per unit of habitat, generally per unit of ground area.
Accuracy	A measure of the closeness of an estimate to the true mean or variance of a population.
Bias	An unidirectional deviation of an estimate from the true mean or variance of a population.
Binomial sampling (presence/absence sampling)	Sampling based on determining the presence or absence of one or more individuals in the sample unit in lieu of complete counting of all organisms. Commonly used for pest management decision-making application. Contrast with enumeration sampling.
Census	Complete enumeration of every individual within a defined sample universe. Contrast with sample.
Classification	A sampling plan that classifies population density as being either above or below some predetermined level (e.g., economic threshold), or belonging within some density class (e.g., low, medium, high). Commonly used in pest management decision making application. Contrast with estimation.
Dispersion/distribution	The spatial patterning of individuals in a population in their habitat. This pattern can be broadly described as uniform, random or, most commonly, aggregated. Dispersion can be quantified by explicit spatial indices, or more typically by probability models (e.g., Poisson, Negative-binomial) or empirical models (e.g., Taylor's power law). The measurement of dispersion is dependent on the sample unit size and population density. Most often the term is used to denote the sampling dispersion/distribution and not true spatial patterning. Dispersion is an important element in the development of a sampling plan.
Double sampling	A sampling approach in which an initial sample (usually small) is drawn and used to determined the necessary sample size for a subsequent sample within the same time period.
Efficiency	A measure of the level of precision or accuracy per unit of cost (time or currency).
Enumeration sampling	Sampling based on the complete counting of all individuals in the sample unit. Contrast with binomial sampling.
Estimation	A sampling plan that numerically estimates population density or intensity. Commonly used for detailed population dynamic and experimental studies. Contrast with classification. The term can also denote the process of calculating various statistical parameters such as variance.
Fixed-sample size sampling plan	A sampling plan in which a predetermined number of sample units is collected based on a prescribed level of desired precision, classification accuracy, or level of confidence. Contrast with sequential sampling.

Sampling Arthropods, Table 1 **Definitions of some common terms associated with arthropod sampling (Continued)**

Mean-variance model	A model, generally a regression model, which predicts the variance of a sample from an estimate of the sample mean. Such models can characterize dispersion over a large range of population densities and are commonly used in developing sampling plans. Common examples are Taylor's power law and Iwao's patchiness regression.
Operating characteristic	A measure of the accuracy of a classification sample. An operating characteristic curve shows the probability of classifying density below a critical value (e.g., economic threshold) as a function of true mean density. Ideally, probabilities should be near 1 at densities far below the critical value, near 0.5 at densities very near the critical value and near 0 at densities far above the critical value. Often abbreviated as OC.
Population index	A sampling method that attempts to provide an indirect estimate of population density based on an associated product (e.g., frass) or effect (e.g., defoliation).
Precision	A statistical measure of the repeatability of an estimate relative to a group of estimates from the same population at the same time. Typically measured as the quotient of the standard error of the mean over the mean. Low numerical values indicate high precision, high numerical values indicate low precision. Precision is a key element in developing and evaluating the performance of sampling plans.
Probability model	A mathematical description of the dispersion or distribution of individuals in a population based on numbers per sample unit. Common models include Poisson, Negative-binomial, Binomial, Normal, and Neyman Type A. Such models can form the foundation of a sampling plan.
Random sampling	A method of allocating sampling units within a sampling universe in which each sample unit has an equal chance of being selected. Random sampling ensures an unbiased estimate, but is rarely used in the practice of arthropod sampling due to time and cost constraints.
Relative method	A sampling method that results in numbers per unit effort. Generally much faster and easier than absolute methods. Sometimes possible to convert counts to absolute density. Common examples are sweep nets and sticky traps.
Robust	Within statistics and sampling, the quality of being widely applicable. For example, a sampling plan is robust if it can be used to precisely estimate the density of an arthropod under many different environmental conditions.
Sample	A collection of sample units from a sampling universe. Contrast with census.
Sampling method/technique	A particular tool or technique used to gather information on population density from the sample universe. Examples include sweep nets, beat clothes, visual counts, suction devices, and various kinds of attractive and passive traps.

Sampling Arthropods, Table 1 Definitions of some common terms associated with arthropod sampling (Continued)

Sampling plan/program	A structured set of rules for collecting a sample that is based on delineation of the sample universe, knowledge of dispersion, a specific sample unit, a predetermined sample size (but see sequential sampling), time of sampling, and a given allocation of sample units throughout the sample universe (e.g., random, stratified, systematic).
Sample size	The number of sample units collected from the sample universe for a given sampling effort. Ideally, sample size is based on prior information about dispersion and the desired level of precision or accuracy. Sometimes referred to as average sample size, abbreviated ASN.
Sample unit	A proportion of the habitable sample universe from which counts of individuals are taken. The sample unit is based on a specific sampling method, should be representative of the behavior and size of the organism, and should strike a balance between cost and variability. Examples include whole leaves, branches or plants, a set number of sweeps along a row, a sticky trap set at canopy height, 10-min timed count, a 1 m^2 quadrat, etc.
Sample universe	The physical area that contains the population of interest. Typical examples include a single crop field, an orchard, a section of stream, the cows in a pasture or barn, etc. Synonymous with the management unit in agricultural production systems.
Sequential sampling plan	A sampling plan in which "stop-lines."continually assess the need for additional sample units during the sampling effort on a given day or time interval. These stop lines are typically based on a prescribed level of desired precision or classification accuracy. Sequential sampling is efficient because no prior knowledge of density is required and no more sample units than necessary are collected. Contrast with fixed-sample size sampling.
Stratified sampling	A method of allocating sampling units in which the sample universe is subdivided into two or more sections and sample units are randomly collected from each subdivision in proportion to their size or relative variability. Examples include the subdivision of a crop field into border and interior sections, the subdivision of a plant along vertical strata, or different rooms within a structure.
Systematic sampling	A method of allocating sample units within a sample universe in which sample units are collected at fixed intervals along a predetermined pattern. Examples include sampling along transects or along V or X shaped patterns in crop fields. Often, the starting point of the pattern is determined randomly. Systematic sampling is probably the most common method for allocating sample units in most agricultural systems because it is simple and time-efficient.
Tally threshold	In binomial sampling, the number of individuals required to be present per sample unit to consider the sample unit infested. Proper selection of the tally threshold can improve the accuracy of classification sampling.

Sampling Arthropods, Table 1 Definitions of some common terms associated with arthropod sampling (Continued)

Variable-intensity sampling plan	A sampling plan that shares the characteristics of fixed-sample size and sequential sampling plans in which prior sampling information is used to evaluate the number and allocation of subsequent sample units, but ensures that sample units are collected throughout the sample universe.

program is to clearly define the goal(s) of sampling. Is the goal to survey for the abundance or presence of one or more insect species over a large geographical region? Or is the goal to intensively study the temporal dynamics and examine rates of mortality of a single insect species in a relatively small area? Perhaps the goal is to develop a simple procedure that a field scout can use to determine the need for remedial pest control in a field crop. A researcher may be interested in testing the effect of a control tactic on populations of a pest insect using replicated field plots. Although some of the information that will be necessary to devise sampling plans is shared among all these and other applications, as we will see below, there are also differences in the sampling methods that may be used and the levels of accuracy and precision that may be required to provide useful data. For example, a quick and simple relative sampling method such as a sweep net or a colored sticky trap may be sufficient for survey detection or for monitoring the relative abundance of one or more insect species over a large region. Here the premium would generally be placed on extensive spatial coverage at the expense of precise estimation of density, which may not be necessary. In contrast, detailed population studies involving the construction of life tables would require an absolute sampling method, such as quadrat or whole plant counts, and fairly large sample sizes so that mortality factors and recruitment to subsequent life stages could be precisely estimated. The development of a decision-aid for pest scouting could use either an absolute or a relative method of sampling depending on the pest and would likely involve the use of a sequential sampling plan that would allow the classification of pest density as either above or below an established economic threshold.

The time and resources that one has to devote to the activity of sampling are almost always in short supply, even in well-funded research programs. Thus, clear delineation of the goal(s) of sampling is the first step towards ensuring that available time and resources will be put to the best use to answer the questions that are being asked of the sample data.

Sampling Methods

Many sampling methods have been devised by entomologists for sampling all types of insects, mites and spiders. Each arthropod poses its own unique challenges. In fact, there are probably as many sampling methods as there are entomologists using them. It would be impractical to try and cover all of the available techniques that have been developed. Instead, focus will be placed on relatively few methods that have been widely used to provide a flavor of the diversity. Readers are referred to the excellent and comprehensive treatment of all aspects of sampling provided by Southwood (1978).

For purposes of organizing this discussion, it is convenient to classify sampling methods according to the type of information that they can potentially provide the sampler. These include absolute methods, relative methods, and population indices. Sometimes the difference between an absolute and a relative method is not distinct and a technique that provides an absolute method for one insect will not do so for another in the same habitat. Absolute sampling methods attempt to provide an estimate of density from a specific and quantifiable fraction of the habitat in which the arthropod lives. Generally, these counts have the unit of numbers per square meter or some other unit of ground area or space within structures. Common examples include quadrat sampling in which a square, rectangle or circle of known area is placed on the ground and all arthropods of interest falling within that area are counted in situ or the vegetation is collected and later examined in the laboratory. In agricultural, horticultural or rangeland situations the quadrat delineates a volume that may be relatively small if dealing with low-growing grasses or forbs, or relatively large if dealing with corn plants or fruit trees. Quadrats may also be used to sample arthropods within barns, houses or other structures. Often, the quadrat is placed the day before sampling to minimize disturbance. For arthropods that are found only on the plant surface, absolute counts can be made by counting all individuals on a single plant, groups of plants, or even specific parts of plants such as whole leaves, stems, or branches. Sometimes these efforts are aided by the use of various sorts of enclosure devices (e.g., cages or sacks) to confine the arthropods until they can be counted. In many cases, conversion to unit ground area can be accomplished by knowing the number of habitable plants, leaves or branches per unit area. For certain arthropods that are readily dislodged from plants, various kinds of beat cloths and buckets can be used (Fig. 4). Suction samplers may provide absolute counts for certain arthropods depending on plant size and growth characteristics. Absolute sampling of soil-dwelling arthropods can be achieved by taking soil cores or digging trenches of a known volume. Surface-dwelling arthropods can be counted directly or collected from the litter within a quadrat. Arthropods can be extracted from collected soil, plant or litter material using a variety of approaches including simple inspection, dry and wet sieving, flotation in concentrated salt solutions, leaf brushing machines, and other methods. Live arthropods can be extracted by chemical fumigation or heat (e.g., Berlese funnel). Emergence traps can be used in some instances to measure the absolute density of adult stages of insects that pupate in or on the soil. Suction traps or aerial nets towed by an airplane or vehicle can be used to obtain absolute samples of flying insects (Fig. 5). In this instance the unit is a given volume of air that can be calculated by knowing the volume of air drawn by the motor per unit time (or speed of the vehicle) and other environmental factors such as wind speed.

Relative methods are so named because they generally provide estimates of density that are comparable in relation to other estimates made in the same way in the same type of habitat. Relative sampling results in counts per unit of effort and it is not always possible to define the physical units of a method. In contrast with absolute methods, relative methods are generally less costly, easier to perform, and tend to concentrate arthropods. As such they are well-suited to extensive detection and survey work and as components of decision aids in IPM. Relative methods are also widely used in experimental field work where it is often necessary to sample a large number of plots in a short period of time, and only comparative results are sought. In some cases relative estimates can be converted to absolute estimates, but this depends on the specific arthropod and the nature of the sampling method. Common examples of relative methods include the ubiquitous sweep net which is almost the *de facto* standard for estimating densities of arthropods associated with many field crops (e.g., cotton, soybean, small grains, alfalfa). The sweep net can cover a large area of habitat in a short period of time and the particular pattern and number of swings can be standardized across samplers. However, it also samples only a proportion of the population (that inhabiting the tops of plants) and this proportion can change with plant growth, environmental conditions, and time of day. Various methods involve the dislodgement of arthropods from plants into buckets, cloths, nets, trays

Sampling Arthropods, Figure 4 **Examples of various kinds of sampling methods: (a) beat-bucket in which a plant is shaken against the sides of a bucket to dislodge arthropods; (b) beat-cloth in which a piece of white cloth is placed on the ground and plants are shaken or beaten to dislodge arthropods; (c) beat-net (or cloth) in which arthropods are dislodged into a net with a beating stick; (d) plant cage that encloses a specific portion of habitat; arthropods are dislodged from the enclosed plant material; (e) example of a Berlese funnel in which arthropods are driven from litter or soil into a collection bucket by the application of heat and light from above; (f) sweep net; (g) D-vac suction sampler; (h) high powered suction sampler designed for field row crops; (i) trench for sampling soil-dwelling arthropods; (j) quadrat; (k) visual inspection of a leaf, (l) visual inspection of a whole plant. or other surfaces. Depending on the behavior and biology of the arthropod and the portion of the plant sampled, this may provide either absolute or relative sampling information. In most cases only a small portion of the plant is sampled. The same is true of various suction sampling devices such as the well-known D-vac, modified leaf blowers, or high-powered vacuums attached to carts or tractors. Visual inspections of various plant parts such as leaves or branches are generally considered relative methods, although in many cases, counts on these parts can be related to counts per plant or tree. Timed-counts, which simply involves enumerating all the arthropods that can be counted in a specified period of time are commonly used, especially when the goal it to compare densities of a specific arthropod in a number of different habitats.

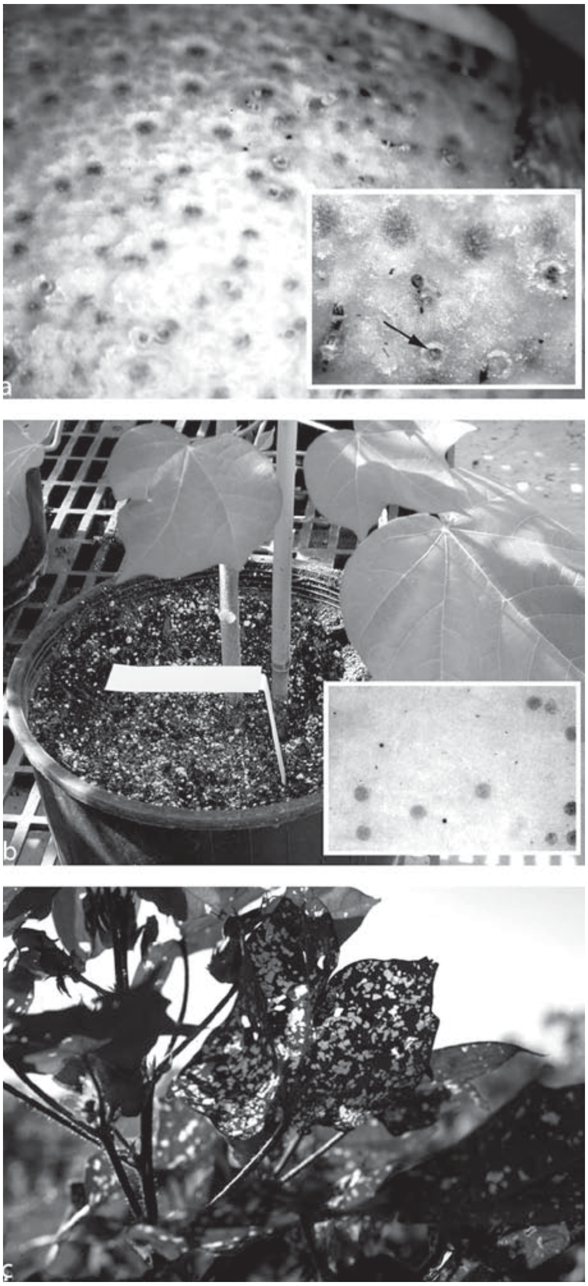
By far, traps of various kinds represent the broadest diversity of relative methods. Traps and trapping are the subject of an entry in this volume and so will only be briefly discussed here. Traps can be delineated into those that passively intercept and those that attract actively moving arthropods. Examples of the former include canopy traps, window-pane traps, malaise traps, pitfall traps, and white or clear sticky traps. Examples of the latter include semiochemical- or food-baited traps, traps of various colors (yellow is most common) generally coated with a sticky material, light traps, and sound traps. Mammals and birds also may be used as baits to trap arthropods of medical and veterinary importance. In general, trap counts are very difficult or impossible to convert to absolute counts because they rely on behavior that can be influenced by an array of biological and environmental factors.

Finally, the product or effect of an arthropod population rather than counts of individuals can be used to gauge relative abundance. Common examples of products include the collection of insect frass underneath plants or trees, the collection of larval or pupal exuviae, or the counting of spider webs. Examples of arthropod effects include the assessment of defoliation by foliage-feeding insects, tunneling by stalk-boring insects, or root pruning soil-dwelling insects (Fig. 6). Acoustic monitoring can be used to detect the presence and relative abundance of insects inside fruit, grain bins or within the walls of structures. Both products and effects can sometimes be related to more quantitative measures of population density. The examination of arthropod effects can be important in their own right in terms of assessing economic damage.

Development of a Sampling Plan/ Program

A sampling plan or program is a structured set of rules that guide sampling activities. The sampling plan includes delineation of the sample universe, timing of sampling, the size and nature of the sample unit, how many sample units need to be collected, and how these sample units are spatially allocated among potential sample units in the population. Thus, a sampling plan is distinct from a sampling method or technique (a component of a plan) with which it is sometimes mistakenly confused in the entomological literature. Not all sampling activities in entomology require a sampling plan; for example, collections for systematic or taxonomic purposes. However, if the goal includes the estimation or classification of the density or size of an arthropod population, then the user would be best served by considering, at the very least, selected components of a sample plan to ensure that the sample data are trustworthy. Binns et al. (2000) suggest that a trustworthy sampling plan should adhere to four criteria. First, estimates generated by the plan should be representative of actual pest density thereby avoiding or at least being able to account for any bias. Second, sample estimates should be largely independent of the sampler and of uncontrollable environmental variables such as weather. Third, sample information should be relevant to the questions being asked. For example, estimates of pest density in a management context should be have an identifiable



Sampling Arthropods, Figure 6 Examples of methods for estimating population indices: (a) counting entrance holes of neonate pink bollworm larvae on the surface of a cotton boll; (b) counting honeydew droplets from whiteflies or aphids on water-sensitive paper; (c) assessing caterpillar abundance from defoliation. All photographs by the author.

relationship to crop damage. Finally, the sampling plan must be practical for its intended purpose. For example, it would do little good to develop an elaborate and expensive sampling plan for IPM decision-making that scouts would be unable to implement due to time and resource constraints. These criteria can be met by careful attention to the building blocks of a sample plan.

Sample Plan Components

Delineation of the sample universe is often dictated directly by the goals of the sampling plan. For example, the population of interest for IPM of a particular pest species is generally a single crop field or perhaps a set of crop fields on a single farm that share a similar cultivar and planting date. In a rangeland setting the sample universe might be an entire ranch or perhaps sections or partial sections of the operation. The population of interest in an experimental research program would be a replicate plot representing a given treatment. If the population of interest occurs in an area where physical portions of the habitat are distinct and vary in their suitability for the organism under investigation, several sampling universes might be identified or a stratified sampling approach might be employed. This situation will be discussed below.

Likewise, the timing of sampling is often largely dictated by the goals of sampling. Each arthropod species has a distinct phenology and seasonality that will determine the appropriate time to gather samples on the life stage or stages of interest. The timing of occurrence of particular species might be estimated by phenological models, the presence of indicator plants, or historical records. In instances where the timing of occurrence is not well-characterized or highly variable, the use of detection traps may help to determine the need for more intensive sampling by other methods.

Of all the components of a sampling plan, the sample unit is perhaps the most important yet most frequently overlooked element. The sample unit defines the unit of habitat represented by the sample and is the foundation for all further development of an efficient sampling plan. Each sample unit should have an equal chance of being selected from the sample universe. It should contain a consistent fraction of the population over time. Thus, definition of the sample unit may include a time component. For example, arthropods may inhabit different parts of a plant over the course of a day due to changes in temperature, light and other factors. The sample unit should be easy to delineate in the sample universe. The sample unit should be appropriately sized relative to the size and behavior of the species in question. For example, a small disk from a leaf may be suitable for spider mites or aphids, but not for large and mobile insects such as assassin bugs or grasshoppers. Finally, the sample unit should strike a balance between variability of counts and the cost of sampling that unit. Using these criteria helps to ensure that the sample unit is representative of the population and help to minimize or eliminate bias.

The sample unit is based on the sampling method from which it is derived. Examples of sample units include 25 sweeps with a sweep net along a single crop row between 0800 and 1000 h, the lower surface of a leaf five nodes below the terminal apex of a plant, the silks at the tip of one ear of corn, a 8 × 8 cm yellow sticky card oriented horizontally at the top of the crop canopy and exposed for 24 h, five beats to a tree branch one meter above the ground with a stick over an open 38 cm diameter net, 0.001 m^3 of soil dug from within a 100 cm^2 frame, the head or leg of a single cow, or 2 min of suction from a D-vac placed over the top third of a crop plant. Very often the sample unit is selected *a priori* based on knowledge of the biology and behavior of the organism and experience, and is not the subject of further investigation. However, careful attention to the size and nature of the sample unit can greatly increase the efficiency of the overall sampling program by minimizing both variability and cost. Established methods are available for comparing various candidate sample units (see Southwood 1978) based on consideration of precision and cost. However, as a guideline, smaller sample units are generally more efficient than larger units. This generalization is based on the typical aggregated dispersion of many arthropod populations and the lower cost of counting individuals on smaller sample units even when a comparatively larger sample size may be required.

Dispersion, or spatial distribution, is a characteristic of populations and can be influenced by a host of biological, behavioral, ecological and environmental factors. Patterns of dispersion are typically categorized as uniform, in which individuals are evenly spaced throughout a habitat, random, in which the location of one individual bears no relation to the location of others, or aggregated (contagious), in which individuals are found in clumps of varying sizes. Many arthropod populations are described as having an aggregated dispersion. Knowledge of dispersion is an important element in the development of sampling plans, influencing both the determination of sample size and the allocation of sample units. The measurement of dispersion is spatially contextual. That is, patterns of dispersion depend on the spatial scale under which they are observed. As a result, the dispersion of a population is greatly influenced by the size of the sample unit. For example a population could be aggregated at the level of a whole plant, but randomly distributed at the level of a single leaf. Thus, in sampling work, dispersion generally refers to the sampling distribution rather than the true spatial distribution. A number of methods are available to explicitly measure dispersion or to provide indices of dispersion. A common index is to simply divide the sample variance by the sample mean. Values <1, ~ 1 or >1 indicate uniform, random or aggregated distributions, respectively. For sample plan development it is more typical to characterize dispersion with probability models or empirical mean-variance models. Common probability models include the Poisson for random distributions, and the

Negative-binomial for aggregated distributions. The primary limitation of using probability models is that sampling distributions typically vary with changing arthropod density and it is not always possible to account for these changes in the model. Empirical regression models offer a solution to this problem by permitting prediction of sample variance from the sample mean. Such models can provide useful information over a wide range of densities. Common examples include Taylor's power law and Iwao's patchiness regression, both of which can be parameterized with simple linear regression.

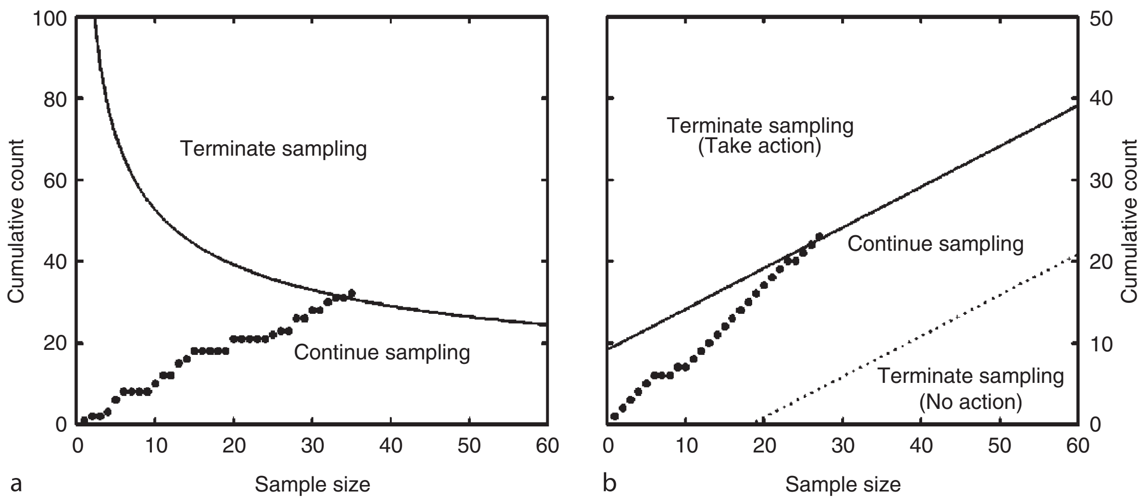
Once the sample unit has been selected and the sampling distribution has been characterized by either a probability or empirical model, the sample size can be calculated. How this is done depends on the goals of sampling, the criteria for determining the adequacy of the population estimate or classification, and the resources that can be devoted to sampling activities.

Types of Sampling Plans

Fixed-sample-size sampling plans, as the name implies, are based on the collection of a set number of sample units. The optimum sample size is the minimum number of sample units that achieves a desired level of performance. Fixed-sample-size sampling can be applied to density classification as well as estimation; however, it is more commonly used for the latter and so consideration will be restricted to estimation here. Several approaches can be used depending on how dispersion is characterized and how precision is quantified. The simplest approach is to calculate the optimum sample size such that the standard error is within a specified proportion of the mean, or that the mean falls within a certain confidence interval of the true mean with a specified probability. Variations on this approach explicitly account for sampling distribution (e.g., Poisson, Negative binomial). A slightly more complicated and robust approach uses a mean-variance model such as Taylor's power law to solve for sample size using the same measures of precision. The main advantage of this approach is that the optimum sample size is dependent on the mean density of the population. Typically, sample size decreases exponentially with increasing density. The reader is referred to Southwood (1978) and Pedigo and Buntin (1994) for mathematical details.

One of the main advantages of a fixed sample size is that sample allocation (see below) can be structured so that sample units are collected from throughout the sample universe. The main disadvantage is that the mean density is unknown for the population under study at any given point in time. One solution would be to calculate sample size for the lowest expected density or the average expected density and then apply that in all cases. This would clearly be inefficient at high densities, or require too many or too few sample units depending on density at any point in time, respectively. The use of double sampling would be an alternative solution. Here a small sample would be collected and used to solve for the required sample size at that point in time.

Sequential sampling is another alternative that solves the problem of unknown density and generally maximizes sampling efficiency. Sequential sampling was developed for military application during World War II and has since become the most widely applied approach for developing sampling plans for arthropods based on both density estimation and density classification. Efficiency is optimized because in sequential sampling the need for further sample information is assessed following the collection of each individual sample unit. Regardless of the mean density, sequential sampling ensures that no more sample units are collected than necessary in order to achieve a predetermined level of precision or classification accuracy (Fig. 7). Sequential sampling for estimation of mean density operates by accumulating counts over subsequent sample units and then consulting a "stop-line." This stop-line represents the cumulative count as a function of sample size and the desired precision. It can be plotted or presented



Sampling Arthropods, Figure 7 **Hypothetical examples of (a) sequential sampling plan for estimating mean density with a fixed precision and (b) sequential sampling plan for classifying mean density relative to an economic threshold. The lines denote the stop-lines and the data points represent a hypothetical sample that terminates after crossing the stop-line.**

in table form. Matching the current cumulative count and sample size relative to the stop-line determines whether more sample units are need or whether sampling should be terminated. Once sampling is terminated the mean is calculated by simply dividing the cumulative count by the number of sample units collected. Sequential sampling plans for mean estimation can be developed on the basis of probability or mean-variance models. Frequently, a minimum and maximum sample size is specified as part of the sequential plan. The reader is referred to Nyrop and Binns (1991) and Pedigo and Buntin (1994) for mathematical details.

A second application of sequential sampling involves the classification of population density. Most often this approach is applied to the development of decision-aids for IPM where one simply wants to know whether pest density is above or below the economic threshold. Operationally, sequential sampling for classification is similar to that described above for mean estimation except that a critical density (e.g., economic threshold) and upper and lower decision boundaries must be specified. The calculation of the stop-lines is also more complex. Several approaches have been developed. One goes by the daunting name of the sequential probability ratio test (abbreviated SPRT) and can be based on various probability models including the Poisson, negative-binomial, normal or binomial. A second technique termed Iwao's confidence interval method is based on the normal distribution, and a third called the sequential interval procedure is based on the binomial distribution. All three approaches result in pairs of stop lines rather than a single one, delineating three distinct decision zones. More complex plans can be developed involving multiple stop lines designating even finer decision zones. Such sampling plans are popular for use in IPM because of their high degree of efficiency. Very few sample units are required when densities are much smaller or larger than the critical density and the maximum number of sample units is required only when the density is very near the critical density. Sequential sampling plans for classification are developed and evaluated on the basis of two criteria, the operating characteristic (OC) and the average sample number (ASN). The OC estimates the probability of classifying density below the critical density as a function of the true mean density. Various parameters of the sequential plan can be adjusted to increase or decrease the level of classification accuracy and the associated sample size.

Up to this point the discussion has focused on enumerative sampling in which all individuals inhabiting a sample unit are counted. However, depending on program goals, the general efficiency of sampling can be potentially improved by determining only the presence or absence of individuals in the sample unit. This approach, referred to as binomial sampling has been widely used in the development of decision aids for IPM and is typically implemented as a sequential classification sampling plan as described above. Generally, the foundation for this approach is the development of a relationship between mean density and the proportion of sample units containing at least T individuals. T is known as the tally threshold and traditionally has a value of 1 (true presence/absence); however, it can take on any value and proper selection of T can often improve the accuracy of classification. This mean density-presence/absence relationship can be determined using various probability models or it can be represented by one of several empirical models. In some instances it is more convenient to base the economic threshold simply on binomial counts and, thus, there is no need to develop a relationship with mean density. A well-devised and tested binomial sampling plan can significantly reduce the cost of sampling without sacrificing accuracy of density classification in IPM decision-making. Binomial sampling can also be an efficient approach for estimating population density, although its application for this purpose has been limited. The reader is referred to Nyrop and Binns (1991), Pedigo and Buntin (1994), and Binns et al. (2000) for mathematical details on sequential sampling for classification using both enumerative and binomial sampling.

A final sampling approach, termed variable-intensity sampling, is a classification method that shares some of the attributes of both fixed-sample-size and sequential sampling plans. It was developed primarily to address a potential deficiency in sequential sampling having to do with adequate coverage of the sample universe. As a result of its high efficiency, sequential sampling often terminates sampling after only a small portion of the sampling universe is observed. Variable intensity sampling solves this problem by delineating a transect (see allocation below) across the sample universe, dividing that transect into equal lengths, and requiring at least one sample unit in each section. Thus, the sample is more representative, especially in situations where pest density might be highly variable across a field. The overall number of sample units taken in each transect section ultimately depends on prior sampling information much as in a traditional sequential sampling plan. Variable intensity sampling can be based on enumerative or binomial counts.

Allocation of Sampling Units

The final element of a sampling plan is the collection of sample units from the sample universe. Random sampling assumes that every possible sample unit within the sample universe has an equal chance of being selected. As such, random sampling ensures that the sample will provide unbiased estimates (assuming that the proper sample unit is used and sample size is adequate). Random sampling can be accomplished by enumerating every sample unit and then selecting them using a random number table, drawing numbers from a hat, or using a computer random-number generator. This assumes that the spatial location of each sample unit can be correctly identified which may be extremely difficult. In field crops, orchards or greenhouses with evenly spaced plants, sample unit location can be simplified somewhat by defining a coordinate system and randomly selecting a random row and a random number of steps or plants along the row from the edge. A variation of random sampling is stratified sampling. This approach may be used if there is some a priori knowledge that the population being sampled is heterogeneously distributed. Common examples are the differential distribution of insects in border rows compared with interior rows of a crop field, the differential distribution of insects within the vertical strata of a plant, or differences in distributions of arthropods within structures. In instances such as these a more precise estimate may be achieved by allocating sample units to different strata in proportion to the size of each strata, or in relation to variability within each strata. More sample units would be collected in strata that are known to be more variable and vice versa. The allocation of sample units within a stratum is random, preserving the benefits of random sampling, but different formulae are needed to estimate mean density and variance.

Despite the desirable qualities of random sampling, it is rarely used in practice mainly because proper implementation is costly. It is much more common for sampling plans to be implemented using some sort of systematic sampling. In systematic sampling, some predetermined path is chosen and sample units are collected at fixed intervals along this path. Typical examples are diagonal transects, or X-, V-, or Z-shaped patterns laid out across the sample universe. Aside from being easy and inexpensive to implement, systematic sampling generally allows sample units to be collected from throughout the entire sample universe, resulting in a more representative sample. A degree of randomness can be added by randomly selecting the starting point of the transect and the interval between sample units. A disadvantage to systematic sampling is that it can produce biased estimates if there is some underlying pattern in the population that closely mimics the pattern of sample unit collection. Further, there are no exact formulae for calculation of variance and so estimates based on random sampling are often assumed. The overall effect of these limitations is not well-known, however, proper testing and evaluation (see below) can help to ensure that the sample obtained is reliable and provides the necessary levels of precision and accuracy.

Testing and Evaluation of Sample Plans

Ideally, sampling plans should be developed from observations that encompass the geographic area and range of environmental conditions that future users of the sampling plan are likely to encounter. In reality, however, sampling plans are often developed from a more restricted range of observations and then applied to similar or novel situations. In addition, regardless of the extent of data collection, any sampling plan is based on observations that are measured with some amount of error. Thus, it is important that the performance of a sampling plan be evaluated so that its limitations and strengths can be better defined. This evaluation process is known as validation. In the past, generally little attention was paid to sample plan validation, however, this situation is changing and several validation approaches have been formalized in the last 10–15 years. The simplest involves the use of Monte Carlo simulation. In this method the sampling plan is applied to sample units counts that are randomly drawn on a computer from a probability distribution (e.g., Poisson, Normal, Negative binomial) that is representative of the sampling distribution of the arthropod in question. This procedure is repeated a large number of times (usually 500 or more) to represent a large number of possible sampling outcomes and average precision or classification accuracy (and their variances) are calculated. An alternative approach uses real sample data independently collected at the time of sample plan development or collected from an area where the sample plan is to be implemented. These real data are then resampled on a computer much as in the Monte Carlo approach. The advantage of the resampling method is that the data rather than a probability distribution are used to represent the sampling distribution. The result is a more robust test of the sampling plan and the assumed probability model upon which it may be based. A disadvantage is that larger amounts of data collection are required. With both approaches, the validation data can have an explicit spatial arrangement so that issues of sample unit allocation can be tested as well. The reader is referred to Naranjo and Hutchison

(1997) and Binns et al. (2000) for further detail and available computer software.

Sampling Plan

A structured set of rules for collecting a sample that is based on delineation of the sample universe, knowledge of dispersion, a specific sample unit, a predetermined sample size (but see sequential sampling), time of sampling, and a given allocation of sample units throughout the sample universe (e.g., random, stratified, systematic).

► Sampling Arthropods

Sanderson, Dwight

Dwight Sanderson was born at Clio, Michigan, on September 25, 1878. He earned B.S. degrees from both Michigan State University and Cornell University. He then worked in entomology in Maryland, Delaware, and at Texas A&M and the University of New Hampshire. At New Hampshire he became Director of the Agricultural Experiment Station and was elected president of the American Association of Economic Entomologists. In 1910 he became dean of the College of Agriculture at West Virginia University and then director of the experiment station. He was awarded a doctorate in sociology from the University of Chicago in 1921. Sanderson was interested in insect development and in insect pest control. He authored "Insects injurious to staple crops" (1902), and "Insect pests of farm, garden, and orchard" (1911). He was a founder of the Journal of Economic Entomology and was instrumental in getting the Federal Insecticide Act of 1910 passed by the United States Congress. He also wrote four books on rural sociology. He died at Ithaca, New York, on September 27, 1944.

Sandfly Fever

This is an influenza-like viral disease caused by several bunyaviridae and transmitted by *Phlebotomus* flies (Diptera: Psychodidae), especially *Phlebotomus papatasii*. Hence, it is also called phlebotomus fever. The vectors feed on vertebrate blood, often being found in rodent burrows and other animal shelters. Symptoms of human infections are flu-like, and include headache, fever, chills, shivering, muscle and joint pain, and eye and vision problems. The flies bite at night and in the early morning hours. The disease is endemic to the Mediterranean region, and has been known to incapacitate large numbers of military personnel during regional conflicts. It is not fatal. Prevention includes sleeping under bed nets, and use of insect repellent.

Sand Fly

A name applied to various small biting flies (Diptera), including members of the family Psychodidae, Simuliidae, and Ceratopogonidae, though this name refers most correctly to members of the family Psychodidae.

► Flies
► Biting Midges, *Culicoides* spp.

Sanitation

The practice of eliminating pests by removal or destruction of materials or sites that might harbor pests.

Sap Beetles (Coleoptera: Nitidulidae)

DALE HABECK
University of Florida, Gainesville, FL, USA

The family Nitidulidae belongs to the superfamily Cucujoidea in the suborder Polyphaga of the order Coleoptera (beetles).

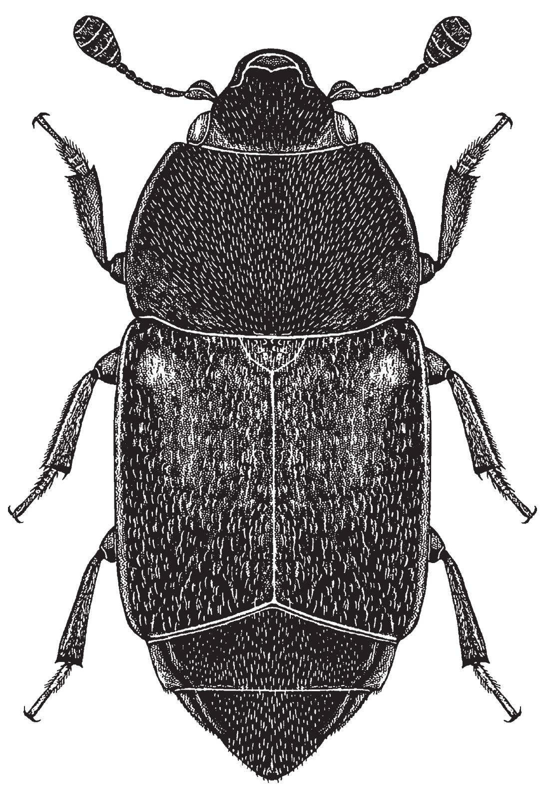
Order: Coleoptera
Suborder: Polyphaga
Superfamily: Cucujoidea
Family: Nitidulidae

Six subfamilies of Nitidulidae are recognized, although the classification at both the generic and subfamily levels is still in a state of flux. One subfamily, Brachypterinae, was recently elevated to family status. The subfamily Cybocephalinae is often placed in its own family Cybocephalidae, and sometimes Cateretidae, Brachypteridae, Cybocephalidae and Smicripidae are included in the Nitidulidae.

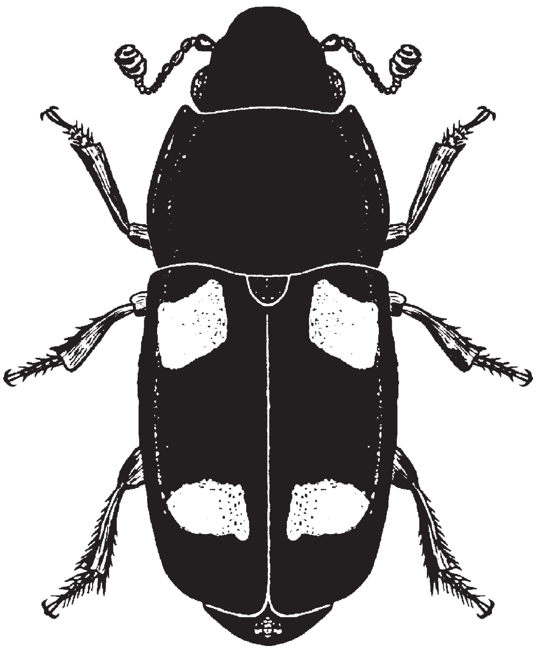
The Nitidulidae are a small family of mostly small beetles. There are 165 species in North America and about 3,000 described worldwide, although many more remain undescribed.

Adults

The length of adult Nitidulidae ranges from about 1 to 12 mm. Bodies are often depressed, usually oval shaped, but some elongate. The adults often bear red or yellow spots. The head is prognathous. The antennae are 11-segmented, with the apical three segments forming a club (Figs. 8 and 9). The antenna is often received in a groove on the underside of the head. The tarsi are 5-segmented on all legs, but with only four segments in the Cybocephalinae.



Sap Beetles (Coleoptera: Nitidulidae), Figure 8 Adult dusky sap beetle, *Carpophilus lugubris*.



Sap Beetles (Coleoptera: Nitidulidae), Figure 9 **Adult fourspotted sap beetle, *Glischrochilus quadrisignatus*.**

Larvae

The larvae are elongate, and 2–20 mm long, but most <12 mm, parallel sided and frequently flattened. In many larvae, the mandibles bear a well-developed prostheca. Most larvae with paired, fixed appendages (urogomphi), but they are lacking in the Meligethinae and Cybocephalinae. The spiracles are two openings at the end of tubes (except in Cybocephalinae). The pupae are exarate.

Food

Nitidulidae display a wide range of feeding habits, though they are generally considered to be saprophagous and mycetophagous. As the common name (sap beetles) implies, many (especially *Carpophilus* and *Glischrochilus*) are found at sap flows on injured trees. Cybocephalinae are predatory on scale insects, and Glischrochilus have been reported to be predators of wood-boring larvae. Many species (e.g., *Pallodes*, *Pocadius*, *Thalycra*, *Cychramus*, *Aphenolia*) feed on fungi. Pollen and nectar-feeding occur in the *Meligethes*, most *Conotelus* and some *Carpophilus*. *Nitidula* and *Omosita* are carrion feeders and *Amphotis* are associated with ant colonies at least part of the year.

Economic Importance

Aethina tumida is a serious pest in bee hives. *Carpophilus dimidiatus* is a minor pest of stored grains, and *C. lugubris* is a pest of sweet corn. Several species in the genera *Carpophilus*, *Glischrochilus*, *Epuraea* and *Colopterus* are involved in transmitting the pathogenic fungus causing oak wilt.

Feeding on dead or dying plant or animal tissue.

Sapygidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Sarcophagidae

A family of flies (order Diptera). They commonly are known as dung flies.

► Flies

Sarcoptic Mange

A disease caused by mites of the genus *Sarcoptes*; scabies.

► Mites

Sarcosomes

Large mitochondria found in muscle, especially thoracic muscle.

Saturniidae

A family of moths (order Lepidoptera). They commonly are known as giant silkworm moths, emperor moths, or royal moths.

► Emperor Moths
► Butterflies and Moths

Satyrs

Some members of the family Nymphalidae, subfamily Satyrinae (order Lepidoptera).

► Brush-Footed Butterflies
► Butterflies and Moths

Saucer Bugs

Members of the family Naucoridae (order Hemiptera).

► Bugs

Saunders, William

William Saunders was born in England in 1820, and moved from Devonshire to Canada in 1832, where he became known as a pioneer in horticulture and entomology, and Canada's first economic entomologist. Though lacking much formal education he received some technical training in chemistry and became a druggist in London, Ontario. However, he loved nature and took to the study of plants and insects. He became a specialist in medicinal plants, and became well-known as a supplier of quality products to the medical profession. He also became a professor at the University of Western Ontario (Fig. 10). Saunders was co-founder (with C.J.S. Bethune) of the Entomological Society of Canada in 1863, and also co-founder of the Canadian Entomologist, in 1868. Interestingly, the co-founders were also the only two authors of the first two editions of this journal! Saunders managed the journal for 5 years, ending in 1886 when he moved to Ottawa. In 1883 he published an important treatise, "Insects injurious to fruit." He was also appointed Director of Experimental Farms of the Dominion in Ottawa, in 1886, and helped establish the first experimental farm. He died on September 13, 1914, in London, Ontario.

Saussure, Henri Louis Frederic De

Henri Saussure was born at Geneva, Switzerland, on November 27, 1829. A noted specialist in Hymenoptera and Orthoptera, Saussure initially studied social wasps, but is best known for work on the grasshoppers. He received his education in Switzerland and Paris, and also studied with the entomologist François Jules Pictet de la Rive. Saussure traveled to the West Indies, Mexico and the United States, returning to Europe with valuable collections of animals. His interests were quite broad, and in 1858 he founded the Geographical Society of Geneva. In Geneva, he was also associated with the Natural History Museum of Geneva. Saussure died at Geneva on February 20, 1905.

Sawflies (Hymenoptera: Symphyta)

CHRISTOPHER ASARO
University of Georgia, Athens, GA, USA

Sawflies are members of the order Hymenoptera, suborder Symphyta. Adult sawflies can be distinguished from the other members of that order (Suborder Apocrita: the parasitic Hymenoptera, wasps, bees, and ants) by their saw-like ovipositor, lack of constriction at the base of the abdomen, fly-like appearance and more extensive wing venation. Sawfly larvae are eruciform (caterpillar-like) and phytophagous (except members of the family Orussidae) rather than grub-like and parasitic or predatory. They are often confused with lepidopteran larvae, but have numerous distinguishing characteristics, including six or more pairs of abdominal prolegs, a lack of chrochets on the abdominal prolegs, one lateral ocellus on each side of the head, and distinctly segmented maxillary and labial palpi. Furthermore, sawfly larvae generally lack long hairs, spines, or tubercules, common characteristics of many lepidopteran larvae.

There are approximately 8,000 species of sawflies worldwide, with most of the diversity found in the Northern Hemisphere. Diversity appears to be relatively low in the tropics. However, this may reflect a lack of significant sampling and study of sawflies in this region. Most sawflies, whose hosts are woody plants, are external leaf or needle feeders, and are relatively monophagous. In northern forest ecosystems, sawflies are the second most dominant group of defoliators behind the Lepidoptera. A number of introduced species have major pest status and many can periodically cause severe localized damage. Because studies of this group have not been extensive, they are not as well known to the public and it is likely that sawfly damage has often been attributed to other groups, particularly the Lepidoptera.

There are thirteen families within the Symphyta (Table 2). The Diprionidae and the Tenthredinidae contain most of the economically important species, with the latter family being by far the most speciose group. The table describes the species diversity, distribution, major hosts, and feeding habits of each sawfly family.

Adult sawflies are sexually mature upon emergence. Following mating, females of most species use their saw-like ovipositor to create a slit in the host plant tissue, into which they insert their eggs. Like other Hymenoptera, sawflies have haplodiploid sex determination, in which unfertilized eggs become males and fertilized eggs become females. Larvae of many species feed gregariously, particularly during the early instars. In most species, male larvae pass through five instars, females six. Mature larvae that have finished feeding usually drop off from the host plant, burrow into leaf litter or soil, and enter dormancy as a pre-pupae,

Sawflies (Hymenoptera: Symphyta), Table 2 Families of sawflies

Family	Approximate No. of species	Distribution	Hosts/feeding habits
Xyelidae	75	Holarctic	Pollen of *Pinus*, bud and twig borers of *Abies*, external leaf feeders on *Ulmus* and *Carya*.
Pamphiliidae	300	Holarctic	Web-spinning and leaf-rolling species on hardwoods, conifers, and shrubs.
Megalodontidae	50	Palearctic	Web spinners on herbaceous plants only.
Pergidae	500	Worldwide, most abundant in neotropics, dominant in Australia	Known hosts include species of *Eucalyptus*, *Quercus*, *Carya*, and *Nothofagus*. Hosts and habits are unknown for most species.
Argidae	800	Worldwide, most abundant in neotropics, dominant in Africa	All genera but one feed on angiospermous trees, shrubs, and herbaceous plants. One Australian genus feeds on *Cupressus*.
Diprionidae	125	Holarctic, with extensions into the northern tropics	Feed exclusively on conifers, primarily *Pinus*.
Cimbicidae	150	Holarctic	Defolators of woody plants.
Blasticotomidae	6	Palearctic	Stem borers of ferns.
Tenthredinidae	5000	Worldwide, rare in Australia	Many subfamilies, feed on a variety of plants including horsetails, ferns, grasses, sedges, hardwoods, and conifers.
Xiphydriidae	100	Worldwide, most diverse in sub-tropical Asia	Wood borers of hardwoods.
Siricidae	100	Mostly holarctic, some tropical	Wood borers of conifers and hardwoods.
Cephidae	100	Holarctic	Twig and stem borers of grasses, serious grain crop pests.
Orussidae	75	Worldwide, most diverse in tropics and subtropics	Only non-phytophagous group of Symphyta, parasitic on wood borers, especially Coleoptera.

often within a cocoon. For most species, the pre-pupae is the overwintering stage, and pupation occurs in the spring.

There is considerable variation in life history and voltinism (number of generations per year) within the Symphyta. Voltinism can even vary within a species depending on latitude and within a population depending on local microclimate. Most species in the Northern Hemisphere are univoltine (one generation per year), with an increase in multivoltinism towards the tropics and semivoltinism (more than 1 year required to complete life cycle) towards the poles. The red-headed pine sawfly, for example, has one to five generations per year throughout its range from Ontario, Canada to Florida, respectively.

A handful of sawfly species have major economic importance, particularly those that have been introduced from other regions. Some important conifer pests that were introduced into North America from Europe include the European pine sawfly, *Neodiprion sertifer*, the introduced pine sawfly, *Diprion similis*, the European spruce sawfly, *Gilpinia hercyniae*, and two European strains of the larch sawfly, *Pristiphora erichsonii*. Other native species in North America that frequently plague conifer plantations are the red-headed pine sawfly, *Neodiprion lecontei*, and the yellow-headed spruce sawfly, *Pikonema alaskensis*. The European woodwasp, *Sirex noctilio*, along with a symbiotic fungus, has been a substantial problem in the Southern Hemisphere where it was introduced into the highly profitable radiata pine plantations of Australia. It poses a similar threat to pine plantations in other regions such as South America. It is likely that new sawfly pests will emerge as species continue to be introduced into new areas in the absence of their natural enemies.

Sawflies (Hymenoptera: Tenthredinidae)

JEAN-LUC BOEVÉ
Royal Belgian Institute of Natural Sciences, Brussels, Belgium

The Tenthredinidae belong to the Hymenoptera, suborder Symphyta. “Sawflies” is a generic term generally designating the superfamily Tenthredinoidea. In this section, the term “tenthredinid” will be used for clarity.

Systematics and Geographic Distribution

The superfamily comprises the Argidae, Blasticotomidae, Cimbicidae, Diprionidae, Pergidae and Tenthredinidae. The oldest fossil record of the tenthredinids is from the Early Cretaceous, whereas the other families evolved much later, namely from the Middle Tertiary.

Class: Insecta
Order: Hymenoptera
Superfamily: Tenthredinoidea
Family: Tenthredinidae

Over 5,000 tenthredinid species are described worldwide and distributed approximately in 430 genera. Major genera that contain over 50 species are *Amauronematus* (approximately 170 species described), *Athalia* (80), *Dolerus* (200), *Nematus* (240), *Macrophya* (170), *Pachyprotasis* (110), *Pristiphora* (180), *Tenthredo* (700), *Tenthredopsis* (60). Today, seven or sometimes eight subfamilies are recognized, as follows: Allantinae (represented approximately by 110 genera; e.g., *Athalia*, *Eriocampa*), Blennocampinae (105; e.g., *Blennocampa*, *Monophadnus*, *Periclista*), Heterarthrinae (40; e.g., *Caliroa*, *Fenusa*, *Profenusa*), Nematinae (55; e.g., *Cladius, Euura*, *Hemichroa*, *Hoplocampa*, *Nematus*, *Phyllocolpa*, *Pontania*, *Priophorus*, *Pristiphora*, *Trichiocampus*), Selandriinae (including Dolerinae; 75; e.g., *Dolerus*), Susaninae (1), and

Tenthredininae (50; e.g., *Macrophya*, *Pachyprotasis*, *Tenthredo*, *Tenthredopsis*).

Tenthredinids occur as native species on almost all continents, being absent in Antarctica and New Zealand, and rare in Australia and smaller islands. They are the most diverse and abundant in the temperate zones of the northern hemisphere, preferring humid biotopes. However, some subfamilies are the most diverse in (sub) tropical zones (Selandriinae, Tenthredininae), while the Nematinae are virtually the only sawflies in the subarctic zone. The geographic distribution of tenthredinids is limited by the fact that adults are not strong fliers and by the distribution of the larval host plant. In contrast, the distribution of some species has been expanded in the last centuries by accidental introductions, mainly from Europe to North America.

The monophyly of the tenthredinids remains under debate since no unambiguous apomorphies could be found so far.

Morphology

Adults vary in size from 2.5 to 15 mm. Their color pattern consists of black as well as pale orange, yellow or green (that fade to straw coloration in dead specimens). Most tenthredinids can be identified by a combination of the following characters: antennae filiform and composed of nine flagellomeres; thorax with mesoscutellar appendage distinct; pronotum markedly concave along the posterior margin; fore-tibiae with two apical spurs, hind tibiae without subapical spurs; forewing with subcosta absent or as cross-vein; ovipositor saw-shaped (and that gave the name "sawflies" to the group). The subfamilies are separated mainly on the basis of wing morphology (Fig. 11).

Tenthredinid larvae are eruciform, meaning subcylindrical in shape and resembling caterpillars. The body is depressed only in some species. The larva possesses seven or eight pairs of pseudopods, or prolegs, on abdominal segments 2–8 and 10 (in most subfamilies), 2–7 and 10 (Nematinae), or 2–8 (e.g., *Caliroa*), except in the mining taxa where pseudopods are reduced or absent. A tenthredinid larva can be distinguished easily from that of a lepidopteran since the latter never possess more than five pairs of pseudopods, and never a pair on the second abdominal segment. The abdomen of tenthredinid larvae consists of ten segments, each one composed of 3–7 annulets. The head capsule is well developed and antennae are short with 3–5 segments. The nervous, tracheal, muscular, circulatory and reproductive systems are roughly similar and comparable to other insects, whereas the digestive and excretory systems, fat body and integument show interspecific differences of systematic interest.

Sawflies (Hymenoptera: Tenthredinidae), Figure 11
Adult (a) and larva (b) of the tenthredinid *Hoplocampa flava* (drawings by Marylise Leclercq).

Life History and Habits

The biology of the Tenthredinidae is highly diversified, of course by comparing one species with another. However, all species of a genus or subfamily can show a similar biological trait. Examples of such taxa are given in brackets from now on throughout the text. Another preliminary remark is that general characteristics are given, while exceptions usually are omitted.

The emergence of adults is strongly linked in non-(sub)tropical regions to the phenology of the host plant (of the larvae, see later). In holarctic regions, Dolerinae and many *Amauronematus* emerge early, at the very beginning of the spring, but most tenthredinid species occur as adults in May and June.

After its molt from pupal to adult stage, the tenthredinid will remain during 1–7 days in the cocoon. Newly emerged sawflies will drink rain or dew droplets. Later, they can feed on honeydew, but they feed most typically on pollen and nectar, thus helping somewhat in pollination, whereas several species are carnivorous (*Tenthredo*) and some others do not feed at all. On a still, sunny day, one might commonly find adults, especially on flowers of the Apiaceae, Ranunculaceae, Rosaceae, Saxifragaceae, Compositae, and on catkins of Salicaceae, Betulaceae, etc. Tenthredinid adults generally do not fly very much, and usually only for a short distance.

In captivity, females live 1–2 weeks, males only a few days. The effective occurrence of adults in the field might spread over weeks or months. Male emerge somewhat earlier than females. Individuals of both sexes will find each other by optical and chemical cues. During copulation, lasting generally 1–2 min, the two bodies point in opposite directions, facing away from each other (i.e., stophandry).

Tenthredinids reproduce sexually or asexually. Parthenogenesis is a typical and frequent feature. It is generally either facultative (arrhenotokous, i.e., unfertilized eggs produce males, whereas fertilized eggs produce females), or obligatory (thelytokous, i.e., eggs always produce females, males being unknown). For arrhenotokous species, males can be obviously absent or rare in given populations and geographic areas. In most tenthredinid species, the number of chromosomes is $n = 7–10$, extreme values being $n = 5–22$. A trend seems to be that the chromosomes become more numerous during evolution.

Normally a female possesses from 40 to 250 eggs. Eggs that will be laid are generally already mature in the emerging female. Egg sizes range from 0.4 to 3.9 mm in length, and from 0.2 to 0.9 mm in width. The female cuts with a saw-like ovipositor such plant tissue as a petiole, leaf vein, or fertilized flower. Then, eggs are deposited in the created slit, more often singly than in small clusters. In the particular case of leaf galling species, the female will lay eggs and concurrently a secretion that will start the development of the leaf gall (later on, the larva will continue to stimulate this process). In a few other species, it has been observed that females lay their eggs on plants different from the larval host plant. Once deposited, the egg will mature (into an embryo) by which its volume will increase, swelling, thereby, the surrounding tissue. Egg eclosion will occur 1–3 weeks after eggs are laid, depending on temperature; eggs also are particularly sensitive to a moisture deficiency.

All tenthredinid larvae feed on plant material. Their host plants are horsetails and ferns (Pteridophyta), resinous trees (Coniferae) as well as flowering plants (Angiosperms), namely herbs, shrubs and deciduous trees, but mosses, Compositae, Lamiaceae and Apiaceae are rarely attacked. Compared to other herbivorous insects, tenthredinid larvae have a relatively narrow diet breadth; most species are "specialists" feeding on one given plant genus or even one plant species. Exceptions to this rule are found among the Tenthredininae. The host range observed today in tenthredinid species suggests, to some extent, a radiation of the insects parallel to the evolution of their host-plants.

Larvae generally feed freely on leaves, but some species groups are leaf miners (Heterarthrinae), leaf rollers (*Phyllocolpa*, *Blennocampa*), leaf gallers (*Pontania*), shoot gallers (some *Euura*), fruit borers (*Hoplocampa*), etc. Within the Nematinae, it is likely that from free-feeding larvae evolved the habit to live more and more deeply in the plant (tissue), namely from leaf rollers through leaf gallers to shoot gallers.

There are four to eight larval instars, males showing often one instar fewer than females. Larval growth can be best followed, beside weight, by measuring the head capsule width. This will allow the instar to be determined. The feeding larval stages together require approximately 10–30 days. This period and the feeding rhythm are influenced by species, sex, climatic conditions, etc.

The location of a larva feeding freely on a leaf can be the leaf edge (Nematinae). The leaf edge generally corresponds to the external border of the leaf, but it can be an internal border when a larva makes a hole on the edge of which the larva will continue to feed. Furthermore, the location of a larva can be on one of both sides of a leaf. The larva then either only feeds on the parenchyma (*Caliroa*) or from the edge of the leaf while it remains with its body on the underside of the leaf (*Trichiocampus*). A case of acoustic communication has been reported in the gregarious species *Hemichroa crocea*. By scratching the leaf surface with the abdomen, the larvae of a group remain together and are informed on food quality.

The last larval molt leads to a so-called prepupa. This instar either feeds (most Nematinae), or not (Blennocampinae). The prepupa can be different in color and external morphology compared to the previous instars (Blennocampinae, Tenthredininae). It will drop off and crawl into the soil (litter) in order to build a cocoon. Some species not going into the soil will bore into a fruit or bark of a plant that is, generally, not the food plant, and some species (in the Tenthredininae, Selandriinae) do not spin a cocoon. The prepupa undergoes an apolysis leading (without a molt) to a form that is somewhat retracted. This is generally the resting, overwintering stage. Then, at the end of the winter the prepupa molts into the pupa that is an instar lasting only a few weeks.

Most species have one generation per year (univoltine), but they can have up to three or four. Conversely, within one species, a part of a population can overwinter more than one winter. Most northern species enter diapause that then needs to be broken by a specific temperature and by light.

The influence of abiotic parameters on the life cycle of sawflies can be listed as follows: light (photoperiod) on diapause; light, relative humidity and air pressure on emergence timing and on activity of adults; temperature on development time of eggs and larvae as well as on larval and pupal weight. Moreover, larva and pupa are highly sensitive to dryness, but a very moist soil will enhance risk for the (pre)pupa to be attacked by fungi and micro-organisms.

Natural Enemies and Defense Strategies

Numerous arthropods are known to prey upon tenthredinids, as follows: Acari (on the egg stage); Insecta: Hemiptera, Pentatomidae (larva); Cimicidae (egg); Thysanoptera (egg, larva); Dermaptera (larva); Coleoptera, Elateridae (prepupa and pupa); Mecoptera (adult); Diptera, Asilidae (adult); Hymenoptera, Tenthredinidae (adult), Vespidae (larva), Formicidae (larva). Spiders seem to avoid tenthredinids due to the occurrence of chemical defenses (see later).

Birds such as tits, woodpeckers, cuckoos, partridges, chaffinches and starlings have been observed preying sometimes heavily on tenthredinid larvae. Avian predation seems to be especially important in the regulation of prey populations when these populations are at low densities. Mammals such as shrews and voles are well known to destroy overwintering prepupae and pupae, and are important as well in the regulation of populations. Deleterious compounds originating from a toxic host plant and which the feeding larva previously sequestered can deter shrews from attacking tenthredinid cocoons. Amphibians and reptiles, which can feed on tenthredinid adults and larvae, are probably less important predators than birds and mammals.

Many tenthredinid adults drop off when disturbed. Then they feign death for a few seconds with the antennae and legs pressed to the body as at the pupal stage. On the contrary, other species are rather aggressive, and can use their strong mandibles to bite an aggressor (for instance, your finger) as well as predators. Most tenthredinid adults are cryptic in appearance, but some species do mimic dangerous insects (e.g., *Tenthredo vespa* resembling a wasp).

Deposition within the plant tissue protects tenthredinid eggs. One tenthredinid species is known to defend the eggs after oviposition: the female of *Pachynematus itoi* remains with stretched wings upon her cluster of eggs until their hatch.

Larvae living within plant tissue are protected mechanically against some predators, but when attacked, their escape capabilities are of course reduced. In contrast, some free-feeding larvae can drop off the plant when disturbed. The stimuli eliciting this escape behavior are visual or mechanical (by vibration, touching). On the ground, they will often curl their body so that the abdomen protects the head. A regurgitated droplet can be emitted simultaneously (*Dolerus*).

The visual appearance of the larvae is generally one of the following patterns. Most free-living larvae are greenish (cryptic), resembling the leaf color, whereas others are brightly colored (e.g., black head and black spots and lines on a yellowish background of the body). To these opposite trends are linked a different level of gregariousness, larvae being solitary or gregarious, respectively.

The integument of tenthredinid larvae often presents adaptations acting as a form of protection (that is passive) and/or a defense (that is linked to a given behavior). The larvae of most Nematinae species raise up their abdomen once disturbed. Gregarious larvae can perform such movements of the body simultaneously, which can visually frighten birds at distance. The movement of a single larva can deter an approaching parasitoid. Larvae can also dislodge, using their abdomen, an attacking predator. If Nematinae larvae with an already raised up abdomen are continued to be disturbed, then ventral glands of the abdomen can be evaginated. The glandular secretion will evaporate and will be able to repel arthropods such as ants. In some Nematinae species, the ventral glands are developed enough to allow a chemical protection against birds. Larvae can be covered by developed setae (*Cladius*) or spines (*Periclista*), by a wax secretion (*Eriocampa*) or a slimy liquid (*Caliroa*). The hemolymph of many tenthredinid species is distasteful to ants. Larvae can sequester in their hemolymph toxins originating from plants. The hemolymph can be released by bleeding, spitting, or upon wounding.

A majority of tenthredinid parasitoids belong to the Ichneumonidae (Hymenoptera), which are believed to be often specialized on one host species. Tenthredinids are also frequently parasitized by Chalcidoidea (Hymenoptera) and Tachinidae (Diptera). Most parasitoid species attack the tenthredinid at the larval stage, but some species are either egg, or cocoon (i.e., prepupa) parasitoids. The parasitoid female lays one or several egg(s) per tenthredinid individual. The egg is laid either on the body surface or directly in the body of the larva. When a parasitoid egg is in the body of a larva, hemolymph cells of the latter can encapsulate the parasitoid egg, killing it. This is a form of counter-adaptation of the sawflies that become, consequently, resistant to a parasitoid.

Tenthredinids can be attacked by Nematodes (Mermetidae) as well as by fungal, bacterial, protozoan and viral agents. Pathogenic micro-organisms are unknown from the galling sawflies *Pontania* and *Euura*, so that inhabiting the plant tissue might constitute a protection towards diseases (and more generally to natural enemies such as parasitoids).

Economic Importance

Tenthredinid pests are especially important as forest defoliators. Pests are known on deciduous trees (e.g., *Fenusa* on birch, Nematinae species on willow, poplar, birch), their economic effect being probably stronger on conifers (e.g., *Pristiphora abietina* on spruce, *P. erichsonii* on larch). However, there exist only a few real outbreak species among tenthredinids. On the other hand, tenthredinid species are sometimes regional pests in orchards (*Hoplocampa* spp. on apple, plum and pear; *Nematus ribesii* and *Pristiphora appendiculata* (= *pallipes*) on red-current and gooseberry), in agriculture (e.g., *Athalia rosae* on several Brassicaceae such as turnip) and on ornamental plants (e.g., *Blennocampa phyllocolpa* (= *pusilla*) on rose, *Pristiphora rufipes* (= *aquilegiae*) on columbine).

Tenthredinids can be beneficial. Monophagous species are used sometimes as biological control agents of weeds (e.g., *Monophadnus spinolae* introduced in New Zealand and feeding on *Clematis recta* that is invasive there; *Priophorus brullei* (= *morio*) in Hawaii on *Rubus*). At a local level, tenthredinid richness and/or the occurrence of given "indicator" species can inform us on the biodiversity of a studied biotope.

Say, Thomas

Thomas Say was born at Philadelphia, Pennsylvania, USA, on July 27, 1787, and is considered by most to be the "father of American entomology," and the first great American systematist. Others argue that F. V. Melsheimer was the father of American entomology, but none dispute that Say was the first American of equal stature with the European entomologists of the era. He was educated as a pharmacist in Philadelphia, where his father was an apothecary and physician. He lacked interest in medicine, however, favoring natural history. In 1812 he became a member of the Academy of Natural Sciences of Philadelphia, and became influenced by this enthusiastic group of naturalists who were in the very early stages of building a fabulous museum collection. The Academy became his home as well after a business failure, and he slept and ate at the Academy. Say began to publish in 1817. He participated in collecting trips to the Georgia and Florida coasts, the Rocky Mountain region, and western Canada, eventually taking up residence at a utopian Quaker commune in New

Harmony, Indiana. At New Harmony, Say became superintendent for literature, science and education for the community. Say is well known to economic entomologists because he described many of the economically important pests found in the United States. He published a three-volume treatise, "American Entomology," during the period of 1817–1828, as well as numerous papers. He was a member of all the important entomological societies. Say is also credited with being the "father of American conchology," publishing six papers on the subject while living at New Harmony. Say died in New Harmony, Indiana, on October 10, 1834.

Integrated pest management (IPM) has been defined as a control system that, in the context of the associated environment and the population dynamics of the pest species, utilizes all suitable techniques and methods in the most compatible manner possible and maintains pest populations at levels below those causing economic injury. Conceptually, IPM operates at the interface of two multidimensional systems: the ecological and the socioeconomic systems, which are hierarchically ordered in ascending levels of complexity and expanding spatial scales.

From a socioeconomic standpoint, IPM schemes are designed to maximize the benefits from control measures, minimize adverse environmental impact and maximize social benefits. Presumably, these objectives are easier to meet on industrialized agricultural holdings than on subsistence farms. African agriculture is characterized by a large majority of small-scale farmers who cultivate small landholdings of less than one hectare to a few hectares and practice intercropping in horticulture-based production systems. Often, farmers do not have titles to the land, and ownership of the harvest is not restricted to the ones cultivating it, which is important when it comes to implementing IPM.

From an ecological standpoint, IPM schemes integrate compatible pest control methods by considering the population dynamics of a pest and its interaction with the commodity. Even the most basic level of population dynamics involves the problem of multiple scales. The problem of multiple scales permeates the study of ecological process and pattern, uniting aspects of space, time and organizational complexity.

Concepts of Scale and Hierarchy

Scale has numerous definitions in the ecological literature. One common definition is that it denotes the resolution within the range of a measured quantity. Scale, therefore, is the unit measure (resolution) relative to the largest multiple (range). This definition applies to space, time and mass. Scale differs from hierarchical levels in that it is recorded as a quantity and involves (or at least implies) measurements and measurement units. Scale-dependent patterns can be defined as a change in some measure of pattern with change in either the resolution or the range of measurement. Scale also refers to power law relations between variables. Specifically, a quantity Q scales with another measured quantity Y (e.g., area, duration, mass) as follows.

$$\frac{Q}{Q_{ref}} = \left(\frac{Y}{Y_{ref}}\right)^{\beta} \qquad [1a]$$

Hence

$$Q = (Q_{ref}\, Y_{ref}^{-\beta})\, Y^{\beta} \qquad [1b]$$

The exponent of these power laws can sometimes be obtained by dimensional analysis. In ecology, power laws are typically obtained empirically, by regressing the logarithm of Q against the logarithm of Y. Examples of power law scaling in ecology include body size allometry (Y = mass), species area curves (Y = area), and Taylor's Power Law (Y = mean density).

Like the word "scale," hierarchy has multiple meanings in ecology. One common definition is that it refers to discrete levels in hierarchically organized systems, where levels are distinguished by rates that differ by one or more orders and magnitude. Rate differences cause structural differences among levels. Hierarchical organization means that higher level processes can steer and constrain lower level processes, while, at the same time, higher level features might emerge from lower level dynamics. Hierarchical organization can be described a two step procedure: top-down across two or three levels of organization at a time by analysis, then bottom up across the same levels by synthesis. Also, natural laws do not apply equally at all scales, but are formulated at particular levels of space, time and complexity. At each level of organization phenomena exist that require new laws and principles which still cannot be predicted from those at more fundamental levels. As one proceeds away from those levels at which a law was cast, the explanatory capability wanes. Hierarchy theory takes into account the problem of aggregation errors by identifying levels of nested systems within larger systems. From this perspective, it is natural to analyze data across multiple scales to seek discontinuities that define changes in the levels. Translating hierarchical concepts into equations that can be used in applied ecology has proven difficult. Hierarchical levels are useful in labeling different levels of human organization as it affects ecosystems including agroecosystems where IPM applies.

Application of Scale and Hierarchy Concepts to IPM

Human institutions and their economic activities introduce levels of field, farm and village and beyond. Clearly, the hierarchy levels are identified on organizational rather than observational ground. Often, the IPM literature refers to the hierarchical organization of decision-making in IPM ranging from farmers to extension agents and policy makers. To simplify the treatment of the topic, this discussion is restricted to a single-species pest population and does not elaborate on its interaction with the commodity or with social institutions and policy. Recognize that there is a connection between temporal and spatial scales. Nevertheless, for the sake of simplicity, they are treated separately.

An adequate understanding of spatio-temporal dynamics is a prerequisite for planning and undertaking control measures within an IPM framework. This understanding is often obtained by the analysis of age-structured populations changing in time and space, via statistical inference or mathematical modeling. Both methods require scale considerations. Statistical inference in IPM relies on spatial design considerations of plot size and layout, which introduce considerations of spatial scale. As shown below, changes in the sample unit size and in the distribution of the samples in the sampling universe also require scaling considerations. Inference from a sample to a larger area introduces questions of scale that bear on population density estimation used for decision-making in threshold-based IPM.

Spatial Scales

In homogenous fields, there is no standing pattern in underlying physio-chemical environment, individual sites may vary from one another at any particular time due to history, but will exhibit similar statistical features over long periods of time. For example, the overall dynamics of an acarine predator-prey system in a greenhouse is composed of local dynamics. Homogeneous sampling universes enable the use of simple random sampling procedures, i.e., a method of selecting units so that every one of the samples has an equal chance of being drawn. In heterogeneous sampling universes it is advantageous to use stratified sampling procedures and work with subpopulations having known sampling probabilities.

The design of a sampling plan requires the definition of the physical size of the sampling unit and recommends cost-benefit procedures. There are significant advantages of a large number of samples with small units over a small number with large units. Also, sample size should be chosen according to the nature of the organisms, and with consideration of the objective of the study.

Homogeneous Sampling Universe

The range of measurement, or sampling universe, is given by the dimension of a field. In weed control, there is no doubt of the importance of field-level management, while this is not always true for other pests. Many invertebrates show few differences between field and farms, and seemed to be changing evenly across the whole area in response to factors operating at higher levels.

The design of efficient agricultural experiments requires minimizing residual variability in order to detect small effects with the least effort. To overcome spatial heterogeneity, the efficiency of many small plots versus a few big plots needs to be assessed. The number of samples required to meet reliability criteria depends on the spatial distribution of the pest population. Frequency distributions, or variance δ^2 to mean μ relationships, are generally used for the design of sampling plans. Selected here as an example is Taylor's power law even though other descriptions as well as frequency distributions could be used with equal justification. According to this law, the variance in density of organisms $\delta^2(\mu)$ scales as a power law of the mean μ.

$$\delta^2\,(\mu) = a\mu^{\mathrm{b}} \qquad [2]$$

The parameter a be definition depends on the units of μ and is thus largely, possibly wholly, a sampling or computing factor. The scaling exponent b ranges typically from 2 to 4 and was interpreted as an index of aggregation. There are publications with the explicit or implicit assumption of a constant species-specific b. In simulation studies, however, b varies with the sample unit size. This result has important implications both for the design of sampling plans and for the interpretation of spatial distributions. Namely, b describes a consistent relationship between sample variance and sample mean over a range of densities, on a spatial scale connected to the sample unit size. This is consistent with observation that different sampling unit sizes detect different spatial patterns.

The dependence of Taylor's Power law on sample unit size can be estimated from data or by deriving it from assumptions regarding population processes and models as well as frequency distributions. A diffusion-limited aggregation model to derive [3] and yields:

$$\delta^2\,(q) = \delta^2\,(1)q^b \qquad [3]$$

That is, the variance for a unit size quadrate q is scaled up by a factor q^b when the quadrate size is increased by the factor q. Similar scaling relations describe fractal symmetry, then from this proposes that the exponent b can be interpreted as a fractal dimension.

Heterogeneous Sampling Universe

Consider the case of an inhomogeneous field and the extension of the range of measurement to neighboring fields. In statistical terminology, the measurement is strata and, therefore, reliance is on stratified sampling procedures for population estimation. Sawyer and Haynes use [1] to represent the spatial distribution of cereal leaf beetle trap catches in each stratum (field) and for the region, with mean density v

$$\delta^2 (v) = a_s v^b \qquad [4]$$

These authors recognize that the intercept contains strata-specific information. However, Sawyer and Haynes stress the need to validate the assumption of constant proportions, e.g., density invariant, distribution of individuals in the different strata. Stratification addresses discontinuities in the sampling universe. To the degree that it is effective, it indicates a shift from the homogeneous to heterogeneous distributions. Stratification can be based on physical conditions (e.g., soil moisture). It also can be based on imposed levels of organization of land use practice at the scale of the field, farm and village.

Spatial Range Extension

A wide spatial range is addressed when pest movements and control operations require that density estimates are done on village levels. Mass trapping is an efficient technique for the control of the savannah tsetse flies *Glossina pallidipes* and *G. morsitans* submorsitans. The minimum range for control operations covers an area of several km^2, and typically includes many farms and villages. The scale is related to the area of attraction of an odor-baited trap that may attract flies within a 50–100 m radius. For monitoring purposes, traps are deployed on a $0.25 \times 1.0\ km^2$ grid. Control operations are carried out with 4–12 traps per km^2, depending on the fly density. In both cases, the sampling universe is assumed to be homogeneous.

In a highly structured sampling universe, subsampling procedures may be appropriate for density estimation. Thereby, a relatively small scale sample is cast over two or more levels or stages. Subsampling refers to the fact that a unit on a given level is not measured completely but is itself sampled.

Temporal Scale

A temporal range covering a crop growing period may often be too short for a complete pest generation to develop. Often, however, the crop may be exposed to either single generation or even multi-generation infestation patterns. In any case, the infestation patterns influence the temporal scale for density estimates.

Models on the dynamics of physiologically structured populations often represent infestation patterns adequately. For example, the outcome of weed-crop plant interactions and thus, yield loss, is determined by temporal coincidence: a scale of 12 h may affect yield.

Temporal Range Extension

The temporal range is extended to cover a series of growing periods at the field, or at higher levels. For example, the immature life stages of the European cockchafer *Melolontha melolontha*, develop in one or more crops during an often 3-year period, and soil samples with surface of $0.5 \times 0.5\ m^2$ and adequate depths are taken at the field level. The adults operate in areas of several km^2, hence, adult flight patterns are studied during the time of adult occurrence, at the level of villages.

In general, the extension of the temporal range and frequent measurements allow the use of spectral analyses, where the measure of association, plotted against the frequency of measurement, depends on the time scale used. Hence, the results obtained by spectral analyses are specific to the time scale used, and for generalization purposes, should be completed by scaling up work.

Mass Scale

In many cases, the amount of food consumed by a pest can be linked to yield losses. In a small range of pest organism masses, it may be considered as proportional to the body mass, while scaling up for higher body mass may require nonlinear functions. Likewise, respiration costs do not increase proportionally to an increase in individual body mass. Often, the relationship

$$r(m) = r(1)m^c \qquad [5]$$

is used. That is, the respiration r for a unit mass organism is scaled up by a factor m^c. This is important when explaining the population dynamics on the basis of the supply-demand theory.

Concluding Remarks

The IPM literature often refers to concepts of hierarchy and scale, but does not rely on a coherent terminology adopted in this paper. Often, the IPM literature refers to spatial levels of fields, farms and villages and beyond as well as to levels in hierarchical decision-making organization, ranging from farmers to policy makers. Presumably, this is because human institutions and economic considerations allow a convenient organizational identification of levels. There are strong indications, however, that these levels may not have the same importance in pest population dynamics, hence their relevance for studies and management should be supported by data. Scale related problems including the implications of scale selection have received little attention in IPM, but we expect an increasing interest in the treatment of scaling and in the design of field experiments. These studies might confirm that, from an ecological standpoint, scaling functions (variants of equation [1]) are easier to define from data than hierarchies.

IPM schemes remain often narrowly designed for field-specific measures and do not appear to fully consider the ecological knowledge obtained in the past decade. When addressing hierarchies, bottom-up approaches receive more attention than top-down approaches. This could be corrected by putting IPM into a landscape context. This approach could complement field- and species-specific IPM programs and become useful when designing IPM schemes at the community and ecosystem level. When dealing with landscape concepts, however, the distinction between the level of organization and the level of observation should be taken into account.

Scale Insects and Mealybugs (Hemiptera: Coccoidea)

PARIS LAMBDIN
University of Tennessee, Knoxville, TN, USA

Scale insects, including mealybugs, comprise a diverse group of insects within the superfamily Coccoidea in the suborder Sternorrhyncha containing more than 7,500 species worldwide. Scale insects initially were called coccids, a name derived from *Coccus* meaning berry. These small, often cryptic plant-feeding insects are considered pests with several species capable of inflicting substantial economic damage. Scale insects are distinguished from other hemipterans by several morphological and behavioral traits. The adult females are always wingless and usually have a powdery covering or waxy test protecting their body. Their mouthparts arise between the front coxae. When legs are present, they have 1 (rarely 2) segmented tarsi with a claw. The first instars always are mobile, while later instars often are sedentary. Most females deposit their eggs either beneath their tests or in ovisacs. The adult males may be winged or wingless. When present, a pair of wings is located on the mesothorax and a pair of hamulohalteres often occurs on the metathorax. The head of the male is distinguished by two or more pairs of various types of eyes and non-functional mouthparts. Because females are present longer throughout the year, the taxonomy of the group is based on their morphology.

The scale insects usually are arranged in 22 families worldwide that include: the Aclerdidae (grass scales), Asterolecaniidae (pit scales), Beesoniidae, Carayonemidae, Cerococcidae (ornate pit scales), Coccidae (soft scales or coccids), Conchaspididae (false armored scales), Cryptococcidae (bark crevice scales), Dactylopiidae (cochineal scales), Diaspididae (armored scales), Eriococcidae (felted scales), Halimococcidae, Kermesidae (gall-like scales), Kerriidae (lac scales), Lecanodiaspididae (false pit scales), Margarodidae (giant scales), Micrococcidae, Ortheziidae (ensign scales), Phenacoleachiidae, Phoenicococcidae (date scales), Pseudococcidae (mealybugs), and Stictococcidae. Six families (Electrococcidae, Grimaldiellidae, Inkaidae, Jersicoccidae, Kukaspididae, and Labiococcidae) are represented by extinct species found in amber. In the U.S., 856 species are known representing 16 families. The families Diaspididae, Pseudococcidae, Coccidae, and Asterolecaniidae, respectively, contain the highest numbers of species. Adult females in the more primitive families often have well-developed legs providing them more mobility than adult females in the more advanced families that often are sessile.

Economic Impact of Scale Insects

Many species are important pests of fruit, nut, forest and ornamental trees, greenhouse and house plants, as well as several agricultural crops. Losses due to plant death and increased production costs are estimated to exceed five billion dollars annually worldwide with losses in North America approaching 500 million dollars annually. The most economically important infestations of scale insects are in cultivated plantings, nurseries, greenhouses, and other urbanized areas where ecological disturbances have occurred. These minute scale insects often go unnoticed on the branches and leaves until a heavy infestation is present, which results in loss of plant vigor, dieback, leaf drop, fruit damage, or eventual death of the host plant. Over an extended period, the tests or scale covers from successive generations encrust the stems and limbs that not only damage the plant, but diminish their aesthetic appeal. Some scale insects can injure the plant surface by injecting their needle-like stylets into the tissue, producing open wounds, which may allow plant pathogens to enter into the plant. For example, damage caused from feeding by the beech scale is believed to be responsible for the outbreak of beech bark disease that now threatens the beech groves in the Great Smoky Mountains National Park. In addition, several species of mealybugs are known vectors of pathogens that may lead to the death of the plant.

In some instances, the saliva injected during feeding may be toxic to the host plant resulting in gall formation, deformed areas, or discoloration around the feeding site. Species of several families (e.g., Eriococcidae, Asterolecaniidae, and Beesoniidae) induce gall formation on their hosts. Where the mouthparts are inserted, normal growth of the host is disrupted and eventually the tissue forms a closed or open gall around the scale. Some scales (mostly in the Australian region) develop inside these galls on leaves, stems, and twigs. Those species that develop within closed galls often exhibit morphological changes that may include an enlarged head and more posteriorly located thoracic spiracles, with the spiracles in Beesoniidae positioned near the anal opening. Species of the gall-forming genus *Apiomorpha* develop an elongated and constricted abdomen. Open galls in the form of slight depressions or pits are induced by species of Asterolecaniidae and Lecanodiaspididae. While golden oak scales produce distinctive open galls on oaks, galls formed by sweetgum scales appear as reddish to whitish specks on the ventral surface of the leaf of sweetgum. Damage around the feeding sites often is manifested in the formation of chlorotic spots. The feeding activity by San Jose scales may produce discolorations in the form of red rings on apples, while Florida red scales produce light circular areas on citrus. The birch margarodid is found embedded within the bark of birch with only a hollow, waxy tube-like filament linking it to the external environment.

Secondary injury to the plant host by most soft scales and mealybugs results from exuding a liquid excretion (often referred to as honeydew), which is a by-product of the large volume of sap they ingest. The excreted honeydew that falls onto the lower leaves and branches serves as a substrate for the development of sooty mold, which inhibits growth, lowers fruit yields and sugar content, and reduces the aesthetic value of the host plant. Honeydew also attracts ants that collect and feed on the sugary residue. In return, the ants often protect the scales from natural enemies.

Several species have been beneficial to cultures over the past centuries. Species of *Kermes* and cochineal scales were used as a dye source from antiquity to the present. Carminic acid is a natural red dye from the cochineal scale (*Dactylopius* spp.), a family of scale insects that feed on cacti. This dye has been used commercially worldwide since the sixteenth century and was the dominant dye source used in cosmetics, food, medicine, and textile products until its replacement by aniline dyes. The white waxy tests of the Chinese wax scale were used to make wax candles and figurines in China. Also, candles made from the tests of this species were used in religious ceremonies as a symbol of purity. Ground-dwelling margarodids, known as ground pearls, are collected and strung into bracelets and necklaces in several South American countries. For centuries, the secretions from lac scales have been processed into shellac and used to protect a variety of items including furniture, machinery, etc. Also, adult females of the giant scale, *Llaveia axin*, are processed for their "fat" content that is used as a lacquer coating on wood products, especially art and sculpture creations, in Mexico and Central America. The ornate pit scale, *Cerococcus quercus*, was used as a glue source and as a chewing gum by native American Indians of the southwestern U.S. In addition, a few species are effective in suppressing invasive weeds, such as some species of cochineal scales on cacti.

General Morphology

Dramatic sexual dimorphism is particularly exhibited within the scale insects. The adult male's appearance is so different from the adult female that pairing them as a species can be difficult. Because of the diverse differences between the males and females, taxonomists use a different morphological nomenclature to describe the two sexes.

Female development in the more primitive species consists of the egg, first instar (crawler), second instar, third instar, in some species, and adult stage. Although exceptions occur (e.g., Pseudococcidae), females of the more advanced species differ by having the egg, first instar (crawler), second instar, and adult. Adult females are pyriform, subcircular or elliptical, wingless, and usually without any constriction between the head and thoracic regions. Ocelli often are present in species of the more primitive families (e.g., Margarodidae, Ortheziidae, and Phenacoleachiidae). However, the ocelli may be reduced to a slight protuberance, pigmented spots, or completely absent in adult females in the remaining families.

Antennal segments range from zero in Beesoniidae, 1-segmented in several families (e.g., Aclerdidae, Asterolecaniidae, Cerococcidae, Diaspididae, and Phoenicococcidae), to as many as 13 segments in some species of Margarodidae (except Margarodinae) and Phenacoleachiidae. Mouthparts consist of a clypeolabral shield and a labium with species within scale insect families exhibiting a 1- to 4-segmented labium. Two pairs of thoracic spiracles are present in all families; however, species of Margarodidae and Ortheziidae also have submarginal abdominal spiracles. Legs are absent in adult females of several families (e.g., Aclerdidae, Asterolecaniidae, Beesoniidae, Phoenicococcidae, and Diaspididae), but range from 1-segmented stubs (e.g., most Cerococcidae, species of Cryptococcidae with metathoracic plate) to 5-segmented with a tarsal claw in other families. Leg development may be variable among species within some families ranging from absent to 5-segmented legs (e.g., Lecanodiaspididae and Pseudococcidae). When present, the leg types vary from digging in Margarodidae to walking or running in most other families.

Body segmentation is pronounced in the more primitive families (e.g., Margarodidae and Ortheziidae) and in some species of a few advanced families (e.g., Pseudococcidae and Eriococcidae). Segmentation of the cephalothorax is indistinct in most species, but the presence of marginal setae often is used to distinguish segments. Ventrally, the thoracic segments are demarcated by the attachment of the legs, when present, and the location of the spiracles on the mesothorax and metathorax. Segmentation is more visible on the ventral surface of the abdomen than on the dorsum. Segments often are delineated by transverse creases and marginal setae. However, the number of discernible segments often varies among species with two to three segments visible in Phoenicococcidae to eight or nine in Cerococcidae. In diaspidids, the last four segments of the abdomen are fused into one pygidial structure with plates and small lobes on the margin. Apparent segmentation also is reduced in Aclerdidae, Asterolecaniidae, Conchaspididae, Crytococcidae, Kermesidae, and Kerriidae. The vulva is located on the eighth segment, and an anal ring often denotes the terminal segment. The anal ring is covered and protected by a pair of anal plates in Coccidae, while a single plate occurs in Aclerdidae and Cerococcidae. A pair of anal plates with an associated arched anal plate surrounds the anal ring in Lecanodiaspidae and some species of Asterolecaniidae.

Male development consists of the egg, first and second instars, prepupa, pupa, and adult stages. Males are nearly always linear in appearance, possessing prominent cephalic, thoracic, and abdominal regions. Adult males have 9- to 10-segmented antennae, a non-functional mouth, a pair of compound eyes is present in Margarodidae and Ortheziidae, and dorsal and ventral ocelli occur in most species in other families. The thorax of most species contains a pair of mesothoracic wings, metathoracic hamulohalterae (except Aclerdidae), and 5-segmented legs. In some species, wings may be present in one generation and reduced or absent in others. On the abdomen, the aedeagus is distinguished by a distinctive penile sheath with 0–3 pairs of caudal filaments. Adult males do not feed and live only 1–3 days. Adult males resemble aphids and small flies.

First instar nymphs (crawlers) are mobile with well-developed 5-segmented legs, 5- to 6-segmented antennae, and a variety of wax pores and ducts. Each anal lobe terminates with a long anal lobe seta. Sexual dimorphism is visible in the first instar nymphs of several species (e.g., Kuno scale and flat grass scales) representing various families. These differences are evident by the number and arrangement of setae and wax-secreting pores and ducts. Sexual differences in the second instars are generally more pronounced than in crawlers with males being more elliptical than the more ovoid females. The presence or absence of legs among scale insect species is variable. In some species, legs may be present in the males, but absent in the sedentary females. Males often are distinguished by the presence of various ducts and glands, which are usually absent or reduced in the females or appear later in the adult stage.

Protective Test or Scale Cover

One of the more prominent features of the scale insects, including mealybugs, is the development of a protective covering over their bodies. The covering may vary from a powdery secretion to a complete soft or hard waxy coating over the body. The wax is produced by an assortment of pores and ducts on the derm, and the covering is often referred to as a test or scale cover. In some families (e.g., Pseudococcidae), a variety of protective coverings occur ranging from a coating of white waxy powder to long wax strands. In species of Ortheziidae, the body is covered by a series of waxy plates. The Kerriidae aggregate and secrete a flexible lac compound for protection. Members of the genus *Cerococcus* also tend to aggregate close together resulting in wax production completely covering their bodies and sections of adjacent scales. The species within the families Asterolecaniidae and Lecanodiaspididae secrete a papery to waxy test with the individual located in a pit or depression on its host. Many species of Eriococcidae secrete a felt-like sac completely enclosing the female. The Coccidae have a variety of test forms ranging from felt-like in *Eriopeltis*, papery in *Lecanium*, waxy in *Ceroplastes*, to cottony in *Pulvinaria*. Females of Beesoniidae develop within galls and no longer produce tests to cover their bodies. In several species of Margarodidae, the waxy excretions that flow over and cover the body aid in the development of a cyst-like covering.

The protective test or waxy covering over the body allows most species to maintain a favorable humidity level, while preventing rapid temperature changes. The test also functions as a protective barrier against predators and parasitoids. The tests of several species provide protection by blending in with the color and texture of the bark on the plant host and are most often in shades of gray or brown. However, some species display ornate shapes and colors. A stellate appearance is common with waxy extensions projecting from the margins or from the complete test. A number of species in various families are covered by individual wax strands presenting the appearance of a cotton ball. The colors of the waxy scale covers range from hues of brown to a brilliant white to rosy pink to vibrant yellows. The tests of several species display a disruptive pattern. For example, some soft scale species are vivid red to crimson with white zebra-like markings (e.g., calico scale), and others have dark backgrounds with series of irregular white spots to break up the outline of the body, perhaps making them less conspicuous to parasitoids and predators. Some mealybugs aggregate in small groups and appear berry-like, while species of Kermesidae resemble galls or plant buds.

Life Cycle and Behavior

The life cycle is quite varied among the Coccoidea depending upon the family and species. Development also differs between the female and the male. Most species have one or two generations per year, but some have multiple generations. A number of polyphagous species have two or more overlapping generations outdoors, but reproduce continuously in greenhouses. Generally, all stages of development are present throughout the year in species with multiple generations. Developmental time for the various stages is usually influenced by temperature and humidity. However, the development time for a number of species may take several years. For example, the spruce mealybug has a 4-year life cycle that involves multiple migrations annually from the foliage to bark crevices or the duff at the base of the tree. The Chilean margarodid *Margarodes vitium* may remain in a cyst-like state for 7 or 8 years and only after heavy rains emerges as adult females. This adaptation may provide this species the ability to survive periods of extended droughts.

Although most scale species reproduce bisexually, some Coccoidea exhibit parthenogenetic and hermaphroditic reproduction. Adult females that possess protective tests covering their bodies usually have a sedentary nature and a limited active courtship. Some species (e.g., San Jose scale) are known to produce sex pheromones to attract males. The mobile males must locate and mate with females on the host plant. Upon finding a receptive female, the male of Diaspididae inserts the stylus under the pygidial region with the hind legs assisting in the insertion. Although adult males are ephemeral, living only about 1–3 days upon emergence, they can fertilize several females during this period. Virgin females of the San Jose scale are known to exert their pygidia from beneath their tests and slowly move it back and forth in a short arc. During this activity, females probably release sex pheromones to attract males.

Some females (e.g., Pseudococcidae and Dactylopiidae) actively seek out males for mating. In a species of *Pseudococcus*, the two sexes live apart during the winter with the female inhabiting the smaller branches and the males, still in the pupal stage, on the trunk of the host tree. The adult females become active during early spring and travel down the branches to the trunk where they continue their search for males. Adult females usually precede the emergence of males by several days. After mating, females return to the branches, construct their ovisacs, and lay their eggs. In the fall, the nymphs separate and the males descend to the tree trunks to pupate. A similar behavior is found in northern red oak kermes. Males travel down to the lower levels of the tree trunk, and occasionally leave the tree to pupate, while females remain on branches in the canopy. Upon adult emergence, males fly into the tree canopy to locate and mate with females.

Females protect the eggs during embryonic development, and also the newly hatched crawlers, by laying them under the scale cover or in an ovisac. During the course of egg deposition, the bodies of females in several families (e.g., Asterolecaniidae and Diaspididae) shrivel up to eventually occupy only the anterior one-third of the waxy test. In several species of Coccidae and Kermesidae, the female's exoskeleton hardens providing protection for the eggs against adverse environmental changes and many natural enemies. Most species lay eggs, producing from less than a few dozen to over five thousand eggs. A variety of species in several families (e.g., Margarodidae, Ortheziidae, and Coccidae) deposit their eggs in an ovisac. The type of ovisac and the number of eggs produced vary with the species. The ovisac may completely cover the insect's body, be reduced to cover only part of the abdomen, or be positioned ventrally. Females of Ortheziidae produce a long, cylindrical ovisac for egg deposition. Several species of Eriococcidae and some Coccidae make a fine structured felted sac to retain the eggs until hatching. One of the strangest means of protecting the eggs in some species (e.g., Margarodidae) is the development of a deep invagination of the integument forming a cavity. Females that produce eggs that hatch within their bodies, such as the pineapple mealybug, hairy mealybug, and tuliptree scale, shield the crawlers for a short period by covering them with their abdomens and tests. Most species overwinter in the egg stage (e.g., oystershell scale), while others overwinter as second instars (e.g., European fruit lecanium), or in the adult stage (e.g., golden oak scale).

Parthenogenesis has been documented in several species (e.g., golden oak scale and brown soft scale). It has been speculated that parthenogenesis favors a higher reproductive potential for sedentary species in harsh environments. Some species exhibit life cycles that include a combination of bisexual and parthenogenetic reproduction (e.g., oleander scale and oystershell scale). One of the rarest forms of reproduction is hermaphroditism that occurs in a few species, such as the cottony cushion scale.

A mutualistic relationship exists among species of several scale insects and ants. In exchange for honeydew, a soft scale or mealybug population may be attended and protected by ants, or physically taken within the ant's tent or nest where they are not only protected from parasitoids and predators, but also against adverse environmental changes and fungal infestations. For example, tuliptree scales often are found in association with ants that construct a paper-like tent over a group of adult females protecting them from parasitoids and predators. When leaving the nest on the nuptial flights, females of the ant *Acropyga paramaribensis* always carry a fertilized rhizoecus coffee mealybug female in their mandibles. These mealybugs are maintained within a special chamber in the nest where they are cared for, and in return, provide honeydew to the ants when stroked. Another remarkable way of dispersal occurs in species of *Hippeococcus* that have long raptorial legs and digitules for clinging to attending *Dolichoderus* ants. When disturbed, they cling to the ants and are carried into their nests. The presence and active associations of ants with scale insects and mealybugs result in an increase in their numbers, and a subsequent reduction in the scale insect populations following the removal of the ants. Because ants are so protective, some predators have adapted by mimicking the appearance of their prey to move freely about and feed on mealybugs, such as the larvae of the lady beetle, *Cryptolaemus montrouzieri*.

Host Selection and Distribution

The age of the Coccoidea is placed in the Cretaceous Period which basically coincides with the time angiosperms became the dominant plant form. This adaptation to the angiosperms was so successful that the majority of present day species cannot leave the host plant and survive. Only a few species are found on gymnosperms. Species may be monophagous (e.g., sweetgum scale), oligophagous feeding on plants in one genus (e.g., kermes oak scales on *Quercus*) or one plant family (e.g., flat grass scales primarily on Gramineae grasses), or polyphagous (e.g., juniper scale on Cupressaceae and Taxodiaceae). Members of some families (e.g., Pseudococcidae) feed on both deciduous and conifer hosts with some being polyphagous, while others are oligophagous or monophagous. Most species feed on a variety of plant species within a given generic or family level. Although most coccid species are polyphagous, members of several families have specific plant associations. These include members of Dactylopiidae on cacti, Halimococcidae on palms, most Kermesidae that feed on oaks, and Phoenicococcidae on palms. Also, most species of Aclerdidae, some Coccidae and Pseudococcidae feed on grasses, while the eriococcid genus *Apiomorpha* feeds exclusively on *Eucalyptus*. A number of species prefer particular habitats. Several members of Ortheziidae are found in wet meadows, mosses, and in the soil of slopes and forest areas, while the boreal ensign scale commonly is found in leaf litter.

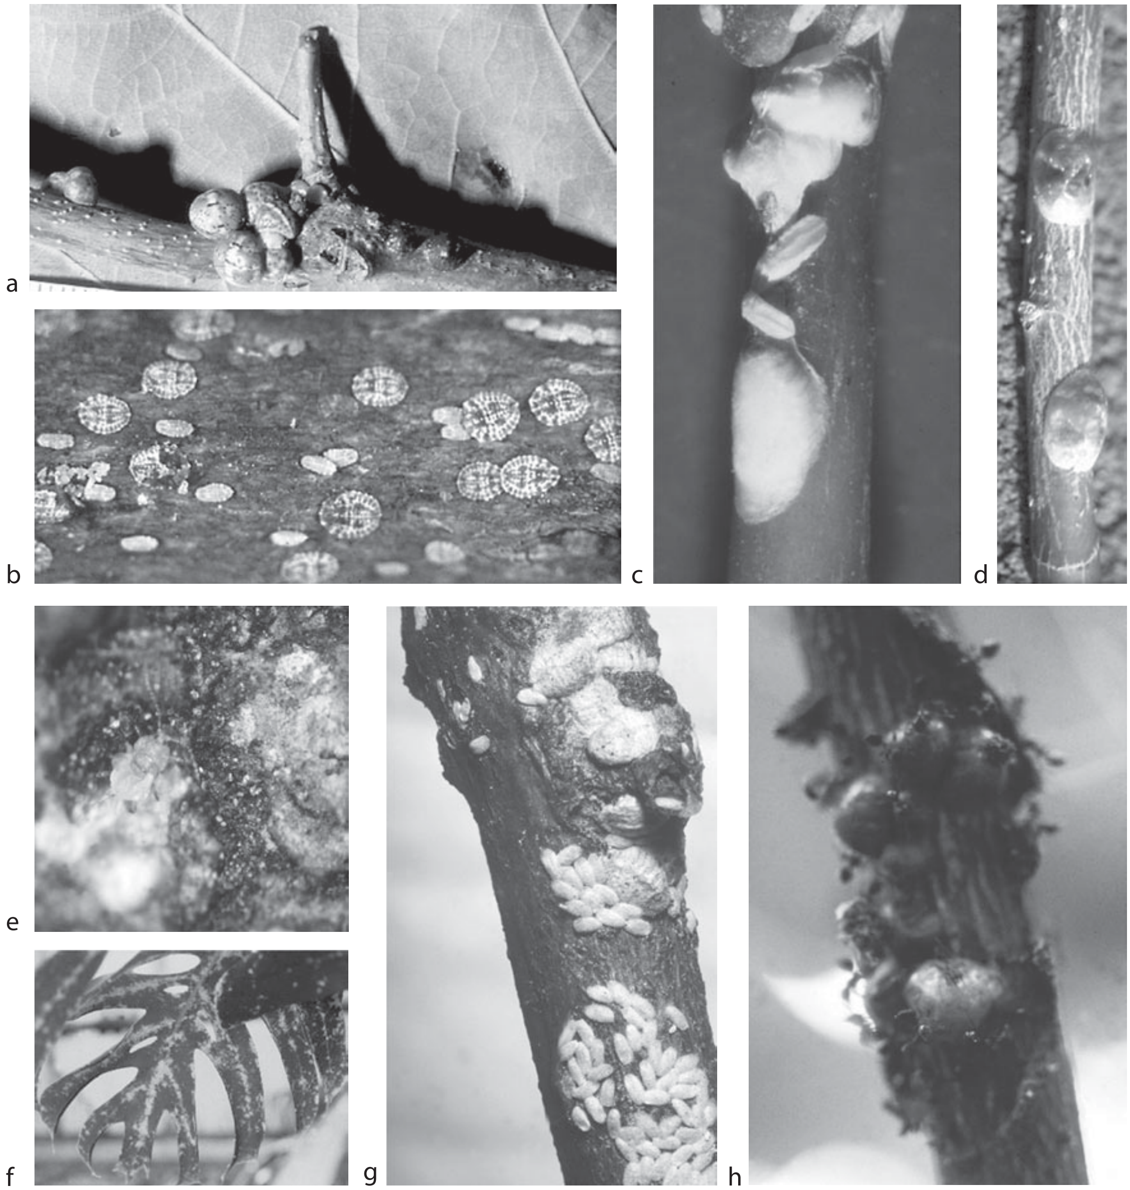
Species of several families actively seek out the host in many instances. For example, species of Margarodidae, Ortheziidae, and Pseudococcidae are mobile throughout their various life stages, and are able to walk from area to area on a given host or even to different hosts. Several species overwinter in the detritus or in cracks on the trunk of a tree and migrate the following spring to the stems and fruits to feed. For those sedentary adult females, the problem of finding food is resolved by the female ovipositing on the host plant.

The mobile crawler is the usual stage that finds a suitable host and feeding site. Dispersal takes place primarily through the movement of the crawlers from tree to tree, by wind, or on the bodies of other insects, spiders, mites, birds, and mammals. Within a day or two after hatching, crawlers migrate, either by walking or with the aid of wind, to new feeding sites on the host plant or adjacent plants. Upon locating a suitable site, crawlers settle, insert their stylets, begin to feed, and continue to mature. Once they establish their position on the host, an adequate food supply is available throughout their development. Species that infest annual plants are unique because their hosts are present for only a short period of the year. Several species have adapted some unusual development patterns. For example, the male crawlers often settle on the leaves, while females tend to settle more often on the twigs (e.g., black willow scale). A common habit exhibited by species in a number of families is for a cluster of male crawlers to settle and develop around a female or group of females increasing the potential of finding a mate upon maturity (e.g., walnut scale). In those species where the crawler settles and develops on the leaves, the leaf veins often are the preferred sites. There is usually a progressive migration back to the stems or twigs by members of the overwintering generation in species with multiple generations. The distance covered on the host plant may vary from species to species depending upon the number of generations per year. While some species settle on specific areas of the host, others (e.g., euonymus scale) do not appear to differentiate between the leaves or stems as preferred sites. Many species commonly infest the underside of limbs and stems of host plants that may protect them from adverse weather conditions, exposure to direct sunlight, and predators. Successive generations force specimens to disperse to other areas to obtain feeding sites that eventually result in a heavy encrustation of the branches.

Several species are known to select multiple locations on the host. The position depends upon the time of year, available space, and their stage of development. The solenopsis mealybugs feed in the crown of their host in the summer, but migrate onto the roots before winter. Members of Eriococcidae may be found on the upper or lower leaf surfaces of one or several hosts, in the axils of leaves and smaller stems, on the surface of smaller stems, on the bark of larger branches, or on the main tree trunk. Sugarcane mealybug crawlers actively walk to the tops of stalks where the developing new tissue allows for easy insertion of their stylets. The females aggregate around the nodes of the stalk. In early spring, they may go to the leaf axil, but development time is slow until they later migrate to the stalks. Orientation of first instars on the underside of leaves and on stems does not appear to be at random; for instance, cottony cushion scales position themselves with their heads upward on the stems. Aside from the numerous species that feed above ground, an enormous fauna of subterranean species exists that feed on the roots of plants. These under-explored niches hold the potential for the discovery of new species, even in North America.

Morphological changes in body shape and size often are influenced by population density and site location. In crowded conditions, the tests usually develop abnormally around other females or around projections of their host (oystershell scale). The position and location on the host often have an effect on the shape of the individual. Species that settle on or between the leaf sheaths and stems of grasses exhibit a dorso-ventrally flattened appearance (e.g., *Aclerda*, *Antonina*, and *Chaetococcus*). The immature azalea bark scale, *Acanthococcus azaleae*, often settles between the petiole and branch at the axillary bud, and frequently acquires a wedge-shaped appearance (Fig. 12). Kermesids that reside on the limbs of their host are gall-like or spherical. Host-induced variation results in shape, size, and color variations among populations (e.g., European fruit scale).

Population density is affected by several biotic and abiotic factors. Seasonal abundance is highest in the summer and fall, and declines during the winter months. Mortality is attributed to adverse weather conditions, such as heavy rains washing crawlers off the host, high relative humidity, fungal development on the test and insect, or hot and dry conditions. In some instances, drier environments produce more females, while more moist environments produce more males (e.g., citrus mealybug). Distributional patterns of species in several families imply macroenvironmental preferences as to the elevation, regions inhabited, and climatic conditions. The number of species and family taxa tend to be fewer as the elevation increases. Microenvironmental preferences are demonstrated by the host plants selected and the area and position taken by the species on the host. It is postulated those increases in the population size of endemic species



Scale Insects and Mealybugs (Hemiptera: Coccoidea), Figure 12 Some scale insects: (a) *Allokermes kingi* (Cockerell) on *Quercus rubra* L. (Kermesidae); (b) *Lecanodiaspis prosopidis* (Maskell) on *Aescules* sp. (Lecanodiaspididae); (c) *Chionaspis salicisnigrae* (Walsh) on *Salix nigra* Marsh. (Diaspididae); (d) *Neolecanium cornuparvum* (Thro) on *Magnolia acuminata* L. (Coccidae); (e) *Quadraspidiotus juglansregiae* (Comstock) on *Cornus floridensis* L.: male and female (Diaspididae); (f) *Pseudococcus longispinus* (Targioni Tozzetti) on *Dieffenbachia* sp. (Pseudococcidae); (g) *Acanthococcus quercus* (Comstock) male and female clusters on *Quercus borcalis maxima* Ashe. (Eriococcidae); (h) *Toumeyella liriodendri* (Gmelin) attended by ants on *Liriodendron tulipfera* L. (Coccidae).

in disturbed habitats are in part due to air pollution and lower levels of natural enemies.

For many species, favorable environmental conditions often result in several generations of scales within one season. The movement of the crawlers is directly affected by temperature with increased activity as the temperature rises. The length of time the crawlers remain under the female ranges from a few hours to 2–3 days depending on the temperature. Newly emerged crawlers remain under the test on cool, cloudy days, but leave immediately during warmer days. The ephemeral adult males are feeble fliers and more often rely on walking over the host plant for a successful encounter with a female. Their range is generally believed to be restricted to that of the population; however, some males in flight are carried to other parts of the host plant or to other plants. In those sessile stages where individuals retain their legs, a short mobile period may occur between molts. The degree of mobility is dependent on the flexibility of the test that extremely limits the distance they can travel.

Control

The transport of exotic species from one country to another is enhanced by the international trade in plants and fruits. As a result, several exotic species have entered the United States on imported plants. Many of these species are destructive and pose substantial threats to native trees and shrubs, as well as plants grown in commercial greenhouses. Monitoring plants for ant activity, sooty mold growth, or abnormalities in color and structure of stems and leaves can help locate scale insect infestations in landscape and plant production systems. Several chemicals are available for use against pest populations with the most effective results obtained when applied against the emerging and unprotected first instars (i.e., crawlers). Infestations of house plants and shrubs around the house may be controlled by handpicking or spraying with soapy water, insecticidal soaps, or oils. Several natural enemies including parasitic wasps primarily in the families Encyrtidae and Eulophidae, and predators in the families Coccinellidae, Anthribidae, and Nitidulidae, also are effective at maintaining pest populations at low levels. To obtain the most effective control of pest species, identification of the species or family groups is essential. A key to identify the families in the U.S. is provided.

Key to Families of Coccoidea in the U.S. (Modified from Kosztarab, 1996)

1 Abdominal spiracles present 2

– Abdominal spiracles absent 3

2(1) Anal ring distinct, with band of pores and 6 setae; eyes usually stalked; antennae 3- to 8-segmented ....Ortheziidae

– Anal ring reduced, with no pores or setae; eyes rarely stalked; antennae 1- to –13-segmented ....Margarodidae

3(1) Anal opening covered by 2 two triangular anal plates (except *Physokermes* with one plate); abdomen with a well-developed anal cleft … ……………………........................... Coccidae

– If anal plate present, only one cover over anal opening (although sclerotized plates lat eral of anal opening may be present); anal cleft, if present, not as well developed, as in Coccidae.. 4

4(3) Caudal margin with furrows; usually under leaf sheaths of grasses and reeds… Aclerdidae

– Caudal margin without furrows and ridges; habitat and host variable 5

5(4) Cluster pore plate present below each posterior thoracic spiracle; anal ring surrounded by short and stout setae.......................Cryptococcidae

– Cluster pore plate absent; anal ring not surrounded by setae 6

6(5) Dorsal spine on abdomen; with dorsal brachial plate and tube; anterior spiracle larger than posterior .... Kerriidae

– Dorsal spine on abdomen absent; without dorsal brachial plate and tube; spiracles similar in size 7

7(6) 8-shaped pores present on dorsum 8

– 8-shaped pores absent from dorsum.........11

8(7) 8-shaped pores on dorsum and in a submarginal band on venter; ventral tubular ducts scattered over entire body; antennae 1- to 9-segmented; on various hosts..................... 9

– 8-saped pores restricted to dorsum; ventral tubular ducts form a submarginal band around body margin; antennae 5-segmented; on Fagaceae only .... Kermesidae

9(8) Tubular ducts with inner filaments; antennae 1- to 9-segmented; with cribiform plates.... 10

– Tubular ducts without inner filaments; antennae 1-segmented; without cribiform plates ....Asterolecaniidae

10(9) Antennae 1-segmented, with an associated cluster of 5- to 7-locular pores; with sclerotized triangular plate lying over anal opening; tubular ducts without constriction on outer ductile .... Cerococcidae

– Antennae 7- to 9-segmented, without associated 5- to 7-locular pore cluster; with arched and anal plates around anal opening; tubular ducts with constriction on outer ductile .... Lecanodiaspididae

11(7) Usually with dorsal ostioles, cerarii, ventral circuli, and trilocular pores; anal ring with inner and outer rows of pores.. .... Pseudococcidae

– Without dorsal ostioles, cerarii, ventral circuli, and trilocular pores; anal ring variable; tubular ducts invaginated 12

12(11) Terminal abdominal segments fused into a pygidium; anal opening simple; body covered with thin, hard shieldlike test, with exuviae of previous instars 13

– Terminal abdominal segments not fused to form a pygidium; anal opening often setiferous; test not as above or body covered by waxy powder or strands 4

13(12) Antennae 1-segmented; labium 1-segmented; legs absent; without dermal slits on venter ....Diaspididae

– Antennae 3- or 4-segmented; labium 2-segmented; legs present; with dermal slits on venter .... Conchaspididae

14(12) 8-shaped tubular ducts on dorsum and ventrum; anal ring reduced, without pores but with 2 minute setae; antennae 1-segmented; legs absent .... Phoenicococcidae

– 8-shaped tubular ducts absent; anal ring normally with pores and setae; antennae well developed; legs present 15

15(14) Without dorsal clusters of 3- to 5-locular pores; cruciform pores usually present; on hosts other than Cactaceae .... Eriococcidae

– With dorsal clusters of 3- to 5-locular pores; cruciform pores absent; only found on Cactaceae .... Dactylopiidae

Scaly Crickets

A subfamily of crickets (Mogopistinae) in the order Orthoptera: Gryllidae.

► Grasshoppers, Katydids and Crickets

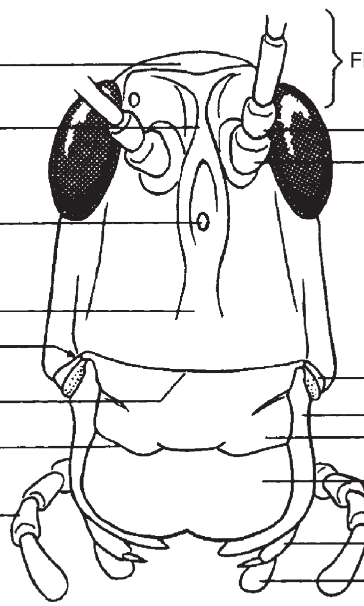
Scape

The basal segment of the antenna (Fig. 13).

► Antennae of Hexapods

Scarabaeiform Larva

A larval body form resembling a scarab beetle larva (white grub). Characteristics include hairy,



Scape, Figure 13 **Front view of the head of an adult grasshopper, showing some major elements.**

thick bodied, well-developed thoracic legs, the absence of prolegs, and C-shaped in overall body form. This also is known as scarabaeoid. It is found in the beetle families of the superfamily Scarabaeoidea.

Scarabaeidae

A family of beetles (order Coleoptera). They commonly are known as scarab beetles.

► Beetles

Scarab Beetles (Coleoptera: Scarabaeoidea)

RONALD D. CAVE[1], BRETT C. RATCLIFFE[2]
[1]University of Florida, Ft. Pierce, FL, USA
[2]University of Nebraska, Lincoln, NE, USA

The superfamily Scarabaeoidea is one of the largest and most diverse superfamilies of Coleoptera, including over 35,000 described species and 2,500 genera worldwide. Based on studies of insect diversity, it is estimated that the Scarabaeoidea may include up to 50,000 species. Some of the most beautiful and largest insects on Earth belong to this superfamily of beetles. Of all the beetles, scarabaeoids are among the best known because of their beauty, fascinating life histories, and economic importance. In the Nearctic region, the taxonomy of most scarabaeoids is now fairly well known although there remain a few areas of uncertainty.

Scarab beetles are adapted to most habitats, and they can be fungivores, herbivores, necrophages, coprophages, saprophages, and sometimes carnivores. They are widely distributed around the globe, even living in the Arctic in animal burrows. Some scarabs exhibit parental care and sociality. Some species live in close association with ants (myrmecophiles) or termites (termitophiles). Many possess extravagant horns, others are able to roll into a compact ball, and still others are highly armored for inquiline life. A very few are occasionally agricultural pests that may destroy crops and turf, while others are used in the biological control of dung and dung flies.

Morphology and Development

Adult scarabs range from 2 to 160 mm in length. The robust body form may be ovate, obovate, quadrate or cylindrical (Figs. 14 and 15). Color varies from dull brown to black to brightly metallic green, blue, gold, or silver (e.g., *Chrysina strasseni*); many species have bright color patterns of yellow, red, or orange (e.g., *Gymnetosoma stellata*). Coloration is due to pigments present in the cuticle and/or the cuticle's microstructure that absorbs and reflects different light waves. The integument may be wholly glabrous or covered with dense hairs or scales. Antennae are 7- to 12-segmented with a 3- to 8-segmented, asymmetrical, usually lamellate club (e.g., *Polyphylla petiti*). The head is not covered by the prothorax which is often highly modified for burrowing (with large coxae that are strongly transverse or conical and projecting below the prosternum). The head and/or pronotum may have horns (e.g., *Megasoma elephas*, *Spodistes mniszechi*, *Phanaeus eximius*), usually present only in males. The protibia has 2–3 teeth or is serrate on the outer margin. The tarsal formula is 5–5–5; rarely, the anterior tarsi are absent. The hind wings have reduced venation, but are well developed with a strong intrinsic spring mechanism for folding. Tergite 8 forms a true pygidium not concealed by tergite 7.

Larvae are C-shaped, with a distinct head capsule (e.g., *Dynastes maya*). Antennae are 4-segmented and ocelli are present or absent. Six thoracic legs are present and are 2 or 4-segmented, but in the Passalidae the hind legs are reduced to a stub with apical teeth that rub against the mesothoracic coxae for stridulating. Abdominal segments 1–6 or 7 usually have three annuli, each with one or more transverse rows of setae. Body color varies from pale yellow to white, thus giving them the name white grubs. Larvae usually pass through three instars and completion of development may take 1–3 years. A short period of pupation follows during which the larva transforms to the adult insect. Emergence from the pupa occurs after a specified time or in reaction to environmental cues such as rainfall or temperature.

Taxonomic Composition

Significant changes have occurred in the classification of the Scarabaeoidea during the last 20 years. These changes are a result of intensified study of the family groups using traditional morphological evidence combined with increasingly insightful molecular studies. Monophyly of the superfamily Scarabaeoidea is well founded and undisputed. However, the hierarchical level of families and subfamilies within the Scarabaeoidea is in disarray and remains unresolved. Underlying the classification problem is the fact that our classification constructs are 200 years old and pre-date evolutionary theory. Thus, some groups within the superfamily are not monophyletic lineages; instead, they are groups that were created historically because they superficially resembled each other. In most US literature prior to the 1970s, the Scarabaeoidea included three families: Passalidae, Lucanidae, and Scarabaeidae. Phylogenetic research indicates, however, that the family Scarabaeidae (in the traditional sense) is not a monophyletic group. Accordingly, most workers now follow the 12-family system that places emphasis on the differences that separate taxa rather than the similarities that unite them. The classification of Scarabaeoidea is summarized as:

- Order: Coleoptera
  - Suborder: Polyphaga
    - Series: Scarabaeiformia
      - Superfamily: Scarabaeoidea
        - Family: Lucanidae
        - Family: Diphyllostomatidae
        - Family: Passalidae
        - Family: Glaresidae
        - Family: Trogidae
        - Family: Pleocomidae

Family: Geotrupidae
Family: Belohinidae
Family: Ochodaeidae
Family: Hybosoridae
Family: Glaphyridae
Family: Scarabaeidae

Lucanidae

Commonly called stag beetles, the species of this family number about 1,000 worldwide. Most species occur in Asia. They are associated with decaying wood and logs in coniferous and deciduous forests. Adults vary from <1 to 9 cm in length. Males of several species, e.g., *cyclommatus imperator*, possess greatly enlarged, curving mandibles that are used in combat with male rivals.

Diphyllostomatidae

This is a small family of only three species in one genus, all occurring in California. Females have reduced eyes and wings.

Passalidae

This family of insects commonly called bess beetles (e.g., *Passalus punctiger*) is found on all continents except Antarctica but is most speciose in the tropics. There are over 500 described species divided between two subfamilies. All life stages live in well decayed logs and stumps. Adults excavate galleries in which eggs are laid and larvae develop. Larvae and adults form subsocial groups and communicate by stridulation. Adults feed the larvae chewed wood mixed with saliva, and both stages consume adult feces to enhance the microflora in their digestive system. The elongate and dorsoventrally flattened body, sublamellate antennal club, and deeply emarginate mentum distinguish adult passalids from all other scarabaeoids.

Glaresidae

Fifty species in a single genus constitute this family found worldwide except Australia. Adults are small (2.5–6.0 mm) and inhabit arid and sandy regions. Nothing is known about the larval biology.

Trogidae

This worldwide family consists of approximately 300 species in four genera. Excellent revisionary, larval, and phylogenetic studies are available for this group. The pronotum and elytra of adults is warty, and brown to gray to black in color but usually heavily encrusted with dirt. Adults and larvae live in the dried remains of dead animals or in nests of birds and mammals, where they feed on hair, feathers and skin. For this reason they have been given the common name of hide beetles. Adults will also feed on dung.

Pleocomidae

This family of large (16–45 mm) and ventrally pubescent beetles is geographically restricted to western North America from Washington to Baja California. It consists of a single extant genus encompassing 26 species. Larvae are subterranean and feed on tree roots. Adults emerge during fall or winter rains to mate and disperse. Only males are fully winged and capable of flying. Due to their propensity for increased activity during precipitation, these scarabs are referred to as rain beetles.

Geotrupidae

Excellent monographs are available for identifying the approximately 620 species and 68 genera of Geotrupidae, and these provide the foundation for addressing relationships within this group. However, the classification of the family has been the topic of debate. Diversity of larval and adult morphology provides evidence that the group includes two distinct lineages. Some taxonomists separate one lineage as a distinct family, Bolboceratidae. Food resources for adults and larvae include decomposing plant or animal material, dung, and fungi. Adults will provision subterranean burrows with food for larvae, but do not tend the larvae. Their excavating behavior has earned them the common name earth-boring scarab beetles.

Belohinidae

This family consists of a single species, *Belohina inexpectata*, which lives in southern Madagascar. This rare species is known by only a few specimens.

Ochodaeidae

This small but widespread family contains ten extant genera and about 80 species. Adults are small (3–10 mm), capable of stridulating, and primarily active at night. Sandy areas are the preferred habitat, so these beetles are commonly called sand-loving scarab beetles. One species has been found in association with detritus deposits of harvester ants. Nothing else is known about the biology of adults and larvae.

Hybosoridae

This family is divided into five subfamilies represented by more than 220 species placed in 35 genera. Adults of Anaidinae, Hybosorine, Liparochrinae, and Pachyplectrinae feed on vertebrate and invertebrate carrion, dung, fungi, or turf, thus they are called scavenger scarab beetles. *Hybosorus illigeri* is known to be predaceous. Larvae are found in decomposing plant material and are capable of stridulation. Adults of Ceratocanthinae are able to roll themselves into a ball by deflexing their head and pronotum ventrally, and are therefore called pill scarab beetles. Adults and larvae occur on bark and branches of dead trees and vines, on fungi, in passalid burrows, in wet tree holes, and in association with termites and ants.

Glaphyridae

Adults of this family are active day fliers, many of which are brightly colored and hairy, thus resembling bees and bumblebees. Larvae live in riparian and coastal dunes, feeding on decaying leaf litter and detritus in the sand. *Lichnanthe vulpina* is a pest of cranberry bogs in North America. The family includes six genera and about 70 species worldwide.

Scarabaeidae

Members of this, the sixth largest family in the order Coleoptera, are popular beetles due to their large size, bright colors, and interesting natural histories. Early Egyptians revered the scarab as a god, Jean Henri Fabre studied their behavior, and Charles Darwin used observations of scarabs in his theory of sexual selection. Species of scarabs are important agricultural pests, are used in the biological control of dung and dung flies, are pollinators, and have been used as bioindicators of high-quality forest habitat. Classification of the family is variably resolved. The classification of the world Dynastinae is fairly well established. Most Melolonthinae, Rutelinae, and Cetoniinae remain relatively poorly known taxonomically, and many Neotropical genera cannot be reliably identified. Classification of the Scarabaeinae and Aphodiinae is fairly well established, although the Aphodiinae in particular have recently been the subject of extensive taxonomic inflation. The taxonomy of the North American scarab beetles is relatively stable, although no one volume is available for identification to species. Regional works are sometimes the best sources for identification of scarabs.

There are currently about 2,000 known genera and over 31,000 described species of Scarabaeidae. Aphodiinae and Scarabaeinae are widepread, with approximately 6,850 species representing about 22% of scarabaeoids and 25% of Scarabaeidae. The worldwide subfamilies Orphninae, Melolonthinae, Dynastinae, Rutelinae, and Cetoniinae include approximately 20,950 species (about 69% of scarabaeoids and 75% of Scarabaeidae). Three subfamilies (Cretoscarabaeinae, Lithoscarabaeinae, and Prototroginae) are known only from fossils.

Aclopinae

This subfamily contains four genera with 19 known species distributed in Australia, Borneo, and southern South America. Little is known of their ecology and biology. In Australia, adults may be taken at lights, but morphological characters suggest that females may be flightless. No larval stages are described.

Allidiostomatinae

This group contains a single genus with 11 species, all restricted to South America. The ecology, biology, and immature stages of this subfamily are unknown.

Aphodiinae

There are more than 300 genera and at least 3,000 species divided among 11 or 12 tribes comprising this worldwide subfamily. Many species are highly specialized dung feeders (e.g., feces in nests of pocket gophers, prairie dogs, and gopher tortoises), while many others are generalist dung feeders. Some species feed on decaying plant material, often in riparian or littoral habitats. A few species live as inquilines in ant colonies.

Cetoniinae

Twelve tribes containing 510 genera and approximately 4,000 species constitute this subfamily. The adults are referred to as fruit chafers or fruit beetles because they usually feed on ripe or decomposing fruits, but they will feed also on pollen or slime flux. Many species are very brightly colored with metallic reflections or multicolored patterns. The goliath beetles (genus *Goliathus*) of Africa are among the largest insects known.

Dynamopodinae

This group contains a single genus with three species found in central Asia and northern Africa.

Dynastinae

This subfamily is divided into eight tribes containing more than 1,500 known species in 196 genera. It occurs in all major biogeographic regions, but most species live in the tropics, particularly the New World tropics. The adults are herbivores, feeding on fruits, pollen and leaves, while the larvae are consumers of decomposing wood and roots. Larvae of a few species of *Tomarus* and *Cyclocephala* are pests of turf grass and crops. In English they are called white grubs, but in Spanish they are referred to as "gallina ciega" or "joboto." The males of several species have prominent and spectacular horns on the head and/or prothorax, which have earned them the vernacular names "hercules," "rhinoceros," "elephant," "unicorn," and "atlas" beetles.

Euchirinae

This subfamily contains three genera and 16 species of mostly Asian distribution; a single species each are found in Turkey and Cyprus. Their common name is long-armed chafers due to the very long front legs of the males.

Melolonthinae

The members of this large and diverse subfamily are divided into 26 tribes encompassing approximately 750 genera and nearly 11,000 species. Adults are usually leaf or pollen feeders, but some will consume flowers and ripe fruits. The larvae live in the soil feeding on roots and other organic matter. In North America the adults are referred to as May beetles or June bugs and the larvae as white grubs. In Mesoamerica, the adult is called "ronrón" and the larva "gallina ciega" or "joboto". The larvae of several species of *Phyllophaga* are serious pests in crops and nurseries.

Orphninae

This subfamily includes about 80 species divided into two tribes: the New World Aegidiini with four genera and the Old World Orphnini with ten genera. Adults of some species were found feeding on decaying banana stems in coffee-cacao plantations. The larva of one species was found under rotten logs.

Pachypodinae

This is a small subfamily of only one genus and three species occurring in Europe.

Phaenomeridinae

This is an African subfamily of only 12 species split between two genera.

Rutelinae

Six tribes containing 200 genera and approximately 5,000 species worldwide constitute this subfamily. The adults are phytophagous, feeding on leaves, flowers, and pollen; larvae feed on roots and decomposing plant material. A few species are pests of turf grass and crops. The males of some species have enlarged hind legs with robust teeth for grasping the female during copulation. The genus *Anomala*, with over 1,000 known species, is one of the largest genera of animals. The jewel scarabs, members of the genus *Chrysina*, are a favorite among collectors because of their bright colors.

Scarabaeinae

This subfamily is divided into 12 tribes with 234 genera and more than 5,000 species. Members of this group are for the most part coprophagous, but several species also consume carrion, mushrooms, rotting fruit, and other decomposing plant material. The males of some species have long cephalic horns and other ornate protuberances arising from the pronotum.

Ecology

Scarab beetles live in a diverse array of microhabitats and consume a wide range of food. Adults and larvae of many species feed on dung, carrion, hides, feathers, or decaying plant material, but several species have evolved the ability to utilize unique resources. A great number of species feeding on dung are specialists, feeding only on one type of vertebrate dung (e.g., deer dung, elephant dung, sloth dung), whereas many other species are generalist dung feeders. Some species will feed on both dung and carrion. Many species of *Aphodius* (Aphodiinae) live in the nests of prairie dogs and pocket gophers. *Auperia denominata* (Aphodiinae) in Florida lives in tree squirrel nests. In the southeastern USA, *Onthophagus polyphemi* (Scarabaeinae) inhabits the subterranean tunnels of gopher tortoises. A number of species have developed the habit of feeding on fungi. Species of *Scarabaeus*, *Sceliages*, *Onthophagus*, and *Canthon* (all Scarabaeinae) have been observed using injured or dead millipedes for food whereas at least two species of *Deltochilum* (Scarabaeinae) (e.g., *Deltochilum lobipes*) are known to actively prey on live millipedes. A few species of Hybosoridae will feed on earthworms. Myrmecophilous scarabs are not uncommon. Adults and larvae of *Coelosis biloba* (Dynastinae) and *Ptichopus angulatus* (Passalidae) occur in leaf-cutter ant nests, where the larvae eat not only the decaying leaf material accumulated by the ants but also the fungus cultivated by the ants. Species of *Cremastocheilus*, *Genuchinus* (both Cetoniinae) and *Euparia* (Aphodiinae) also live in ant nests. Less common are the termitophilous scarabs, e.g., *Afroharoldius ennearthrus* from the Congo and *Scarabatermes amazonensis* (both Scarabaeinae) from Colombia. Adults of the South American genus *Zonocopris* (Scarabaeinae) feed on the mucosal secretions from terrestrial snails.

The feeding habits of phytophagous species are quite variable. Most adults of Dynastinae, Melolonthinae, Rutelinae, and Cetoniinae are herbivores consuming leaves, flowers, fruits, and pollen. *Chrysina quetzalcoatli* (Rutelinae) and *Polyphylla decemlineata* (Melolonthinae) feed on fresh pine needles. Species of *Podischnus* (Dynastinae) excavate burrows in the stalks of sugarcane and bamboo. Adults of many *Cyclocephala* (Dynastinae) species are often found within the spathe of aroids where they feed on the spadix. Some species readily feed on rotting fruits or the slime flux emanating from tree wounds. The larvae of these herbivorous adult scarabs feed, for the most part, on roots, decaying wood, or other organic matter accumulated in the soil, in tree holes, or in epiphytic plants. Their digestive system holds symbiotic microbes which aid in the digestion and assimilation of nutrients from cellulose and lignin.

Behavior

The adults of most species of scarab beetles are nocturnal or crepuscular and are readily attracted to lights. Some species, such as those of *Heterogomphus* and *Strategus* (Dynastinae), are active soon after dusk then are no longer seen at lights. On the other hand, *Golofa pizarro* (Dynastinae) will have a peak flight activity for only an hour around midnight, whereas species of *Dynastes* (Dynastinae) and *Amithao* (Cetoniinae) are most frequently active in the hour or two before dawn. Some species of *Chrysina* (Rutelinae) have dual flight activity periods, one in early evening and another during the pre-dawn hours. *Chrysina spectabilis* (Rutelinae) and species of *Viridimicus* (Rutelinae) and *Pleocoma* (Pleocomidae) fly more actively during a rain shower. The colorful cetoniine species and some scarabaeines are diurnal in their activity.

Feeding behavior of dung beetles is classified into four types. Feeding without burial is done by dwellers (Type 1) and is practiced by coprophagous species of Aphodiinae. Tunnelers bury dung without overland transportation (Type 2) but dig their tunnels before provisioning them. Tunnels are excavated below or very near the primary dung source. Dung is removed from the primary source and carried or dragged into the tunnel by backing into the entrance. In overland transportation without formation of a ball (Type 3), tunnels are excavated separate from the primary dung source and dung is carried or dragged to the burrow by either grasping it with the front legs and walking backwards, rolling the food source by walking forward and pushing with the head and front legs, or grasping the dung with the front tibiae and running forward using only the middle and hind legs. Overland transportation with formation of a ball (Type 4) consists of forming a portion of dung into a round mass, rolling it a distance from the primary dung source by pushing backwards with the middle and hind legs or front and hind legs, then burying it intact. Practitioners of Types 2–4 are all members of the Scarabaeinae. Females lay an egg in the provisioned food source where the larvae feed and develop until pupation.

A number of dung beetle adults attach themselves to mammalian animals to be close to dung nutrients leaving the host. Examples are *Canthon quadriguttatus* (Scarabaeinae) residing near the anus of *Callicebus brunneus* (Titi monkey) in Peru, *Macropocopris parvus* (Scarabaeinae) on the anal hairs of the Australian wallaby, and *Trichillum adisi* and *Uroxys besti* (Scarabaeinae) on the pelage of three-toed sloths (*Brachypus* sp.) in Brazil.

The males of several species of Dynastinae (e.g., *Megasoma elephas* and *Spodistes mniszechi*) and Scarabaeinae (e.g., *Phanaeus eximius*) are endowed with elaborate head and/or pronotal horns, the uses of which provide interesting lessons in intraspecific behavioral interactions and natural selection. The extravagant armaments serve as effective tools in contests between members of the same species over critical resources such as mating privileges with females, feeding sites, and dung provisions for oviposition. They may be employed as a crowbar for prying a rival from a substrate so that it may be pushed away from the contested resource, or as forceps for lifting rivals and dropping them from a tree or log to the ground. Head horns and pronotal protuberances are prevalent in tunneling male dung beetles, who employ them to effectively block tunnel entrances or push opponents out of tunnels. Horns are often serrated or hairy to increase prying or gripping.

Males of some species of Rutelinae have greatly enlarged hind legs (e.g., *Macropoidelimus mniszechi* and *Macropoides crassipes*), often with strong, sharp protuberances that they use to grasp the female firmly during mating. Males of Euchirinae and Dynastinae often have very long front legs for the same purpose. Many male dynastines in the tribe Cyclocephalini have enlarged front tarsi that they use to grasp the elytral margins of the female during copulation; the female's elytral margins will often have small, rounded protuberances to accommodate the grasp of the male. These marginal protuberances are also evident on the elytra of female jewel scarabs (*Chrysina* spp.).

Ecological Importance

The larvae of scarab beetles play a crucial role in recycling nutrients from decaying plant material, dung, and carrion. The consumption of stumps and fallen logs by saprophagous scarab larvae, with assistance from symbiotic intestinal microflora, decomposes cellulose and lignin and returns carbon and nitrogen to the soil so that these elements can be utilized by plants. Likewise, vertebrate animal feces and carrion are incorporated into the soil by dung beetles and necrophagous scarabs, which maintains ecosystem health and contributes to soil fertility.

Dung-feeding scarab beetles have been useful in classical biological control. In 1968, several species of dung beetles were introduced into Australia to aid in the decomposition of cattle feces which is utilized as a breeding resource by noxious flies. Domesticated cattle produce feces different from native Australian herbivores. Native Australian dung beetles were not adapted to feed on the dung of domesticated cattle. As a result, cattle feces accumulated at such a rate that grasses and forbes were smothered and killed and noxious fly populations erupted. Dung beetles, such as *Onthophagus gazella* (Scarabaeinae), were introduced from Africa, and these scarabs readily feed on cattle dung, thus enriching the soil with dung, allowing grasses and forbs to thrive, and eliminating a resource which led to a reduction in noxious fly populations.

Diurnal species of Cetoniinae are frequent visitors to flowers and as such are important agents in cross-pollination. The adults of *Erioscelis* spp. and *Cyclocephala* spp. (both Dynastinae) are also recognized as important pollinators of palms and aroids. After visiting male stage flowers of *Philodendron selloum* and exiting with their bodies laden with pollen, adults of *Erioscelis emarginata* are attracted to female stage inflorescences at dusk by a mixture of visual and olfactory stimuli. Odoriferous inflorescences in the female stage of flowering induce adult beetles to remain within the inflorescence during this stage. *Cyclocephala atripes* and *Cyclocephala conspicua* are frequent pollinators of *Cyclanthus bipartitus* in Costa Rica. The beetles arrive during the pistillate phase, feed on pollen and specialized tissue on the bracts of the inflorescence, and remain in the flower until the end of staminate anthesis. The inflorescence also serves as an aggregation site for mating.

Species diversity and endemism in faunal assemblages of Passalidae and Scarabaeidae (particularly Dynastinae, *Chrysina* spp., and *Phyllophaga* spp.) have been used to prioritize the conservation of cloud forests in Guatemala. Faunal similarity indices have been used to compare these high montane forest habitats where endemism can be high. Advantages to using these beetles as bioindicators for prioritizing conservation efforts and analyzing relationships among cloud forest areas are (i) they are continually present year-round, (ii) they are easy to collect in a short period of time, and (iii) they are relatively well known taxonomically. Other potentially useful scarabaeoid groups are Geotrupidae and Scarabaeinae. The patterns of endemism in scarab beetles are similar to those observed with longhorn beetles (Cerambycidae), salamanders, birds, small mammals, and trees, thus making them good indicators. The methodology using scarab beetles, as developed in Guatemala, may be adapted for use in understanding areas of endemism and high species diversity for better conservation efforts in other countries.

Agricultural and Medical-Veterinary Importance

The following table (Table 3) presents a partial list of scarab beetles known to be pests of annual and perennial crops, ornamental plants, turf, and forests. The larvae of at least 27 species of *Phyllophaga* (Melolonthinae) are documented as pests of maize, potatoes, sugarcane, wheat, sunflower, cranberry, and beans in North and Central America. Adults of *Phyllophaga falsa* are capable of defoliating pine trees in nurseries. Not <15 species in 13 genera are recognized as pests of turf grass in the United States. Adults of the Japanese beetle, *Popillia japonica* (Rutelinae), feed on over 300 host plants in eastern North America.

Scarab beetle have also played a significant role in medical and veterinary entomology. Several species, mostly in the subfamily Scarabaeinae, whose larvae develop in dung, carrion, or compost, are known to serve as intermediary hosts of parasitic nematodes and cestodes whose definitive hosts are mammals. The excrement of the definitive hosts contains eggs of the parasitic worms, which are then ingested by the larval scarabs. The larval stages of the parasites develop within the larval beetle hosts. The infective scarab grubs, and the pupae and adults that develop from them, are then ingested by uninfected definitive hosts (e.g., pigs, sheep, goats, cattle, dogs, rodents) to complete the cycle.

Chickens and other domestic birds that eat the adults of the rose chafer, *Macrodactylus subspinosa* (Melolonthinae), take on a drowsy appearance, droopy wings, closed eyes, and a slightly trembling body. Death may occur 5–24 h after consumption. Beetles removed from the crop of a killed chicken and fed to a second chicken will cause the death of the second chicken, indicating that the beetles need not be alive to cause death. A toxic substance is suspected since mashed bodies of dead beetles fed to chickens killed the birds and filtered solutions prepared from crushed beetles and intravenously injected into rabbits killed the mammalian subjects.

In July 1957, a bizarre case of ear invasions by *Cyclocephala borealis* (Dynastinae) and *Maladera castanea* (Melolonthinae) occurred in 186 Boy Scouts at Valley Forge State Park, Pennsylvania, USA. All but two boys were sleeping on the ground at the level at which the beetles are known to fly looking for mating and oviposition sites; no cases were reported in persons sleeping on cots. So deep were the intrusions that the beetles could not be seen without an otoscope. The presence of a beetle in the ear canal was extremely painful because the tibial spines pierced the delicate skin as the insect forced its way in. Cotton ear plugs or neckerchiefs provided mechanical barriers preventing additional invasions.

Scarab Beetles (Coleoptera: Scarabaeoidea), Table 3 Partial list of scarab beetles known as pests of crops, ornamental plants, turf, and forests

Pest scarab	Affected plants
Scarabaeidae	
Aphodiinae	
Aphodius granarius	turf
Aphodius tasmaniae	many host plants
Ataenius spretulus	turf
Cetoniinae	
Cotinis nitida	vegetables, turf
Euphoria sepulcralis	many host plants
Protaetia pryeri	many host plants
Dynastinae	
Adoryphorus couloni	pasture
Cyclocephala spp.	maize, sugarcane, guava, turf
Diloboderus abderus	pastures, cereals
Dyscinetus morator	carrots, radishes, caladium bulbs
Euetheola spp.	rice, sugarcane
Heterogomphus chevrolati	coconut
Heteronychus arator	cereals
Oryctes rhinoceros	coconut
Podischnus spp.	bamboo, maize, sugarcane
Strategus aloeus	dates
Strategus antaeus	turf
Tomarus spp.	carrots, sugarcane, turf
Melolonthinae	
Amphimallon majale	turf
Apogonia spp.	cacao
Costelytra zealandica	pasture
Holotrichia spp.	groundnuts, beans, cereals
Hoplia callipyge	roses
Hoplia modesta	cranberry
Macrodactylus subspinosa	many host plants
Maladera matrida	many host plants
Melolontha spp.	fruit trees, forests
Phyllophaga spp.	many host plants
Diplotaxis spp.	ornamental trees
Serica spp.	avocado
Rutelinae	
Adoretus sinicus	many host plants

Scarab Beetles (Coleoptera: Scarabaeoidea), Table 3 Partial list of scarab beetles known as pests of crops, ornamental plants, turf, and forests (Continued)

Pest scarab	Affected plants
Anomala spp.	bamboo, turf
Exomala orientalis	many host plants
Popillia japonica	many host plants
Strigoderma arbicola	various ornamental plants
Geotrupidae	
Peltotrupes sp.	turf
Glaphyridae	
Lichnanthe vulpina	cranberry
Hybosoridae	
Hybosorus illigeri	turf

Cultural Importance

Scarab beetles, because of their size, numbers, and beauty, have played various roles in their interactions with humankind, especially religion and folklore, folk medicine, food, and ornamentation of regalia. Scarabs are often used in modern cultures for art (painting, sculpture, baskets, wood, and lacquer ware), toys (plastic), and as entertainment in the form of betting on fights between adult rhinoceros beetles.

The first documented use of scarab beetles by humankind was a small alabaster case made in the shape of a dung beetle by the ancient Egyptians (3000 B.C.). Historically, dung beetles played a prominent role in the mythology of ancient Egypt. Collectively known as the sacred scarab, these insects and their ball-rolling behavior symbolized certain parts of the Egyptian polytheistic theory of the universe. Ra, in Egyptian theology, was the Sun God responsible for the daily shepherding of the sun across the sky. Ra, in this belief system, was also the first ruler of Egypt. A cult developed whereby Ra was symbolized by the scarab and the sun was represented by the dung ball. The scarab pushing its ball was an earthly manifestation of Ra escorting the sun on its daily journey across the sky.

After 200 B.C., during the Middle Kingdom, older interpretations of the role of scarabs changed so that the beetle was credited with the supernatural power of insuring rebirth after death. The scarab's likeness was fashioned into amulets, jewelry, and seals that were used as good luck charms by many cultures, including the later rulers of Egypt and Persians, Macedonians, Romans, and Phoenicians. The Romans especially had great faith in the scarab's protective powers, particularly in battle, and many artificial scarabs have been found in Roman graves dating from before 400 A.D.

The larvae and adults of many scarabs were (and are) used as food by peoples in Europe, Africa, Asia, and Latin America. Insects are consumed because they have a high nutritive value and are abundant. Many Indian tribes in South America routinely use insects in their diets. The larvae constitute a rich source of proteins and fats. Some Australian aboriginals used scarab beetles both as totems and as food. The aversion to insects as food is a recently established custom and prejudice of western civilization.

The use of scarabs in folk medicine was once widespread in Europe and remains so in Asia, especially China. Roasted, pureed, or pulverized scarabs are used as a medicine for diarrhea, stomach cramps, dysentery, and even cancer.

The use of scarabs in regalia decoration and as ornaments occurs in South America. The Jivaro, of the eastern lowlands of Ecuador, make beautiful headdresses and necklaces using the brilliant, metallic green bodies of *Chrysophora chrysochlora* (Rutelinae). The horns of large rhinoceros beetles are fashioned into necklaces in Brazil, Venezuela, and Colombia.

Some South American Indians eat large rhinoceros beetles in the belief that the special powers associated with the size of these animals (150 mm) could be acquired by eating them (imitative magic). To the Aymara of the Lake Titicaca Plateau in Bolivia, a certain scarab beetle was believed to cause madness, and occasionally, in referring to an insane person, they would say "someone has given him a scarab to drink."

Collecting beetles is a very popular hobby practiced by many worldwide, and scarab beetles are avidly sought after by collectors. There are a number of companies that advertise scarabs for trade or sale on the Internet. The more common species sell for only a few dollars per individual, whereas rare or extravagant species may sell for a few hundred dollars for an individual or several hundred dollars for a mated pair. Jewel scarabs (*Chrysina*) and other colorful Rutelinae, horned species of Dynastinae and Scarabaeinae, and Lucanidae are the more popular, and expensive, scarab beetles in the marketplace.

Scatophile

An organism that is attracted to or lives on animal waste or excrement (sometimes called "scat"). Such animals are said to scatophilous.

Scarabaeidae

A family of beetles (order Coleoptera). They commonly are known as scarab beetles.

► Beetles
► Scarab Beetles

Scatopsidae

A family of flies (order Diptera). They commonly are known as minute black scavenger flies.

► Flies

Scavenger Moths (Lepidoptera: Blastobasidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Scavenger moths, family Blastobasidae, total over 296 species worldwide, with many known from North America and Europe, in three subfamilies; actual fauna probably exceeds 600 species. There are two subfamilies: Holcocerinae and Blastobasinae (Symmocinae have been included as well but now are a tribe of Autostichinae, Oecophoridae). The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (5–35 mm wingspan), with head smooth-scaled; haustellum scaled; maxillary palpi 4-segmented. Maculation mostly somber shades of gray with few markings. Adults nocturnal as far as is known. Larvae are scavengers or detritus feeders, sometimes feeding on plant fruits, flowers, or seeds, among a number of plant families, but few are known biologically. At least one species lives with coccids (Hemiptera) but predation on the coccids has not been confirmed (Fig. 16).

Scheerpeltz, Otto

Otto Scheerpeltz was born near Olomouc, Czech Republic, on July 16, 1888. He enrolled in the Technische Hochschule, in Vienna, to become an engineer, but instead became a teacher. He continued at this profession until his retirement in 1945. In 1922, while still employed as a teacher, he entered the University of Vienna to study zoology and botany, and graduated in 1930. There he became interested in the Staphylinidae. Scheerpeltz amassed one of the largest collections of Staphylinidae, containing 300,000 specimens and 10,000 types. He authored 286 papers describing 1,405 species and 181 genera, and is considered to be an important contributor to our knowledge of this family. He died at Vienna, Austria, on November 10, 1975.

Schneiderman, Howard Allen

Howard Schneiderman was born at New York, NY, USA, on February 9, 1927. He received a bachelor's degree from Swarthmore College in 1948, and a M.S. and Ph.D. from Harvard University in 1949 and 1952, respectively. Early in his career he became recognized as an authority on juvenile hormone chemistry. He was a member of the faculty at Cornell University from 1953 to 1961. Schneiderman helped found the Developmental Biology Center at Case-Western Reserve University, where he also served a chairman of the Biology Department. During this period he was co-discoverer of JH II. In 1969 Schneiderman moved to the University of California at Irvine, where he chaired the Department of Developmental and Cell Biology, and later became dean of the School of Biological Sciences. During this period Schneiderman's focus shifted from the developmental biology of Lepidoptera to *Drosophila*. In 1979 he joined the Monsanto Company, and eventually was chief scientist and senior vice president of research and development. His activities with Monsanto and collaborative arrangements with universities earned him national prominence as one of the architects of industrial biotechnology research, and one of the leading figures in physiology, development, and genetics of insects. Schneiderman published over 200 papers during his career, and was awarded many honors, including election to the National Academy of Sciences. He died on December 5, 1990, in St. Louis, Missouri.

School IPM, or Pest Management on School Grounds

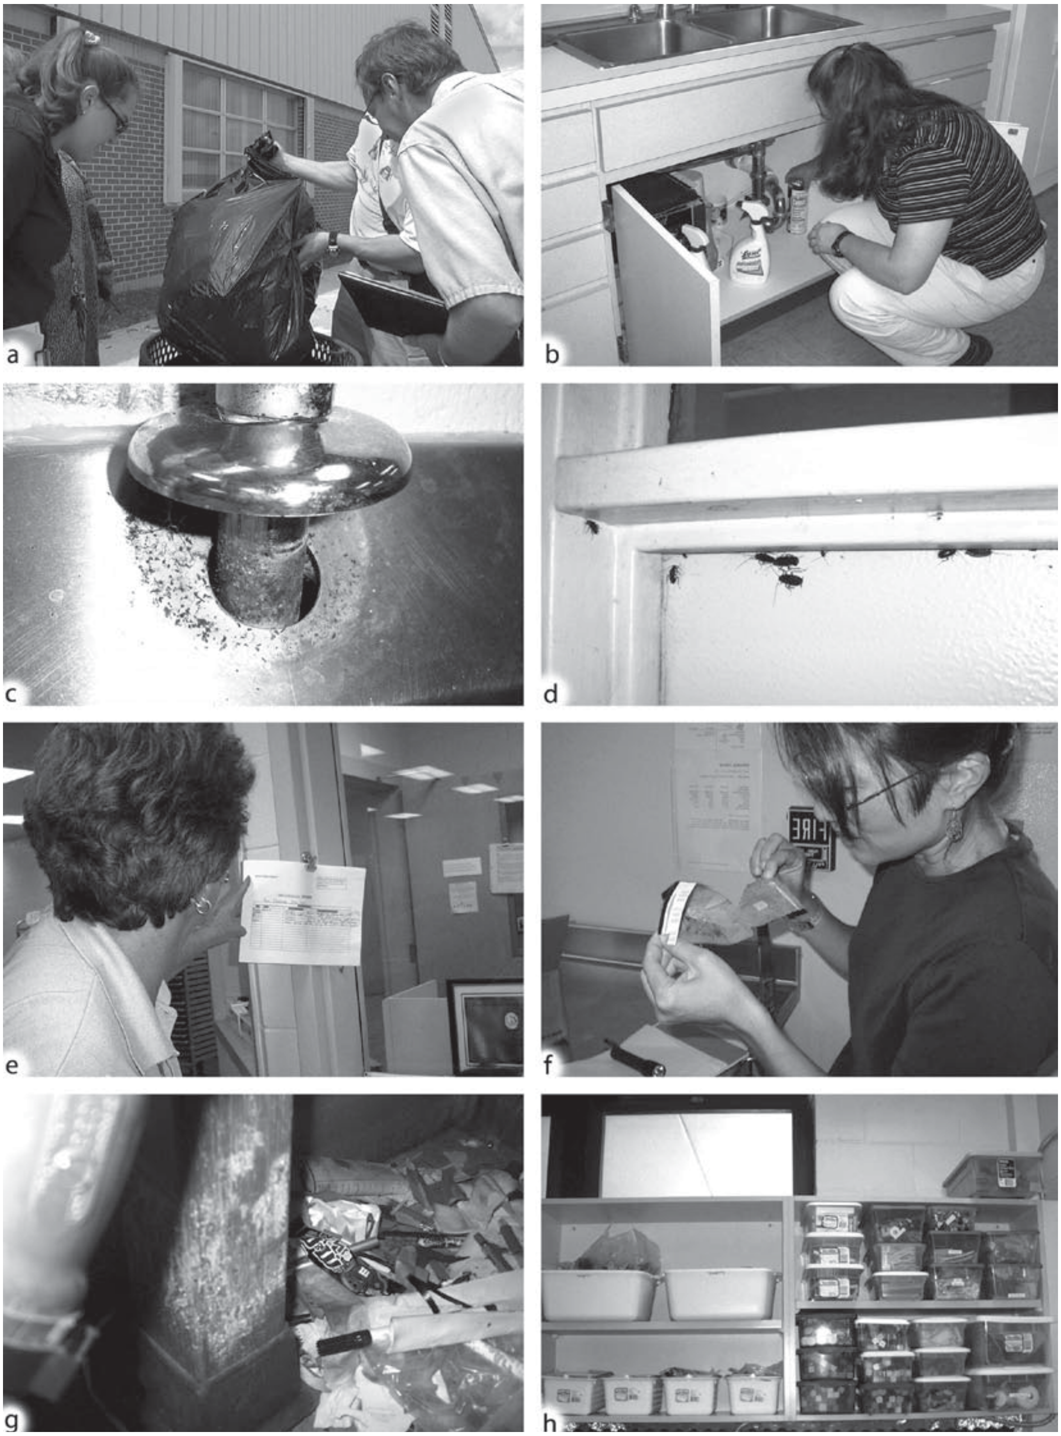
REBECCA W. BALDWIN,[1] CLAY W. SCHERER[2]
[1]University of Florida, Gainesville, FL, USA
[2]DuPont Professional Products, Wilmington, DE, USA

The purpose of school IPM (integrated pest management) is to reduce the risk to students from pests, to eliminate unnecessary pesticide use by promoting IPM in schools, and to provide the support, resources and training needed to accomplish these tasks. To be very clear, IPM is a process. This effort has developed in response to concerns surrounding the potential hazards of pests and pesticide use in schools. The school environment is an important element in the life of nearly every child, a place where he or she spends a great deal of time. This is not an environment where students should be at risk from either pests or pesticides, but sometimes this has occurred due to lack of knowledge by administrators, parents, and others. School IPM is a community-wide approach involving education of school administrators, parents, students, building maintenance people, food service personnel and pest management professionals (PMP), as well as the application of appropriate pest control technologies.

A number of pests and pest-related problems are encountered in the school environment (Fig. 17). The pests occurring in school buildings are typically ants, cockroaches, head lice, fleas, flies, spiders, termites, bedbugs, rats, mice, and bats. Pests affecting the school outdoor environment include grasshoppers, house flies, deer flies, midges, mosquitoes, honey bees inc luding Africanized bees, yellow jackets and hornets. Some schools have butterfly gardens or demonstration vegetable gardens, which introduce another group of plant pests such as caterpillars, aphids, whiteflies, and beetles. The most common pest situations involve head lice on young students, cockroach contamination of cafeterias and classrooms, termites affecting the structural integrity of the building, rodents infesting food storage and preparation areas, nuisance ants and flies in classrooms, and stinging and biting insects in the schoolyard. To address these pest threats, pesticides are sometimes used. For both pest and pesticide issues, there is particular risk associated with hypersensitive children that have a physiological reaction to these stimuli, requiring emergency medical treatment.

The Role of Parents

Often parents can provide the most influential voice on issues regarding school policies. Getting integrated pest management (IPM) into a school or even the entire school district can begin at the grass roots level by organizing concerned parents. Parental involvement requires that parents become knowledgeable about what is and isn't being done in the schools. The involvement of the parent-teachers organization (PTA) is helpful. PTA officers likely are among the decision-makers at the school. The more informed they are about IPM, the better equipped they will be to lobby the local school board. The school's principal should be kept fully informed of parents concerns about pests or about excessive pesticide use in the school, and that alternatives such as IPM exist. One of the most important steps in getting IPM into a school is to get the local school board to approve an IPM policy statement district-wide. Often a trial period is desirable, because any change involves discomfort for someone, and even small adjustments can seem difficult to implement if it involves changing well-established procedures or protocols. A trial could consist of switching several schools over to IPM, switching just one entire school, or just a few isolated structures (e.g., the media center or administration wing) at one school. Usually it is desirable to have a school IPM committee made up of concerned parents, pest managers, administrators, etc. Establishment of such a committee will increase sustainability of a school IPM program. The role of this committee is to review the IPM program periodically and incorporate feedback from the schools into possible policy changes.



School IPM, or Pest Management on School Grounds, Figure 17 **Key elements of implementing school IPM programs: inspection of trash (a) and under-sink harborages (b) favored by cockroaches; cockroaches commonly follow plumbing (c) to gain entry, resulting in high population densities (d); record-keeping (e) helps assess the abundance of pests, as does trapping (f); trash accumulations beneath or within desks and cupboards (g) provides shelter for pests, but neatly organized and covered containers (h) can eliminate harborage, making detection easier and survival more difficult for pests.**

The Role of Administrators

It is important that administrators understand the IPM concept and the implementation process. The faculty, staff, students, and parents will expect the administrator to be knowledgeable about IPM.

If pest management is handled by in-house staff, the administrator should contact the supervisor of pest management to convey an interest in IPM. If the pest management supervisor is unfamiliar with IPM, the pest management supervisor should be advised of the benefits of IPM, including the reduced health risks associated with IPM implementation, and allowed time to become familiar with the concept and procedures.

If pest management is handled by a private pest management firm, the administrator should contact the person listed in the school's pest management contract as the supervisor or "contact" person. This information usually can be found by contacting the school district's purchasing agent. It is important to let the supervisor know that you are interested in getting IPM implemented. The supervisor should be willing to cooperate with your efforts depending upon certain contractual obligations. Keep in mind that you are the customer, and that the pest management industry is customer driven.

There is no sense in "re-inventing the wheel." Contacting school administrators from neighboring schools or neighboring districts can be extremely helpful. Other schools in the district may have already gone through the process of converting to an IPM program and might be able to offer valuable suggestions. If they haven't, they may become interested in IPM and be willing to combine their efforts with yours.

It probably will be important for you to make a brief presentation to the local school board and initiate the process of establishing an official school IPM policy statement. Adoption of an official policy statement is important because it gives school officials the authority to make decisions regarding pest management. In the case of an IPM policy, it provides administrators the foundation from which to implement IPM.

Your local county extension agent should have considerable expertise in insect pest identification and pest management. The extension agent may also be able to provide assistance in developing and supporting an IPM program. Because the Cooperative Extension Service is also a governmental resource, the extension agent has the ability to contact outside IPM experts and bring considerable information to the local level. There may also be individuals within the county administration that could provide expertise. Many local resources such as the county health department or environmental services employ professionals who possess experience in pest related health risks, pest management, and sanitation. All of these individuals can provide support for an IPM program in schools.

It is important to create a mechanism through which the IPM program can be maintained. The best method of accomplishing this is to create a school IPM advisory committee. This committee should have representatives from pest management (whether in-house or contracted), teachers, school administration, sanitation staff, and concerned parents (PTA). Because IPM is a process, it will be important for this committee to help make decisions on pest management that may be unique to your school or school district. Additionally, periodic feedback from these individuals will help improve the IPM program.

The Role of School Faculty and Staff

Faculty and staff frequent classrooms and food service areas. As a result, teachers and staff are exposed to all the same risks as the students. However, faculty and staff are often expected to "take charge" of unpleasant situations such as the occurrence of pests. It is important not to introduce "bug sprays" into the classroom. Commonly used "over-the-counter" products available at local stores can contain the same ingredients as those products used by licensed PMPs. When used in the classroom, these sprays are potentially dangerous to chemically sensitive children. Also, these products can make some pest problems worse because they may interfere with or even reduce the effectiveness of treatments made previously by the pest management staff. Finally, using pesticides sets a precedent that this is the way to deal with pest problems, and students will imitate this behavior at home. In an effective school IPM program, a mechanism exists whereby the faculty and staff can notify the pest management technician (by telephone, email, or written report) of any pest problems so they can quickly treat the problem.

Food or beverage items are a major source of pest problems, and should not be introduced into the classroom except in sealed containers (e.g., lunch boxes). It is very important to continually remind children that food and snacks are to be eaten in the cafeteria, not the classroom. Even a few crumbs are a full meal for rodents, cockroaches or ants. If food incentives are used in the classroom, they should be stored in plastic, sealable containers. If items are small, freezer bags are recommended because they are made of a thicker material that is more pest resistant than the less expensive food storage bags. If food is consumed in the classroom, remove food trash from the classroom once the meal is over; don't wait for the custodial staff to deal with it hours later. Also, remember that serving utensils need to be thoroughly cleaned and rinsed before storage.

Sanitation, not pesticides, makes the biggest impact on many pest populations. Cleaning up after any pets in the classroom and after parties is an absolute must. Empty soda cans, used paper plates, food wrappings, etc. should be placed in the trash can and then taken to an outside disposal area before the end of the day. Trash containers full of this type of food-contaminated debris left overnight in the classroom are often sources of pest problems. Indoor recycle bins should also be emptied daily.

Whether pest management is handled in-house or is contracted out, the faculty and staff should interact with the pest management technicians as often as possible. The more communication that occurs between the faculty/staff and the pest control technician, the more effective pest control will be. It is very important for teachers/school staff to communicate with the pest control technicians about the kind of pest problems that exist. Specifics such as where the pests are (e.g., near the sink in the rear of the classroom), what kind of pests exist (e.g., cockroaches, ants, wasps, rodents), and when they are a problem (e.g., only in the morning or all the time) is valuable information to the pest control technician. The technician will be better prepared to treat the pest problem with this sort of information.

A great way to communicate pest problems to the pest control technician is by using a "pest sighting log." Pest sighting logs are used by school employees to communicate pest problems to the pest control technician. The log is a record of when the pests were seen, by whom, where, and what kind of pests were present. The pest control technician checks the log and then uses the information provided to treat the problem. The pest control technician also records what action was taken to treat the pest problem on the pest sighting log. It is important to record such information such as what pests were identified, what the cause of the pest problem was, and what action was taken (including exclusion, sanitation, or pesticides, if any). The pest control technician also makes recommendations to building maintenance staff about what changes in maintenance might help prevent future pest problems (installation of proper door sweeps, turning off unnecessary lights at night, installing proper window screening). A pest sighting log should be kept in an accessible area such as the main office, cafeteria manager's office, or teacher's lounge area.

Faculty should consider IPM as a topic at a school PTA and/or faculty meeting. Faculty can help build support for the idea of switching to a school-wide IPM program by distributing IPM materials to others. A knowledgeable *group* of people who support an issue is often more effective than a single voice of concern.

The Role of Pest Management Personnel

Integrated Pest Management (IPM) is a viable alternative to traditional pest control. There are many sources available to pest management personnel if they are not familiar with IPM practices. Most professional pest management professionals have such knowledge, but sometimes schools entrust pest management to maintenance or janitorial staff, who may lack proper knowledge of pest management. Local regulatory agencies and the Cooperative Extension Service are good sources for additional information. In addition, many manufacturers also supply technical bulletins and documents with their products which describe IPM techniques and application methods. Lastly, many WWW sites contain pertinent information.

To reduce pests in schools, you must reduce pest-conducive conditions. These conditions are found most often in "pest vulnerable areas." These are areas that have food, water and harborage available to pests. In order to identify these pest vulnerable areas, it is important for pest managers to monitor the school for pests. There are many pest monitoring methods including the use of monitoring stations. This is done through monitoring stations placed throughout the school. Typically, the pest vulnerable areas consist of:

- Offices
- Food service areas
- Dry food storage
- Custodial closets
- Classrooms
- Storage areas
- Gyms and locker rooms
- Teachers' lounge
- Landscape

Not only do pest managers monitor for pests, but they look for pest harborage sites as well. Once an infestation is identified, measures are taken to reduce the infestation including exclusion, reduction of food, water and harborage, and the careful use of pesticides, usually in a targeted bait application. By using integrated pest management principles, schools can reduce the numbers of pests as well as maintain a healthy learning environment.

Successful Out-Sourcing of IPM

When discussing the issue of IPM with the purchasing agent it is important to alert the agent that an IPM program can be quite a different method of controlling pests than traditional pest control and therefore requires different contract language. If pest management is to be conducted by a private pest management firm, it is very important that recommendations from the IPM advisory committee and others associated with the school be passed on to both the purchasing agent and the PMP. Ideally, a mechanism for regular feedback from the school (perhaps including the pest sighting log) be part of the contract. If recommendations from the advisory committee are viewed as outside of the scope of service provided by the PMP, these recommendations should be adequately detailed and given to the purchasing agent to consider incorporating into the next pest management contract when contract bids are solicited. Following are definitions and important elements of a model school IPM contract for interior services [lice and termite control are excluded], although they may be adjusted according to needs (e.g., inclusion of outdoor IPM services):

- *Integrated pest management (IPM)*
  IPM is a process through which pest risk is minimized while simultaneously minimizing risk associated with pest treatment such as pesticide exposure. IPM involves several decision-making steps based on all available information to ensure the most appropriate treatment method is employed and students, staff, and faculty are protected from the potential dangers of pests and pesticides.
- *Risk of pest exposure*
  It is recognized that pests present health hazards to the occupants of school buildings. These hazards

exist in the form of insect stings or bites, allergens generated and/or dispersed by insects, or human pathogens mechanically vectored by insects.

- *Risk of pesticide exposure*
  It is recognized that pesticides can present a potential health risk. Depending on toxicity of the pesticide and exposure, pesticides can cause severe harmful effects to humans if misused.
- *Thinking (decision-making process) versus applying pesticides*
  Integrated pest management stands as a contrast to traditional regularly scheduled pesticide applications to structures. Integrated pest management involves preventing pest problems, treating only documented pest problems, treating pest problems through precision targeting with the most appropriate material (least toxic while still being effective) and technique. This process requires decisions to be made at every step. Integrated pest management requires a high level of communication between the pest manager and the school official supervising pest management (IPM Coordinator). Communication between pest managers and school officials should be well documented.
- *Pest prevention and exclusion*
  Exclusion is a method of keeping pests out of structures and therefore preventing pests from becoming an indoor pest problem. Techniques used in exclusion include but are not limited to installing door sweeps to exterior doors to prevent pests from entering the structure under the door, installing hardware cloth to any appropriate opening in structures such as air vents and sealing of exterior windows with appropriate caulking material.
- *Sanitation*
  Sanitation is critical in pest management because food debris left behind by humans often attracts pests. Sanitation improvements that help prevent pests include but are not limited to placing plastic liners in trash cans and removing them daily, placing trash away from any entrance to the structure, keeping trash receptacle lids closed, proper cleaning of the food handling and preparation area daily, and eliminating water sources available to pests in all structures.
- *As-needed application of treatments*
  Only after a pest infestation has been documented through inspection and/or monitoring should a treatment be initiated.

Inspection involves a thorough examination of structures to assess pest identification, pest infestation levels, evidence of pest activity, and identification of potential pest encouraging circumstances. Monitoring is a technique to evaluate the presence/absence of pests, the identification of pests, and the location of pest infestations.

Treatment includes any action that serves to reduce or exclude pest populations.

- *Least toxic methods and non-chemical treatments*
  Several treatments for pest management do not include the use of pesticides. Examples of such treatments include vacuum devices or mechanical traps. Additionally, non-chemical treatments can include structural modifications and sanitation measures.
- *Non-use of space sprays*
  Use of space sprays is not typically considered part of an IPM program. Only on the rarest occasion would this method be considered. Space spraying is the technique of applying liquid pesticides to entire surfaces within a structure including baseboards, floors, and walls.
- *Crack and crevice treatments*
  Crack and crevice treatments intentionally apply pesticides in areas difficult for children to contact. Crack and crevice treatments might include treatment of wall voids, behind electrical outlets, or behind stationary equipment or furniture.
- *Baits*
  Baits are pesticide formulations which contain a pest attractant, a toxicant, and a carrier substance. Baits are generally considered a choice treatment method because they contain relatively small amounts of toxicant and generally are applied such that it is difficult for children to contact any residue. Baits are formulated as granules, gels, liquids, and in containerized stations.
- *EPA hazard categories*
  The use of a Category I pesticide in a school is considered unnecessary and is not part of an IPM

program. Use of a Category II pesticide is considered for use in only those unusual circumstances where alternative treatments have failed. The vast majority of pest management strategies within an IPM program should be adequate utilizing either category III or IV pesticides.

- *Banned products*
  Use of any product being phased out or banned by state or federal agencies is prohibited under this contract.
- *Precision targeting*
  Precision targeting treatments is essential in attaining the most efficient pest management without increasing risk. Precision targeting is placing treatments only where the pests are present and where children are not present. Precision targeting is using the least amount of pesticide necessary to solve the pest problem.
- *Indoor pest control (contract does not include "outdoor"/landscape turf)*
  This contract is for in-door pest control. This contract covers those pests which may occur in classrooms, cafeterias, offices, bathrooms, gymnasiums, locker rooms, and other in-door areas of the school. This contract does not include landscape pest management or turf pest management including athletic fields, playgrounds, and other out-door areas.
- *Service call*
  A service call is that service provided by the contractor outside of regularly scheduled visits generated by contact.
- *Integrated pest management (IPM) coordinator*
  The IPM coordinator is a school official designated to communicate with contractor on school's behalf and supervise contractor's service.
- *Service list*
  The service list identifies all buildings and/or areas to be serviced by the contractor by number or name.
- *Necessary qualifications of service provider*
  Contractor shall possess a certified pest control operator's license. Contractor employees servicing the school must have completed extensive training in Integrated Pest Management. All employees of service provider must possess proper identification and proof of credentials while on school premises.
- *Areas of service*
  This contract for pest management includes all buildings and immediate perimeters of buildings (approximately 5 ft. from exterior walls) on school grounds except those identified by IPM Coordinators as not requiring pest management service. The area of service does not include those areas generally regarded as athletic fields or other outdoor turf areas not associated with buildings. (In some cases the IPM coordinator may wish to include areas designated as "playgrounds" under this contract. This "model" contract should be amended appropriately in those cases). The contractor and IPM coordinator shall agree prior to contract initiation which buildings on school grounds will be under service and which will not. Each building should be identified by number or name and this shall be known as the service list.
- *Specified services*
  The primary service rendered by the contractor in an IPM program is the contractor's knowledge about pests and their management; not the contractor's ability to apply pesticides. The service provided by the contractor will include (i) regularly scheduled inspections, (ii) regular monitoring for pests, (iii) proper identification and treatment of pests consistent with IPM principles and (iv) recommendations to IPM coordinator to reduce future infestations of pests.

Regularly scheduled inspections will consist of examining the entire inside and outside of all buildings on the service list for pests or evidence of pest activity not less than once per month. During inspection, the contractor will complete an inspection form for each building. On the inspection form the contractor will report the date and time of the inspection and any pests observed or evidence of pest activity. The contractor will report any structural features that could be improved to prevent current or future pest problems. The contractor will report on the inspection form specifically where within the building any pests were observed and specifically where the structural improvements should be made. In addition, the contractor will report results of monitoring devices placed within the building. Copies of all inspection forms will be made available to IPM coordinator upon completion of inspection and signed by the contractor and IPM coordinator documenting communication. The IPM coordinator will maintain these records at a central location for a minimum of 1 year. It is recommended that the contractor maintain records of all inspections as well. As a part of the inspection service, the contractor will also inspect the Pest Sighting Form for each location where a Pest Sighting Form exists. The contractor will use the information provided on the Pest Sighting Form to aid in locating pest infestations. The contractor will initial his/her name next to each pest sighting recorded in the Pest Sighting Form upon completing investigation of that pest sighting.

Regular monitoring for pests will provide documentation of where and when pests occur and will help to focus treatment efforts to only those areas which are infested. Monitoring may include the use of devices known as "sticky traps" or "trap monitors." These devices contain no pesticides but have sticky surfaces such that pests are retained within the device. The types of monitors and the number of monitors placed in each building on the service list should be agreed upon by the contractor and IPM coordinator at the time of contract "signing." As a default setting, no fewer than ten monitors should be used in school cafeterias or lunchrooms (including food storage areas) and all other rooms (classrooms, teacher's lounges, offices, vending machine areas, custodial closets,) etc. monitored with no fewer than two monitors each. The number of monitors placed in each room and the exact location of each monitor within each room can be modified by the contractor as deemed appropriate. Monitors are to be inspected not less than monthly by the contractor and results of monitors reported on the inspection form. The type and number of pests observed through the monitoring program should be reported on the inspection form. The specific location of the monitors with pests should be noted on the inspection form. Monitors should be in good working condition at all times. Any change in overall monitoring program should be communicated to the IPM coordinator on the inspection form.

Correct identification of pests and proper treatment is crucial. Upon properly identifying the pest, the contractor will determine the most effective method of treating the pest problem considering specific pest behavior, biology, location within structure, and potential health hazards of the pest and treatment. The first consideration for solving the pest problem will always be a treatment without using pesticides. Such treatments are sanitation, the use of vacuum devices, mechanical traps, or mechanisms for exclusion. If the contractor determines that a pesticide treatment will be necessary, the contractor should evaluate the various products labeled for use in the specific circumstance and make a decision on which product and treatment method is most appropriate considering potential health hazards of the pest and the treatment.

If a treatment will include the use of a pesticide not formulated as a bait or in a containerized bait station, a consideration may be to have the contractor notify the IPM coordinator prior to application. If the treatment will include only a pesticide formulated as a bait or in a containerized bait station the contractor does not have to notify the IPM coordinator prior to application.

All treatments, whether including a pesticide or not, must be reported on the Record of Treatment form. Copies of the Record of Treatment form should be made available to the IPM coordinator immediately upon completion of the treatment.

The contractor shall make recommendations to the IPM coordinator regarding unsatisfactory structural features which unnecessarily attract, encourage, support, provide entry to, or otherwise increase the levels of pest infestation. These features are termed conducive conditions. The contractor will report such recommendations to the IPM coordinator using the Pest Proofing form. The contractor shall complete this form as necessary during regular inspection periods. The contractor should record which building and a specific location within the building where the pest conducive condition(s) exists and provide details on what kind of pest(s) may be influenced and why.

- *Inspection form*
  Inspection forms should be used by the contractor to record any pest activity or evidence of pest activity during inspection periods. The inspection form should indicate the date and time of the inspection, building number, specific location within the building, type of pest observed, and an assessment of the level of infestation. Copies of all inspection forms should be made available to the IPM Coordinator immediately upon completion of all inspections. Any treatments performed by the contractor upon completion of an inspection should be justified by reported sightings of pests on the Inspection Form.
- *Pest Sighting Form*
  A Pest Sighting Form shall be placed in a central location within each school, building, or room as determined most appropriate by the contractor and IPM coordinator. A Pest Sighting Form is to be the responsibility of a predetermined individual for each location where a Pest Sighting Form exists. All employees of the school working within that area are to be notified of the existence of the Pest Sighting Form and report any pest sightings to this individual. When pest sightings are reported this individual should then enter the date, time, specific location, and estimated type of pest sighted on the Pest Sighting Form. The Pest Sighting Form must be made available to the contractor during treatments or scheduled inspections.
- *Pest Proofing Form*
  A Pest Proofing Form should be used by the contractor to communicate possible structural modifications which would improve pest management. During regular inspections the contractor should identify specific locations and conditions within buildings which require attention by IPM coordinators. Copies of the Pest Proofing Form should be made available to the IPM coordinator upon completion of inspections.
- *Record of treatment*
  A Record of Treatment form should be completed by the contractor whenever treatment is enacted to correct a pest problem. Details of the treatment such as date, time, building, location, type of pest, method of treatment, and any materials used should be reported on the Record of Treatment Form. Copies of this form should be made available to the IPM coordinator immediately upon completion of the treatment.
- *Notification of pesticide applications*
  The IPM coordinator may want to be notified prior to insecticide applications. If targeted applications are used, such as crack and crevice bait applications, the need for prior notification may be unnecessary. Notification shall include type of material used, building, location, and time of treatment. It is the responsibility of the IPM coordinator and the Contractor to ensure that all treatments are in compliance with local, state, and federal law regarding notification requirements to parents and students. A well-structured mechanism should be in place, regarding proper notification guidelines, prior to contract initiation.
- *Materials used for service/treatment*
  No Category I pesticides shall be used on school grounds. EPA Category II pesticides shall be used only after consideration of less toxic alternatives. If pesticides are regarded as being a necessary component of the treatment then the contractor shall use primarily EPA Category III or IV products.
  Monitoring devices include those devices which

contain no pesticides but collect samples of pests. These are commonly known as sticky traps, capture devices, or pheromone traps.

Any device or product, not excluded above, which has been registered by appropriate regulatory agencies which the contractor has determined is a proper component of an integrated pest management program.

- *Methods of service/treatment*
  Contractor's first consideration in all treatments should include non-pesticidal solutions. If the treatment requires use of pesticides, the contractor shall evaluate the most appropriate method considering potential health hazards of the pest problem and those associated with the treatment. All methods of service and/or treatment shall be in accordance with Integrated Pest Management.
- *Timing of inspections/monitoring*
  Inspections by the contractor shall be conducted during regular business hours to facilitate access to buildings and communication between school employees. Additional inspections deemed necessary by the contractor outside of regular business hours should be arranged through the IPM Coordinator.
- *Timing of treatments*
  No pesticide, with the exception of crack and crevice gels, containerized baits, or in an emergency situation, is to be applied in any room or area while in use or occupied by faculty, staff, or students. Contractor will make attempts at conducting pesticidal treatments at times such that the potential of faculty, staff, or students being contacted by treatment residues are minimized. Contractor will follow all requirements present on product labels regarding re-entry periods. Contractor should make every effort to treat areas when not occupied.
- *Service calls*
  Service calls will be conducted after IPM Coordinator has contacted the contractor regarding a pest problem that requires immediate attention. The contractor will address service calls using the same procedure as described under "Specified Services."
- *Pests included/excluded under this contract*
  Contractor shall adequately suppress the following pests:

Indoor populations of cockroaches, ants, flies, silverfish, wasps, spiders, rodents, or other arthropods not excluded below. Also, insects such as red imported fire ants that may nest primarily outdoors but forage around building perimeters and indoors should be managed.

Pests excluded in this contract

- Vertebrate pests other than rodents
- Termites or other wood destroying organisms
- Head lice
- Pests that primarily feed on outdoor vegetation

- *Evaluation and Review*
  Periodic evaluation of contractor's service by IPM coordinator shall occur no less than three times per year and consist of a review of (i) materials/methods used, (ii) level of communication, and (iii) pest sightings by school staff.

IPM Coordinator shall review the methods of pest management being utilized based on records that appear on Inspection Forms, Treatment Forms, Pest Proofing Forms, and Record of Treatment Forms. Any concerns regarding contractor's treatment strategies should be communicated to the contractor at this time. IPM Coordinator shall review all records and forms provided by the contractor for the previous service period and confirm adequate details exist describing the types of service being provided by the contractor. Any changes to documentation forms deemed necessary by the IPM Coordinator should be communicated to the contractor at this time. The IPM Coordinator shall review Pest Sighting forms and anecdotal records to evaluate contractor's ability to address pest sightings by school staff.

Schreckensteiniidae

A family of moths (order Lepidoptera). They are commonly known as bristle-legged moths.

► Bristle-Legged Moths
► Butterflies and Moths

Schwarz, Eugene Amandus

Eugene Schwarz was born in Liegnitz, Germany, on April 21, 1844. He was educated at the University of Breslau and University of Leipzig. He moved to the United States in December of 1872. He left Germany because he had deceived his father, who expected his son to study philosophy when, in fact, he studied zoology and entomology. Schwarz joined the Museum of Comparative Zoology at Harvard University in 1872, and initially worked as a preparator. He moved to Detroit where he co-founded the Detroit Scientific Association and helped initiate the Hubbard-Schwarz collection of Coleoptera. In association with this effort many collecting trips were made in the Great Lakes region and to Florida. Beginning in 1878 he was employed by the Division of Entomology of the United States Department of Agriculture, and he remained in this capacity for most of the period of employment, which ended with retirement in 1926. During the early years of his employment he studied cotton pests in the southern United States, and fig pests in California. His principal interest, however, remained the systematics of Coleoptera, and he amassed a large collection in the U.S. National Museum, where he was named curator of Coleoptera. He was one of the founders of the Entomological Society of Washington and reportedly had significant influence in the Department of Agriculture and National Museum. Schwarz published 395 papers over the course of his career. He died at Washington, DC, on October 15, 1928.

Scientific Name

A Latin or Latinized name given to all biological organisms and consisting of two parts, a genus and species. The first of the two names is the genus and is capitalized. The second is the species and is not capitalized. Both words are italicized. The author's name (the person who first provided a technical description of the species) often follows the scientific name. If the genus name has been changed since the organism was named by the author, then the author's name is placed in parentheses to indicate that a change has been made. When several species in the same species are discussed together, then "species" may be abbreviated spp. For example, in discussing the genus *Spodoptera*, we might refer to the members as *Spodoptera* spp. On the other hand, a single species is indicated as "sp."

► Scientific Names and Other Words from Latin and Greek

Scientific Names and Other Words from Latin and Greek

J. HOWARD FRANK
University of Florida, Gainesville, FL, USA

These words are often misused by people who do not understand the rules governing them. The rules are explained here simply.

Words from Latin and Greek Adopted into English & Singular and Plural Forms

Words such as larva, sensillum, and elytron appear to be Latin or Greek. Many of them were invented by scientists and were never part of classical Latin or Greek. They were invented because new words were needed to name newly described structures. For hundreds of years they had to be in Latin (or Greek) because books about biology and medicine were written in Latin (with a few entries in Greek), which was the international language of science. When such books began to be written in English, those invented words were not changed. Instead they were adopted into English. More were added later, also with a Latin or Greek origin, because by then the tradition was to use words of that form.

Most English nouns form the plural by adding -s (or -es) to the singular. There are exceptions (man, ox, goose, mouse, etc.) but these are relatively few.

However, almost all words adopted from Latin or Greek still form their plural in the way this is done in Latin or Greek, not by adding -s. Exceptions are the words abdomen and trochanter, whose English plurals are now spelled by adding -s.

If you have studied Latin you will know that you need to remember only a small subset of that grammar to use the correct singular or plural form of each word. Some of those words are shown in the table below, in two columns, giving the singular and plural forms that may be memorized. They are grouped (by their last letters) according to their placement in Latin grammar, which helps to place others of similar form.

The form of these words is not fixed because poorly trained news writers commonly use the plural forms algae, bacteria, data, larvae and media as if they were singular. This misuse confuses a large audience and may influence the future direction of English.

Words that are Considered to be Latin (Not English)

Scientific (Latin) names of insects and other animals are either singular or plural, not both. Whether they are singular or plural depends upon the rank (species, genus, tribe, family, etc.).

Names of species are singular

Danaus plexippus is (not are) a species of butterfly

The name of each and every species consists of two words. These two words are conventionally printed in italic font. When written by hand or typed on a typewriter, they are underlined, which indicates to a publishing company that they should be set in italics. The two words are normally written or printed using upper and lower case (large and small letters), and then the first letter of the first word should be capitalized, and the first letter of the second word should not be capitalized. In titles, all letters of both words may be capitalized.

When upper and lower case letters are used, it is incorrect to capitalize the first letter of the

Scientific Names and Other Words from Latin and Greek, Table 4 Singular and plural forms of some words from Latin

Singular (is)	Plural (are)
alumnus	alumni
circus	cerci
fungus	fungi
ocellus	ocelli

Scientific Names and Other Words from Latin and Greek, Table 5 Singular and plural forms of some words from Greek

Singular (is)	Plural (are)
chrysalis	chrysalids
	(or chrysalides)
proboscis	proboscides
criterion	criteria
elytron	elytra
ganglion	ganglia
protozoon[a]	protozoa
stemma	stemmata
stigma	stigmata
stoma	stomata
thorax	thoraces
	thoraxes (American)

[a]protozoan is an English word formed from Protozoa

second word of the name of a species of insect or any other animal (according to current and recent editions of the International Code of Zoological Nomenclature). The rules of botanical nomenclature differ, so that it is permitted for names of certain plants, and it once was permitted to do the same for some animals.

The convention of putting these words into italics came about to indicate that these words are

Latin, not English. Neither of the two words may have any diacritical mark (accent) because Latin has none.

The first word of a species name is the name of the genus to which it belongs. The second word of a species name has variously been called the specific epithet, the trivial epithet, or even the "specific name" although this last is a confusing term (because it is not the name of a species).

Most if not all scientific journals require that the name of a species be spelled out in full at its first mention in a text. In subsequent uses of the name in the same text, it may be abbreviated by reducing the generic name to a single capital letter followed by a period (full stop), as in:

D. plexippus

Some entomologists have adopted other conventions for abbreviating generic names of insects (for example, mosquitoes) in the names of species.

Names of genera, too, are considered to be Latin, are conventionally italicized, and are singular:

Names of genera are singular

Danaus is (not are) a genus of butterfly

Names of all Higher Categories are Plural:

The Latin (or Greek) terminations of these scientific names make it plain that they must be treated as singular (species and genera) or plural (all higher categories). Article 11.7 of ICZN (1999) declares that "family-group names" (names of tribes to families) must be in the nominative plural (see a Latin grammar for further explanation), so cannot be construed as singular.

To follow the rules, we must write "Coleoptera are a huge order" and "Culicidae have many species that transmit disease." Why, then, do some people write "Coleoptera is a huge order" or "Culicidae has many species that transmit disease?"

Scientific Names and Other Words from Latin and Greek, Table 6 Names of tribes, families, orders, classes and phyla are plural

Tribe:
Brachinini are (not is) the bombardier beetles
Subfamily:
Cicindelinae are (not is) the tiger beetles
Family:
Culicidae are (not is) the mosquitoes
Order:
Plecoptera are (not is) the stone flies
Class:
Insecta are (not is) the insects
Phylum:
Arthropoda are (not is) a phylum of invertebrates

There seem to be three reasons why some writers treat these words as singular:

1. They have not learned that the words are plural. This is quite common among students. Even some more experienced writers thoughtlessly copy the erroneous style of earlier writers.
2. They argue that when they write "Coleoptera is speciose," what they really mean is "the order Coleoptera is speciose," but scientific writing should have no hidden meanings, so this excuse is not valid.
3. They perversely refuse to accept what they are told are the established rules, or want to flaunt their ignorance of Latin and Greek and disdain for the International Code of Zoological Nomenclature, and want to make their own rules.

It is of course acceptable to write "the order Coleoptera is speciose."

Another error is made by students in such expressions as "A Culicidae was seen feeding" by which they mean a mosquito (not the whole family!) was seen feeding. This may be written as "a culicid was…" or "a mosquito was…" or "an individual of the family Culicidae was…" or "individuals of a species of Culicidae were…"

Although the names of higher categories (tribe and above) are considered to be Latin, they are not conventionally printed in italic font. Each must have a capital initial letter.

Sciomyziidae

A family of flies (order Diptera). They commonly are known as marxh flies.

► Flies

Scirtidae

A family of beetles (order Coleoptera). They commonly are known as marsh beetles.

► Beetles

Sclerite

A rigid section or plate of cuticle forming a component of the insect's body wall, and bounded by sutures or membranous areas.

Sclerogibbidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Sclerotin

Cuticular protein that has been irreversibly hardened and darkened by chemical cross-linking of the molecules.

Sclerotization

The process of sclerotization, or tanning, results in the hardening of the cuticle after an insect molts. Sclerotization involves the cross-linking of proteins, aided by quinones, which typically contribute to the darkening of the cuticle.

Scolebythidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Scoliidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Scolopidium (pl., scolopidia)

A mechanoreceptor sensillium located beneath the cuticle that perceives vibration, stretch or pressure.

Scolus (pl., scolli)

An extension of the integument, in the form of a projection or tubercle, that bears stout setae. These are found on some highly spinose insects, such as the caterpillars of Saturniidae.

Scolytidae

Considered by some to be a family of beetles (order Coleoptera). They commonly are known as bark beetles or ambrosia beetles. Here they are treated as a subfamily (Scolytinae) of Curculionidae.

► Beetles

► Weevils, Billbugs, Bark Beetles and Others

Scopa

Patches of branched hairs occurring on the body of bees, and used to collect and hold pollen. The location of the scopa varies among bees.

Scopuridae

A family of stoneflies (order Plecoptera).

► Stoneflies

Scorpionflies (Mecoptera)

JAMES C. DUNFORD, LOUIS A. SOMMA
University of Florida, Gainesville, FL, USA

This is a small, primitive order of holometabolous insects. Some scorpionflies are known as hangingflies or earwigflies. Mecoptera are small to moderately large in size, ranging in body length from 2 to 35 mm. The order name is derived from the Greek words *mecos* (= length) and *pteron* (= wing). At present there are approximately 600 known, extant species arranged in 34 genera and 9 families worldwide. Two families, Panorpidae and Bittacidae, comprise most of the species. During recent decades, increasing taxonomic information on extant Mecoptera has necessitated a reevaluation of the systematics and evolution of this group. Traditional "Mecoptera" lack defining, unifying characters, thus they may not represent a monophyletic grouping. Recent DNA and older morphological data suggests that Mecoptera (particularly Boreidae) are closely related to fleas (Siphonaptera). It is also likely that Nannochoristidae, and perhaps Boreidae, typically hypothesized to represent basal mecopteran taxa, may be part of a distinct order. Molecular support for a monophyletic grouping known as the Antiliophora (Diptera and (Mecoptera + Siphonaptera)) is strong. The Antiliophora in turn share a common ancestry with Amphiesmenoptera (Trichoptera and Lepidoptera).

The origin of Mecoptera may still be in doubt and fossil evidence of "Protomecoptera" is confusing, but the earliest fossils originate in the lower Permian geological period (approximately 270 million years ago). Mecoptera are well represented in sedimentary rocks of the lower Permian, and based on additional fossil records, were relatively abundant insects during the Mesozoic Era. The extant family Meropeidae, has been hypothesized to have arisen in the Paleozoic Era, and was once thought to represent living Protomecoptera, but currently only thought to be basal to more derived Mecoptera. There are nearly 400 known fossil species in approximately 87 genera and as many as 34 families (although researchers disagree on the exact number of extinct families) exhibiting a greater diversity than extant mecopteran taxa.

Worldwide, Mecoptera distributions presently show two divergent trends: greater diversities of families and genera exist in the Australian, Nearctic, and Neotropical regions, with relatively few species (approximately 30% of all of the known mecopteran species); slightly less diversity at the familial and generic levels occurs in the Ethiopian, Oriental, and Palearctic regions, with a greater diversity at the species level. Mecoptera are largely absent on islands; for example, no species are known from Madagascar, and they are known only from Trinidad in the Caribbean. In most island areas where Mecoptera are represented (e.g., Japan, Taiwan, Trinidad), there is a geological history of relatively recent land connection to the adjacent continent, suggesting that Mecoptera are poor dispersers.

Carl Linnaeus described and named the first mecopterans in the eighteenth century, and at that time he placed these European taxa (i.e., *Panorpa communis*, *P. germanica*, *Boreus hyemalis*) in the order Neuroptera. North American Mecoptera were first described by N. Swederus, and since that time several prominent American and European entomologists have worked within the order. Nathan Banks, J.S. Hine, and

P. Esben-Petersen published catalogs and described several species, F.M. Carpenter revised the Nearctic Mecoptera fauna and published several papers on their distributions, and G.W. Byers has published numerous papers on world-wide mecopteran fauna covering a wide variety of topics and has described many species. Comprehensive, regional studies on Mecoptera have been published by Byers (Africa and Southeast Asia), C.-S.H. Chau and Byers (Indonesia), T. Miyaké (Japan), and E.F. Riek and C.N. Smithers (Australia). The morphology of Mecoptera has been fairly well described (Fig. 18), and research completed by G.C. Crampton on genitalia, E. Potter on reproductive and digestive tracts, H.R. Hepburn on the adult skeletomuscular system, and R. Willmann on several internal and external structures has provided useful taxonomic information pertinent to present day mecopteran systematics.

The ancient origin of Mecoptera has allowed for the evolution of diverse life histories and morphologies. Approximately one-fifth of the genera have acquired flightlessness (e.g., Apteropanorpidae [*Apteropanorpa*], Boreidae [including *Boreus*], Bittacidae [*Apterobittacus*], and Panorpodidae [some species of female *Brachypanorpa*]), two families have adapted to cold climates (Boreidae and Apteropanorpidae), two others are cockroach-like (Meropeidae and Eomeropidae), and some have predaceous life stages (Bittacidae and Nannochoristidae) while most are saprophagous or herbivorous. The diversity of forms and behaviors in this small insect order may indicate that these taxa are the remnants of a nearly extinct group.

Extant Mecopteran Families and their Continental Distributions

Order Mecoptera

- Family Nannochoristidae – southeastern Australia, Tasmania, New Zealand, and southern South America
- Family Bittacidae (hangingflies) – North America, South America, Europe, Africa, Asia, and Australia
- Family Boreidae (snow scorpionflies, "snow fleas") – mostly boreal and montane North America, Europe, and parts of Asia
- Family Meropeidae (earwigflies) – eastern North America and southwest Western Australia
- Family Eomeropidae – southern South America
- Family Apteropanorpidae (wingless scorpionflies) – Tasmania, Australia
- Family Choristidae – southeastern Australia
- Family Panorpodidae (short-faced scorpionflies) – Appalachian region and Pacific Northwest of North America, eastern Asia
- Family Panorpidae (scorpionflies) – North America, Europe, Asia

Characteristics and Life History

Eggs are generally ovoid and smooth to finely reticulate. At oviposition, the chorion is smooth, only lightly sclerotized, and usually whitish to yellowish-brown in many groups. Eggs vary in size between and within species and are deposited in a variety of ways. Some are placed in loose cavities in the soil (*Panorpa* spp.), dropped randomly to the ground (*Bittacus* spp.), or are deposited in rows on leaf litter near water (*Nannochorista* spp.). *Boreus* place their eggs singly or in small clusters near the stem bases of mosses on which the larvae will feed. The duration of the egg stage varies greatly, depending on the species and environmental conditions. In *Panorpa*, duration can range from 5 to 10 days for many species. In contrast, the eggs of *Boreus* laid in early winter may not hatch until the following spring.

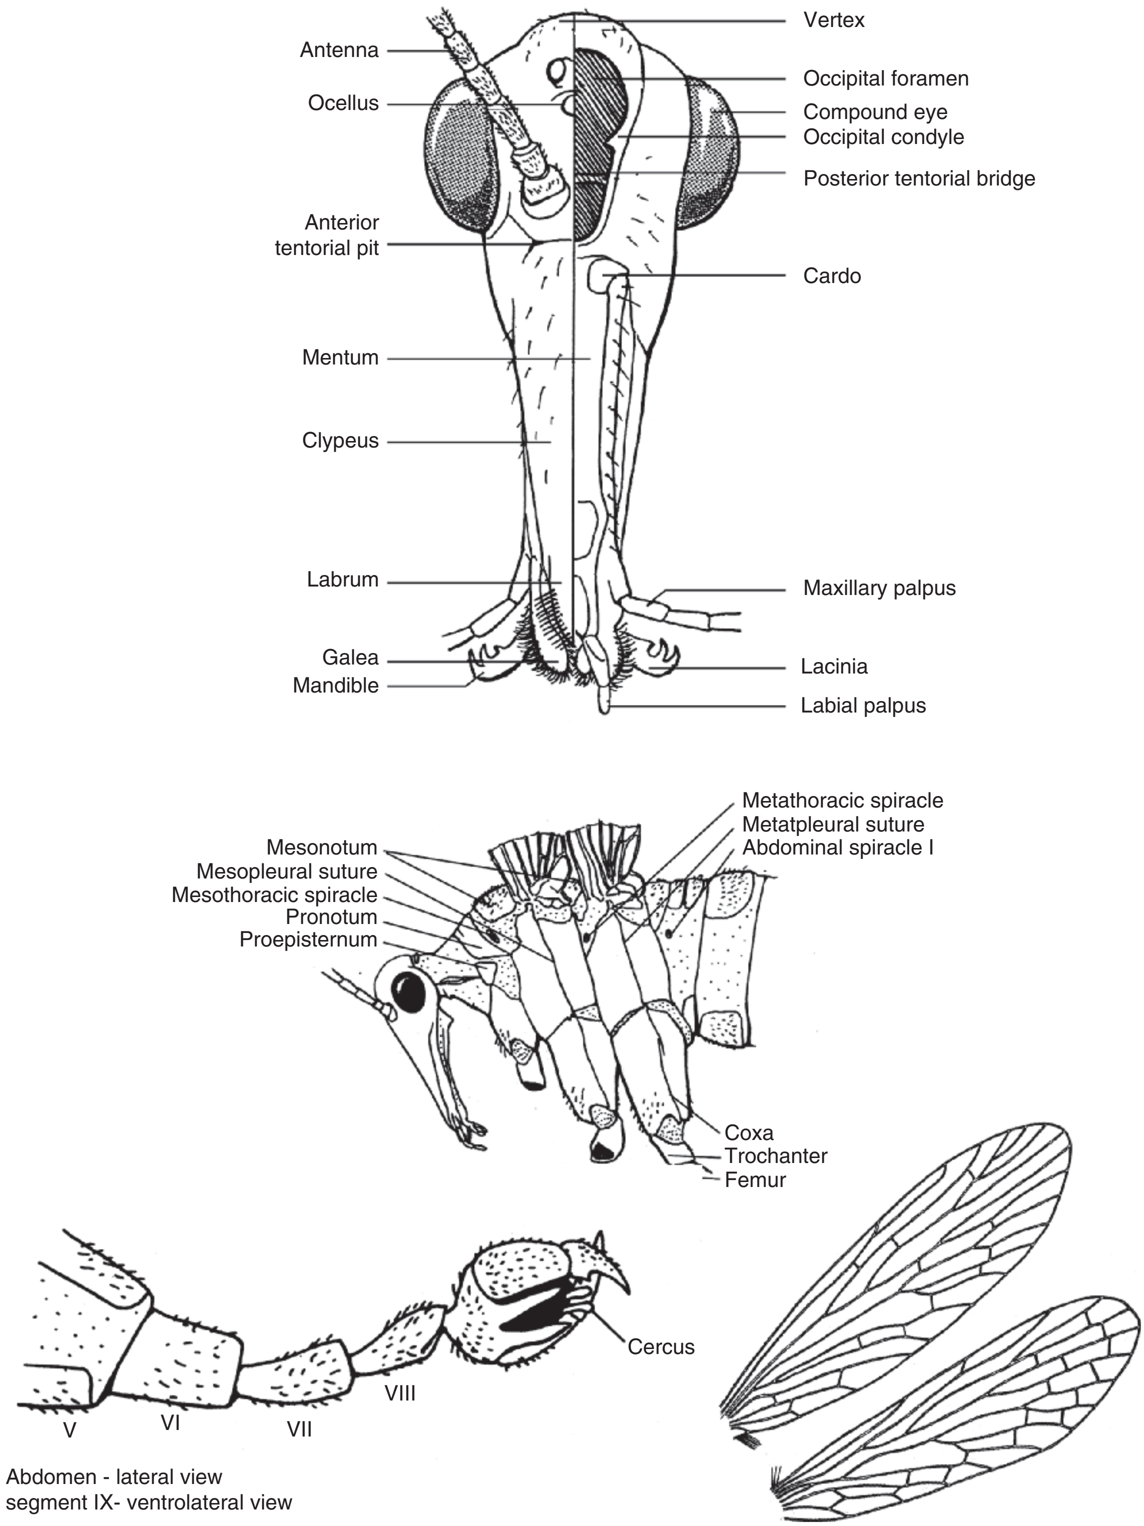
Larval Mecoptera are generally eruciform or caterpillar-like (e.g., Panorpidae, Bittacidae), while a few groups are grub-like in form (e.g., Boreidae, Panorpodidae). There are fleshy or setiform projections on the larvae in many groups and these may be used taxonomically. Larvae bear a well-sclerotized head capsule with compound eyes comprised of 3–30 ommatidia, or eyes may be absent (e.g., Panorpodidae: *Brachypanorpa* and *Panorpodes* spp.). Many groups have thoracic legs and fleshy prolegs on the first eight abdominal segments, or in some taxa the prolegs are absent (e.g., Nannochoristidae). *Panorpa* larvae pass through four instars and will remain in a prepupal diapause for as long as 7 months to overwinter. The larvae of Meropeidae (*Merope tuber* and *Austromerope poultoni*) and Eomeropidae (monotypic: *Notiothauma reedi*) are unknown.

The pupal stage is exarate in form (adult-like and capable of abdominal movement) with the wings compactly folded in sheaths. The mandibles are decticous (able to move) and are larger, and more larval-like than adult-like. Pupation typically occurs in a cell or burrow prepared by a fourth instar larva. Some bittacids cover their dorsal parts in fecal and soil particles. The time from pupal ecdysis to adult emergence varies between groups; it ranges from 10 to 21 days in *Panorpa*, 15–24 days in *Bittacus*, 14–50 days in *Harpobittacus*, or 37–40 days in *Boreus*.

Adult Mecoptera are largely defined on the basis of wing venation and tarsal structure, but have undergone relatively few structural changes since their first appearance geologically (Fig. 18). At the family level, extant Mecoptera are significantly diversified. *Boreus*, *Panorpa*, and *Neopanorpa* possess a distinct rostrum or "beak," but the heads of *Panorpodes* are comparatively less specialized and orthopteran-like in form. Compound eyes are typically large and many species bear three ocelli (these reduced or absent in *Boreus*, Meropeidae, and Apteropanorpidae). In general, Mecoptera have chewing mouthparts with short mandibles in phytophagous taxa, longer mandibles in saprophagous taxa, and elongate and blade-like mandibles in carnivorous groups such as bittacids. The nannochoristids have short but sharp mandibles that may be functionless. Antennae are typically filiform with the scape and pedicel enlarged, and depending on the taxon, range from 14 to 60 flagellar segments (Fig. 19).

The thorax is elongate in some groups (i.e., Panorpidae, Bittacidae, Choristidae) with the pronotum generally saddle-like, wider than long, and often with transverse ridges. Adult legs bear 5-segemeted tarsi with the basitarsus usually the longest. The pretarsus has two claws, except in Bittacidae, where a single, large claw is located at the end of each tarsus. Mecoptera have four membranous wings with several crossveins, and many species bear spots or transverse, colored bands. Hindwings are slightly shorter than the forewings and usually have similar markings. A few species are apterous (e.g., *Apteropanorpa*, *Apterobittacus*, and some female *Brachypanorpa* spp.) or brachypterous (e.g., *Boreus* spp.). The forewings and hindwings are not effectively coupled in flight, but there is a jugal lobe located on the forewing and stout setae at the base of the costal margin of the hindwing. *Merope tuber* has an enlarged jugal lobe that is utilized for stridulating against ridges located on the thorax (Fig. 20), hypothetically for communication between the sexes.

The abdomen is 11-segmented and is often slightly constricted at the attachment of the thorax. A genital bulb, resembling that of a scorpion "stinger," is located on the ninth abdominal segment of male panorpids, giving rise to the vernacular name "scorpionflies." Similar but less pronounced male genital morphology can be found in apteropanorpids, panorpodids, and boreids. Adult longevity depends in large part to reproductive biology, as males in certain groups may engage in risky activities associated with mating. For example, male meropeids have clasper-like terminal abdominal segments (see also, Earwigflies) that hypothetically may be used in male-to-male combat for females. Adult longevity in *Panorpa nuptialis* rarely exceeds a month, while adult *Hesperoboreus notoperates* in southern California can be observed from November to March. Under laboratory conditions, adults of various Mecoptera species are reported to live for 2–3 months.

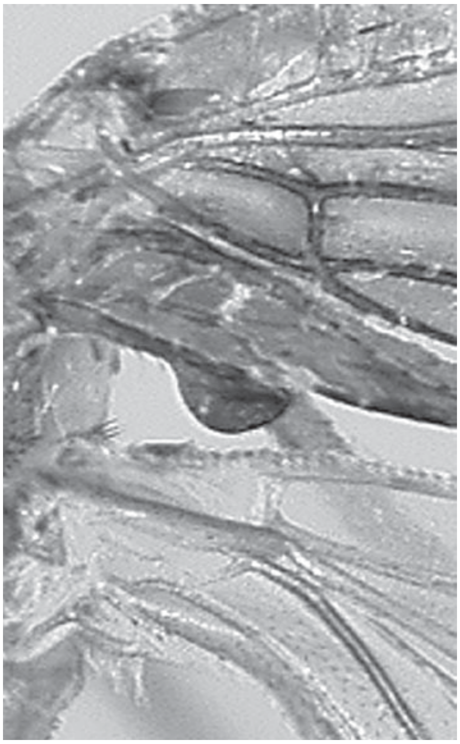


Scorpionflies (Mecoptera), Figure 18 **Morphology of adult scorpionfly (Mecoptera: Panorpidae): *above*, the head, showing anterior aspect on left, and posterior aspect on right; *center*, lateral view of the thoracic region; *lower left*, lateral view of the tip of the male abdomen; *lower right*, the front and hind wings.**

Dunford); (b) *Merope tuber* (Meropeidae), male; Wisconsin, USA (image by Steven J. Krauth); (c) *Apterobittacus apterus* (Bittacidae), female; California, USA (image by James C. Dunford); (d) *Panorpa nuptialis* (Panorpidae), male; Missouri, USA (image by James C. Dunford).**

Biology

Most Mecoptera inhabit moist environments, although a few species inhabit semidesert environments. Adults are frequently associated with broad-leaved plants, and can be occasionally observed in open, sunny areas. Scorpionflies (Panorpidae) are likely to be encountered in wooded habitats where there are deciduous trees growing in rich, shaded soils. Boreid adults occur in the winter months, and in montane habitats are often seen on the surface of snow or on mosses in which the larvae feed and can jump like fleas. Bittacids are known to inhabit grasslands, forests, and caves where high moisture levels occur. Since most mecopterans inhabit moist forests, any disturbance reducing moisture levels (i.e., deforestation) could adversely affect or extirpate the Mecoptera present. In general, Mecoptera are weak fliers, and dispersal can be severely limited if suitable habitat is reduced.



Scorpionflies (Mecoptera), Figure 20 Jugal lobe located on base of *Merope tuber* forewing (image by David Serrano).

The larval stage is often difficult to locate and unknown in some families, but they typically occur in mosses, dead leaves, and in soil cover in wooded areas. At least one species of nannochoristid, *Nannochorista philpotti*, has aquatic larvae. Many mecopteran species feed on decaying vegetation, or dead or dying soft bodied arthropods as larvae and/or adults; some groups are reported to feed on nectar, pollen, carrion, mosses, and larval midges, or less often dead mice and frogs. Bittacidae bear modified legs for grasping and holding prey such as Diptera, Hymenoptera and Lepidoptera. Kleptoparasitic *Panorpa* scorpionflies are known to feed on dead or dying insects captured in spider webs as well as the spiders inhabiting the web.

The males in many genera (e.g., *Panorpa*, *Bittacus*) emit pheromones to attract females, in some cases from several meters in distance. Mating behavior usually involves an offering of food from the male, and this is often a dead insect or a brown salivary secretion. The males of many boreid species bear slender, hook-like wings that are used to carry females on their backs during mating. Males are reported to run alongside the female for a short distance and then grapple with and grasp the female at the base of the abdomen with their modified wings, placing the female upon their backs during copulation. Male *Panorpa* vibrate their wings rapidly, and some species may stridulate as they approach the female and seize them just before copulation takes place.

A few natural enemies of Mecoptera have been reported in the literature, such as web-building spiders, damselflies, reduviid bugs, and asilid flies. Hymenopterous parasitoids are reported in some *Boreus* larvae. Although no economic importance is associated with Mecoptera, predatory *Harpobittacus nigriceps* (Bittacidae) adults have reportedly interfered with the biological control of ragwort by feeding on the cinnabar moth in Australia, and Bittacidae may be regarded as beneficial as they are known to feed on adult mosquitoes. Although Mecoptera are of little apparent economic significance, they represent a systematically and biologically important, ancient insect lineage.

Scorpions (Class Arachnida, Order Scorpiones)

DAVID. B. RICHMAN
New Mexico State University, Las Cruces, NM, USA

The scorpions are an ancient group of arachnids that date back at least as far as the Silurian, over 400 million years ago. They probably began as aquatic arthropods, as evidenced by the lack of tarsal claws on the earliest fossil scorpion such as *Palaeophonus*. Some of the earliest forms may have had gills, although this is not firmly established. While scorpions had certainly invaded the land by the Devonian, at least some were probably terrestrial by the Silurian (ca. 420 million years ago). By the Carboniferous (350 million years ago) many were almost indistinguishable from modern scorpions. At least some (including the earliest) appear to have had compound eyes, but these have been lost except for a small cluster of "simple eyes" at the front corners of the carapace. Scorpions are now considered to be closely related either to the harvestmen (Opiliones) or to the extinct Eurypterida (often placed with the horseshoe crabs in the Class Merostomata). The exact relationships are still being worked out and both claims are found in the literature.

Scorpions are primarily nocturnal and have adapted to live in very dry deserts, as well as tropical and subtropical forests and scrub, high mountains, grasslands, caves, intertidal zones of the oceans and other habitats. In deserts they survive largely by living in deep burrows or under rocks and only coming out at night to feed and mate. Like most arachnids, scorpions are predators and use their claw-like pedipalps to capture and hold prey while stinging it with the stinger at the end of their long curved postabdomen.

The anatomy of scorpions is unusual among the Arachnida. In addition to the claw-like pedipalps, 5-segmented postabdomen (metasoma) and stinger segment (telson), scorpions also have four pairs of walking legs, a pair of jointed and claw-like chelicerae, a pentagonal (most), triangular (Buthidae and Microcharmidae) or elongated split (Bothriuridae) sternum, a genital plate, and a pair of odd comb-like sensory structures called pectines. The exact function of the pectines is still debated, but they seem to function in habitat scanning and in chemoreception. Other important sense organs include the eyes (both median and lateral), which function in vision, light level perception and entrainment of daily biological rhythms, and the trichobothria, which are primarily air-borne vibration and touch receptors.

The biology of scorpions is much better known now than in J. Henri Fabre's time. Fabre, working in the latter half of the nineteenth century, did not discover the male's production of a spermatophore toward the end of the "promenade a deux" of scorpion courtship. He was under the mistaken impression that the mating actually took place under a rock or other object, after which the female ate the male. In reality, the walk or dance of the scorpions starts when male and female contact each other and the male grasps the female's pedipalps. The spermatophore is produced and the male pulls the female over the package of sperm, which is then picked up in her genital opening. Then he either escapes (probably in most cases in the wild) or gets caught and eaten (as Fabre observed in the close confines of his scorpion cages). A few species, notably a few *Tityus* from northern South America, reproduce parthenogenetically and have few or no males.

Young scorpions are produced alive by viviparity. The young of some species actually are attached to the mother at their mouth, forming a sort of placenta. At birth the baby scorpions clamber onto the mother's back and ride until the first molt, after which they typically disperse. Scorpions may live for at least several years, even after reaching adulthood. Some, such as *Hadrurus*, as well as some of the diplocentrids, ischnurids, and scorpionids have been reported to live as long as 20 years, about the same at that reported for some tarantulas.

The taxonomy of scorpions has been undergoing great changes in the last few years. Sissom recognized nine families in 1990 (Bothriuridae, Buthidae, Chactidae, Chaerilidae, Diplocentridae, Ischnuridae, Iuridae, Scorpionidae and Vaejovidae). By 2000 this had nearly doubled to 16 families (Bothriuridae, Buthidae, Chactidae, Chaerilidae, Diplocentridae, Euscorpiidae, Heteroscorpionidae, Ischnuridae, Iuridae, Microcharmidae, Pseudochactidae, Scorpionidae, Scorpiopidae, Superstitioniidae, Troglotayosicidae and Vaejovidae). Two more families, the Hemiscorpiidae and the Urodacidae, have been proposed by Prendini, the new families being separated from the Ischnuridae and the Scorpionidae, respectively. A cladistic analysis published by Soleglad & Sissom (2001) has now placed the Scorpiopidae as a subfamily under the Euscorpiidae. More recent proposals have become quite controversial and until a consensus is reached it seems wise to retain the classification of 2000–2001, while keeping in mind that this will probably change.

The North American species of scorpions are primarily in the families Buthidae, Chactidae, Diplocentridae, Iuridae and Vaejovidae. The family Superstitioniidae is represented in the United States by the southwestern species *Superstitionia donensis*. The family Euscorpiidae includes several species in tropical Mexico and Guatemala and South America, but is otherwise all Old World, including Asia. Most scorpion species in the United States are found in the southern tier of states, with the largest number in Texas, New Mexico, Arizona and California. One species reaches British Columbia in the west and another reaches Virginia in the east. There are no scorpions in the northeastern United States and most of Canada.

Of the buthids, only the genus *Centruroides* is found in the United States. There are five known species, with three (*C. gracilis*, *C. hentzi* and *C. guanensis*) occurring in Florida and two (*C. exilicauda* and *C. vittatus*) in the midwestern and southwestern United States (Fig. 21). The genus *Centruroides* is more complex in Mexico, where it contains a number of dangerous species, such as *C. noxious*, *C. limpidus*, *C. infamatus, C. elegans*, and *C. suffusus* (the so-called Durango scorpion). All are very slender scorpions, with the metasoma especially elongate in the male, and most have a subacular tubercle just anterior to the stinger on the ventral side of the telson. Most are straw-colored, except for *C. gracilis*, which is dark and gets as large at 11 cm in total length, and a similar large and dark-colored species, *C. margaritatus*, found in Mexico and Central America, south into South America. *Centruroides gracilis* has also been introduced to the Canary Islands and *C. margaritatus* is known from the Cape Verde Islands, Sierra Leone and Gambia. These are the only members of the genus found outside the New World.

In the rest of the world there are a number of buthid genera. In South America and nearby islands the genus *Tityus* includes several

Scorpions (Class Arachnida, Order Scorpiones), Figure 21 ***Centruroides vittatus*** **male from New Mexico. Photo by D. Richman**

dangerous species. In the Middle East and North Africa there are several genera including dangerously venomous species. These include *Leiurus* and *Androctonus*. These scorpions are large (8–10 cm) in length and possess highly potent neurotoxins. There is a record of a healthy adult dying in 4 h after being stung by *Androctonus australis*. Oddly, the effects of the venom differ from population to population and some local populations are "hotter" than others. In the rest of Africa there are other genera that may be dangerous, such as *Hottentotta*. Some members of *Buthus*, which is widespread from southern Europe into Asia and Africa, can also be dangerous. Common, but apparently much less dangerous and widely ranging genera include *Isometrus* and *Lychas*. *Isometrus maculatus* is common in Hawaii, where it is likely introduced. Although readily available through the exotic pet trade, live specimens of the more venomous buthids, such as *Androctonus australis*, should only be kept by experienced researchers.

Chactids occur from Mexico south into Central and South America. Only the genus *Nullibrotheas* is known from North America. The family is closely allied to the Vaejovidae and was initially difficult to separate from it. All chactids are known now to have many accessory trichobothria (slender sensory hairs), while almost all vaejovids have the basic trichobothrial pattern without accessories.

Diplocentrids are represented in the United States by the genus *Diplocentrus*, which ranges south into Mexico. This genus consists of chunky, highly polished rock-dwelling scorpions with large pedipalps and pronounced subacular tubercles. None are known to be dangerous. Other genera occur in Mexico, Central America, South America, the Caribbean and parts of Asia.

Iurids include the largest of North American scorpions in the genus *Hadrurus*. These desert dwelling scorpions can reach over 12 cm and make an impressive sight when out foraging after dusk. The genus *Anuroctonus* (only recently removed from the Vaejovidae) contains only one species, which is distinguished from all other scorpions by the male having a bead-like swelling on the stinger (Fig. 22). It lives primarily in burrows under rocks in desert and coastal mountains from Utah and northern Arizona through California. Of the remaining four genera, *Hadruroides* is known from Ecuador and Peru, including the Galapagos Islands, and *Iurus* (the type genus for the family) is found in Turkey. None are known to be dangerous.

Scorpions (Class Arachnida, Order Scorpiones), Figure 22 ***Anuroctonus phaiodactylus*** **male from California. Photo by D. Richman.**

Vaejovids make up the largest part of the North American fauna. The genus *Vaejovis* is by far the largest, with over 60 species known from the United States and Mexico. *Vaejovis spinigerus* is the common "devil scorpion" of the Southwest United States. *Vaejovis coahuilae* replaces it in the Chihuahuan Desert (Fig. 23). *Vaejovis carolinianus* is found in the Southeast, north of Florida. A number of other species are known from Arizona, New Mexico and Texas, with many more in Mexico. Other common genera include *Paruroctonus*, *Serradigitus*, *Smeringurus* and *Uroctonus*. Most of these were in the old genus *Vaejovis*, which is still huge despite the deletions.

Recognized families (until 2003) not found in North America include Bothriuridae (South America,

Scorpions (Class Arachnida, Order Scorpiones), Figure 23 ***Vaejovis coahuilae*** **from New Mexico. Photo by D. Richman**

Scorpions (Class Arachnida, Order Scorpiones), Figure 24 ***Hadogenes troglodytes*****, the flat rock scorpion from South Africa. Photo by D. Richman**

Africa, India and Australia), Chaerilidae (one genus from southern and southwest Asia), Heteroscorpionidae (all from Madagascar), Ischnuridae (Europe, Asia, Africa, South America, and Australia), Microcharmidae (Africa), Pseudochactidae (Asia), Scorpionidae (Africa and Asia), Urodacidae (Australia), and Hemiscorpiidae (Asia and northeastern Africa). Some of the Ischnuridae and Scorpionidae genera are commonly sold in the exotic pet trade, especially *Scorpio* and *Pandinus*.

Scorpions (Class Arachnida, Order Scorpiones), Figure 25 ***Pandinus imperator*** **from West Africa. Photo by D. Richman.**

The latter and the Ischnurid genus *Hadogenes* include the largest living scorpions known, reaching around 20 cm in length (Figs. 24 and 25). These giants have venoms with very low toxicity and thus are not really dangerous. Several species of *Pandinus* are now on the CITES list and so trade in these giant scorpions is monitored for wild-caught individuals.

Scouting

Systematic, regular monitoring of plants or animals, normally as part of an effort to determine the need for suppression.

► Sampling of Arthropods

Scramble Competition

Competition for limited resources, often intraspecific competition, wherein all individuals have equal access and a free-for-all occurs, with resources being dissipated among the many individuals, and in some cases inadequate supply for any individuals. This also is known as exploitation competition.

Scraper

In some Orthoptera (katydids and crickets), the anal angle of the tegmen, which rubs against a file; part of the stridulatory apparatus.

Scrapers

Insects in aquatic communities that feed by grazing on algae growing on rocks.

Scraptiidae

A family of beetles (order Coleoptera). They commonly are known as false flower beetles.

► Beetles

Screwworms, *Cochliomyia* spp. (Diptera: Calliphoridae)

E. S. KRAFSUR
Iowa State University, Ames, IA, USA

American screwworms, the larvae of *Cochliomyia hominivorax* (Coquerel 1858) (Diptera: Calliphoridae), are obligate parasites that cause wound myiasis in mammals. Also called "primary" screwworms, American screwworms are now referred to as "New World Screwworms," or "NWS," to distinguish them from the unrelated "Old World screwworm" *Chrysomya bezziana*. The epithet "screwworm" is derived from the screw-like appearance of a larva and its vertical orientation, head down, in the wound of a host animal. Picture a hole in the skin in which a tightly packed cluster of woodscrews wiggle and squirm in a soup of blood and lymph. An infestation often attracts additional females to lay their eggs, leading to an growing infestation, increased tissue loss and death of the host if untreated.

New World screwworms are indigenous in tropical and subtropical region of the Americas and they can extend their range to temperate regions during warm seasons. In North America, screwworm outbreaks have been recorded as far north as Nebraska, South Dakota, Iowa, Illinois, Wisconsin, and Minnesota in the upper midwestern states of the USA, and North Carolina in the east. They have occurred also in California, Nevada, and Colorado. Screwworms were unknown in eastern North America until 1933, when they introduced via infested livestock imported from the southwestern USA. NWS became established and overwintering successfully in southern Florida. In 1934, they spread in a devastating epizootic to Mississippi, Alabama, Georgia, and the Carolinas. Screwworms east of Texas were eradicated by using the sterile insect technique in 1959. New World screwworms also became established in 1988 in Libya, via infested sheep imported from South America. They have since been eliminated from Libya as well as North and Central America, as reviewed below.

Morphologically similar and easily confused with screwworm flies is the saprophagic blow fly, *Cochliomyia macellaria* (Fabricius 1775), now referred to as the "secondary screwworm." In 1933, Cushing and Patton recognized the differences between *C. americana* and *C. macellaria*, with which it had been confused Later it was determined that *hominivorax* (Coquerel 1858) had priority over *americana* (C & P). The median mesonotal stripe of screwworm flies is shorter than the two lateral stripes (Fig. 26). In *C. macellaria*, the three mesonotal stripes are of equal length. Although rarely found in wounds of living animals, larvae of *C. macellaria* feed only on dead or necrotic tissue whereas screwworm larvae invade and feed on healthy, living tissue. New World screwworm larvae show two dark posterodorsal tracheal trunks but the tracheal trunks of secondary screwworm larvae are not darkly pigmented. Even before screwworms were eliminated from North America, *C. macellaria* was far more common than *C. hominivorax*.

Economic Importance

Female screwworm flies are attracted to wounds of cattle caused by dehorning, castration, branding, and tick infestations, especially those of the Gulf Coast tick, *Ambylomma maculatum* Koch. Shearing wounds in sheep and goats also are attractive. Animals are at particular risk during parturition, as are their newborns, via screwworm oviposition on the vulva and the umbilical cord, respectively. Screwworm infestations usually lead to death in untreated animals. Screwworms cost the animal industry in several ways. Damaged hides and dead animals are important losses. Also costly is continuous inspection and treatment, and restriction of certain husbandry practices to times of predictably least risk. Apart from their economic importance to livestock production, screwworm infestation of humans is an important health consideration.

The total financial cost of screwworm eradication over the 45 year effort, including appropriations from Mexico and the Central American countries, was about $1.3 billion. The annually recurring benefits of screwworm eradication were estimated to be $1.312 billion in a 1996 study.

Screwworms no longer occur in North America, but remain in South America (except Chile) and some Caribbean islands, including Cuba, Hispaniola, Trinidad, Tobago, and Jamaica. The disappearance of screwworms from North America and Central America can be attributed to application of the sterile insect technique, together with extension and quarantine measures carried out by the United States Department of Agriculture, the Mexico-American Commission, and national agencies of Belize, Nicaragua, Guatemala, El Salvador, Honduras, and Panama. Eradication programs are reviewed briefly after a discussion of relevant screwworm biology.

Screwworm Biology

To understand the epizootiology of screwworm infestations, we must consider the fly's reproductive biology and ecology. Ovarian development in screwworms is, of course, temperature dependent. Females are autogenous so they do not require a protein meal to initiate the first ovarian cycle. They do, however, require exogenous protein to support subsequent ovarian cycles. Females can be seen feeding on serous fluids in mammalian wounds. The number of eggs produced in a clutch varies with the size of the fly. The range is about 250–425 eggs and some or all may be oviposited on a single wound (Fig. 26). At summer temperatures, second and subsequent cycles of ovarian development occur at about 3-day intervals. Females usually become inseminated by day five after eclosion and single matings are the rule. Screwworm demography suggests a mean adult female expectation of life of about 7 days at summer temperatures. Expectation of life is longer at cooler temperatures, but oviposition intervals become greater.

Screwworms do not exhibit diapause or a quiescent period that allow them to survive winter or dry seasons. Generations continuously overlap. Early studies indicated that screwworms die out completely when daily mean temperatures drop below 10°C for 3 months. Adults become inactive when temperatures drop below 21°C but the threshold temperature for ovarian

Screwworms, *Cochliomyia* spp. (Diptera: Calliphoridae), Figure 26 Screwworm fly ovipositing at wound.

development is only ca. 9°C. In most winters, screwworm overwintering in USA was confined to southern Texas and southern Florida, but overwintering also occurred in Arizona, New Mexico, and southern California in mild winters. Because pupal development and ovarian development are temperature dependent, generation times can require up to 2 months or more in the cooler months. Eggs and larvae are insulated from diurnal temperature fluctuations because they are on or in their mammalian hosts.

The chief limiting factor in screwworm abundance is thought to be the availability of suitable oviposition sites. Indeed, before screwworms were eliminated from North America, control and inspection of wounds on domestic animals was the chief method of preventing screwworm infestation. Other limiting factors have been shown to include high summer temperatures and low winter temperatures. Extensive studies in Texas do not support the contention that wet weather *per se* favored screwworms.

Screwworm fly densities, averaged over time and space, often are quite low, but sampling distributions are highly aggregated. A typical distribution shows the most frequent daily sample is zero, a large number of ones, and progressively fewer samples showing multiple flies or ovipositions or cases. Thus, most screwworms tend to occur in a small fraction of sampling units. This means that densities can be quite high locally, but transiently so, whereas most sampling units experience comparatively low risk most of the time. Such clumped distributions have an important bearing in planning sterile fly releases because a local screwworm outbreak is begun by fertile flies that cannot later be made sterile. Sterile males must be distributed in such a way as to be present when wild virgin females eclose. Thus, sterile fly dispersions must be made continuously wherever screwworms may occur.

The Sterile Insect Technique and Screwworm Eradication

Biological Considerations

Essentially, the sterile insect technique (SIT) is applied birth control. Sterility via dominant lethal mutations is induced in factory produced males (and females) which are continuously released into a wild, target population. Sterile matings result in no progeny. In theory, as a target population declines, the ratio of sterile to fertile increases, leading to higher frequencies of sterile matings and decreasing natural population size until it is no longer self-sustaining.

A number of key advances in our knowledge of screwworm biology led to the development and practical application of the SIT. First was the finding by Emory Cushing and colleagues at the Liverpool School of Tropical Medicine that the erstwhile screwworm, *Cochliomyia macellaria* (Fabricius 1775), as it was then known, was a complex consisting of *C. americana* (now *hominivorax*), an obligate parasite, and the saprophagic *C. macellaria*. The second key advance was learning how to rear screwworms and maintain them in continuous laboratory culture. This eventually led to mass rearing, an endeavor that continues to develop incremental improvements. The third advance was learning to sterilize flies with ionizing radiation – in the first instance, with x-rays. Mass production of sterile flies eventually depended on Cobalt-60 and more recently Cesium-137. It is now planned to return to using X-rays to induce sterility in the new Panama screwworm production plant. Rather high doses are administered (80 Gy) in efforts to inhibit ovarian development in the females. This causes an incremental loss of male competitiveness. Another advance was to falsify the assumption that sterile male flies behaved as the females in dispersal behavior. Recapturing sterile females after aerially or ground releasing large numbers suggested screwworm flies dispersed over wide distances. Released male flies, however, were recaptured in very low numbers but it was assumed erroneously that they demonstrated the same dispersal behavior as females. It was shown in 1976 that males did not actively disperse, but perched on vegetation awaiting opportunities to mate with screwworm females in the immediate area. Appropriate modifications to program release tactics as practices in the southwestern USA program greatly improved sterile mating rates beginning in 1977. The improvements included maximizing the chances of placing sterile males at potential breeding sites by packaging sterile flies in smaller boxes and releasing them from flight lanes set two miles apart instead of five or ten miles apart, as had been the practice in the southwestern eradication program.

Monitoring Screwworm Abundance and Program Effectiveness

Screwworm adult populations were sampled by using Bishopp traps baited with rotting liver. Beginning in 1975, a chemical attractant called "swarmlure" was developed and replaced liver as the bait. Trap catches consist mostly of *C. macellaria* and other blow flies, but include female screwworm flies as well. Wherever sterile fly dispersions are made, traps rapidly accumulate large numbers of released females. But trapping is inefficient for monitoring fertile screwworm distribution and abundance because labor requirements are great, and visually distinguishing wild from released flies is highly uncertain.

Screwworm infestations were monitored by animal inspection and laboratory identification of larvae from wounds. In the USA, stockmen removed larvae from infested animals, placed them in tubes containing ethanol, and submitted them postpaid to the responsible USDA laboratory where specific diagnosis was made. Each confirmed submission was termed a "case" and these were summed by month, county, and state. The efficiency of the procedure depended on the willingness and timeliness of stockmen to submit larvae. Case incidence was used to plan sterile fly releases and monitor program effectiveness.

Historical Aspects of Screwworm Eradication

The first trials of the SIT were carried out on Sanibel Island, offshore from Ft. Myers, Florida, USA, in 1951–1953. Sterile screwworm flies (both sexes) were ground released in small packets. Native screwworm fertilities approached zero, as measured by egg hatch on artificially wounded, sentinel animals, and case incidence dropped to low levels. Remaining cases were attributed to immigrating flies from the mainland, some 3.2 km distant. Plans were then made to attempt eradication in an environment at no detectable risk of immigration. The location chosen was Curaçao, an island of 444 km^2 in the Netherlands Antilles, one of the Leeward Islands in the southern Caribbean, 65 km north of Venezuela. Here, in a classic experiment carried out in 1954, sterile flies were released from aircraft over the entire island. Pens of artificially wounded, sentinel sheep were used to monitor sterile mating rates and simultaneously provide estimates of wild population density. The island was declared free of screwworms after 6 months. The next SIT trial was in Florida, where screwworms could overwinter in the southern half of the state. This experiment developed into an eradication program, a massive undertaking compared with the Curaçao project. The Florida program became operational in 1958, producing and distributing up to 60 million sterile flies weekly (half males) over areas up to 226,00 km^2, and was successfully concluded in 1959.

A far more extensive program than Florida's was established in the southwestern USA in 1962. Screwworms were known to overwinter in Texas south of San Antonio and in small areas of southern New Mexico, Arizona, and California, but all the border states, from Texas west to California, were subject to annual invasion from Mexico. Given screwworm propensity to disperse rapidly and widely, a containment strategy instead of eradication was necessary. For this reason, arrangements were made with the Mexican government in 1962 jointly to carry out extension, inspection, and sterile fly releases in a "barrier zone" on the USA-Mexico frontier that extended 160 km into Mexico. The area to be treated rapidly expanded northward during the warm season, April to October. As monthly screwworm cases increased in the USA, sterile fly dispersions were withdrawn from Mexico. It was decided, therefore, to attempt eradication in Mexico north of the Isthmus of Tehuantepec, where a much smaller barrier could be established and maintained. A joint Mexico-American Commission for the Eradication of Screwworms was then established in 1972. The agreement included provision to construct a factory for screwworm production in Tuxtla Gutierrez, Chiapas State, Mexico, with weekly production capacity of up to 550 million sterile flies. The factory went into production in 1976 and is still operational as of this writing (March 2007).

An unexpected epizootic in the southwestern USA occurred in 1972 and continued with varying intensity through 1976. The epizootic attracted international attention from scientists and generated a rich literature in which climatic and genetic hypotheses to explain the epizootic and concomitant control failures were advocated and later falsified.

The last autochthonous screwworm cases in North America were detected in 1982. The course of eradication in Central America included Mexico north of the Isthmus of Tehuantepec in 1984, but movements of livestock from untreated Yucatan Peninsula to eradicated areas north of the isthmus were a constant risk and divided Mexico's livestock industry into two regions. A barrier further to the south was necessary. The Darien Gap in Panama is the smallest area that could serve as a barrier. It was estimated that such a barrier would require for its maintenance only 50 million sterile flies (half males) weekly. That goal was reached in 2004 and no self-sustaining screwworm populations have been detected in the barrier since then. The barrier, which includes proximal portions of Colombia, is now treated with 40 million sterile flies weekly.

Sterile fly production for the Central American and Libyan eradication programs was carried out at the Tuxtla Gutierrez plant in Mexico. Pupae were shipped by air to dispersal centers in participating countries, placed in boxes, and the boxes dispersed from aircraft. Further progress in elimination of screwworms includes the Yucatan and Quintana Roo states of Mexico in 1991, Belize and Guatemala in 1994, and Central America south to the Darien Gap in Panama in 1999. Screwworms have also been eliminated from Puerto Rico and the Virgin Islands.

An effort to eradicate screwworms in Jamaica by using SIT was begun in 1997 and terminated in 2006 when it became clear that program management and administration was inadequate, unresponsive, and unchanging.

A new screwworm production factory has been built in Panama and it is scheduled go into production in 2007. It will have the capacity to produce 150 million sterile flies weekly.

New World Screwworms in Libya

The first Libyan collections of American screwworm larvae were made in March 1988, from humans, and specific diagnosis was confirmed the next December. A total of 234 human cases was diagnosed in 1988. It was clear that screwworms were well established and an epidemic/epizootic encompassing 26,500 km^2 was recorded in Northwest Libya that continued until 1990. Intensive efforts by the International Atomic Energy Agency, the United Nations Food and Agriculture Organization, and Libyan authorities began in December 1990 and involved the aerial dispersal of up to 40 million flies weekly. Equally important, 70 teams of livestock inspectors traveled throughout the infested region helping stockmen to locate, treat, and report screwworm cases. All detected wounds were treated prophylactically, and active cases were treated definitively. The last infestation was detected in early April 1991, but intensive surveillance continued until July 1992 when eradication was declared complete.

Risks of Screwworm Incursion

The Libya infestation highlights a risk of modern commerce and travel, that of unknowingly distributing dangerous plants, animals, disease agents, and pests. Introduction of New World Screwworms to old and new habitats is a clear and present danger, given the increasingly heavy volume of commercial and international transport including pets and livestock on the hoof. There have been numerous recent detections of screwworm-infested livestock, pets, and humans in North America, Europe, New Zealand, and Australia. In all instances, the infestations originated in countries where screwworm remain enzootic. There have been no autochthonous cases in the USA, but two instances of screwworm outbreaks in Mexico were traced to sabotage from workers worried about becoming unemployed when eradication was achieved, thus illustrating the danger of accidental or intentional introductions.

Screwworm Detection and Treatment

Detection can be difficult because close, detailed inspection for wounds is required. Ideally, animals from screwworm endogenous regions should be quarantined, with inspection for up to 7 days to detect maturing larvae before they drop out of the wounds and pupate.

Chloriform, benzol, or ethyl ether can kill most larvae and cause others to exit wounds. Insecticidal treatments include brushing 5% coumaphos powder in cooking oil on wounds, and application of puffed fenchlorophos or coumaphos powders or aerosols of dichlorofenthion. Infesting larvae can be killed by using ivermectin applied topically or subcutaneously by injection. For human cases, oral administration of ivermectin at 200 μg/kg or a topical application of 1% in propylene glycol are recommended.

Larvae from myiasis cases should be preserved in ethanol solution and submitted to animal health authorities for specific identification. In the USA samples should be sent to the US Department of Agriculture, Animal and Plant Health Inspection Service, Veterinary Services, National Veterinary Services Laboratories, 1800 Dayton Avenue, Ames, IA 50010. Important information can be found on their website: http://www.aphis.usda.gov/vs/nvsl.

Scudder, Samuel Hubbard

Samuel Scudder was born at Boston, Massachusetts, USA, on April 13, 1837. He is known for his pioneering work in the Orthoptera and Lepidoptera, but especially in insect paleontology, and is considered to be the founder of insect paleontology in the United States. He was educated at Williams College and Harvard University, in Massachusetts. He was appointed custodian of the Boston Society of Natural History in 1864, and assistant librarian of Harvard University in 1879. Scudder was one of the founders of the Cambridge Entomological Club, founder of the journal Psyche, and editor of Psyche from 1883 to 1885. He served as president of the Boston Society of Natural History from 1882 to 1887, and was employed as paleontologist with the United States Geological Survey from 1886 to 1892. Scudder described over 2,000 fossil insects and published the "Index to the known fossil insects of the world, including myriapods and arachnids," in 1891. Scudder's interest in Orthoptera began in 1862 and continued until about 1900; during this period he developed the reputation as being America's foremost orthopterist. He described about 630 species and 106 genera of grasshoppers. Among his important publications on Orthoptera were "Catalogue of the Orthoptera of North America described previous to 1867," and "Catalogue of described Orthoptera of the U.S. and Canada." Scudder's work on Lepidoptera began in 1889 when he published a 3-volume treatise "Butterflies of the Eastern United States and Canada." Over the course of his career, Scudder published 791 papers and was a member of numerous scientific societies. He died in Cambridge, Massachusetts, on May 17, 1911.

Scutelleridae

A family of bugs (order Hemiptera). They sometimes are called shield-backed bugs.

► Bugs

Sculpture

The insect integument and insect chorion possess various ridges, grooves, and depressions that collectively are called sculpture or ornamentation. They may be obvious, but often require magnification. They usually serve some function, though their purpose may not be immediately apparent. Often the sculpture proves to be an aid in identification of the insect.

Scutate

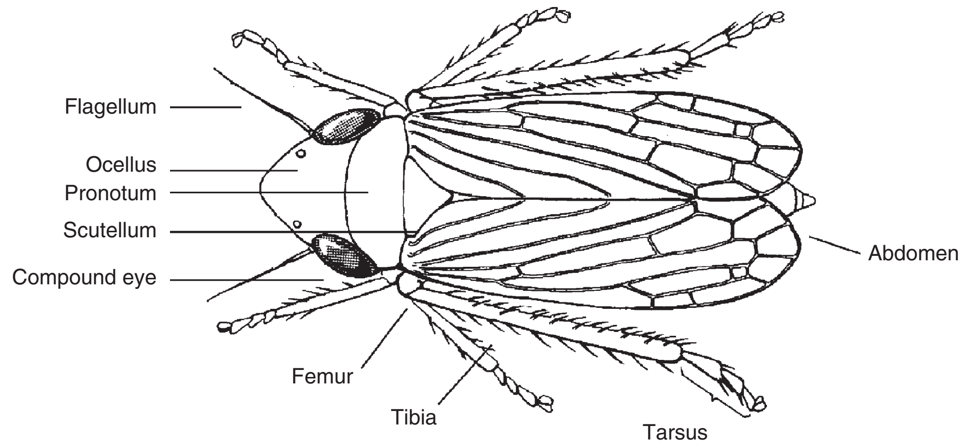
This has two meanings: (i) it is used to describe a structure that is covered with large plate or scales, and (ii) it is sometimes used to describe a structure that is shield-shaped.

► Scutellum
► Scutum

Scutellum

In Hemiptera, the triangular mesothoracic region between the base of the wings; in other winged insects, a small posterior section of the meso- and metanotum, separated from the scutum by a suture (Fig. 27).

► Thorax of Hexapods



Scutellum, Figure 27 **Adult leafhopper (Hemiptera: Cicadellidae).**

Scutum

The middle region of the meso- and metanotum, set off from the scutellum by a suture.

► Thorax of Hexapods

Scuttle Flies, (Diptera: Phoridae)

Members of the fly family Phoridae are sometimes called scuttle flies or coffin flies.

► Myiasis
► Flies
► Decomposition by Insects

Scydmaenidae

A family of beetles (order Coleoptera). They commonly are known as antlike stone beetles.

► Beetles

Scythrididae

A family of moths (order Lepidoptera). They commonly are known as flower moths.

► Flower Moths
► Butterflies and Moths

Seal Lice

Members of the family Echinophthiriidae (order Phthiraptera).

► Chewing and Sucking Lice

Seaside Earwigs

Some of the earwigs in the family Carcinophoridae (order Dermaptera).

► Earwigs

Sea Spiders (Pycnogonida)

ALLEN CROOKER
Hartwick College, Oneonta, NY, USA

The Pycnogonida (Gr. *pyknos*, thick, dense + Gr. *gony*, knee) are a class of small, primarily benthic marine arthropods often called sea spiders because they superficially resemble the true, terrestrial spiders. Like true spiders, pycnogonids possess an anterior pair of chelicerae followed by a pair of pedipalps and four pairs of long, slender legs. However, unlike spiders or any other arthropod, pycnogonids possess an unsegmented anterior proboscis, special brooding appendages (ovigers) in the male, male brooding behavior, an unusual body form with poorly-defined regions, a unique body-coxa joint, multiple gonopores, and polymerous species with 10 or 12 walking legs instead of the usual eight. The cephalothorax is more slender and the abdomen is much smaller than that of true spiders. Unlike true spiders, sea spiders do not possess a specialized respiratory system. Much of the body cavity is filled with the digestive and reproductive systems, both of which extend far into the legs – an unusual feature for any arthropod. The legs of pycnogonids may be two or three times longer than the cephalothorax. The long legs give this group a second name, Pantopoda (Gr. *pantos*, all + Gr. *pous* (gen. *podos*), foot). Sea spiders are classified as follows:

Phylum: Arthropoda
Subphylum: Cheliceriformes or Chelicerata
Class: Pycnogonida

Pycnogonids inhabit all oceans and can be found from the littoral (intertidal) zone to the abyssal and hadal zones at depths of nearly 7,000 m. Most pycnogonids belong to the epifauna and walk slowly about on the substrate; some species can swim. There are a few planktonic and bathypelagic pycnogonids and a few are members of the infauna. Pycnogonids obtain their nutrition by using the proboscis as a piercing-sucking organ to extract fluids and/or tissues from other marine invertebrates such as hydroids, bryozoans (ectoprocts or polyzoans), anemones, soft corals, sponges, and molluscs. Some, possibly many, pycnogonids are scavengers. A few pycnogonids are herbivores of algae that grow on the surface of sessile organisms and a few are detritivores.

Although sea spiders are cosmopolitan, they are easily overlooked because they are not usually numerous and because they are often small and cryptic. Most pycnogonids have a body length of 2–10 mm and a leg span of 5 mm to 3 or 4 cm. However, some species of *Austrodecus* and *Rhynchothorax* have a body length <1 mm and a leg span of 3 mm, while some species of *Colossendeis* regularly attain a body length of 6–10 cm and a leg span of 30–40 cm. The largest leg span reported for a pycnogonid is 70 cm for *C. colossea*; the smallest leg span is 2 mm for *Austrodecus palauense*. Coloration and encrusting organisms on the body of sea spiders contribute to their crypsis. Pycnogonids are often transparent or a translucent cream or white, or they may be an opaque pale brown or pale yellow. Some species, however, are green, purple, orange, bright red or even multicolored. The body may be covered with detritus or encrusting organisms such as hydroids.

There are approximately 1200 living species of pycnogonids in 87 genera and 8–10 families. Living species of the class Pycnogonida are assigned to the order Pantopoda; fossil specimens are placed in the order Paleopantopoda. The poor fossil record of this archaic group includes only a few species that date back to the Lower Devonian of Germany, the Silurian of England, and the Upper Cambrian of Sweden.

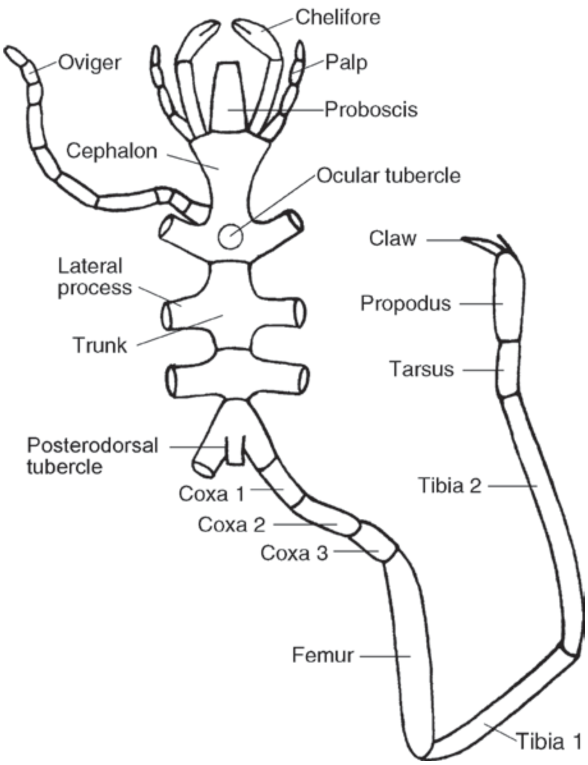
External Anatomy

The body is divided externally into the appendages and a central region that includes a narrow tubular cephalothorax (prosoma) and a short conical abdomen (opisthosoma).

Cephalothorax

The cephalothorax can be divided into the anterior cephalon (head) and the more posterior thorax (trunk) (Fig. 28). The cephalon is comprised of four segments that appear to be one while the thorax possesses three segments that are not always distinct. The cephalon and each of the thoracic segments possess one pair of walking legs.

The cephalon may be compact or elongate and possesses the proboscis anteriorly, the eyes dorsally, and up to four pairs of appendages (one pair each of chelifores, pedipalps, ovigerous legs, and walking legs). The proboscis is a prominent tubular structure that articulates proximally with the cephalon by way of a flexible cuticle (arthrodial



Sea Spiders (Pycnogonida), Figure 28 External features of a long-legged pycnogonid, dorsal view. One walking leg and one oviger are shown.

membrane) similar to that found in the leg joints. The proboscis is triradiate in cross-section and varies considerably in size and shape from relatively short and slender to elongate and bulbous. In some species, the proboscis may be half the length of the cephalothorax. The distal end of the proboscis possesses an opening, sometimes called the mouth, surrounded by three lip-like lobes. The surface of the proboscis cuticle may be smooth, or it may be covered with tubercles or an occasional spine. Setae are present on the proboscis and these may be mechanosensory or chemosensory. Four simple eyes are usually present on a tubercle located mid-dorsally on the cephalon. Species in the genus *Stylopallene* have eight eyes while in some pycnogonids the four eyes may be fused into two. The ocular tubercle may be anterior or posterior on the cephalon and may be small or prominent; in some abyssal forms the tubercle and the eyes are lacking. The posterior portion of the cephalon, with its lateral processes and single pair of legs, is regarded as a trunk segment that has fused with the head to form the cephalon.

The trunk segments possess prominent bilateral processes (pedestals or crurigers) that are often longer than the associated body segments. The walking legs articulate with these processes.

Abdomen

Pycnogonids lack the large abdomen characteristic of most chelicerates. Traditionally, the unsegmented projection (often called the posterodorsal tubercle, Fig. 28) borne distally on the last trunk segment has been called the abdomen (opisthosoma). However, recent evidence indicates that the abdomen includes the tubercle plus the last limb-bearing segment. The posterodorsal tubercle is often truncate and conically shaped or tapering, though it may also be clavate or cuboid, and possesses the terminal anus. Spines or tubercles similar to those often found on other regions of the body may be present on the abdomen.

Appendages

The first pair of appendages, the chelifores (called chelicerae in other chelate arthropods), is present anteriorly on each side of the cephalon at the base of the proboscis (Fig. 28). The chelifores comprise three or four articles (segments), with one or two basal articles forming the scape and two distal articles forming the chelae. Primitively, the fourth article is a terminal moveable digit that opposes the fixed distal portion of the third article. The moveable and fixed digits vary in length among the species and may be curved or straight; they are often toothed on the opposing surfaces. These appendages exhibit varying degrees of reduction such as being present but non-functional in the Ammotheidae, or they may be completely absent as in the Pycnogonidae, Colossendeidae, and Endeidae. The chelifores are used to tear off pieces of host tissue and pass it to the proboscis during feeding. Pycnogonids with reduced or absent chelifores often have a well-developed proboscis that is thrust into the host tissue for feeding. Chelifores are present and functional in all immatures.

The leg-like pedipalps (palps) are located just posterior and lateral to the chelifores. These appendages are primarily sensory; however, in some species they also function in feeding and cleaning. The number of articles comprising the palps is variable and usually ranges from 1 to 11. Palps are absent in some pycnogonids.

Many pycnogonids possess modified legs called ovigers or ovigerous legs. These appendages comprise 5–10 articles inserted ventrally on stout projections located between the pedipalps and the first pair of walking legs. Ovigers are usually well-developed in the male and shorter or less robust in the female; however, they may be well-developed in both sexes, absent in the female, or minute or absent in both sexes. The male uses the ovigerous legs to carry fertilized eggs received from the female; the embryos develop while attached to these legs. In pycnogonids without ovigers, males carry eggs on the ventral surface of the cephalothorax. In some sea spiders, such as *Nymphon* and *Colossendeis*, the ovigers are used to clean other appendages, especially the legs. Cleaning is done by wrapping an oviger around an appendage and then drawing the oviger along the appendage.

Most pycnogonids have four pairs of well-developed legs with an internal volume greater than that of the cephalothorax and abdomen. Each leg comprises nine articles (segments or podomeres); the names given to the articles do not parallel those used in other arthropod groups (Fig. 28). From proximal to distal the articles are: three coxae, a single femur, two tibiae, a tarsus, propodus, and terminal claw. The terminology used to describe the leg articles varies. The most common variations (given in parentheses) are coxa 1, coxa 2 (trochanter 1), coxa 3 (trochanter 2), femur, tibia 1 (patella), tibia 2 (tibia), tarsus 1 (tarsus, basitarsus), tarsus 2 (tarsus, propodus) and claw or dactyl. Auxiliary claws often flank the claw and terminal spines may be present. Leg length varies, resulting in short-legged, compact forms such as *Pycnogonum* or long-legged, elongate forms such as *Nymphon* and *Colossendeis*. Compact forms with stout legs and strong claws are often found in the turbulent littoral or shallow sublittoral zones and are adapted to clinging to the substrate or a host. The long-legged forms are found in somewhat deeper water and are adapted to walking slowly on a substrate of hydroids, bryozoans, or algae. The very large species with elongate bodies and long legs are characteristic of polar and deep water where the long legs may help to keep them from sinking into fine bottom debris.

Polymerous species with either five or six pairs of legs instead of the usual four pairs have one additional trunk segment for each additional pair of legs. This variation in trunk segment and leg number within a group is not found in any other arthropod. There are nine polymerous species in four families of pycnogonids that include the genera *Pentanymphon* (Nymphonidae, two species), *Pentapycnon* (Pycnogonidae, two species), *Decolopoda* (Colossendeidae, two species), and *Pentacolossendeis* (Ammotheidae, one species) with five segments and five pairs of legs and *Hexanymphon* (= *Sexanymphon*) (Nymphonidae, one species) and *Dodecolopoda* (Colossendeidae, one species) with six segments and six pairs of legs.

Integument

Pycnogonids and other arthropods possess an integument consisting of the cuticle (exoskeleton) and the underlying epidermis (= hypodermis) that secretes it. The cuticle is the visible, outer portion of the integument that covers the entire organism; it also lines the foregut (pharynx, esophagus) and hindgut. The cuticle is acellular, hard, and rigid, and comprises the thin outer epicuticle and a procuticle consisting of the exocuticle and the innermost soft endocuticle. In many arthropods the exocuticle is tanned or sclerotized resulting in a hard cuticle; however, in pycnogonids the exocuticle appears to be untanned. The untanned cuticle of pycnogonids provides flexibility at appendage joints and the base of the proboscis; the untanned cuticle also makes growth in length possible during intermolt periods and following the last molt to adult. With the exception of the joints, the endocuticle consists of cross-banded fibrils of chitin similar to that found in the lower crustacea. The ordered structure of the endocuticle may provide rigidity to the cuticle. Epidermal cells beneath the endocuticle possess the extensive rough endoplasmic reticulum and numerous Golgi complexes needed to produce and secrete cuticle as well as the lysosomes needed to digest endocuticle during molting. Integumental glands are remarkably numerous in many regions of the body. The function of many of these glands is unknown, however; some glands apparently secrete mucus or defensive secretions while others may be excretory.

The surface of the integument may be smooth or it may possess spines and/or tubercles. Sensory filaments and setae are distributed over the cuticular surface and may vary among species from few to numerous and from short to long. Many regions of the cuticle are penetrated by a remarkable number of canals that permit the epidermal cells and integumental glands to pass their secretions. The pore canals of the epidermal cells terminate just inferior to the epicuticle while the integumental glands open onto the cuticular surface by way of bilobed valves. Often, the exterior surface of pycnogonids is covered with varying amounts of detritus and may be decorated with small encrusting organisms such as algae, foraminifera, sponges, hydroids and anemones, bryozoans, barnacles, molluscs, or tunicates. The encrusting organisms and detritus are temporarily lost at the molt.

Articulations and Movement

Articulations or joints permit one part of the exoskeleton to move relative to another. The movements possible at a joint are related to joint structure, musculature, and in some cases, hydrostatic mechanisms. Most pycnogonid joints are dicondylic (having two points of articulation) and eudesmatic (powered by muscles). Dicondylic joints possess two condyles on the distal margin of an article that engage acetabula on the proximal margin of a succeeding article. The orientation and location of the condyles and acetabula limit movement to a single plane perpendicular to a line connecting the two points of articulation. Thus, the joints are hinge joints. A flexible membrane (articular corium) associated with the condyles permits the joint to bend. Antagonistic pairs of striated skeletal muscle inserted near the plane of motion of a joint control movement; the origins of these muscles are usually in the preceding article or body structure. In pycnogonids, all muscles are intrinsic to the leg except those of the body-coxa 1 joint which is spanned by extrinsic muscles originating in the bilateral processes. The joint between the second tibia and the tarsus (which lacks an extensor muscle) and the joint between the tarsus and propodus (which has no muscles) may rely on hydrostatic pressure; however, pressure-isolating mechanisms that would permit the use of hydrostatic pressure in limb movement have proven difficult to demonstrate.

Muscles are attached to the cuticle in a fashion similar to that described for other arthropods. Desmosomes ("spot welds") join muscles cells to the base of modified epidermal cells called tendonal cells and to microtubules that run through the tendonal cells. In turn, hemidesmosomes in the apical region of the tendonal cell join the microtubules to muscle attachment fibers (tonofilaments) secreted by the tendonal cells. The muscle attachment fibers pass into the cuticle to complete the link between muscles and the cuticle.

The leg joints of pycnogonids have features that appear to be oriented toward feeding and swaying in currents in addition to locomotion. The body-coxa 1 joint is a hinge with a horizontal axis that provides levator-depressor movements, a condition unique among the arthropods. The levator-depressor movements permit the body to be raised or lowered or swayed side-to-side, especially in long-legged pycnogonids (Fig. 28). Because the leg bases are oriented in different directions, the body can be shifted forward or backward, sideways, or up or down, thus enabling the pycnogonid to move the proboscis from polyp to polyp during feeding while the tarsi remain in a fixed position. This same levator-depressor movement of the body-coxa joint allows the sea spider to sway in the current along with prey such as hydroids, resulting in motion camouflage for the pycnogonid.

The coxa 1-coxa 2 joint of pycnogonids is a hinge joint with a vertical axis and large flexor and extensor muscles originating laterally in coxa 1. This joint has a considerable range of motion and is the only leg joint capable of promotion (lifting, a forward motion made without ground contact) and remotion (pulling or pushing depending on the angle of the joint to the body). In other arthropods, promotion-remotion of the leg is accomplished at other joints. For example, in spiders promotion-remotion occurs at the coxa-trochanter joint, insects utilize the body-coxa joint and harvestmen accomplish promotion-remotion at the articulation between the trochanter and femur. Joints distal to the coxa 1-coxa 2 articulation of pycnogonids are hinge joints that have levator-depressor movements.

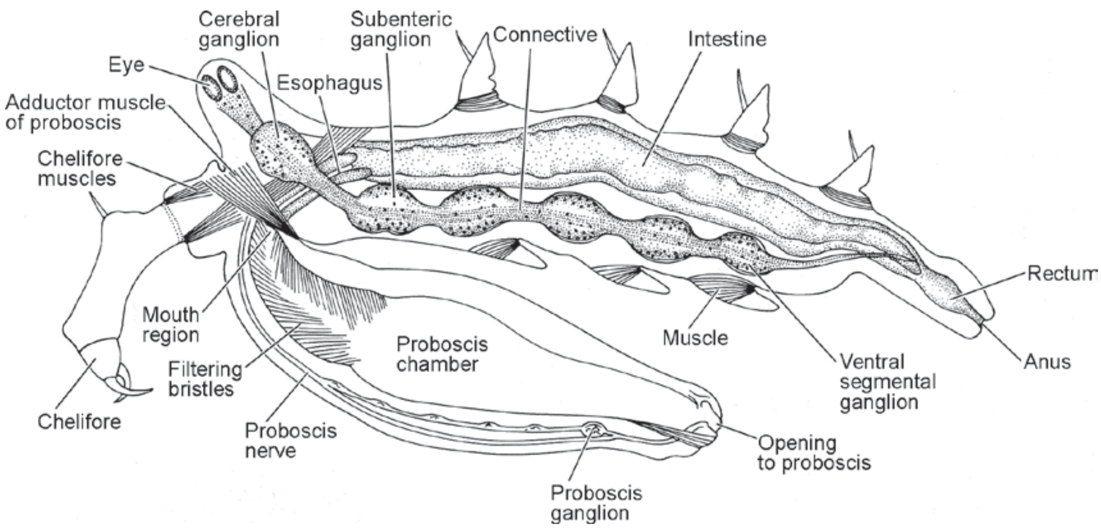
Coordinated movements of leg articles result in an extremely slow walk in pycnogonids. The limb movements are angular with one part of a limb being bent relative to the body or another portion of the same limb. During the movement of a single leg, there is both a promotion and remotion phase. The stepping pattern is diagonal as is commonly observed in arthropods. In the stepping cycle, there is a 0.5 phase difference between successive legs on a side that results in legs one and three on the left side being active together while legs two and four on the right side are also active. The movements of the different legs are not perfectly synchronized, however, resulting in an irregular stepping pattern similar to that of arachnids.

Pycnogonids can use the walking legs to swim. Swimming occurs in genera with short bodies and long slender legs such as *Nymphon*, *Colossendeis*, *Callipallene* and *Anoplodactylus*. Swimming depends on the levator-depressor movements of the leg base to enable the legs to beat dorso-ventrally. The power stroke occurs when the legs beat downward in an extended position; the legs are flexed toward the body during the upward recovery stroke. The locomotory rhythm is such that when one pair of legs performs the downstroke, the adjacent pair performs the upstroke. The legs therefore exhibit the same 0.5 phase difference as in walking. The resulting motion is continuous swimming that pycnogonids can further enhance with slight promotor–remotor movements of the coxa 1-coxa 2 joint.

Some pycnogonids exhibit modifications of the basic swimming rhythm. The large *Colossendeis* has been observed swimming by rapidly bringing its legs together under the body to propel the animal upward, then extending its legs horizontally to slow the sinking rate. *Nymphon* can also control its vertical position in the water column by extending its legs horizontally, and in addition, can move forward or backward. Because of the levator-depressor movements possible at the basal leg joints, both *Nymphon* and *Colossendeis* can assume a "plummeting" posture with legs folded vertically over the body to achieve a rapid descent.

Alimentary Canal, Feeding, and Digestion

The arthropod alimentary canal is an elongate tube that extends from the mouth to the anus (Fig. 29). The canal is differentiated into three main regions: the foregut, midgut, and hindgut. Both the foregut and hindgut are lined with cuticle that is shed at the molt along with the outer exoskeleton. In pycnogonids, the foregut opens at the tip of the proboscis and extends the length of the proboscis to the midgut; the midgut extends through the cephalothorax and is connected to a short hindgut



Sea Spiders (Pycnogonida), Figure 29 **Mid-sagittal view of the pycnogonid *Ascorhynchus castelli* (Ammotheidae) showing the major internal organs. The dorsal blood vessel/heart and gonad, not shown, are superior to the intestine. (From Brusca RC, Brusca GJ (2003) Invertebrates, 2nd edn. Reproduced by permission of Sinauer Associates, Sunderland, MA, USA.)**

(rectum) that passes through the posterodorsal tubercle to open at the terminal anus.

The terminology used to describe the pycnogonid alimentary canal varies. The most common differences involve the location of the mouth and midgut. Some authorities believe the mouth is located at the tip of the proboscis and call the canal in the proboscis a pharynx (the canal has also been called an esophagus); the pharynx extends to a short esophagus that leads into the midgut. Others have termed the canal in the proboscis a proboscis chamber and have placed the mouth between the chamber and the esophagus. In either case, the canal within the proboscis is lined with a cuticle that is shed during the molt. The midgut of pycogonids is sometimes called an intestine, whereas in many other arthropods the term intestine is used for a subdivision of the hindgut.

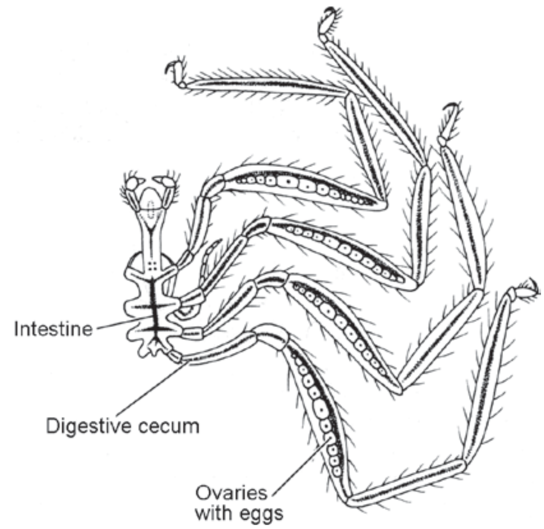
The principal food-gathering organ is the proboscis, a prominent anterior feature of all pycnogonids. The proboscis is attached to the cephalon by a ring of flexible cuticle and is positioned for feeding by extrinsic muscles. There are usually two pairs of well-developed extrinsic muscles originating on a cuticular apophysis behind the ocular tubercle; one pair inserts on the dorsolateral wall of the proboscis, the other on the ventrolateral wall. Some pycnogonids have a smaller, third pair of extrinsic muscles. In conjunction with hydrostatic pressure, muscular action raises or lowers the proboscis. Although the proboscis is non-retractable, it may be protracted or retracted slightly by the extrinsic muscles.

The proboscis opening is encircled by three lip-like lobes; these lobes help regulate the size of the opening and also act as a rasp during feeding. The rasping action of the proboscis helps to pull food off the substrate or gain entrance to a soft-bodied host when the proboscis is used as a piercing-sucking organ. In some species, the chelifores aid the feeding process by tearing off bits of tissue and passing them to the proboscis. The claws and terminal spines of the walking legs, and sometimes the entire leg of clinging species, help anchor the sea spider during feeding.

Most pycnogonids feed on soft-bodied invertebrates such as hydroids, anemones, soft corals, sponges, bryozoans, or polychaetes by piercing the body and ingesting body fluids and tissue fragments. This feeding behavior has been variously described as carnivorous, predaceous, or parasitic depending on the degree of damage inflicted upon the prey or host. Some pycnogonids are herbivores of algae and a few are detritivores. Some adults, perhaps many, are scavengers.

The proboscis opening leads into a cuticle-lined foregut that is triradiate in cross-section and extends the length of the proboscis. Intrinsic proboscis muscles, the radial and interradial muscles, control the diameter of the foregut. These muscles originate on the inner proboscis wall and insert on the outer wall of the foregut. When the muscles contract, the foregut enlarges sufficiently to create a slight suction that brings food into the lumen. A short esophagus at the distal end of the foregut bears several rings of setae, the so-called "oyster basket," that may help to break up particulate food and filter out large particles. The esophagus extends into the cephalon and opens into the midgut near the base of the ocular tubercle by way of the tripartite esophageal valve.

The midgut is the largest part of the alimentary canal and extends throughout the cephalon and trunk. Remarkably, the midgut has diverticulae (digestive caecae) that extend into the legs (Fig. 30), often as far as the tarsi, where diverticulae narrow and attach to the appendage walls by way of connective tissue. In some species, diverticulae extend into the base of the proboscis, chelifores, pedipalps and/or ovigers. Such extensive diverticulae are found in no other arthropod group (spiders come the closest with midgut branches that surround many of the internal organs and diverticulae that extend into the coxae of the walking legs). The unusual diverticulae of pycnogonids are probably a consequence of the small size of the cephalothorax and abdomen. Diverticulae provide a large surface area for digestion and absorption and may partially explain why at least some sea spiders, e.g., *Pycnogonum litorale*, can withstand starvation for several months. A tripartite valve at the end of the midgut leads into a short hindgut (rectum) that passes undigested food to the anal opening at the tip of the posterodorsal tubercle.



Sea Spiders (Pycnogonida), Figure 30 ***Pallene brevirostris*** **female showing egg storage in the femoral portions of the gonad diverticulae. Note also the digestive caecae extending far into the legs. (From Brusca RC, Brusca GJ (2003) Invertebrates, 2nd edn. Reproduced by permission of Sinauer Associates, Sunderland, MA, USA.)**

Digestion in pycnogonids is intracellular; however, details of this process are not well known. Specific mucosal cells take up food from the midgut lumen and later detach from the midgut wall to float freely in the lumen. Other mucosal cells absorb nutritive materials from the floating cells until this material is exhausted and the floating cells are eliminated from the anus.

Circulatory System

The circulatory system of pycnogonids is of the open type typical of arthropods. In this system, there is no pressurized, closed system of blood vessels as seen in vertebrates, nor is there a lymphatic system to return fluid to the circulatory system. Instead, the blood (hemolymph) circulates freely around the internal organs. The hemocoel is the major body cavity through which the hemolymph circulates and a muscular mid-dorsal blood vessel serves as the heart.

The hemocoel of sea spiders extends throughout the cephalothorax and appendages and possesses several septa that help direct hemolymph flow. The largest septum is a horizontal partition in the cephalothorax between the midgut and the overlying dorsal vessel (heart); this septum forms a dorsal chamber (pericardial sinus) and a ventral chamber (perivisceral sinus) in the cephalothorax and also extends into the legs as a partition above the lateral diverticulae of the midgut to create dorsal and ventral sinuses. The septum has slits near the lateral processes that permit communication between the dorsal and ventral chambers. The mid-dorsal heart extends nearly the length of the cephalothorax and is often v-shaped or reduced to muscular lateral walls with two pairs of openings (ostia) near the bases of the second and third walking legs that permit hemolymph entry. The roof of the heart is formed by epidermis of the dorsal body wall and the floor of the heart is formed by the horizontal septum. In some species there is an unpaired posterior ostium.

The general pattern of hemolymph circulation is away from the heart in the ventral chambers and toward the heart in the dorsal chambers. Hemolymph flows in the anterior direction within the heart and is pumped from the anterior end of the heart into dorsal chambers in the proboscis and chelifores. Hemolymph then flows posteriorly in the perivisceral sinus and into the ventral sinuses of the legs. The partition dividing the legs into dorsal and ventral sinuses does not reach the end of the appendages. At the tips of the legs the hemolymph enters the dorsal sinus and flows back toward the cephalothorax to enter the pericardial sinus where it passes through the ostia into the heart. Hemolymph flow is aided by leg movement and by peristaltic contractions of the midgut diverticulae.

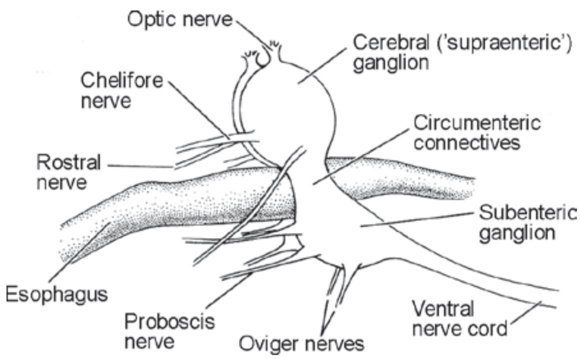
The hemolymph is a colorless fluid that contains several morphological types of hemocytes such as granulocytes and ameboid cells; however, the lineage and function of the different types of hemocytes is poorly known. The hemolymph transports nutrients throughout the body and there is some evidence that it may have a respiratory function.

Respiratory and Excretory Systems

Organs dedicated to respiration have not been found in pycnogonids. Presumably, the small body with its relatively large surface area-to-volume ratio is sufficient for gas exchange. Excretion and osmoregulation are poorly known and may occur by one or more pathways: the body surface, gut, and/or nephridia. The body surface appears to be used by some larvae during the molt to eliminate wastes stored in epidermal cells; adults may also pass wastes from or through the epidermis. Internal routes of excretion may involve passage of materials across the gut epithelium or detachment of waste-laden epithelial cells from the gut wall into the lumen. Nephridia are present in the scape of the chelifores of at least one species, *Nymphopsis spinosissima*, and it seems likely that the examination of additional species will lead to similar findings. The nephridia consist of podocytes that form an ultrafiltration end sac connected to a nephridiopore by a tubule and cuticle-lined duct.

Nervous System

The nervous system can be divided into two principal parts, the central nervous system and the peripheral nervous system. The central nervous system comprises cerebral ganglia (supraesophageal ganglia or "brain") above the esophagus, a subesophageal (subenteric) ganglion connected to the cerebral ganglia by a pair of connectives that encircle the esophagus (Fig. 31), and a ventral nerve cord that extends posteriorly from the subesophageal ganglion. The ventral nerve cord is double and has paired segmental ganglia that are often fused to form bilobed masses (Fig. 29). The peripheral nervous system consists of the many nerves arising from the central nervous system that innervate the eyes, appendage and trunk



Sea Spiders (Pycnogonida), Figure 31 Lateral view of the anterior portion of the nervous system of *Nymphon* (Nymphonidae) showing the cerebral (supraesophageal) and subesophageal (subenteric) ganglia and associated nerves. The unlabeled nerve just dorsal to the esophagus is the stomodeal nerve; the unlabeled nerve just ventral to the esophagus is the palp nerve. Only one pair of proboscis nerves is shown. (From Brusca RC, Brusca GJ (2003) Invertebrates, 2nd edn. Reproduced by permission of Sinauer Associates, Sunderland, MA, USA)

musculature, and peripheral sense organs such as the setae and sensilla.

The cerebral ganglia are located anterodorsally in the cephalon ventral to the eye tubercle and represent a syncerebrum comprising a protocerebrum and tritocerebrum. Pycnogonids, as well as other chelicerates, lack the deutocerebrum that in other arthropods innervates the antennae. The cerebral ganglia give off two pairs of optic nerves that innervate the eyes, paired cheliforal nerves that innervate the chelifores, and a median rostral nerve that, along with paired stomodael nerves, extend forward to innervate the proboscis. Within the proboscis, the rostral and stomodael nerves may be linked by several transverse connectives. The subesophageal ganglion supplies the paired dorsal and ventral proboscis nerves that innervate the dorsal and ventral proboscis muscles and paired nerves that innervate the pedipalps and ovigers. Posterior to the subesophageal ganglion, ganglia of the ventral nerve cord correspond to the legs in number and position and are responsible for innervation of their respective segments. Each ganglion is connected to the adjacent ganglion by two interganglionic connectives of varying length, and each ganglion gives rise to two nerves to each leg as well as a paired nerve that innervates the ventral segmental muscles. In addition to innervating the legs and ventral segmental muscles, the terminal ganglion innervates the posterodorsal tubercle via three short, paired nerves.

Sensory perception is accomplished by exteroceptors such as the eyes, setae and sensilla. The four eyes (ocelli or so-called simple eyes) located on the lateral surfaces of the ocular tubercles are the most studied sensory organs of pycnogonids. These receptors can detect blue and red wavelengths of light, but presumably cannot form images. Cells of the ocelli are contained in a hemispherical depression covered by a biconvex cuticular lens that is thicker than the surrounding cuticle. From superficial to deep, these cells are the hypodermal cells that secrete the lens, translucent vitreous cells, elongate neurons that are the photoreceptive retinal cells, reflective tapetal cells, and the innermost layer of anucleate pigment cells. Light reaches the retinula cells through the vitreous cells. A large number of retinula cells are packed close together without any regular arrangement. On at least one side of a retinula cell a rhabdomere is formed; rhabdomeres of several adjacent cells combine to form a rhabdom. The light sensitive rhabdomeres point away from the lens and incoming light and are therefore of the "inverted" type similar to the secondary eyes of spiders and similar in principle to that of the vertebrate retina. The axon of each retinal neuron passes through the basal portion of the ocellus where they group together to form the optic nerve.

The sensory setae and sensilla widely distributed over the body have a structure similar to that found in other arthropods and are believed to be mechanoreceptors or chemoreceptors. Structural, behavioral and physiological information support this belief.

Neurosecretory cells are found throughout the nervous system; however, little is known about their function. A possible neuroendocrine organ, Sokolow's organ, is present lateral to the optic lobes of the brain in some pycnogonids.

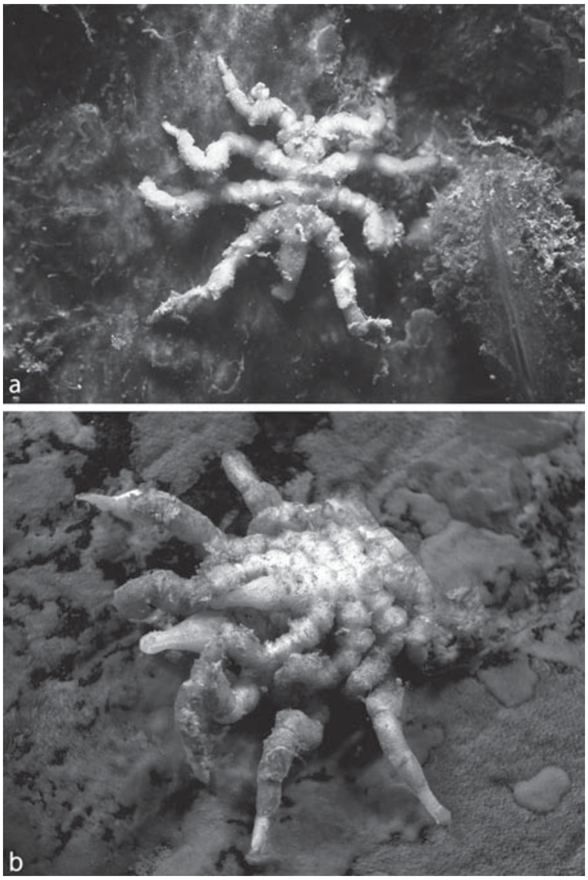
Reproductive System and Development

Except for one hermaphroditic species, *Ascorhynchus corderoi*, sea spiders are gonochoric or dioecious (having separate sexes). Females can often be told from males by examination of the femora which in gravid females become distended with developing ova. Sexual dimorphism may also be evident in the well-developed ovigerous legs of the male and the female's larger size. In both sexes, the gonad is a single, well-developed, bilaterally symmetrical, u-shaped organ located in the trunk above the alimentary canal. Portions of the gonad extend into the leg, a condition likely related to the small size of the cephalothorax. Frequently, diverticula of the testis reach as far as the third joint of the leg and those of the ovary to the fourth. In most species, vitellogenesis is confined to the lateral diverticulae of the ovary; however, ova also develop in the trunk of some *Austrodecus* and in the well-known *Pycnogonum litorale*. Ova are often stored in the dilated femurs prior to egg-laying. A duct connects the genital diverticulae with multiple reproductive openings (gonopores). The position and number of gonopores varies by species and sex; however, gonopores are often located on the anteroventral surface of the second coxae of the last one or two pairs of legs in males and of all legs in females. The female orifice is usually larger to allow egg passage and the orifice often has an operculum. The extension of the gonads into the legs and the possession of multiple gonopores is unusual in arthropods and represents another of the unique features of pycnogonids.

Fertilization is external with the gonopores of the male and female held in close proximity to each other during mating. In some species the male suspends himself beneath the female so their ventral surfaces are opposed. In other species, such as *Pycnogonum litorale*, the male clings to the female's back. Males fertilize the eggs as they are emitted from the gonopores of the female. Mating is usually a quick process in pycnogonids; however, in *P. litorale* the process may last from several days to a month or more, with much of the time being spent by the male in mate guarding (Fig. 32). Depending on the species, females release the eggs from one or more legs (sometimes all legs) at the time of mating. The male gathers the eggs, either singly or in bracelets or balls, onto his ovigerous legs. The eggs are cemented to the ovigers, typically several balls per leg, with the aid of an adhesive produced by femoral cement glands. Males brood the eggs until hatching; some species also brood the young for varying periods of time. Pycnogonids are one of the few animal groups in which the males exclusively brood the offspring.

Embryonic Development

The basic processes that occur during embryonic development are cleavage, blastula formation, gastrulation, and organogenesis. Cleavage of pycnogonid eggs is complete (total or holoblastic cleavage). If the eggs are small and contain a small to moderate amount of yolk, such as in *Pycnogonum*, the resulting cells (blastomeres) are of equal size and the resulting ball of cells (blastula) has a small blastocoele. Larger eggs that are rich in yolk, such as those of *Nymphon*, cleave to produce a blastula with cells of unequal size (micromeres and macromeres). In the small eggs, gastrulation occurs by the inward growth of cells. A superficial blastomere grows into the blastocoele and forms the endoderm; cells adjacent to this blastomere move into the blastocoele to form the mesoderm. The gastrula consists of the outer ectoderm underlain by the mesoderm and the central endoderm. In the larger eggs with more yolk, gastrulation occurs when the macromeres are overgrown by the smaller micromeres in a process sometimes called epiboly. Macromeres in the region of the blastopore become isolated and move to a position under the micromeres to form the mesoderm.



Sea Spiders (Pycnogonida), Figure 32 The North Atlantic *Pycnogonum litorale*, family Pycnogonidae, a short-legged compact form. (a) Dorsal view of adult. The anterior proboscis, between the first pair of legs, is oriented toward the bottom of the photograph. Note the minute posterodorsal tubercle between the fourth pair of legs. Detritus is beginning to accumulate on this newly molted individual. (b) Mate guarding and external fertilization. The male climbs onto the back of the female with his genital openings opposed to those of the female. The genital openings, located on the second coxae of the last pair of legs of both sexes, are on the dorsal surface in the female and on the ventral surface in the male. Both animals may remain in this position for days or weeks before the female releases her eggs. (Photograph (b) courtesy of David Whittemore.)

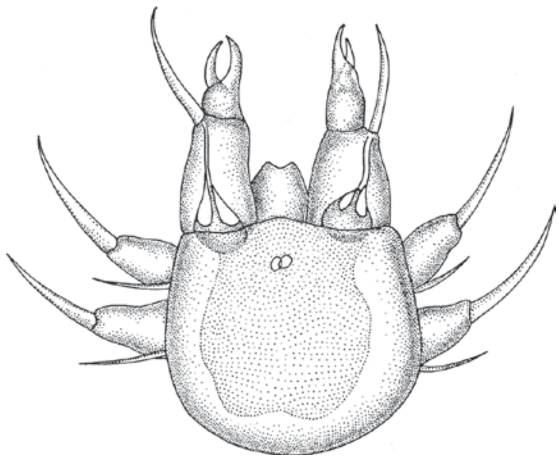
The endoderm is formed of macromeres below the mesoderm. Thus, the gastrula consists of a central mesoderm that is surrounded dorsally by the ectoderm and ventrally by the endoderm. In both small eggs and large eggs, cells of the endoderm fuse to form a syncytium.

The appendage buds and stomodeum (foregut) form early in development. The midgut forms within the endodermal syncytium and then connects to the stomodeum; the proctodeum (hindgut) forms later, a short time before hatching. The cells that line the foregut and hindgut secrete cuticle and are of ectodermal origin. The ectoderm also gives rise to the nervous system as five paired ganglia. The first pair fuse to form the protocerebrum; the second pair are associated with the chelifores and are initially postoral and ventral, but later move anterior to fuse with the protocerebrum. The third and fourth pairs of ganglia are associated with the larval legs and fuse to form the subesophageal ganglion. The fifth pair of ganglia appear later than the others and divide to innervate the adult limbs as the limbs develop.

Duration of the embryonic period varies among and within species and is known for only a few pycnogonids. For *Pycnogonum litorale* reared in the laboratory, the length of time from oviposition to hatching ranges from approximately 1 month to over 3 months.

Post-Embryonic Development

Most pycnogonids undergo indirect development and hatch from the egg at an early stage as a larva bearing little resemblance to the adult. This larva is often called a protonymphon (Fig. 33), a term sometimes used for all pycnogonid larvae. However, there is a second distinct larval type known as the attaching larva, which also exhibits indirect development. Direct development has been observed in some species of *Pallene* and *Nymphon* where the embryos leave the egg with a full complement of adult appendages.



Sea Spiders (Pycnogonida), Figure 33 Dorsal view of the six-legged protonymphon larva. (From Brusca RC, Brusca GJ (2003) Invertebrates, 2nd edn. Reproduced by permission of Sinauer Associates, Sunderland, MA, USA.)

The protonymphon is square to ovoid and appears to be unsegmented externally. Internally, however, a pre-oral region and four post-oral segments can be discerned; there is an unsegmented abdomen. This larva has three pairs of uniramous appendages and superficially resembles a crustacean nauplius larva except that the first pair of appendages is chelate. The appendages are associated with the first three post-oral segments and are the chelifores (whether or not these are present in the adult) and larval legs that correspond in position to the pedipalps and ovigers. Each appendage has three articles and very often possesses either an elongate spine or a filamentous seta on the proximal segment. These spines and setae, along with adhesive produced by cheliforal cement glands (not present in the adult) and muscular grasping by the appendages, help keep the larvae in a cohesive group on the adult. The chelifores terminate with a pair of pincers and the larval legs terminate in a single claw. Eyes are present dorsally and there is a short proboscis.

Most protonymphon larvae leave the male's ovigers by swimming or crawling away or by simply latching onto something nearby; others remain with the male for a species-specific time before dispersing to become free-living, parasitic or commensal in or on an invertebrate host. Hosts include hydroids, coral, jellyfish, anemones, echinoderms, bivalves, and gastropods; the initial host may be different from the host fed upon as an adult. Larvae from eggs with little yolk tend to leave the male's ovigers earlier than those hatched from eggs with more yolk. Most pycnogonids carry the eggs only until they hatch; however, some species have a prolonged association with the male. The longest duration of male parental care has been observed in some arctic species of *Nymphon* and *Boreonymphon* that carry young until they are approximately one-half the adult size.

Recent work indicates that the protonymphon follows one of three developmental pathways after it leaves the male: the encysted larva, typical protonymphon, or atypical protonymphon. The encysted larva burrows into a cnidarian host and remains encysted in the gastric cavity through several molts, the typical protonymphon remains free-living, often in association with another invertebrate, and the atypical protonymphon becomes associated with the interior of a clam or the surface of a nudibranch or polychaete for several molts. Development in the typical protonymphon, encysted larva and attaching larva (next paragraph) involves an anamorphosis in which the larva undergoes a series of molts to add new segments and legs sequentially behind existing ones. During this time, appendages such as the palps, ovigers and legs increase in length and number of articles. Appendages may also be lost during metamorphosis such as when *Pycnogonum litorale* loses the chelifores during transformation from the last larval to the first juvenile stage. The atypical protonymphon acquires all of its limb buds at once at the first molt. In subsequent molts, the size and segment number of the leg articles increase.

The attaching larva is a form that undergoes the first molt in the egg, then hatches and attaches to the male's ovigerous legs. This larva is filled with yolk and does not feed for several molts before swimming away to take up a free-living existence.

The number of post-embryonic stages and duration of the post-embryonic period is variable and is known wholly or in part for about 20 species. In the laboratory, development through nine stages in nine molts from hatching to the adult stage in the Eastern Pacific *Propallene longiceps*, which has an attaching larva, takes about 5 months. The North Atlantic *Pycnogonum litorale*, with a protonymphon larva, passes through five larval stages followed by six (occasionally seven or eight) juvenile stages within a year in nature and slightly longer than a year in the lab. Variation in development time in *P. litorale* can be remarkable in water of different temperature and because these small organisms, like some other pycnogonids, can withstand starvation for several months.

Size increases in pycnogonids are associated with the molt as they are in other arthropods. However, unlike most other arthropods, juvenile pycnogonids increase in size not only when they molt, but also during intermolt periods. Size increases during the intermolt period have been attributed to the stretching of thin flexible membranes at the joints, or to lack of tanning in the exocuticle, so that as the tissue mass increases, the size can also increase.

Adult longevity is poorly known. Adults of *Pycnogonum litorale* reared in the lab have lived for more than 6 years (9 years for one individual) and have undergone repeated mating without further molts.

Classification and Taxonomic Affinity

The unique features of Pycnogonida have long presented difficulties in determining the taxonomic relationship of this group to other arthropods. The proboscis, multiple prosomal gonopores, segmented trunk and lack of distinct tagmata, male ovigers and male brooding behavior, the body-coxa joint, size increases during intermolt periods, digestive system and gonads that extend into the legs, and the additional pairs of walking legs in some genera have no counterpart among the chelicerates nor among other arthropods. Pycnogonids also lack, at any stage of their life cycle, the large abdomen characteristic of the chelicerates. At one time or another, pycnogonids have been associated with most major arthropod groups as well as with the polychaete worms and onychophorans (velvet worms).

Pycnogonids possess many features of the chelicerates – horseshoe crabs, terrestrial spiders, scorpions, and mites. Chelicerate features include the pedipalps, chelicerae (called chelifores in pycnogonids), lack of antennae, body divided into cephalothorax (prosoma) and abdomen (opisthosoma), and the four pairs of slender, multiarticulate uniramous legs. Other chelicerate features are the similar structure of sense organs and brain (including the lack of a deutocerebrum), the suctorial method of feeding, the gut with two to six pairs of digestive caecae, and the four postoral segments in the earliest embryonic stages. Thus, pycnogonids are often classified as chelicerates in the subphylum Chelicerata or as a sister taxon of the chelicerata in the subphylum Cheliceriformes.

The uncertainty of the relationships of Pycnogonida to other arthropods is reflected in multiple classification schemes. Indeed, classification among the pycnogonids themselves is in a state of flux. One common classification places pycnogonids in two orders, Paleopantopoda (fossil sea spiders) and Pantopoda (recent or living sea spiders).

The names Pycnogonida (Latreille, 1810) and Pantopoda (Gerstaecker, 1863) can be a source of confusion. Originally proposed to represent the same taxon, the terms are used in both a linguistic sense and in a systematic-taxonomic context. Linguistically, Pycnogonida is often used in the English and French literature, whereas Pantopoda frequently appears in German works. Systematically, there are several classification schemes involving the terms Pycnogonida and Pantopoda. Most commonly, the Pycnogonida has been divided into the orders Paleopantopoda and Pantopoda, or three orders, Palesoisopoda, Paleopantopoda and Pantopoda.

The Pantopoda are further subdivided into eight to ten families including Ammotheidae, Austrodecidae, Callipallenidae, Colossendeidae (includes the largest known pycnogonids in the genus *Colossendeis*), Endeidae (with one genus, *Endeis*), Nymphonidae (the genus *Nymphon* has nearly 200 species), Phoxichilidiidae, Pycnogonidae (*Pycnogonum* is one of the most common and widely studied genera), Rhynchothoracidae (with one genus, *Rhynchothorax*) and Tanystilidae. Family names and the number of families recognized vary among pycnogonid workers. There are at least 87 genera containing approximately 1200 described species. It is likely that many more species await description.

Much more remains to be learned about the anatomy and physiology, ecology, general biology, and taxonomic affinities of these fascinating creatures.

Seaweed Flies

Members of the family Coelopidae (order Diptera).

► Flies

Secondary Pests

Pests that normally are not considered to be important, but which become important after a change in pest control or cropping practices.

Secondary Plant Substance

Material found in plants that has no apparent role in basic plant metabolism, but which functions to deter herbivory or herbivore survival in some manner.

Secondary Production

Production by herbivores, carnivores and detritus feeders. (contrast with primary production)

Secondary Vector

Arthropods that can transmit disease organisms to animals or humans but which cannot sustain the occurrence of the disease without the presence of a primary (usually more efficient or with a different host range) vector.

Sectorial Cross Vein

Cross veins that connect radius veins at the base of the branches.

► Wings of Insects

Sedge Moths (Lepidoptera: Glyphipterigidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Sedge moths, family Glyphipterigidae, total 431 species from all regions, mostly in the genus *Glyphipterix* (in the past often misspelled as

Glyphipteryx), with the largest number from the Australian-New Zealand region; actual world fauna probably exceeds 800 species. There are two subfamilies: Orthoteliinae (only a single species from Europe) and Glyphipteriginae. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (5–35 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi tufted and somewhat flattened; maxillary palpi 2 -to 4-segmented. Wings elongated and forewings typically with a somewhat falcate apex in many species. Maculation generally dark with various white and metallic-iridescent spots and markings. Adults are diurnal, usually in proximity of the host plants. Larvae are mostly borers in seeds, stems, or leaf axils, and a few are leafminers, but most tropical species are unknown biologically. Host plants are mostly sedges (Cyperaceae), rushes (Juncaceae), and grasses (Gramineae), plus a few other plant families.

Seedcorn Maggot or Bean Seed Fly, *Delia platura* (Meigen) (Diptera: Anthomyiidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Seedcorn maggot was first described in Germany, but attained North America by the mid 1800s. Now it is found in temperate areas throughout the world, but usually is absent from tropical environments. Seedcorn maggot is very difficult to distinguish from turnip maggot, *Delia floralis* (Fallen), so some reports of occurrence and damage are suspect.

Life History

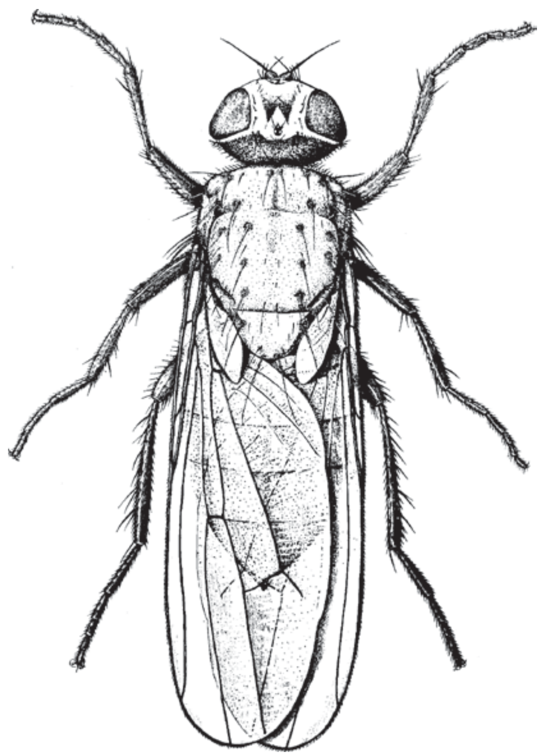
A complete life cycle requires 15–77 days, but during the warm periods of the year 16–21 days is adequate. However, due to aestivation of larvae in the summer and diapause of pupae in the winter, there usually are only 2–4 generations annually. The exact number of generations in a location is often uncertain due to asynchronous emergence, generations that are divided into diapausing and nondiapausing populations, and variable weather. The threshold temperature for egg-adult development is estimated at 3.9°C, but unlike some other *Delia* spp., it has proven difficult to predict accurately the development of seedcorn maggot from temperature accumulations.

The eggs are elongate and ovoid, with one end tapering to a blunt point and the other more bluntly rounded. The egg is slightly curved, with one side being decidedly convex and the opposite being slightly concave. The pearly white eggs are about 0.92 mm long (0.90–0.95 mm range) and 0.3 mm wide. Eggs are usually placed at the soil surface, singly or in clusters of up to 10 eggs. Oviposition occurs readily at 10–27°C. Favorite oviposition sites are sprouting or decaying seeds, decaying plant material, and organic fertilizer such as fish meal or cottonseed meal. Moist, freshly turned soil is quite favorable for egg laying; females avoid both dry and very moist soil. Duration of the egg stage is a function of temperature. It may hatch in as little as 1 day when held at 28°C, but at a more spring-like temperature of 15°C egg hatch requires 2–3 days, and at cool temperatures of 5–7°C about 7–9 days are required. Larvae dig down upon hatching, often burrowing to a depth of 6–8 cm to locate suitable food.

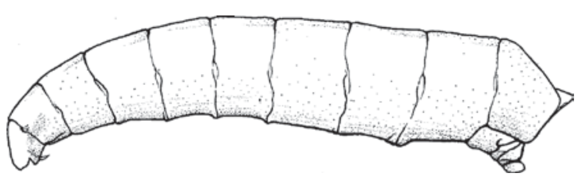
Larvae are white in color, and have three instars. They increase in length from about 0.7 mm at hatch to about 7 mm at maturity. The length of the mouthparts (cephalopharyngeal skeleton) is 0.33, 0.65, and 0.89 mm for the three instars, respectively. Larvae are reported to feed gregariously. First instar larvae cannot successfully attack food such as freshly cut or healed (corked) potato seed pieces; they survive and grow better if they locate food that is decaying. Larvae may develop at rather low temperatures, 4–7°C, but optimal growth occurs at 21–23°C. Larval development time is 20–30 days at temperatures of about 10°C, but 7–12 days under more optimal temperatures of 21–30°C. At about 14–17°C duration of the first instar is 1–3 days, second instar is 3–5 days, and third instar is 5–16 days. The anterior spiracles, a character with some diagnostic value, bears 5–8 lobes (Fig. 35).

The oval puparium is light reddish brown initially, but becomes quite dark prior to emergence of the adult. It is about 4–5 mm long and 1.5 mm wide Following a prepupal period of about 2 days pupation occurs in the soil, often at the site of feeding. When larvae have burrowed into their food, as occurs with potato seed pieces, they leave the food source prior to pupation. Duration of the pupal period is 7–14 days at 18–24°C.

The adults are grayish brown, with few distinctive markings. The male tends to bear stripes on the thorax and a mid-dorsal stripe on the abdomen, but stripes are usually lacking in females (Fig. 34). Flies measure 4–5 mm in length. The legs are black and the wings are unmarked but bear dark veins. Adults seek



Seedcorn Maggot or Bean Seed Fly, *Delia platura* (Meigen) (Diptera: Anthomyiidae), Figure 34 Adult of seedcorn maggot or bean seed fly, *Delia platura* (Meigen).



Seedcorn Maggot or Bean Seed Fly, *Delia platura* (Meigen) (Diptera: Anthomyiidae), Figure 35 Mature larva of seedcorn maggot or bean seed fly, *Delia platura* (Meigen).

food and moisture soon after emerging, and feed on the flowers of a large number of plants. Fish meal, cottonseed meal, and other materials commonly used as fertilizer are quite attractive to ovipositing adults. The duration of the preoviposition period in seedcorn maggot is 7–14 days. Mated adults live 30–40 days, with longevity increased during cool weather and shortened during the heat of summer. There are some reports that temperatures of 28–30°C are fatal to adults. Egg production is estimated at 100 per female, but this may not reflect field conditions.

A number of plants are reported to be attacked. Most vegetables plus alfalfa, cotton, strawberry, tobacco, and wheat are damaged. Seedcorn maggot also has been reported to feed on grasshopper eggs. Seedcorn maggot attacks seeds and seedlings, but there is some question about its status as a primary pest. It is often regarded as saprophagous, associated with plants that have already been damaged by other insects or plant disease.

The natural enemies of seedcorn maggot seem to be largely the same as those attacking the closely related onion maggot, *Delia antiqua* (Meigen). Among the most important are the parasitoids *Aleochara bilineata* (Gyllenhal) (Coleoptera: Staphylinidae) and *Aphaereta pallipes* (Say) (Hymenoptera: Braconidae). General predators such as ants, and the fungus *Entomophthora muscae* (Entomophthoraceae), affect the seedcorn maggot.

Damage

Damage to seeds and developing embryos may occur before the seedling breaks through the soil. Larvae are able to penetrate seeds as the seed coat splits. Rot often develops as they burrow in the cotyledon. Attack by several maggots may completely inhibit seed germination, but seedlings may suffer only deformity, or recover completely, from attack by a single insect. Despite the fact that flies are able to locate emerging seedlings readily, and oviposit freely on seedlings, larval performance is superior on freshly planted seeds. Severe damage characteristically occurs during periods of cool, wet weather, when insect activity is favored but plant growth is inhibited.

There is a strong association between seedcorn maggot and plant disease, and it is believed that some microorganisms secrete attractive volatiles. It is often argued that seedcorn maggot is primarily saprophagous. For example, research conducted in Colorado, USA, showed that seedcorn maggots were associated with *Fusarium*-infected onions, and that, in choice tests, 78% of eggs were deposited on *Fusarium*-infected bulbs. Not all microbial organisms are attractive to seedcorn maggots, however. Also, this association does not mean that crops will not be damaged by seedcorn maggot in the absence of disease, because damage by these insects is reported in the absence of apparent plant disease.

Seedcorn maggot may also be important in transmission of plant disease. They apparently assist in the overwintering and transmission of bacterial soft rot, *Erwinia carotovora*.

Management

Seedcorn maggot flies are attracted to volatiles given off by microbial organisms associated with decay and to other volatiles. Cone traps can be baited for adult monitoring with alcohol, odors of fermentation from honey-yeast or molasses solution, or oviposition stimulants such as meat and bonemeal. Enzymatic yeast hydrolyzate also is an attractive bait. If sticky traps are used, the most attractive color is gray, followed by yellow, white, blue, and other colors. Some success has been reported with yellow water pan traps.

The use of insecticides for control of seedcorn maggot is similar to onion and cabbage maggot, except that usually it is only the period of plant germination and early growth that is of concern. Therefore, there is less need for long-term protection, and for highly residual insecticides. Nevertheless, residual materials have been used, and insecticide resistance has resulted. Granular in-furrow and over-the-row applications are common. Seed treatment is often adequate.

Beans with a dark seed coat are less susceptible to injury than are white varieties, possibly due to the hardness of the seed coat and speed of germination. Seedling response to injury varies greatly among plants, with cantaloupe and watermelon being severely injured, snap bean and lima bean being intermediate, and corn most resistant.

Cultural practices that normally are considered favorable for crop growth are, unfortunately, also sometimes suitable for seedcorn maggot. There are numerous observations suggesting that freshly tilled soil is attractive to ovipositing seedcorn maggots. Buried crop residues and rotting manure also are attractive, and reduced or no-tillage systems exacerbate fly problems due to the abundance of organic material. Egg and larval survival is enhanced when plants are frequently watered. Planting in warm soil, however, favors seedling growth more than it does maggot feeding, so delayed planting is advantageous if it can be timed to avoid the large (usually June) flight. If cover crops or other sources of organic matter are present, it should be disked at least 4 weeks before planting to allow adequate time for decomposition to occur.

Growers can sometimes manipulate planting dates and escape the principal flights of seedcorn maggot, because there is often a mid-season depression in maggot abundance.

Screens and row covers are effective protectants against a wide range of insect pests, but they can be ineffective against seedcorn maggot. Because pupae overwinter in the soil, even early spring placement of a covering will not protect against attack; rather, the insects emerge beneath the covering. This is especially true with seedcorn maggot, which feeds freely on manure and rotting plant material as well as a large number of crops.

Seed Predation by Insects

FABIÁN D. MENALLED[1], MATT LIEBMAN[2]
[1]U.S. Department of Agriculture, National Soil Tilth Laboratory, Ames, IA, USA
[2]Iowa State University, Ames, IA, USA

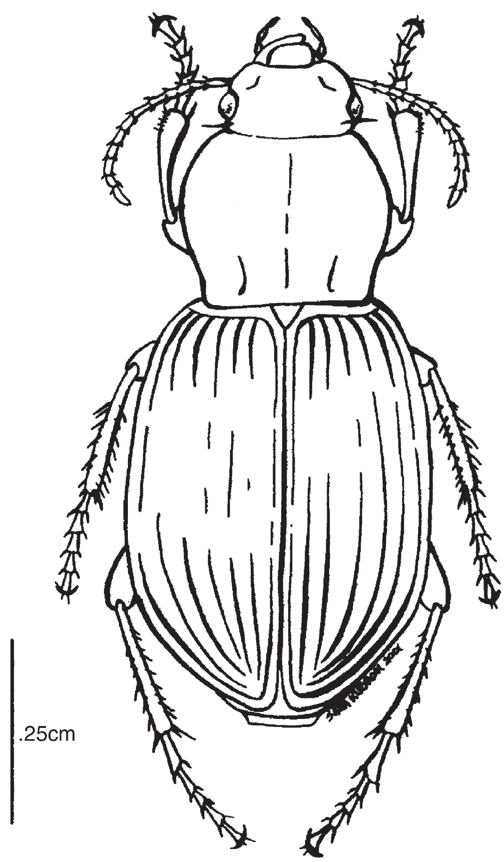
Seeds represent an important food resource. Nearly 70% of all human food comes from seeds or their products, and a large portion of the remainder is produced from animals fed on seeds. Insects also consume large quantities of seeds. Seed predation, also referred to as granivory, represents a particular type of herbivory in which a mobile predator consumes a sessile prey (the seed). This prey constitutes a high food quality, but is usually too small to allow full development of the predator with the consumption of only a single prey item. Because of its magnitude and ubiquity, entomologists and plant ecologists have long recognized the important role that seed predation plays in population and community dynamics, and in evolution. Impacts of seed predation can be found in natural habitats including temperate and tropical forests, grasslands, wetlands, mangroves, prairies, and deserts. Insect seed predation has also been documented in human dominated ecosystems such as forest plantations, orchards, and herbaceous annual crop fields.

Conceptually, and due to differences in mechanisms, seed predation can be divided into predispersal and postdispersal phenomena. Predispersal seed predation refers to the consumption of seeds on the parent plant prior to being shed. These seeds represent a spatially and temporally aggregated resource with defense mechanisms provided by the parent plant. Small and sedentary specialist feeders belonging to the insect orders of Diptera, Lepidoptera, Coleoptera, and Hymenoptera are mostly responsible for predispersal seed predation.

Despite the wide occurrence of predispersal seed predation, it is difficult to generalize about the impact that feeding on flowers, ovules, and seeds has on plant recruitment and population dynamics. Several studies have shown that compensatory flowering or seed development may reduce any consequence of predispersal predation. Nevertheless, insect feeding on flowers and developing seeds has been found to be a key factor determining the spatial distribution and density of certain plant species. For example, experimental exclusion of Diptera, Lepidoptera, Hymenoptera, and Thysanoptera has shown that interactions between insect herbivory and seedling survival could determine variation in plant density along a 100-km gradient from the coast to the inland mountains of San Diego County, California, USA.

Although relatively little is known about the extent and impact of predispersal seed predation by insect in herbaceous crop systems, several researchers have reported its occurrence. For example, in soybean fields, the joint effect of *Niesthrea louisianica*, a scentless plant bug that feeds on seeds, and fungi of the genera *Fusarium* and *Alternaria*, has been proposed as a tool to control velvetleaf (*Abutilon theophrasti*), a common weed of agricultural systems. The combined effect of seed predation and fungal infection significantly reduced the density of viable velvetleaf seeds. Other examples of predispersal seed predation of agricultural weeds include *Orellia ruficauda* (Diptera: Tephritidae) eating large quantities of seeds of Canada thistle (*Cirsium arvense*), as well as fruit fly, weevils, and moths eating giant ragweed (*Ambrosia trifida*) seeds. Glassy

Seeds are inconspicuous once they have been dispersed from the parent plant. These seeds are primarily fed upon by mobile and generalist herbivores in a process referred as postdispersal seed predation. Postdispersal seed predators include vertebrates such as birds and rodents, as well as insects of the order Hymenoptera and Coleoptera. In particular, carabid beetles of the genera *Amara*, *Zabrus*, and *Harpalus* (Fig. 36) are conspicuous seed-eaters. Because of this, considerable research has been conducted on the physiological, behavioral, and morphological adaptation of carabid beetles to seed predation. Carabid beetle larvae consume seeds on the soil surface and accumulate them in below-ground burrows, but seed predation by adult beetles occurs mostly on the soil surface. Seed predation habits of carabids are related to the shape of the mandibles. Specialist granivores of subfamily Carabinae have squat, slender and pointed mandibles, whereas true granivores of Amarini and Harpalini have short, stout, quadrate mandibles with large mandibular muscles, and generalist granivores have intermediate shapes.



Seed Predation by Insects, Figure 36 ***Harpalus pensylvanicus*, a common carabid beetles of many agricultural and natural habitats known to eat large number of seeds (Drawing by S. Kudrom).**

Ants are another important group of seed predators found in many ecosystems. In the Sonoran and Chihuahuan deserts of Arizona, USA, colonies of the specialized genera *Pogonomyrmex*, *Veromessor*, and *Pheidole*, as well as the omnivorous genera *Novomessor* and *Solenopsis* contain thousands of foraging workers. During periods of warm temperature, high humidity, and food availability these workers collect large quantities of seeds and store them in underground galleries. Similarly, in tropical agroecosystems of Mexico the native fire ant, *Solenopsis geminata*, harvests large amounts of weed and stores them underground. Despite the large number of seeds attacked by ants, the implications of this behavior for plant population and community dynamics are not straightforward. On one hand, ant nests may provide microsites rich in essential nutrients such as phosphorus and nitrogen that may boost seed germination and seedling growth. On the other hand, seeds captured by ants suffer high rates of destruction and are buried several centimeters below ground, which reduces seedling establishment and growth.

Much less is known about the seed feeding habits of the field cricket, *Gryllus pennsylvanicus*. This species is one of the most abundant and widely distributed field crickets in the northeastern United States, occurring in various grassy habitats, such as crop fields, pastures, weedy areas, roadsides, and lawns. Recent laboratory and greenhouse studies indicated that *G. pennsylvanicus* actively locates and feeds on seeds of several weed species. In a 24-h period under laboratory conditions, a female cricket ate an average of 223 redroot pigweed (*Amaranthus retroflexus*) seeds.

In contrast with predispersal seed predation, the parent plant can not respond to seed death once seeds have been shed. The lack of a physiological feedback implies that the mother plant cannot compensate for an increase in postdispersal seed predation by producing more seeds. Therefore, changes in the intensity of postdispersal seed predation generate responses that occur at the evolutionary level. Defense strategies against postdispersal seed predation include physical mechanisms (e.g., thorns, hard seed covers), camouflage, toxicity through high concentrations of a variety of chemicals, and mast seeding, i.e., the production of seeds in a bimodal distribution with years of large seed outputs and years of small seed outputs.

In recent years, there as been a growing interest in the potential of pre- and postdispersal invertebrate seed predators to act as biological control agents of invasive plants and agricultural weeds. The probability of success of seed-feeding insects in reducing plant abundance depends not just on the establishment and reproduction of large insect populations, but also on characteristics of plant populations. If seed production is high, seedbank density is large, and there are few "safe sites" for germination and establishment, then the density of these sites, not the number of seeds in the soil, determines seedling densities. It is also necessary to consider the number of seedling plants that reach adult stages of development. Nonetheless, there are several cases in which successful control of invasive plants has been achieved through seed feeding insects. For example, the apionid *Trichapion lativentre* and the weevil *Ryssomatus marginatus* feed on seeds prior to their dispersal. These two insects have been successfully employed in South Africa to reduce the abundance of *Sesbania punicea*, an invasive shrub from South America. Also, two seed-head attacking flies, *Urophora affinis* and *U. quadrifasciata*, are promising biological control agents for control of spotted knapweed (*Centaurea maculosa*), which is a serious problem in rangelands, meadows, and roadsides, especially in sandy soils. Under experimental conditions, the joint effect of these two flies can reduce spotted knapweed seed production up to 95%.

Despite the importance of seed feeding insects as biological control agents, non-target effects may be serious potential problems. For example, the Eurasian weevil *Rhinocyllus conicus* has been released in Canada and the United States since 1968 for the biological control of introduced thistle species. This weevil feeds on thistle seedheads and attacks not just the targeted invasive species, but several species of native thistles.

In herbaceous crop systems, invertebrate seed predation appears to be a relatively safe strategy to control agricultural weeds. The relatively large size that crop seeds have in comparison with agricultural weeds, the short time span between crop planting and emergence, the tendency of invertebrate seed predator populations to peak when crops are harvested rather than when they are planted, the ground-dwelling habits of invertebrate seed predators, and their inability to fed on buried seeds suggest that invertebrate crop seed predation should not be a concern to farmers.

In conclusion, insect seed predation is a particular type of plant/insect interaction occurring in both natural habitats as well as agricultural systems. Because of the extremely diverse nature of insect-seed relations, it is difficult to make generalizations about the dynamics and consequences of insect seed predation. However, several patterns emerge: (i) seed predation involves plant-insect interactions that have coevolved in chemical, spatial, and temporal dimensions; (ii) invertebrate seed predation involves processes spanning from the individual energy budget to dynamics of entire communities; (iii) due to several biotic and abiotic factors, seed predation by insects is highly variable in time and space, (iv) because insects predators are usually selective, seed predation has a strong potential to affect plant population and community dynamics; and (v) the cumulative effects of insect seed predation coupled with other sources of plant mortality, such as seedling herbivory and seed decay, can determine spatial patterns of plant abundance. Finally, entomologists interested in developing a weed biological control program based on pre- or postdispersal seed predation should carefully study the potential for non-target effects prior to the release of natural enemies.

Seed Treatment

A pesticide application to the seed prior to planting to protect the seed, and sometimes the seedling, from injury.

► Insecticides
► Insecticide Formulations

Segment

A major subdivision of the body or appendage, separated from other segments by areas of flexibility.

Selective Pesticide

Pesticides that are toxic principally to the target pest. Pesticides having few adverse effects on non-target (beneficial) organisms.

Selective Pressure

A force acting on populations that results in some individuals leaving more progeny (descendents, genes) than others, contributing to natural selection.

Self-Regulation

The concept that deterioration in the intrinsic quality of individuals regulates populations rather than some external factor such as predators or weather.

Selys-Longchamps, Michel Edmond De

Michel Selys-Longchamps was born at Paris, France, on May 25, 1813. Though lacking formal education, he was a man of wealth, rank, and political influence. He represented various communities in the Belgium parliament and later served as senator and then president of the senate. In addition to such public service, Selys-Longchamps was interested in Odonata, as well as neuropteroid and orthopteroid insects, and in ornithology. His wealth and influence allowed him to amass one of the great insect collections of Neuroptera and Orthoptera. He is now considered to be the father of the study of Odonata. Selys-Longchamps authored about 250 publications, including "Revue des odonates ou libellules d' Europe" in 1850, "Catalogue des insectes Lépidoptères de la Belgique," (1857) and "Memoirs of Odonata from New Guinea, Philippines, Japan, palearctic regions, Europe, Sumatra, and Burma" (1878–1891). He died at Luttich, Belgium, on December 11, 1900.

Sematuridae

A family of moths (order Lepidoptera). They commonly are known as American swallowtail moths.

► American Swallowtail Moths

► Butterflies and Moths

Semelparity

When organisms produce all their progeny in a single reproductive event, or over a short period of time.

Semelparous

This is used to describe insects that are short-lived as adults, and that lay eggs in a short period of time. This is used in the context of mosquito biology.

► Iteroparous

Semilooper

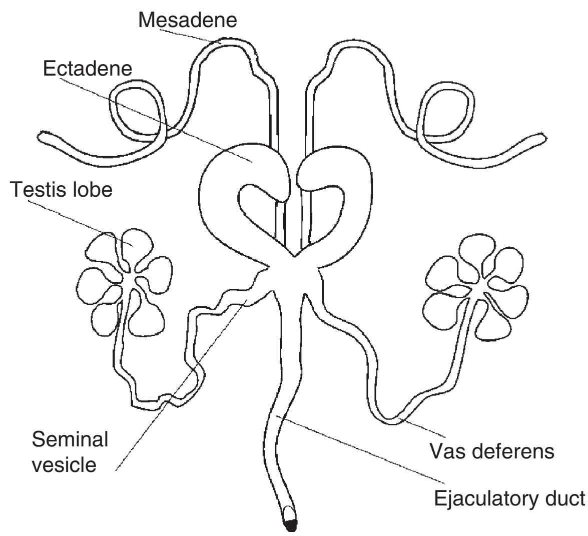
Caterpillars, usually of the order Lepidoptera, family Noctuidae, with a reduced number of prolegs, usually one or two pairs fewer than normal. These loopers move in a looping motion, but the looping movements are small. (contrast with looper)

Seminal Vesicle

An expansion of the vas deferens of the male which stores sperm (Fig. 37).

Semiochemical

Any chemical involved in the chemical interaction between organisms, particularly signaling



Seminal Vesicle, Figure 37 **Diagram of a male reproductive system as found in *Tenebrio* (Coleoptera) (adapted from Chapman, The insects: structure and function).**

chemicals that allow transfer of a message. These also sometimes are called "infochemicals." They may be intraspecific or interspecific. Examples include pheromones, kairomones, allomones, and synomones.

► Chemical Ecology
► Allelochemicals
► Pheromones

Semiochemical Parsimony

The natural products produced by insect exocrine glands (external secretions) serve multiple functions. Many exocrine secretions that have been identified with a single function (e.g., alarm and sex pheromones) often possess additional functions that are highly adaptive for their producers. Thus, insects may exploit the secretions of a single gland for unrelated diverse roles that can include defense, sexual attraction, and communication. The multifunctional compounds secreted by insects are termed "semiochemicals" and primarily include pheromones (communication chemicals) and allomones (defensive chemicals). These compounds, which have been identified in insect species in at least six orders, had often been assigned single functions, but it is now evident that they possess a variety of unsuspected – and vital – additional functions as chemical regulators of a large diversity of behaviors. This phenomenon has been described as "semiochemical parsimony" as a reflection of the great adaptiveness of insects manipulating their exocrine products.

► Multifunctional Semiochemicals
► Allelochemicals
► Chemical Ecology

Semisocial Behavior

A level of sociality less than eusocial behavior. A type of presocial behavior. As in quasisocial behavior, semisocial behavior involves individuals of the same generation sharing a nest and cooperating in brood care. However, it also includes division of reproductive behavior, with a worker caste caring for the young of the reproductive caste.

► Presocial
► Solitary
► Communal
► Subsocial
► Quasisocial
► Eusocial Behavior

Senescence

The process of aging in organisms.

Senescent

The period of life after maturity.

Sensillum (pl., sensilla)

A simple sense organ associated with the integument, often taking the form of a hair or bristle.

Sensorium (pl., sensoria)

A transparent sensory pit on the antennae, usually near the tip.

Sensory Neuron

Nerves that connect a peripheral sensory location with the insect's central nervous system. Types of sensory neurons include: mechanoreceptors (for touch, position and sound), chemoreceptors (for taste and smell), hygroreceptors (for humidity), photoreceptors (for light), and thermoreceptors (for heat).

► Nervous System

Sentinel Host

A method of early detection of viruses transmitted by mosquitoes. Various birds, most often chickens, are caged in areas where mosquitoes are active.

Blood from the birds is sampled periodically and tested for antibodies specific to arboviruses of interest. Antibody presence can trigger warning of mosquito transmitted disease in human and animal populations.

► Mosquitoes

Sepsidae

A family of flies (order Diptera). They commonly are known as black scavenger flies.

► Flies

Septicemia

A morbid condition caused by the multiplication of bacteria in the blood, and accompanied by production of toxins. *Serratia* and *Streptococcus* species commonly are implicated.

Septobasidium

Septobasidium (Order: Septobasidiales, Phylum: Basidiomycota, anamorph: *Harpographium*) is parasitic on colonies of scale insects. *Basidiospores* germinate on the host insect, and hyphae penetrate the cuticle and underlying tissues. Additionally, an extensive hyphal mat forms over the insect as it adheres to the host plants. In *Septobasidium*, this hyphal mat may encase an entire colony of insects with each insect located in an individual chamber. Hyphal mats are often easily recognizable and range in color from brown to yellow, red, or purple. These fungi usually do not kill host scales, but do cause sterility in infected individuals. They cannot survive in nature without the host insects, depending upon them for nutrients and dispersal. In turn, the fungi form an umbrella-like structure that provides a protective environment for any uninfected scales that exist under the mycelial umbrella. At the level of the colony, the relationship between Septobasidiales and scale insects may therefore be considered to be mutualistic.

Sequential Sampling

A sampling plan in which “stop-lines” continually assess the need for additional sample units during the sampling effort on a given day or time interval. These stop lines are typically based on a prescribed level of desired precision or classification accuracy. Sequential sampling is efficient because no prior knowledge of density is required and no more sample units than necessary are collected. (contrast with fixed-sample size sampling).

Sericostomatidae

A family of caddisflies (order Trichoptera).

► Caddisflies

Sericulture

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

The production of silk is known as sericulture. Normally, silk is produced from the cocoons of the mulberry or Chinese silkworm, *Bombyx mori* (L.), though other species may be used. For example, in India most silk is produced by *B. mori* fed on mulberry, but smaller quantities of tasar silk, muga silk, and eri silk are also produced, contributing importantly to the rural economy. Some of the species that have been used for silk production, and area of occurrence, include:

Bombycidae (silkworm moths)
- *Bombyx mori* (silkworm) (Asia, Europe)
- *Bombyx* spp. (India)

Lasiocampidae (tent caterpillars, lappets, etc.)

Gonomera postica (Africa)

Trabala vishnou (Oriental lappet moth) (Southeast Asia)

Notodontidae (prominent moths)

Anaphe infracta (African wild silkworm) (Africa)

Saturniidae (emperor moths, giant silkmoths)

Actias selene (moon moth) (India)

Antheraea mylitta (India)

Antheraea paphia (tussor silkworm) (Southeast Asia)

Antheraea pernyi (Chinese oak silkworm) (China)

Antheraea yamamai (Japanese oak silkworm) (Japan)

Attacus atlas (atlas moth) (New and Old World tropics)

Eriogyna pyretorum (giant silkworm moth) (Southeast Asia)

Naudaurelia spp. (silkworms) (Africa)

Samia cynthia (Ailanthus silkworm moth) (formerly India to China, now also Europe, North America, South America)

Philosamia ricini (Eri silkworm) (India, Southeast Asia)

History of Silk Production

Bombyx mori has been domesticated since about 2700 BC, and probably no longer survives in the wild. According to Chinese history, China's third emperor Huang-ti directed his wife Hsi-ling-chi to examine the silkworm, and to assess its potential for making thread. According to legend, she not only discovered how to rear silkworms, but also how to unravel the silk from the cocoon and to make garments from the silken threads. Initially, only members of the royal family were allowed to wear garments of silk. The usefulness and beauty of the resultant garments eventually led to construction of the "silk road" from China to the Mediterranean region, along which not only silk but also jade, gold, and new ideas spread. The Chinese guarded the secret of silk production closely, but according to legend the Roman Emperor objected to the exorbitant prices he was required to pay to obtain silk, and he recruited spies to discover how silk was cultured. Eventually the secrets spread both eastward to Japan and Korea, and westward to India and to eastern Europe. By the eighteenth and nineteenth centuries, Europe was producing great quantities of silk. The great French scientist Louis Pasteur is remembered for many achievements, but one of the most notable is the rescue of the French silk industry in 1870 through discovery of a disease of silkworms (pebrine) and ways to manage the disease.

It is interesting to note that attempts were made to establish sericulture in America beginning in the 1600s. Unlike introduction of sericulture to Europe, however, it was unsuccessful. Particularly in the early and mid-1800s, the idea of silk culture became very popular in the United States. Promotion of silk culture can be traced to the promotional practices of the agricultural newspapers and journals of the 1820s, a time when sericulture was also being promoted by governments in Europe. Silk production was viewed as attractive because it would be another cash crop, as well as being a crop could be harvested in as little as 6 weeks, one that required little initial cash outlay, and one that would use land that otherwise was unusable for mulberry propagation. It was advanced as a suitable enterprise for anyone who could grow mulberry plants, and coincides with the introduction from China of Asian mulberry (although native mulberry is suitable), and a time when industrialization/mechanization was freeing up labor that was seeking alternative employment. It was also a suitable occupation for women, children, and others not readily employed in occupations requiring heavy labor. Inhabitants of northern states imagined that silk would compete with southern cotton as a wealth-generating commodity. Lastly, silk production challenged America's self-image of being populated by exceptionally creative, ingenious people who could solve any problem if they invented and applied appropriate technology. By 1939 many Americans were actively involved in silkworm culture as a "cottage industry," and some made a profit, but the cold winter of 1939–1940 devastated the Asian mulberry trees, and the industry never recovered. In hindsight, it seems that the principal promoters of sericulture in

America were individuals who benefited from the sale of mulberry plants. Indeed, the principal profits were made by tree speculators who made their profits before the weather-induced collapse.

The reduced availability of cotton following the American Civil War led to further, but more modest, interest in sericulture. Reportedly this led to the introduction of gypsy moth, *Lymantria dispar* (L.), to America from Europe by E. Leopold Trouvelot, an American naturalist. Trouvelot believed that gypsy moth could be a useful source of silk. However, not only did it not prove to be a practical source of silk but it developed into one of North America's worst forest pests. Other attempts to establish silk production in the western hemisphere were made in the late 1800s and early 1900s, but none succeeded. Now, production of silk using *B. mori* is dominated by China and Japan. Considerable quantities of silk are also produced in India, including silk produced using other species. In India, *Antheraea mylitta*, *A. perniyi*, and *A. royeli* are used to produce tasar silk by rearing them on *Terminalia* spp. trees. Also, *Antheraea assama* is reared on *Machilus bombycina* and *Litsaea polyantha* trees to produce munga silk, and *Philosamia ricini* is cultured on castor for eri silk.

Silkworm Culture

Silkworms typically are reared at about 24°C. The egg stage of *B. mori* requires about 10 days, followed by 25–30 days for the larval stage, and 10 days for the pupal stage. There are four instars during the larval stage, with about 95% of food consumption occurring in the terminal two instars. Fresh foliage is provided continuously to the growing larvae, usually spread on paper. Cleanliness and good air-flow are essential to prevent disease. When they are ready to pupate, however, they must be provided with brush or straw on which to construct their cocoons, which are made from silk. Some adults are allowed to emerge from the cocoon to mate and produce eggs, of course, but most are killed by heat to prevent adult emergence because escape of the moth from the cocoon breaks the silk thread. The female moth produces about 400 eggs.

Different strains of *B. mori* are used in silk production. Univoltine and bivoltine strains naturally produce only one or two generations per year, respectively, but by treating the eggs with hydrochloric acid and high temperature it is possible to disrupt diapause and obtain up to four generations. Other, multivoltine strains produce up to six generations per year, but these insects are smaller than the univoltine and bivoltine strains, so they produce less silk per cocoon.

Silk Production

The mature silkworm spins its cocoon from one continuous filament of silk, which makes harvest of the silk possible. The process starts with softening of the cocoon, which is done in hot water. The individual strand can then be unwound from the cocoon; a good-quality cocoon may produce 350–750 m of filament. The individual filament of silk is very fine, so several must be wound together (reeled) to form a thread strong enough to handle. Not all silk can be unwound successfully, but other processes use the waste silk. Once the silk filaments are reeled (this product is called "raw silk") it can be dyed or twisted in several ways to give it unique character. The silk processing can be done by hand, or on machines called "filatures." Once assembled, the raw silk is twisted with other silk to give it further strength and thickness, a process called "throwing." This latter step is typically done by machine in factories. The silk can then be woven into various textiles using standard processes, but using special machinery better suited for the delicate nature of silk.

Silk production is an important enterprise. The leading producers are China, Japan, India, South Korea, and some of the former Soviet republics. In China, mulberry and silkworm cultivation has been fully integrated with fish farming. Pond mud, rich in organic material and nutrients, is used to fertilize mulberry plants. The mulberry leaves are harvested to feed to silkworms, resulting in production of silk. Remnants of the mulberry harvest, caterpillar feces, and other remnants of silkworms are fed to fish in ponds. The fish are harvested for food, but their wastes enrich the pond bottoms, producing fertile mulch to re-initiate the plant and silkworm production processes. Thus, the "mulberry plot-fish pond" concept represents integrated farming with complete recycling of wastes, and spawns affiliated enterprises such as silk reeling.

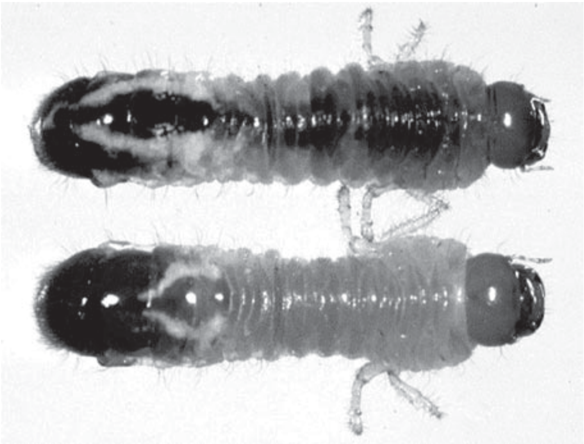
Serrate

Notched, like the teeth of a saw.

Serratia entomophila

Several species within the genus *Serratia*, including *Serratia marcescens*, *S. entomophila* and *S. proteamaculans*, have been identified as entomopathogenic. These species can be isolated using the selective caprylate thallous agar. Many *S. marcescens* strains produce characteristic bright red colonies. Insects infected with *S. marcesens* succumb within 1–3 days and often exhibit a reddish tinge. Whether or not *S. marcesens* is able to actively invade healthy insects is unclear. In many cases, this disease has been associated with poor sanitation and crowded rearing conditions. Certain parasitic hymenoptera have been reported to vector this bacterium on contaminated ovipositors. Very likely, both the pigmented and non-pigmented *S. marcescens* strains are opportunistic pathogens.

Strains of *S. entomophila* and *S. proteamaculans* are true pathogens of the New Zealand grass grub, *Costelytra zealandica*, and are the causal agents of amber disease. *Serratia* strains that induce amber disease possess a common large 140 kb plasmid (pADAP) which, when removed by heat-curing cells, resulted in loss of virulence. These pADAP plasmid bearing strains of *Serratia* exhibit a high degree of host specificity and have been found to infect only *C. zealandica*. Larvae infected with pathogenic *S. entomophilia* and *S. proteamaculans* rapidly cease feeding. It has been shown that infection by pathogenic *Serratia* strains causes a reduction in the trypsin activity in the gut, disrupting the normal digestive process. The gut contents, which are normally black, are clarified, conferring an amber coloration to infected larvae (Fig. 38). The amber larvae are unable to feed and assimilate nutrients and undergo a starvation period that may last from 1 to 4 months. During this period, the bacteria colonize the gut and become attached to cuticular surfaces including the external cuticle. Late in infection, bacteria may penetrate the hemocoel and cause a generalized septicemia. Alternatively, the colonizing population of this pathogen may be displaced by secondary bacteria prior to



Serratia entomophila, **Figure 38 Healthy (*top*) and infected (*bottom*) *Costelytra zealandica* grubs. Note the absence of the dark underlying midgut in the grub infected with *Serratia entomophila*. These amber grubs have voided their guts and have ceased feeding.**

host death. Interestingly, the pathology induced by *S. entomophila* is similar to that caused by *S. proteamaculans*.

A diagrammatic representation of the setae found on the body of larvae.

Setose

The occurrence of large numbers of setae or bristles on the surface of a structure.

Sex Attractant Pheromones

PETER E. A. TEAL

U.S. Department of Agriculture, Center for Medical, Agricultural and Veterinary Entomology, Gainesville, FL, USA

Pheromones are chemicals emitted and secreted by an individual and received by another individual of the same species, in which they induce a species specific reaction. By far the greatest variety of pheromone-mediated systems occurs among insects. Sex pheromones (chemicals, or blends of chemicals, emitted by an individual of one sex for the purpose of inducing sexual behaviors by members of the opposite sex) are the only pheromone mediated system in common usage by members of all insect orders. This undoubtedly stems from the universal need to reproduce and the development of chemosensory organs early in the evolutionary history of Hexapoda, perhaps even before the development of light-sensitive organs. In general, sex pheromones act as sexual attractants when they induce the receiving sex to move toward the releasing sex or as copulatory stimulants, or aphrodisiacs, when released or perceived in close proximity to the receiving sex to induce a receptivity or copulatory behaviors. However, it should be noted that attractant pheromones also may act as copulatory stimulants at close range. Although known sex pheromones act to induce a behavioral change in the receiving sex (releaser pheromones) there is no reason not to assume that sex pheromones could have primer effects and induce physiological changes associated with sex. Indeed, it is quite conceivable that volatile pheromones could induce release of neuropeptides or other rapidly dispersed hormones or cause nervous signals that would induce physiological changes required for effective mating. Quite simply, we have not looked extensively for such effects.

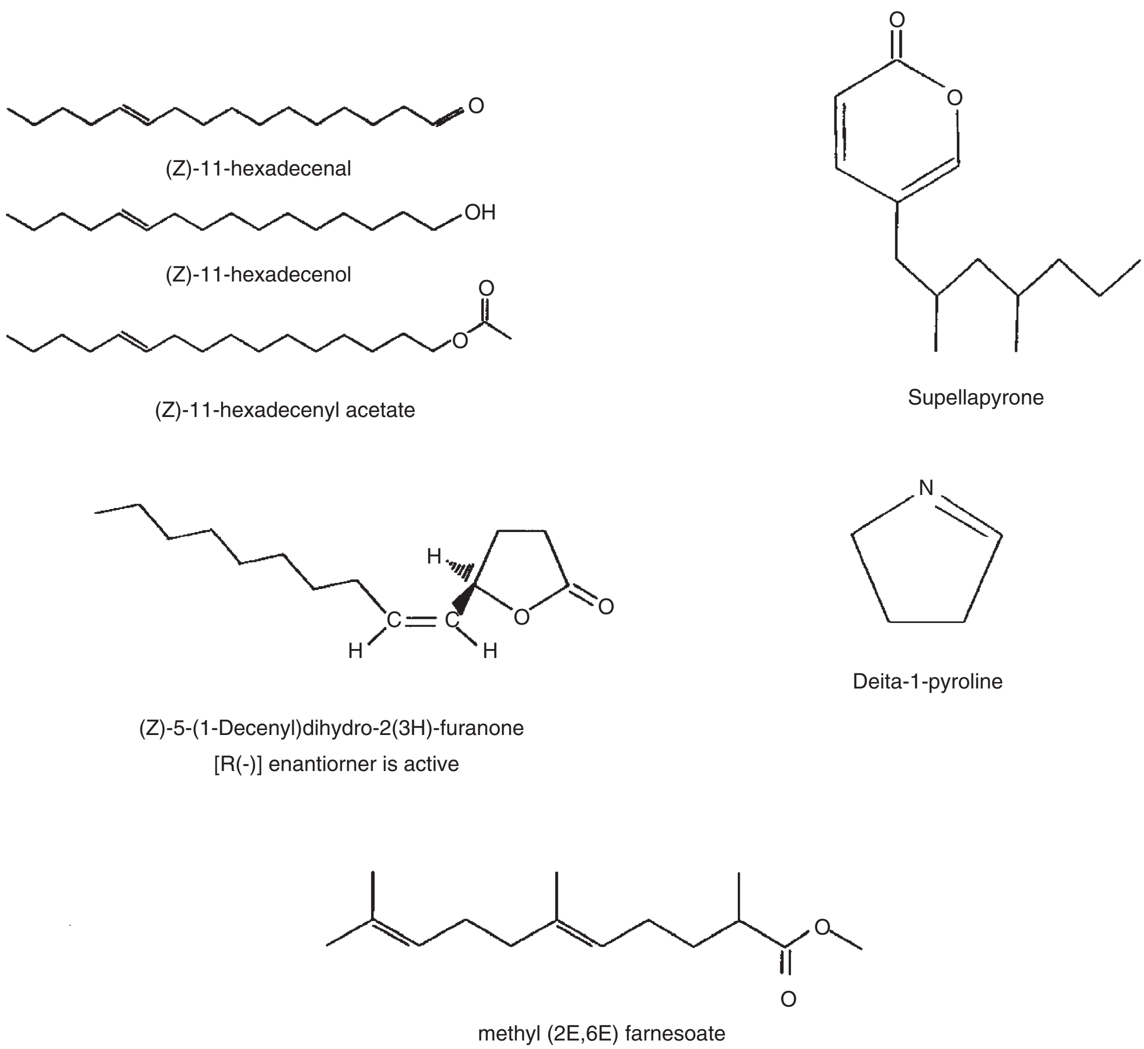
Historically, the use of conspecific attractant pheromones by insects was documented as early as 1690 when John Ray reported several male *Biston betularia* (Lepidoptera) flying around a caged female. This knowledge of the attractive capacity of female Lepidoptera was used by such great naturalists as Fabré for collection of rare specimens; the procedure used was essentially the same as that of Ray. The use of live females, and naturally produced sex pheromones for population monitoring of the gypsy moth, *Lymantria dispar* (L.), began as early as 1914, but by 1920 females had been replaced by organic solvent extracts of abdomen tips, which remained attractive for longer periods of time than did females. Attempts to isolate the chemicals responsible for induction of sexual attraction and behavior also were begun in the 1920s. However, the methods available for chemical analysis were inadequate to obtain concrete identifications and required such tremendous amounts of sample that little headway was made. Butenandt and his colleagues identified the first sex pheromone, produced by females of the silkworm moth, *Bombyx mori* (L.), in 1959. The elucidation of this pheromone, bombykol ((*E*,*Z*)-10,12-hexadecadiene-1-ol), had taken 20 years and required sacrifice of 500,000 females. With the development of improved analytical chemistry techniques, methods for collection of volatile chemicals released by insects, highly sensitive electrophysiological techniques like the electroantennogram detector and sophisticated bioassay techniques, the isolation and identification of sex pheromone components has become much easier, rapid and requires far fewer insects than those used for earlier work. In fact, sex pheromones have now been identified for at least 2,000 species representing more than 90 families of insects, and the list grows every day.

Chemistry

Sex pheromones used by insects are all lipidic in nature, and most are composed of acetogenins and mevalogeninsins. Apart from this, there is no general theme associated with the types of lipids that act as pheromones. However, relatively low molecular weight compounds (20 carbons or less) generally serve as long distance attractants because of their volatility. Most of these contain oxygenated functional groups like alcohols, esters, ketones, aldehydes, epoxides, and lactones, but non-oxygenated monoterpenes, sesquiterpenes and hydrocarbons also serve as long distance attractants. Long chain wax esters and hydrocarbons that are not volatile serve as close range stimulants and require contact by the receiver in order to induce sexual behavior. Often, closely related groups of insects use pheromones synthesized in a similar fashion, as is evidenced by the use of long chain cuticular hydrocarbons as contact sex pheromones by muscid flies, the acetates and propionates of monoterpene and sesquiterpene alcohols used by scale insects, and the blends of 12–16 carbon saturated, and unsaturated alcohols, aldehydes and acetates used by noctuid moths. These moth sex pheromones are formed by δ-11-desaturation of palmitic (or octadecanoic) acid followed by varying degrees of chain shortening via β-oxidation and subsequent modification of the acid moiety to form the oxygenated functional group. Nonetheless, there are many insects that use blends of compounds that are structurally unrelated for sexual signaling. For example, males of the Mediterranean fruit fly release a blend of compounds containing straight chain alcohols, monoterpenes, sesquiterpenes, lactones, and nitrogen containing compounds including 1-pyrroline and 2-ethyl-3,5-dimethyl pyrazine (Fig. 39).

Pheromone Function

The key to effective sexual signaling with pheromones is the use of chemicals, or chemical blends, that are species specific because it is metabolically



Sex Attractant Pheromones, Figure 39 **Examples of insect sex pheromones. Sex pheromones common to noctuid moths include (*Z*)-11-hexadecenal, (*Z*)-11-hexadecenol and (*Z*)-11-hexadecenyl acetate. That of the Japanese beetle is (*Z*)-5-(1-decenyl)dihydro-2(3H)-furanone. Supellapyrone is the pheromone of the brown banded cockroach, *Delta*-1-pyroline is from the Mediterranean fruit fly and methyl (2*E*,6*E*)-farnesoate is produced by male stink bugs.**

very expensive to produce or respond to pheromones if no mating reward results. In fact, sex pheromones of insects are the primary means by which many closely related species achieve reproductive isolation. Although there are instances in which insects use a single component for sexual communication, these cases are rare and, more often than not, involve the use of chiral compounds in which one enantiomer is active and the other inhibitory. For example, the sex pheromone of the Japanese beetle is (*R,Z*)-5-(1-decenyl)-dihydro-2(3H)-furanone and the (*S,Z*) enantiomer is inhibitory. Thus, a significant decline in trap capture has been documented when as little as 1% of the (*S,Z*) enantiomer is incorporated into lures containing the (*R,Z*) enantiomer. The most common method for imparting species specificity is the use of blends of chemical compounds. As such these pheromones are best equated with perfumes because, as with perfumes used by humans, very minor differences in the blend of chemicals results in significant differences in the attractive odor of the pheromone. Blend specificity can be imparted by a number of simple changes in chemistry of the compounds including the use of: (i) compounds having different oxygenated functional groups (aldehydes, acetates, alcohols or ketones); (ii) compounds having different numbers of carbons in the skeleton; (iii) compounds having different degrees of unsaturation; (iv) compounds having different geometries of double bonds; (v) blends of compounds having different ratios of the same components; (vi) blends of compounds containing different numbers of components.

Despite the fact that sex pheromones have been identified from a large number of insect species, detailed studies on perception and signal processing have been conducted on surprisingly few insect species. Thus, we are just beginning to understand the mechanisms involved in peripheral perception and central signal processing. Peripheral perception of pheromones occurs at the antenna, where specialized sensilla act to filter out pheromone molecules from the air. The cuticular wall of the sensilla contains numerous pore tubules through which odorant molecules diffuse into the lumen of the sensilla. Once in the lumen, the pheromone molecules are bound to pheromone binding proteins that solublize the pheromone in the aqueous receptor lymph and carry them to specialized receptors on the surface of dendrites in the sensillum. Binding of pheromone molecules with receptors on the dendrites leads to a G-protein-mediated activation of phospholipase C and generation of inositol triphosphate, which activates inositol triphosphate-gated Ca^{++} channels in the dendritic membrane, and results in electrochemical signal transduction. After release from the dendritic receptor, pheromone molecules must be degraded rapidly. This is accomplished by aggressive pheromone degrading enzymes in the receptor lymph. These degrading enzymes do not distinguish between pheromone molecules that have bound with receptors, or those that have not, so there is competition between pheromone binding proteins and degrading enzymes in the receptor lymph. Pheromone-responsive axons exit the antenna and enter specialized structures in the antennal lobe of the brain called the macroglomerular complex. The macroglomerular complex is sex specific, being found only in the sex that perceives and responds to sex pheromone, and it is here that efferent axons form synapses between interneurons and afferent neurons. The actual mechanisms that translate electrical signals generated by pheromone responsive neurons in the macroglomerular complex into behavioral events associated with response to sex pheromones are, as yet, not known.

Use of Sex Pheromones for Insect Management

Sex pheromones have been targets for development of strategies for insect control because of their species specificity. Initially, sex pheromones were primarily used as monitoring tools to determine population densities of pests in agricultural crops or storage facilities and this is still the major use of sex pheromones. When deployed in traps, sex pheromones can be used as detection tools to provide: (i) an early warning system about the presence of a pest, (ii) a survey tool to determine the population distribution of insects, and (iii) a way to determine if quarantine pests have been introduced to an area. Sex pheromone trapping systems are also effective for determining a population threshold for: (i) the timing of control treatments, (ii) timing of other sampling methods, for example, searching for larvae, and (iii) risk assessment. Population monitoring also provides ways to assess population trends, the effects of control programs and dispersion of pests. Additionally, sex pheromones of insects can be effectively used to determine the distribution and spread of entomophagous insects released as biological control agents.

Sex pheromones also are used for direct control of insect pest populations. Direct control using sex pheromones can be achieved by mass trapping, attraction of pest insects to baits containing pesticide (attract-and-kill protocols) and disruption of mating. Although mass trapping is conceivably possible with sex pheromones alone, the fact that mated females are not normally captured in sex pheromone baited traps significantly reduces the efficacy of this technique. However, sex pheromones are used in combination with other attractants for mass trapping. For example, mass trapping of the Japanese beetle with lures containing the female produced sex pheromone along with the feeding attractants phenethyl propionate, eugenol and geraniol has been shown to be effective. Males are attracted to the sex pheromone in large numbers and inclusion of the feeding lure results in capture of great numbers of females. Additionally, the use of pheromones that act in dual roles has been shown to be effective for mass trapping. For example, the pheromone of the boll weevil acts as an aggregation pheromone in the spring and fall, which results in capture of both sexes, but in summer only females are attracted. Capture of both sexes in spring and fall reduces the populations significantly prior to infesting cotton, and capture of females in the summer keeps the population in check during the growing season.

A second method of population suppression with sex pheromones is the attract-and-kill system in which pheromone dispensers also contain a conventional pesticide. The key to such systems is the use of a pheromone system that is as effective, or preferably more effective, in attracting insects than is the releasing sex.

Mating disruption has become the most successful method for direct control of insect pests using sex pheromones. In this technique, large amounts of pheromone are released throughout control areas, either by strategic distribution of a relatively small number of pheromone dispensers, each of which releases substantial amounts of pheromone, or by broadcasting large numbers of small dispensers which release relatively small amounts of pheromone throughout the entire control area. Although the exact mechanisms responsible for mating disruption with pheromones are not well understood, five mechanisms have been proposed to account for mating disruption. These mechanisms include: (i) sensory fatigue in which constant exposure to high levels of pheromone causes sensory adaptation of pheromone receptors on the antenna or an habituation to pheromone in the central nervous system which, in either case, inhibits the receiving sex from responding to natural pheromone; (ii) competition between natural and synthetic sources (false trail following) in which the number of pheromone plumes in a field generated from synthetic sources is far greater than the number of the signaling sex and, thus, the receivers spend all of their time finding synthetic sources; (iii) camouflage of natural sex pheromone plumes could occur when the amount of pheromone released is so great that it forms a fog permeating the entire atmosphere which does not allow the receiver to track down a natural point source of sex pheromone (i.e., the emitter); (iv) sensory imbalance can occur when an "off blend," not so different from the natural blend that insects fail to respond to it, is completely superimposed over the natural point sources of pheromone and results in the disorientation of the insect; and (v) mating disruption also occurs when compounds that inhibit the response of insects to the natural pheromone blend are included in the synthetic disruptant, as is evidenced by disruption of

Eupoecilia ambiguella using technical grade pheromone which contains the pheromone (*Z*)-9-dodecenyl acetate plus as little as 0.1% of the inhibitory isomer (*E*)-9-dodecenyl acetate.

Sex Ratio Modification by Cytoplasmic Agents

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

The normal sex ratio of progeny produced by mated diploid insects is one female to one male (1:1); typically, unmated diploid females cannot produce progeny. That normal 1:1 sex ratio is modified when unmated insects reproduce by parthenogenesis (called arrhenotoky or thelytoky). With arrhenotokous (haplo-diploid) species, such as bees and wasps in which both haploid males and diploid females occur, the sex ratio of progeny produced by mated females commonly is biased towards females, often with 2 or 3 females for each male. Unmated arrhenotokous females can produce only haploid male progeny. Thelytokous species commonly have only females, although sometimes rare males are produced. These sex-determining systems are based on the chromosomes in the nuclear genome of insects. However, normal sex ratios in insects can be modified by a number of organisms (bacteria, viruses, protozoans) and by genetic elements called meiotic drive elements, which are genes on the chromosomes that modify the normal distribution of chromosomes to egg and sperm during meiosis.

► Meiotic Drive in Insects

Cytoplasmic Agents Distort Normal Sex Ratios

Most cytoplasmic agents (bacteria, viruses, spiroplasmas) are inherited primarily through the mother and thus are cytoplasmically or maternally inherited. Cytoplasmic agents that can manipulate their insect host's sex ratio (usually increasing the proportion of females) and promote their own spread are called cytoplasmic sex ratio distorters. The spread of a cytoplasmic sex ratio distorter often reduces the fitness of its host and can drive insect populations to extinction. Sex ratio distorters are usually suspected if single-pair crosses produce a heavily biased sex ratio in the progeny, although meiotic drive agents are also possible mechanisms.

At least 50 cases have been identified in which cytoplasmic agents alter sex ratios in insects or mites. Examples are found in the Diptera, Heteroptera, Coleoptera, Lepidoptera or

Acari (mites). Cytoplasmic sex ratio distorters may be widespread, but undetected, in other arthropods. Maternal transmission rates of these agents typically are high, although a few daughters may fail to become infected. The altered sex-ratio conditions are found in natural populations at frequencies ranging from low to high. The infections may reduce fitness of the hosts, with egg hatch or larval survival reduced in the progeny of infected females. Specific examples are described below.

Spiroplasmas

The sex ratio condition of *Drosophila willistoni*, and related neotropical *willistoni* group species, is due to a spiroplasma. Spiroplasmas are maternally inherited and transovarially (transmitted in the egg) transmitted. The spiroplasmas are lethal to male embryos. Spiroplasmas can be transmitted between species by injecting hemolymph containing them. Spiroplasmas from different species are different and a virus associated with the spiroplasmas also is different for each spiroplasma. When spiroplasmas from different species are mixed, they clump because the viruses lyse the spiroplasmas of the other species.

L-Form Bacteria

The *Drosophila paulistorum* complex contains six semispecies (subgroups derived from a single species that are thought to be in the process of speciation) that do not normally interbreed in the field. When they are crossed in the laboratory, fertile daughters and sterile sons are produced. Streptococcal L-form bacteria that are associated with the male sterility have been isolated and cultured in artificial media. The L-forms are transferred through the egg cytoplasm and each semispecies is associated with a different L-form bacterium. The L-forms can be microinjected into females and can produce the expected male sterility in the progeny.

Wolbachia

These rickettsia-like organisms are one of the most commonly described microorganisms found in arthropods. *Wolbachia* are intracellular and found in the reproductive tissues, as well as in the somatic cells of some species. *Wolbachia* have different effects on their arthropod hosts, but one that is relevant to this entry is their ability to alter sex ratio. The role of *Wolbachia* as endosymbionts was discussed in the section on Symbionts of Arthropods.

Wolbachia are gram-negative rods that cannot be cultured easily outside their hosts and they are widespread, having been found in up to 76% of all insect species surveyed. In addition to insects and mites, *Wolbachia* have been found in Crustacea and nematodes. Knowledge of the physiological and phenotypic effects of *Wolbachia* on most of their hosts remains limited.

In the Crustacea, *Wolbachia* infect isopods, including *Armadillidium album*, *Ligia oceanica*, *A. nasatum*, *Porcellionides pruinosus*, *Chaetophiloscia elongata* and *Spaeroma rugicauda*. Some *Wolbachia*-infected isopods regularly produce female-biased broods because the *Wolbachia* change genetic males (homogametic ZZ individuals) into functional females. Such individuals are chromosomally male (ZZ) but phenotypically appear and function as females. These "daughters" of infected mothers produce all-female or highly female-biased progeny, resulting in isopod lineages that are chromosomally males but are functional females. Interestingly, there has been speculation that some *Wolbachia* genes have been transferred to the isopod nuclear genome—reminiscent of the movement of genes over evolutionary time from the mitochondria (originally a microbial symbiont) to the nuclear genome of eukaryotes.

Wolbachia can cause thelytoky (production of all females), male killing, and female mortality in insects and mites. Some *Wolbachia* improve fertility or vigor while others appear to decrease these traits in their hosts. Some species appear to have *Wolbachia* only in their germ line (ovaries and testes) while others have *Wolbachia* in somatic tissues, as well. *Wolbachia*-induced thelytoky (production of females only) in the Hymenoptera has been found in the Tenthredinoidea, Signiforidae and Cynipoidea, as well as at least 70 species of parasitoids (Aphelinidae, Encyrtidae, Eulophidae, Pteromalidae, Torymidae, Trichogrammatidae, Cynipidae, Eucoilidae, Braconidae, Ichneumonidae, Proctotrupoidae). Many hymenopteran parasitoids have both arrhenotokous and thelytokous strains, with thelytoky associated with the presence of *Wolbachia*.

In thelytokous populations of parasitoids, unfertilized eggs give rise to females. A number of thelytokous parasitoids (*Ooencyrtus submetallicus*, *Pauridia peregrina*, *Trichogramma* sp., *Ooencyrtus fecundus*) produce a few males, usually less than 5%, when reared at temperatures over 30°C. Heat treatments are known to reduce or eliminate *Wolbachia* infections in some species, so it is thought that the low rates of male production are due to reduction or elimination of *Wolbachia* from some females. Sometimes, the rare males produced by cured females have been shown to mate and transfer sperm, indicating that these males have normal vigor and fertility. In other cases, the rare males are infertile, suggesting that the *Wolbachia* infection had existed for a long time in the population, which could have allowed selection for essential fertility genes to be relaxed over evolutionary time. In addition to heat treatments, several antibiotics (tetracycline hydrochloride, sulphamethoxazole and rifampin) can induce the production of males in some thelytokous parasitoid populations.

The cytogenetic changes that occur during meiosis to restore an unfertilized haploid egg to diploidy (thus permitting thelytoky) has been studied in *Trichogramma*. In the eggs of *Wolbachia*-infected *Trichogramma* females, meiosis progresses to the stage of a single haploid pronucleus but the diploid chromosome number is restored during the first mitotic division. This happens because, during anaphase, the two identical sets of chromosomes do not separate and the result is a single nucleus containing two copies of the same set of chromosomes, resulting in a female that is completely homozygous at all loci.

Wolbachia infection can influence mating behavior of insects, as well as kill males. For example, populations of the butterfly *Acraea encedon* are found across Africa. In many populations, females produce only female progeny while other populations produce both males and females in a normal 1:1 sex ratio. The production of all female progeny is caused by a *Wolbachia* strain that kills males. *A. encedon* typically deposit clutches of 50–300 eggs and newly hatched larvae often cannibalize unhatched eggs, only gradually dispersing into smaller groups.

The evolution of male-killing by *Wolbachia* may be favored when the behavior and ecology of a species makes antagonistic interactions between host siblings or sib cannibalism likely. Under field conditions, the *Wolbachia* infection rates in *A. encedon* females may result in populations with a serious shortage of males. As a consequence, the mating behavior of *Wolbachia*-infected *A. encedon* has been altered. Normally males seek out and compete for individual females that are located near larval food plants. However, when male-killing *Wolbachia* are present in high frequency in a population, *A. encedon* females instead form dense aggregations in grassy areas near trees, perhaps to attract rare males as mates.

B Chromosomes and Cytoplasmic Factors

Sex ratio in the haplo-diploid (arrhenotokous) parasitoid wasp *Nasonia vitripennis* can be altered by at least two different mechanisms. Some natural populations of *N. vitripennis* carry a supernumerary or B chromosome that causes a condition called paternal sex ratio (PSR). B chromosomes are found in many plant and animal species and are small non-vital chromosomes mostly consisting of heterochromatin (DNA that is noncoding for proteins). Most B chromosomes have few genes but they often cause a small fitness cost to their host, making them selfish genetic elements. Some B chromosomes are thought to be derived from normal chromosomes and are transmitted at higher rates than expected, thus exhibiting "drive."

The PSR chromosome is carried only by haploid male *N. vitripennis* and is transmitted via sperm to fertilized eggs. After an egg is fertilized by a PSR-bearing sperm, all normal paternally derived chromosomes condense into a chromatin mass and are lost, leaving only the maternal chromosomes. The PSR chromosome itself survives. Thus, the PSR chromosome changes fertilized diploid (female) eggs into haploid males that carry the PSR chromosome.

Where did the PSR chromosome come from? Molecular analyses suggest the PSR chromosome has sequences that are homologous with sequences found in *Nasonia giraulti*, *N. longicornis* and *Trichomalopsis dubius*, but not with *N. vitripennis*. Thus, the PSR chromosome could have been present prior to the divergence of the genera *Trichomalopsis* and *Nasonia*. Alternatively, PSR may have crossed the species barrier more recently (horizontal transfer) through a series of transfers between species capable of mating. Experimental interspecific transfer of PSR was successful after these species were cured of *Wolbachia* which causes cytoplasmic incompatibility between them. The transferred PSR chromosome continued to function in both recipient species.

The sex ratio of *Nasonia vitripennis* can be modified by cytoplasmic factors, including "Son-killer," a maternally transmitted bacterium that prevents development of unfertilized male eggs and "Maternal Sex Ratio," a cytoplasmically inherited agent that causes female wasps to produce nearly 100% daughters.

Male Killing in Coccinellidae

The Coccinellidae appear particularly prone to invasion by male-killing organisms, with four different groups (*Rickettsia*, *Spiroplasma*, Flavobacteria and *Wolbachia*) having been associated with this phenomenon. Coccinellids may be especially susceptible to invasion by male-killing microbes due to their behavior; coccinellids typically feed on aphid populations that are patchy and deposit eggs in tight batches. This behavior could promote egg cannibalism by newly hatched larvae when normal prey populations are low. Such cannibalism could provide an additional mechanism by which the bacteria are transmitted to new individuals.

The evolution of the male killing ability may have evolved in the bacteria because they are almost exclusively transmitted vertically from mother to eggs; thus, bacteria in male hosts are at an evolutionary dead end, so male-killing has a fitness cost of zero from the bacterial point of view. Furthermore, the death of male embryos could augment the fitness of the remaining female brood members by providing food to those females carrying the relatives of the male-killing bacteria. A full understanding of the evolutionary dynamics of male-killers and their hosts remains elusive.

Sexual Selection

JAMES E. LLOYD, JOHN SIVINSKI
University of Florida, Gainesville, FL, USA
U.S. Department of Agriculture, Agricultural Research Service, Gainesville, FL, USA

Sexual selection is the class (i.e., form, section, axis) of natural selection that is associated with genetic differences among individuals in their ability to (i) compete for, or (ii) select, fertile partners in reproduction (i.e., mates). The former is typically associated with males, and the latter, with the female sexual role, but such distinction is continually eroded as ever more is learned of the details of mating behavior in different kinds of organisms.

Competition and mate attraction on the one hand, and mate choice on the other, can involve: direct physical combat among rivals; physical appearance reflecting health (e.g., symmetry or conformity to "type," as these reflect nutritional and disease history); vigor or strength as demonstrated via "ritualized" displays; the ability to provide or defend resources for partners, and many other comparative and competitive categories and situations.

It can be useful to think of natural selection and sexual selection as the agents of genetic changes that promote individual adaptation (any genetically controlled attribute and e.g., structure, physiological process, or behavior and that increases an organism's probable genetic contribution to succeeding generations; a characteristic that enhances an organism's chances of perpetuating its genes, usually by leaving descendants) in genetic lineages along two axes: the first axis, ecological/somatic adaptation is that connected with growth, development, maintenance, and survival; and the second, reproductive/genetic adaptation is that directly connected with procreation, the successful production of competitive, fertile offspring. Such a separation in a thought experiment quickly reveals the strong connection yet important distinction that exists between natural and sexual selections, and that must be recognized by entomologists in a number of fields and taxonomy, behavioral ecology, ecology, and pest control and management, to mention a few. For example, a taxonomist who wishes to understand the process of speciation and the genetic divergence of populations needs to give special attention to the mate choice aspects of sexual selection and its connection with classical "reproductive isolation" theory.

Examples of sexual selection phenomena in insects include weapons used by males to control resources and gain access to females. If a resource, something that females lay their eggs into or eat is relatively rare, then males that wait on or near the resource are likely to encounter potential mates among the females that come to oviposit or feed. If this resource is relatively small, then a male may be able to keep it and its associated females to himself by defeating intruding males. Under these circumstances males may have evolved weapons that intimidate or help physically remove sexual rivals. In certain wood and dung-feeding beetles (Scarabaeidae), males sometimes have enormous horns arising from the head and prothorax that are used as levers or pinchers to fling or carry other males from branches, logs, and feces.

Examples of male display and female choice are seen when resources are relatively common, and males cannot profitably wait by an oviposition or feeding site to encounter females. In such situations, should females encounter male interference at a resource site they can easily find another, one without males, where they are not forced to fend off or submit to sexual advances. Under these circumstances males tend to evolve courtship displays that persuade females that they are suitable mates. For example, certain Tephritidae, such as *Ceratitis capitata* Wiedemann (the Mediterranean fruit fly), are among the most serious pests of fruits and limit exports wherever they occur. Males produce a buzzing sound (song) with their wings as they attempt to mate, and within limits, females select as mates those with louder songs, even when a male's effort is artificially amplified by playing a recorded song at a higher volume than one could otherwise produce. The "meaning" of (i.e., relevant information within) such displays is often difficult to decipher, but it may be that the song is a display of vigor that advertises an underlying genetic quality.

Sex role reversals sometimes occur in species with male "nuptial gifts." Males sometimes provide females with a food item before mating, and in these circumstances females appear to choose mates based on the quality of the gift presented. It may be that females are primarily interested in the food, but they may also judge the ability of the male, i.e., his underlying genetic quality, by his capacity to find and capture or produce certain items. In a number of katydids (Tettigoniidae), including the agricultural pest the Mormon cricket (*Anabrus simplex* Haldeman), males produce a very large spermatophylax. This protein-containing wad of cheese-like material is associated with the ejaculate and can constitute as much as 30% of a male's body weight. Females use this substance as food and those that receive larger "gifts" have greater fecundity (achieved reproduction). When other foods are scarce, and in species where males produce an exceptionally large gift, there sometimes occurs a sex-role reversal. That is, it is the females that seek out and display toward choosy males. Male Mormon crickets estimate the weight of a potential mate, hence the numbers of eggs she is likely to produce in the future as she mounts him (orthoptera fashion) prior to copulation. Males reject light-weight females in favor heavier ones, and in this way promote the favored outcome, that their resources will be used in the production of greater numbers of offspring.

► Aphids

Shade Tree Arthropods and Their Management

WHITNEY CRANSHAW
Colorado State University, Ft. Collins, CO, USA

There are unique issues associated with arthropod management of shade trees. These include: the high value of the plant material, including replacement costs; the siting of plants in areas of high human traffic; the unique management considerations associated with the above; and the aesthetic issues that can be important in management decisions.

Almost invariably, shade trees are a blend of native species and, increasingly, exotic species that have desirable features for the site. Concurrently, associated arthropod pests are also a mixture of native and exotic species and in many areas, the latter predominate. For example, among the more serious exotic shade tree pest species present in the United States are the gypsy moth, *Lymantria dispar* (L.), oystershell scale, *Lepidosaphes ulmi* (L.), the European elm bark beetle, *Scolytus multistriatus* (Marsham), the twospotted spider mite, *Tetranychus urticae* (Koch), and the Japanese beetle, *Popillia japonica* (Newman).

Hundreds of species of insects and mites seriously affect shade trees worldwide. These are often differentiated using a combination of taxa and feeding habits.

Arthropods with Sucking Mouthparts

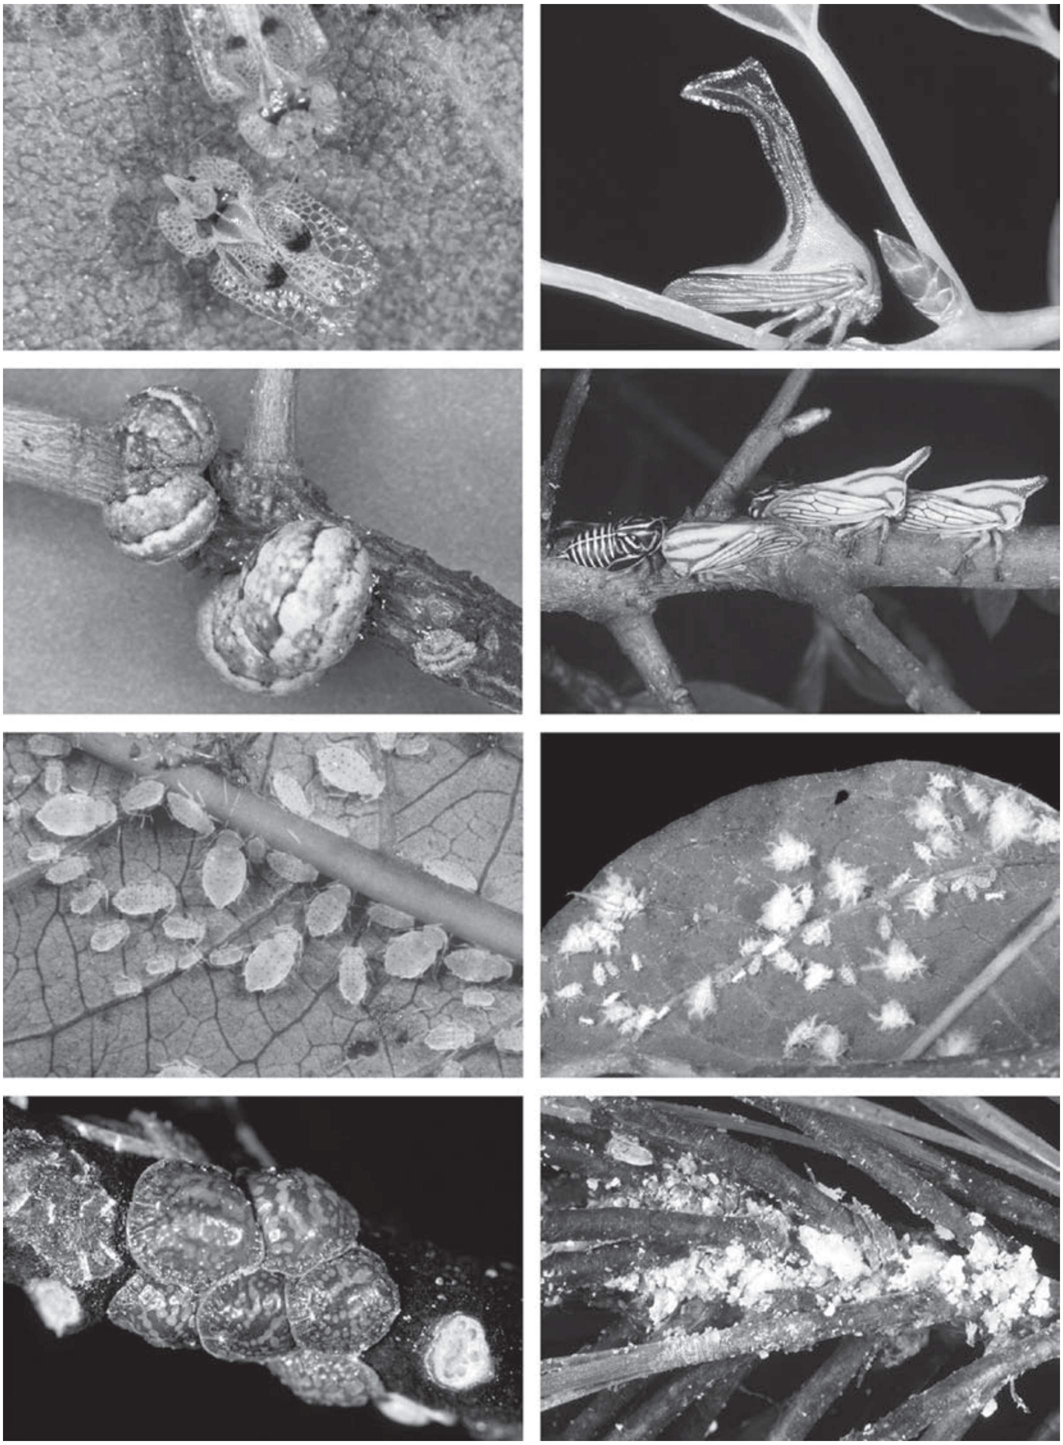
Aphids

These may be considered in a broad sense to include "true aphids" (Aphididae), as well as "woolly aphids" associated with deciduous plants (Aphididae: Eriosomatinae) and adelgids (Adelgidae). Aphids primarily extract sap from the phloem. This injury is often well tolerated by healthy plants, but may be a serious stress. Species that colonize branches and trunks, such as the hemlock woolly adelgid (*Adelges tsugae* Annand), can be particularly damaging. On some plants, aphids colonize during periods of new growth and produce serious curling distortions of leaves or needles that can adversely affect the growth and form of plants. Aphids (Aphididae) also excrete honeydew, a significant aesthetic problem with shade trees. Among the more important aphids associated with North American shade trees are the tuliptree aphid, *Illinoia liriodendri* (Monell), the apple aphid, *Aphis pomi* De Geer, the giant willow aphid, *Tuberolachnus salignus* (Gmelin), the Norway maple aphid, *Periphyllus lyropictus* (Kessler), the leafcurl ash aphid, *Prociphilus fraxinifolii* (Riley), and the woolly apple aphid, *Eriosoma lanigerum* (Hausmann).

Soft Scales

Several families of scales within the superfamily Coccoidea are associated with shade trees. Most share habits that include: phloem feeding with associated honeydew production; mobility after the first instar (crawler stage), often involving migration with early instars on foliage and later stages on small branches and twigs; and the production of hundreds or even a couple thousand eggs. Damage can include loss of vigor, dieback of branches and nuisance problems associated with honeydew.

The most important family is Coccidae, the soft scales. Among the more damaging species in North America are the cottony maple scale, *Pulvinaria innumerabilis* (Rathvon), the striped pine scale, *Toumeyella pini* (King), the European fruit lecanium, *Parthenolecanium corni* (Bouché) and the calico scale, *Eulecanium cerasorum* (Cockerell). Related families of scales of importance to shade trees include giant scales or the margarodids (Margarodidae), gall-like scales (Kermesidae), eriococcids (Eriococcidae), false pit scales (Lecanodiaspididae) and pit scales (Asterolecaniidae) (Fig. 40).



Shade Tree Arthropods and Their Management, Figure 40 **Some shade tree insects: *top left*, sycamore lace bug, *Coryuthuca ciliata*; *top right*, a thorn bug, *Umbonia crassicornis*; second row, *left*, kermes scale, *Kermes* sp.; second row, *right*, a treehopper, *Platycotis vittata*; third row, *left*, crapemyrtle aphid, *Tinocallis kahawaluokalani*; third row, *right*, Asian woolly hackberry aphid, *Shivaphis celti*; *bottom left*, tuliptree scale, *Toumeyela liriodendri*; *bottom right*, acute mealybug, *Oracella acuta* (photo credits: left column by James Castner, right column by Lyle Buss).**

Armored Scales

Armored scales (Diaspididae) include some of the most damaging scale insects associated with shade trees. Unlike the soft scales, armored scales do not feed on the phloem, but confine feeding to the mesophyll and parenchyma cells. Honeydew is not produced, but cells around the feeding site are often killed and sustained infestations can cause foliage loss, branch dieback, and increased susceptibility to canker producing fungi. Typically, armored scales produce no more than 2–3 dozen eggs that hatch within the cover (test) of the female. The first instar nymphs (crawlers) are active for only a few days and then they lose their legs at the first molt. Some important armored scales in North America include the obscure scale, *Melanaspis obscura* (Comstock), the walnut scale, *Quadraspidiotus juglansregiae* (Comstock), the pine needle scale, *Chionaspis pinifoliae* (Fitch) and the California red scale, *Aonidiella aurantii* (Maskell).

Leafhoppers

Many leafhoppers (Cicadellidae) are associated with shade trees. Most feed on the phloem, typically producing minor injuries in the form, loss of vigor and honeydew production. Others feed on the parenchyma, causing white flecking (stippling) injuries. A leafhopper of particular concern in much of eastern North America is the potato leafhopper, *Empoasca fabae* (Harris), that seriously damages the phloem when it feeds, disrupting photosynthesis and producing an injury known as "hopperburn."

One subfamily of leafhoppers (Cicidellinae), known as the sharpshooters, feed on the xylem. Some of these are capable of transmitting certain xylem-inhabiting bacteria that produce diseases of shade trees. Lethal yellowing of coconut, Pierce's disease (bacterial scorch) and ash yellows are shade tree diseases spread by leafhoppers.

Minor Insect Families

Bugs (Hemiptera)

Several families of true bugs can be damaging to shade trees. Plant bugs (Miridae) are primarily important when they feed on new growth, killing the area around the feeding site. This produces distortions of new growth and necrotic spotting; in heavy infestation, some plant bugs may temporarily kill emergent growth. Lacebugs (Tingidae) often produce pale-colored spotting of leaves, caused by the destruction of the mesophyll, which can adversely affect the appearance and vigor of plants.

Some true bugs associated with shade trees are most important not for the injuries they produce to plants, but because of the subsequent nuisance problems they produce when they move to adjacent buildings for winter shelter. The boxelder bug, *Boisea trivittata* (Say), and the western conifer seed bug, *Leptoglossus occidentalis* Heidemann, are notorious for this habit in parts of North America.

Several additional families of Hemiptera suck sap from the foliage and/or woody parts of shade trees including certain whiteflies (Aleyrodidae), mealybugs (Pseudococcidae) and psyllids (Psyllidae). These insects tend to be more important on shrubs and ornamental plants.

Spider Mites

Several species of spider mites (Tetranychidae) are important pests of shade trees. Feeding damage is caused by breaking into the surface cell layers and removing the sap. This results in small, pale colored or necrotic spots that may coalesce and produce a generalized yellowing or bronzing, often with associated premature leaf drop.

Spider mite problems can sometimes be aggravated due to pesticide use practices unfavorable to natural enemies. Most species also thrive under relatively dry conditions. Many spider mites tend to be most abundant during warmer periods of the year, such as the twospotted spider mite, *Tetranychus urticae* (Koch) and the honey locust spider mite, *Platytetranychus multidigituli* (Ewing). Others attain peak population during cooler periods of spring and fall, such as the spruce spider mite, *Oligonychus ununguis* (Jacobi) and the European red mite, *Panonychus ulmi* (Koch).

Eriophyid Mites

Eriophyid mites are commonly associated with the foliage of most shade trees, but few cause visible injury. A few, known as "rust mites," can cause bronzing of the foliage often associated with increased thickening and brittleness of the foliage. Other eriophyid mites, discussed below, produce galls.

Gall-Making Arthropods

Galls are some of the most conspicuous injuries associated with shade trees. Galls are abnormal growths caused by feeding and other activities of insects and mites. Galls on shade trees can range from being fairly simple swellings to bizarre alterations of plant tissue. Galls frequently attract considerable attention and concern, but few are damaging to the health of shade trees. Several families of arthropods produce galls on shade trees with the primary ones summarized below.

Gall-Making Aphids

Some aphids (Aphididae, subfamily Eriosomatidae) produce galls that usually take the form of a simple swelling of the leaves. These insects have complex life cycles that typically involve a spring form that produce galls on the twigs, petioles or leaves of trees followed by a summer form that develops on the roots of a different host plant. The most important gall-making aphids found on shade trees in North America are found in the genus *Pemphigus*.

Adelgids

Adelgids (Adelgidae) are associated with conifers and may produce galls that involve stunting and/or thickening of terminal growth. Typical are the Cooley spruce gall adelgid, *Adelges cooleyi* (Gillette) and the eastern spruce gall adelgid, *Adelges abietis* (L.). Most gall-producing adelgids show alternation of hosts and do not produce galls on the primary host plant.

Phylloxerans

Phylloxerans (Phylloxeridae) are uncommon pests of shade trees, limited to certain leaf and petiole gall-forming species that attack *Carya* spp. (pecan). However, other phylloxerans can be seriously damaging to other woody plants, notably the grape phylloxera, *Daktulosphaira vitifoliae* (Fitch), that produces, alternately, leaf galls and root galls on grape vines.

Psyllids

Several genera of psyllids (Psyllidae) produce galls on the foliage or on the woody parts of plants. Leaf galls on foliage take the form of blisters, pouches, or nipples. Slight swellings are produced on twigs and small branches. A very common genera in North America is *Pachypsylla*, which includes over a half dozen species all of which are associated with *Celtis* spp.

Eriophyid Mites

The eriophyid mites (Eriophyidae) associated with shade trees make an extremely diverse range of gall forms on shade trees. Simple eruptions of blisters on leaf surfaces (blistergalls) are common on some Rosaceae. Other eriophyid mites make more elaborate galls in the form of pouchgalls, or are further extended into elongate fingergalls. A proliferation of plant hairs producing small, felt-like mats is characteristic of other eriophyid mites. These are known as an erineum (erinea, pl.). Other eriophyid mites produce gross disorganization and cell proliferation of buds and flowers.

Gall Midges

Hundreds of species of gall midges (Cecidomyiidae) are associated with woody plants. Galls typically are fairly simple, involving stunting and/or swelling of foliage. Leaves and needles that are galled usually shed prematurely.

Gall-Making Sawflies

Some sawflies in the family Tenthredinidae make galls in the form of simple balls or swellings in leaves or stems, primarily of willow.

Gall Wasps

The largest family of gall making insects are gall wasps (Cynipidae). Hundreds of species produce galls of very determinate form on leaves and stems. These galls may involve ball like growths (Fig. 42), sometimes with bizarre projections and spines, that have a very different appearance from the tissues from which they are differentiated. Some galls produced by gall wasps exude honeydew.

Life cycles of many gall wasps can involve alternating forms that produce different types of galls at different periods in the life cycle. Despite their abundance, essentially, all galls produced are limited to *Quercus* spp. and *Rosa* spp. Only a very few, limited to gall production on stems and twigs, cause significant plant injury.

Defoliators

Leaf feeding on shade trees is a habit widespread among the orders Lepidoptera, Coleoptera and Hymenoptera. Phasmida and Orthoptera are minor orders associated with shade tree defoliation.

Defoliation injuries to established shade trees are often well tolerated in terms of plant health. Usually only sustained, high levels of defoliation over several years significantly increases risks to plant health. However, defoliation stresses can favor increased incidence of wood borers, bark beetles and certain fungal pathogens that act more aggressively in weakened plants.

Defoliation of shade trees can have serious aesthetic effects. In addition to leaf injuries and loss, some defoliating insects may also produce large amounts of silk, a habit particularly common among some Lepidoptera in the families Lasiocampidae and Arctiidae. Dropping excrement can also be a nuisance issue with defoliating insects of shade trees.

Leafminers

Insects that develop between the leaf surfaces are known as leafminers; species with this habit that are associated with conifers are known as needleminers. Common leafminers that are associated with shade trees are found in three orders: Coleoptera (primarily Chrysomelidae), Hymenoptera (primarily Tenthredinidae) and Lepidoptera (several families). Some Diptera, primarily Agromyzidae, are occasionally associated with shade trees, although they are more important on shrubs and ornamentals. Leafminers tend to be classified by the pattern of the mine that they produce; blotch, serpentine, or tentiform are terms commonly used in their description. Leafminers on shade trees can seriously affect the aesthetic appearance of foliage, but are very rarely significantly damaging to the health of established shade trees.

Bark Beetles

Bark beetles (Scolytidae or Curculionidae: Scolytinae) develop under the bark, scoring the cambium during their production of larval galleries and producing girdling wounds (Fig. 41). Although bark

beetles sometime can kill shade trees, they often are considered secondary pests that largely limit infestations to trees that are wounded, diseased, recently transplanted or otherwise weakened. Almost all bark beetles have an association with fungi, primarily in the genera *Ceratocystis* or *Ophiostoma*. The transmission of fungi can greatly increase the importance of bark beetles. The most spectacular example of this involves Dutch elm disease. This devastating disease of the American elm has largely eliminated this formerly very popular shade tree in much of North America. Dutch elm disease is produced by infection with *Ophiostoma ulmi*, which is primarily spread by the smaller European elm bark beetle.

Wood Borers

Most insects that develop within wood are collectively known as wood borers. This general term includes several families from three insect orders.

In the Coleoptera, the metallic wood borers (Buprestidae), known as flathead borers in the larval stage, are particularly damaging to shade trees. The larvae make meandering tunnels beneath the bark, sometimes causing girdling of the plants. Members of the genus *Agrilus* are particularly important as shade tree pests in North America. Many longhorned beetles (Cerambycidae), known as roundhead borers in the larval stage, are also important. Larval injuries tend to involve tunneling of the interior of the trunks and branches, sometimes producing significant weakening and predisposing plants to breakage. A few species of weevils (Curculionidae), also develop as wood borers.

The most aggressively damaging wood boring insects are found in the order Lepidoptera. The clearwing borers (Sesiidae), include dozens of important species of woody plants. Larvae make irregular gouging wounds under the bark, with most species concentrating feeding around the crown of the trunk. In the Pyralidae, the genus *Dioryctria* includes several species that tunnel the trunks and branches of pines. Carpenterworms (Cossidae), is quite a large species that is associated with a wide variety of trees and shrubs.

Relatively few Hymenoptera develop as borers in shade trees. Most prominent are the horntails (Siricidae). Although they primarily limit attacks to trees that are in serious decline or recently killed, the ability of some to transmit white rot fungi can cause premature tree death.

Tip and Terminal Borers

Several insects develop by tunneling tips and terminals. This habit is particularly common among certain families of Lepidoptera and Coleoptera; Hymenoptera are a minor order with species of this habit. A particularly common group that girdles the twigs and the new growth of pines are known as "tip moths," primarily found in the lepidopteran genera *Rhyacionia* and *Eucosoma*. Some insects, such as the weevils in the genus *Pissodes*, only develop within the terminal growth of conifers.

Root Damaging Species

Roots are consumed by the larval stages of several families of Coleoptera and some Lepidoptera. The adults of many root-feeding species typically feed above ground on leaves and twigs and may be important in both stages. For example, several root-feeding weevils (Curculionidae) in the genus *Otioryhnchus*, consume roots as larvae and later chew on foliage as adults. The larvae of root-feeding species in the family Scarabaeidae also commonly feed on foliage as adults.

Sharp, David

David Sharp was born at Towcester, England, on October 18, 1840. He studied at St. Bartholomew's Hospital and the University of Edinburgh, and received a medical degree in 1866. He was torn between his interest in insects and his career as a physician, and sought positions that would allow him the leisure to also study insects. In 1885 he moved to Cambridge to serve as Curator of the University Museum, effectively ending his medical career. Sharp made many important contributions to our knowledge of Coleoptera, including "Fauna Hawaiiensis" (1899, 1908), "Beetles of Central America" (1894), "Insecta" (1895, 1899), a large portion of the Cambridge Natural History (1895 and 1899), and many other voluminous works. He authored more than 250 publications. He also worked tirelessly on behalf of "Entomologist's Monthly Magazine," "The Entomologist," and "Zoological Record." Sharp served as president of the Entomological Society of London, and was fellow of several societies. He died August 26, 1922, at Brockenhurst, England.

Sheath

A structure enclosing others cells or structures.

Shelf Life

The period of time that a pesticide can be stored without losing its effectiveness.

Shelford, Victor Ernest

Victor Shelford was born at Chemung, New York, USA, on September 22, 1877. He received his bachelor's degree in 1903 and his Ph.D. in 1907, both from the University of Chicago. He remained on the staff of the University of Chicago until 1914 when he moved to the University of Illinois at Urbana. Although he retired in 1946, he remained active and continued to publish for many years. Shelford's contributions to entomology included several important and long-term studies on the relationship of insect abundance to weather and climate. However, he also worked with vertebrate populations, and made major contributions to characterization of ecosystems in North America. Some of his important publications included "Animal communities in temperate America" (1913), "Laboratory and field ecology" (1929), "Bio-Ecology" (with F.E. Clements, 1939), and "The ecology of North America" (1963). Shelford was a pioneer in the ecological sciences, was named Eminent Ecologist by the Ecological Society of America in 1968, and has been called the "father of animal ecology in the United States." He died on December 27, 1968.

Shellac

Several scale insects (Hemiptera: Kerriidae) can be grown on trees in Southeast Asia and used as a source of lac, a resin that is the principal ingredient of shellac. *Laccifer lacca* Kerr is the species most commonly cultured for this purpose. In Bangladesh, lac producers use ber (*Zizyphus mauritiana*) as a host plant, whereas in India they use ber, dhak (*Butea monosperma*), and kusum (*Schleichera oleosa*), in Thailand they use rain tree (*Samanea saman*) and pigeon pea (*Cajanus cajan*), and in China, pigeon pea and *Hibiscus* spp. are used. Lac culture probably dates back at least 4,000 years in China, though cultivation in India and Bangladesh has been practiced for only a few hundred years, and it is a recent introduction to Thailand.

For production of lac, the eggs of the scale insects on branches (called "broodlac") are attached to trees without insects. There they hatch, and the young scales disperse, settle and feed on the plant sap. Like most scale insects, they exude a covering that protects their bodies as they grow, but in this case the covering is a resinous secretion. After a few months, branches covered with resin are harvested as "sticklac." The resin is scraped off the twigs and dried before it is crushed, sieved, and washed to remove impurities. The resultant material is called "seedlac." Its quality varies according to the host plant, weather, and harvesting procedures. Seedlac is then processed by heat and filtering, or solvent (ethyl alcohol) extraction to produce shellac. Traditionally, shellac was used as wood finish, but it also has been incorporated into cosmetics, pharmaceuticals, and phonographs, and in the production of textiles and in printing. India produces the largest proportion of shellac on the world market, though production has fallen greatly due to the availability of synthetic resins.

Shelter Tubes

Earthen tubes constructed by termites on exposed surfaces such as brick or concrete surfaces. These tubes allow the workers and soldiers to move between the food supply and colony with minimal risk of predation and with elevated humidity.

Shield Bearer Moths (Lepidoptera: Heliozelidae)

John B. Heppner
Florida State Collection of Arthropods,
Gainesville, FL, USA

Shield bearer moths, family Heliozelidae, total 106 species from all regions, with more than half the species split between North America (31 sp.) and Australia (36 sp.); actual fauna probably exceeds 200 species. The family is in the superfamily Incurvarioidea, in the section Incurvariina, of division Monotrysia, infraorder Heteroneura.

Adults minute to small (3–9 mm wingspan), with very smooth head scaling (one sp. has roughened head scales in the Neotropics); haustellum scaled and scales usually merging with head scaling to form a triangular-appearing face; labial palpi porrect; maxillary palpi minute, 5-segmented. Maculation usually dark with shining metallic-iridescence, plus some light markings. Adults are diurnal. Larvae make serpentine leaf mines at first, then make blotch mines in later instars. Host plants include a variety of hardwood trees and bushes.

Shiny Head-Standing Moths (Lepidoptera: Argyresthiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Shiny head-standing moths, family Argyresthiidae, include 160 species, mostly from Holarctic regions; actual fauna probably exceeds 450 species. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. The family is placed as a subfamily of Yponomeutidae by some researchers. Adults small (6–15 mm wingspan), with head slightly roughened; haustellum naked; labial palpi upcurved; maxillary palpi minute, 1-segmented. Wings elongated and hindwings usually more linear and with long fringes. Maculation various shades of tan with white and darker spots, often with forewings lustrous. Adults mostly crepuscular, but many may be diurnal. Larvae are leafminers and needleminers, and some mine in various plant parts. Numerous plants are recorded as hosts, with many records in Cupressaceae, Ericaceae, Fagaceae, Pinaceae, and Rosaceae, among others. Adults typically angle their bodies with the head down when at rest, with the wings held tightly onto the body. Several species are economic in the genus *Argyresthia*.

Sibling Species

PETER H. ADLER
Clemson University, Clemson, SC, USA

Two or more species that are nearly identical in their appearance, yet reproductively isolated, are referred to as sibling or cryptic species. Although they have been discovered in organisms from protozoans to elephants, they are probably best known and abundantly documented among the insects. As small organisms, insects can exploit a multitude of niches, changing physiologically and behaviorally during speciation while retaining their structural similarity. Two or more sibling species constitute a species complex, and in some groups of insects, the existence of five or more sibling species is common.

Differences in habitat, host preferences, reproductive behavior, pheromones, seasonality, or other attributes within a so-called species may first suggest the presence of sibling species. What appears to be a generalist species using a broad range of hosts or occupying a diversity of habitats is often a group of sibling species, each a specialist. For example, the treehopper *Enchenopa binotata* originally was considered a single polyphagous species, but is actually a group of at least six species, each developing on a different species of plant.

Confirmation, or even discovery, of sibling species often comes from detailed behavioral, chromosomal, ecological, or molecular studies.

These studies demonstrate conclusively that populations on different hosts or in different habitats are not merely host races or varieties. Once sibling species are revealed and studied, they can be formally named. With appropriate scrutiny of pure material, they often can be distinguished morphologically from one another. Often, however, only one or two life stages offer distinguishing morphological characters. In some species complexes of mosquitoes, for instance, only the eggs are morphologically distinct.

The frequency of sibling species is unknown for most insect groups because many are still being discovered. Perhaps half of the crickets in North America have been discovered by the sounds that they make. Among North American black flies, more than one quarter was first discovered through studies of the giant polytene chromosomes in their larval salivary glands.

Sibling species often overlap broadly in their distributions and have been used to illustrate probable examples of sympatric speciation. In the *Rhagoletis pomonella* species complex, sympatric speciation might have produced the various sibling species when these fruit flies shifted and adapted to new host plants in the same geographic area.

The recognition of sibling species is critical to meaningful biological research and effective pest management. The *Simulium damnosum* (black fly) species complex consists of as many as 40 sibling species, each biologically distinct but only some of which actually transmit the filarial nematode that causes human onchocerciasis, or river blindness. Many sibling species of mosquitoes also differ in their ability to transmit agents of disease. Successful management of pest species, many of which are members of species complexes, relies on precisely targeting them in the appropriate habitats. Natural enemies, especially parasitoids, used in biological control are often complexes of sibling species. The success or failure of biological control programs can rest on the recognition of sibling species because parasitoids are often highly host specific.

Silk

Silk is produced only by arthropods, and specifically by members of the classes Arachnida, Insecta, and Myriapoda. Silk is produced to provide shelter, as in cocoons in Lepidoptera (insects) or retreat silks (spiders). Silk is produced to provide structural support, as in egg stalks in Neuroptera (insects) or egg sac suspension threads (spiders). Silk is produced to aid in reproduction, as in restriction of female movement during mating by Thysanoptera (insects) or production of sperm webs by males (spiders). Silk is used in foraging, as in underwater nets for prey capture by Trichoptera (insects) or aerial nets (spiders). Silk is used to aid dispersal of neonate larvae in Lepidoptera (insects) or neonate spiderlings (spiders).

Silks are fibrous proteins that are stored as a liquid and formed into fibers when "spun" at secretion. Insects produce many types of silk proteins, though each species produces only one type. In contrast, spiders produce a number of types of silk, and each individual is capable of producing several types. Following are the common proteinaceous silks found in insects:

- Alpha-helical silks are produced by Siphonaptera, Hymenoptera, Mantodea, Isoptera, and Blattodea using their colleterial glands. Structures produced by these insects include reinforcement of wax combs (Hymenoptera), cocoons (Siphonaptera), and ootheca (Mantodea).
- Parallel-beta pleated sheet silks are the most common type of silks, and are found in the typical silks of Lepidoptera cocoons, and created by their labial glands.
- Cross-beta pleated sheet silks are created by larval Malpighian tubules or derived from the peritrophic membrane, and though uncommon, are found in Neuroptera, Coleoptera, and Diptera. These silks are especially resilient, tolerating considerable stretching.

Other fibrous proteins are produced by insects, such as collagen-like silk produced by perigid sawflies (Hymenoptera). They are created by a dedicated silk gland derived from a salivary gland. Chitin is a nitrogenous polysaccharide, and found in cocoon threads of certain beetles. It is produced in the peritrophic membrane.

Thus, most insect orders produce silk in some form and in some manner, though in most cases it comes from organs that evolved primarily for some other purpose. The best known silk is a product of silk moths, *Bombyx* spp. The cocoon filament is spun by the fifth instar larva of *Bombyx mori* and other silk moths. The cocoon filament contains two cylinders of fibroin, each surrounded by three layers of sericin. Fibroin is secreted by the cells of the posterior region of the silk gland. The fibroin gene is present in only one copy per haploid genome, but these silk gland cells undergo 18–19 cycles of endomitotic DNA replication before they begin transcribing fibroin mRNAs. The sericin proteins are so named because they contain abundant serines (over 30% of the total amino acids). Sericins are secreted by the cells from the middle region of the silk gland.

Silkworms

This name refers to the family Bombycidae of the order Lepidoptera, but more commonly is used to designate the Chinese silkworm, *Bombyx mori* L. Chinese silkworm is the most important of the silkworms because it is the principal source of silk used by humans to construct silken cloth. With the possible exception of the European honey bee, *Apis mellifera*, it is the most beneficial insect to humans. For centuries, Chinese silkworm has been the basis of large industries in both Asian and European countries, where raw silk is produced. In turn, it is manufactured into articles of clothing in many countries. The production of silk, called sericulture, is very labor intensive, so increasingly it is concentrated in Asian countries where labor costs are lower. A single cocoon produces a single thread measuring from 300 to

900 m in length. About 3,000 cocoons are required to manufacture a pound of silk.

A by-product of silk production is the silkworm pupae. The pupae are used as animal feed. Production is estimated at 50,000–100,000 tons annually in India and China, and is fed to pigs, chickens, rats and fish. In addition, ground silkworm pupae sometimes are used as a bait in food-based baits for pest ants.

As the common name suggests, *Bombyx mori* is native of Asia, where it has been domesticated for so many centuries (approximately 5,000 years) that, like many domestic animals, it has lost the ability to survive without human intervention, and cannot fly. Selective breeding has resulted in races that differ in the quality, quantity, and color of silk produced by the insect. It apparently no longer occurs in the wild.

The adult moth has a wing span of 4–6 cm. They are heavy bodied and creamy white, with dark wing veins and sometimes several weak dark transverse lines crossing the wings. Adults do not feed. Each adult female produces about 300 nearly spherical eggs. The eggs are white initially but soon darken to bluish gray. Larvae normally feed on white or black mulberry leaves (*Morus* sp.), though they will accept other foliage. They are whitish in color, and bear a pronounced anal horn similar to that found in the hornworms of the Sphingidae. There are five instars. Larvae complete their development in about 45 days, attaining a length of 45–55 mm. At pupation, they spin a large, oval, white or yellow cocoon. If allowed to complete their development, the adult will emerge from the cocoon in 12–16 days, and they can produce up to 16 generations per year. If allowed to emerge, however, the silk is damaged, so in silk production systems the silkworm pupae are killed in hot water. Silkworms are readily reared in containers if mulberry foliage or artificial diet is provided. Because they are easy to culture, they are popular for use in schools. However, silkworms are quite susceptible to disease.

Silkworm Moths (Lepidoptera: Bombycidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Silkworm moths, family Bombycidae, total 166 described species, all Old World and primarily Oriental (146 sp.), with only five species known for Africa. Two subfamilies are involved: Bombycinae and Prismostictinae. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (19–64 mm wingspan), with head scaling roughened; haustellum absent; labial palpi reduced, 1-segmented; maxillary palpi absent; antennae bipectinate (serrate or filiform in females); body robust. Wings broadly triangular (Fig. 43), usually with acute and falcate forewings; hindwings rounded. Maculation is mostly subdued browns and grays, with various striae or other markings; or white as in the domesticated silkworm moth. Adults are nocturnal. Larvae are leaf feeders. Host plants predominate in Moraceae. The silkworm (*Bombyx mori*), used for silk production, is related to other native species in China (probably *Bombyx mandarina*), but is now completely white after centuries of breeding in culture.

Silverfish (Zygentoma)

This is a primitive order of insects known as Zygentoma or Thysanura. The order name is derived from the Greek words *zyg* (bridge) + *entoma* (insect) because when Carl Börner first introduced the name in 1904 he believed that this group represented an evolutionary link or "bridge" between the wingless (subclass Apterygota) and winged (subclass Pterygota) insects. Alternatively, if the more traditional "Thysanura" is used, the derivation is *thysanos* (bristle) + and *oura* (tail). Because these insects are wingless and none of their ancestors appear to be winged, this order is placed (with the order Archeognatha) in the subclass Apterygota; in this regard apterygotes differ from all other insects. In the past, these two orders were united into a single order, the Thysanura.

Classification

There are about 320 species found throughout the world, grouped into three families:

- Class Insecta
  - Subclass Apterygota
    - Order Zygentoma
      - Family Lepidotrichidae
      - Family Nicoletiidae
      - Family Lepismatidae
      - Family Ateluridae
      - Family Maindroniide

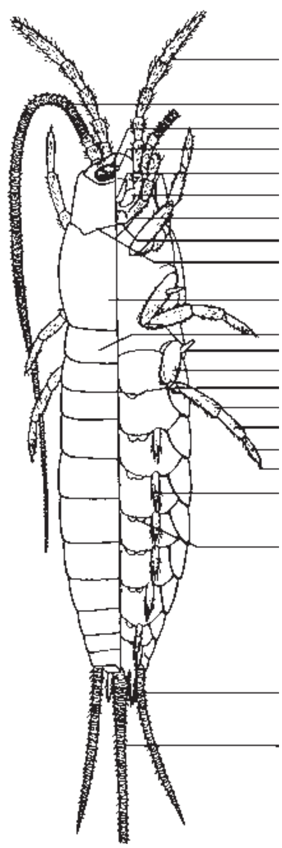
Characteristics

Silverfish are small, measuring 2– 20 mm. They are elongate and somewhat flattened, with three tail-like appendages. The body is soft, and may or may not bear scales. They are whitish, gray, or brownish. The median appendage is only slightly longer than the lateral cerci. The antennae are variable in length, but often long. The compound eyes are small and separate, or absent, and ocelli are absent. The more advanced form of the mouthparts (mandibles) is the basis for separation of the Zygentoma from the Archeognatha. They tend to be more flattened and lack the distinctive "humped" shape of Archeognatha. Most have two or three-segmented tarsi. There is no evidence of external metamorphosis; the immatures and adults differ only in size.

The number of molts is considerable; 20–70 have been reported. They can live from 1 to 4 years.

Ecology

Silverfish are found in cryptic (beneath bark) and subterranean (animal burrows, caves, ant and termite nests) habitats. Some are inquilines; some reproduce parthenogenetically. Often they require high humidity, though some can survive within buildings, where they are minor pests. Silverfish feed on plant materials, and those that inhabit buildings feed on starchy material such as book bindings and wall paper glue (Fig. 44).



Silverfish (Zygentoma), Figure 44 A diagram of a silverfish showing a dorsal view (*left*) and a ventral view (*right*). Note that the medial caudal filament is abbreviated, and normally is about twice the length of the lateral caudal filaments.

Silverleaf Whitefly, *Bemisia argentifolii* Bellows and Perring (Hemiptera: Aleyrodidae)

JAMES H. TSAI
University of Florida, Gainesville, FL, USA

The silverleaf whitefly, *Bemisia argentifolii* Bellows and Perring, is also known as B-type of *B. tabaci* Gennadius. *B. tabaci* is commonly known as the cotton, sweetpotato or tobacco whitefly, and is believed to have originated in the Orient. To date there are over 1,100 species of whiteflies recognized worldwide. Among these, only three (*B. tabaci*, *Trialeurodes vaporariorum* (Westwood), and *T. abutilonea* [Hald].) are known as vectors of plant viruses. *B. tabaci* is the most common and important whitefly vector of plant viruses. This species is multivoltine and polyphagous, attacking at least 506 dicot and monocot species in 74 families. However, host specialization is commonly observed for certain *B. tabaci* populations. It is commonplace that populations raised on one host species may be difficult to establish on another, although the populations may eventually become well adapted to the new host. In the last decade, *B. argentifolii* has become prominent because of its ability to cause silverleaf symptom on squash and other

Cucurbita spp.; irregular ripening in tomato and stem whitening in *Brassica* spp., and to transmit numerous plant viruses. The etiology of silverleaf of squash and irregular ripening of tomato is not known. It is believed that this disorder is toxicogenic derived from the whitefly saliva, because symptoms increase in severity with increasing whitefly numbers, and removal of whiteflies after silverleaf development results in non-symptomatic new growth. The whitefly-transmitted plant viruses are divided into three categories based on their particle morphology, and nucleic composition: carlavirus-like virus, closterovirus, and geminivirus. The latter is the largest group, and all geminiviruses have a paired particle morphology. They either have a monopartite DNA genome of 2.6 kb or bipartite DNA genome of 5.2 kb. Transmission of geminiviruses by whitefly vectors are similar to that of leafhoppers and aphids; virus acquisition and inoculation efficiency increases with increasing aquisition access times, a minimum of several hours latent period is required, and the virus persists after molting and for life. The acquisition efficiencies of a Florida isolate of bean golden mosaic virus (BGMV) (a geminivirus) are 27.1, 27.3, 38.7, 48.8, 67.1, and 72.9% after 2, 4, 8, 24, 48 and 72-h acquisition access periods, respectively. The respective inoculation efficiencies by single adults after 1, 4, 8, 24 and 48-h inoculation access periods are 4.3, 3.3, 21.9, 38.2 and 67.6%. The minimum inoculation time by individual adults is 15 min. Viruliferous adults can retain BGMV until the death of insect.

Morphological similarities (Fig. 45) between *B. tabaci* A and B types are evident. *Bemisia argentifolii* was described as a distinct species in 1993 based on pupal cases, PCR-based DNA analysis, allozymicfrequency, crossing experiments and mating behavior differences. In retrospect, it is quite possible that many plant viruses reported to be transmitted by *B. tabaci* prior to 1993 might well be transmitted by *B. argentifolii*.

The length of the life cycle of *B. argentifolii* varies with temperature, host plant and whitefly

Silverleaf Whitefly, *Bemisia argentifolii* Bellows and Perring (Hemiptera: Aleyrodidae), Figure 45 Adult and immature silverleaf whitefly, *Bemisia argentifolii* (photo J. Tsai).

population. The average egg incubation period decreases as temperature increases from 15 to 30°C, ranging from 4 to 26 days. Within 15–30°C, the developmental time for four instars decreases significantly as temperature increases, ranging from 79 to 9 days. However, the average nymphal development time at 35°C is significantly longer than that at 25–30°C.

The adult longevity of females averages from 44 days at 20°C, to 22 days at 35°C. The oviposition of *B. argentifolii* averages 324 eggs at 20°C, to 22 eggs at 35°C. The average generation time ranges from 46 days at 20°C, to 18 days at 30°C.

Host plants affect nymphal development times. At 25°C, there is a uniform egg incubation period of 6 days when *B. argentifolii* are reared on eggplant, tomato, sweet potato, cucumber and garden bean. The average developmental time from egg to adult emergence on these host plants varies significantly, ranging from 20 days on garden bean, to 17 days on eggplant. The body lengths of second, third and fourth instars are not different when reared on these different hosts, but the males are always smaller than females, regardless of their rearing hosts. The average female longevity on these plants is 24, 21, 17, 10, and 13 days, respectively. The average number of eggs laid per female on these host plants are 234, 168, 78, 66 and 84 eggs, respectively. The mean generation time of *B. argentifolii* on these hosts ranges from 23 to 27 days.

Whiteflies are difficult to control with insecticides, and frequently they develop resistance to pesticides. Barriers such as row covers and reflective mulches have been effective in reducing disease incidence when the vector populations are low. Biological controls, and cultural controls such as removing volunteer crops and weeds within and around the field, planting trap crops, and practicing crop free periods, are commonly used with various degrees of success. However, the classical plant breeding technique incorporating engineered types of resistance into a single cultivar or variety would probably have a greater potential for a long term control strategy.

Simple Metamorphosis

A type of metamorphosis characterized by slight changes in body form during the developmental period, and the presence of the egg, nymphal and adult stages. The pupal stage is lacking. This is also known as incomplete metamorphosis or hemimetabolous development. Some of the aquatic insects displaying simple development (Odonata, Ephemeroptera, Plecoptera) differ in the degree of difference between the mature and immature stages, and so are sometimes said to have gradual metamorphosis or paurometabolous development.

Simulium spp., Vectors of *Onchocerca volvulus*: Life Cycle and Control

PAULINE O. LAWRENCE
University of Florida, Gainesville, FL, USA

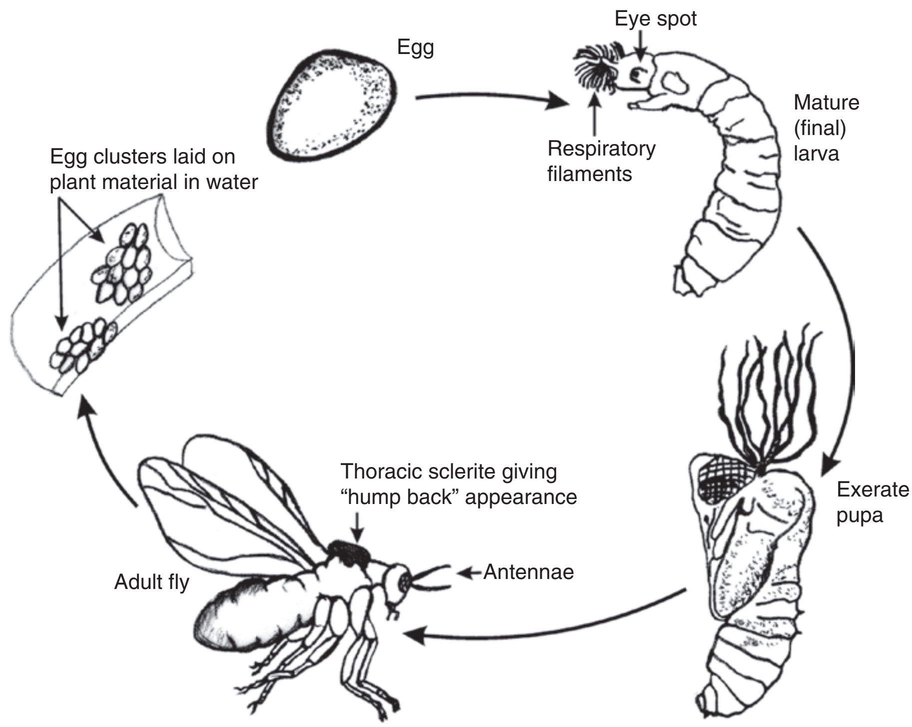
Members of the dipteran genus *Simulium* are of significant medical and veterinary importance. They belong to the suborder Nematocera and family Simuliidae, usually called black flies. These flies have long segmented antennae of about 11 segments, and all immature stages are aquatic, or at least live in very moist environments. Members of the family have a reduced mesothoracic segment giving them the appearance of having a humped back hence their alternate name humped back flies. Some members are also called buffalo gnats. Most of the species belong to the genera *Cnephia*, *Simulium*, and *Prosimulium*.

Simulium damnosum (the most widely known), and *S. neavei* vector the filarial parasite *Onchocerca volvulus* that causes human onchocerciasis (oncho) or river blindness in several East and West African countries. *S. ochraceum*, a smaller species, is the most common vector of the parasite in Mexico and several Central and South American countries. Other species of *Simulium*, and those of *Cnephia* and *Prosimulium*, attack livestock and birds worldwide and in some cases cause toxemia and anaphylactic shock. Their bites also are irritating to man. *S. meridionale* are irritating pests of poultry, while *S. vittatum* and *S. articum* in the United States and *S. colombaschense* in Canada attack cattle. In Australia, several other species of *Simulium* transmit the filarial worm *Onchocerca gibsoni* to cattle.

The female is haematophagous, using the protein from the blood meal for egg development, but feeds on plant juices at other times while the male feeds only on plant juices. When the short piercing-sucking mouthparts of a female fly previously infected with the *O. volvulus* parasite is inserted into the skin of the victim, the infective L3 (third instar) nematode enters the wound. Molting, maturation and offspring production of *O. volvulus* occur in the connective tissues of the host, inducing symptoms of onchocerciasis.

Simulium damnosum is actually a complex of different strains, and are known to use aggregation and oviposition pheromones to mate in swarms followed by mass oviposition in riverine habitats. A female may oviposit up to 800 eggs in her lifetime. Eggs are attached to rocks or plant material just below the water surface. The larva is elongate, with a distinct head, and adheres itself by means of a hook on its abdominal segment to a silken pad spun from its salivary glands on a rock, stick, or other submerged vegetation. The larva is thereby suspended in the fast running water from which it extracts microscopic organisms using a special filtering apparatus around its mouth. Fast running, well-oxygenated water is necessary for larval development (Fig. 47).

There are 6–7 instars if conditions are favorable. Prior to pupation, the last instar spins a silken cocoon around itself. Long filaments that serve as gills facilitate respiration. The pupal stage may last up to 4 weeks but *S. damnosum* adults usually emerge after 8–12 days and live for up to 4 weeks.



Simulium spp., Vectors of *Onchocerca volvulus*: Life Cycle and Control, Figure 47 **Life cycle of *Simulium* spp. Eggs are deposited in clusters on plant debris in or near fast-running rivers. Each egg is ovoid to wedge-shaped. There are three larval instars and the third stage (mature) larva has two well-defined eye spots and a delineated head, thorax, and abdomen. The pupa is exerate with well-developed eyes and elongate cephalic respiratory filaments. Adult flies have a characteristic "hump back" because of the modified thoracic sclerite.**

Chromosomal variation and morphological keys have been used to identify adults, larvae, and pupae of the Simuliidae in various European, African, and South American countries.

A major *Simulium* and onchocerciasis control effort was successfully initiated in West Africa by the Onchocerciasis Control Programme (OCP) in 1974 by the World Health Organization, the Food and Agricultural Organization (FAO), the United Nations Development Program, and other international and non-governmental agencies. The OCP employed several strategies to decrease the incidence of "oncho" and improve economic conditions in the affected regions. In addition to educating local people and administering chemotherapy with the antifungal drug ivermectin against the nematode infection, the OCP significantly reduced the *Simulium* population with aerial spraying of the large riverine habitats. They used a mixture of several larvicides, at minimum concentrations, and biological control agents including *Bacillus thuringiensis* and mermithid nematodes that parasitize the insects. The OCP utilized computers and satellites at hydrological stations to predict the flow of the river and estimate the appropriate dose of larvicides needed. Thus, the program successfully controlled black fly populations with minimal negative effects on the environment.

In Central America as in Africa, in addition to the spraying of breeding habitats, the *Simulium* populations have been controlled by clearing vegetation around housing, and decreasing irrigation that causes fast flowing water.

Skin-Piercing and Blood-Feeding Moths, *Calyptra* spp. (Lepidoptera: Noctuidae: Calpinae)

JENNIFER M. ZASPEL
University of Florida, Gainesville, FL, USA

Blood feeding is an ordinary way of life for many insects, but within Lepidoptera, the ability to pierce mammalian skin and take a blood meal is restricted to the moth genus *Calyptra* Ochsenheimer (Lepidoptera: Noctuidae: Calpinae). *Calyptra* consists of seventeen described species and two subspecies. These are medium-sized moths with wingspans ranging from 35 to 72 mm in size. *Calyptra* species have modified proboscides equipped with strongly sclerotized tearing hooks used for piercing the skin of hard fruits such as peaches and citrus, and of mammals. The number of apical tearing hooks of the proboscis varies between species and among specimens, but this variation does not appear to be in any way associated with one piercing behavior or the other (e.g., sucking fruit juices versus sucking blood). The tearing hooks are unique to a tribe of apparently closely related fruit-piercing moths consisting of at least six genera: *Calyptra*, *Eudocima*, *Gonodonta*, *Oraesia*, *Plusiodonta*, and *Phyllodes*. The tearing structures observed in these genera arise from a socket and thus are not homologous with other forms of modified sensilla of the proboscis found among fruit-sucking and tear-drinking moths within the Lepidoptera (Fig. 48).

The first species recorded piercing the skin of a mammal and feeding on its blood was *Calyptra eustrigata*, and was discovered feeding on water buffalo, deer, tapir, and antelope in Malaysia by Hans Bänziger in 1968. The moths were described as feeding on all parts of the animals for up to 10 min. Human blood feeding behavior under laboratory conditions by this species was also observed and documented by Hans Bänziger in his 1968 article. The moths inserted the tip of the proboscis into the subject's hand and began sucking blood. Blood-feeding moths are subcutaneous pool-feeders, severing the capillaries below the surface of the skin in order to form a pool of blood from which they can feed. The moths cut the tissues by moving the two straw-like tubes, or galae, of their proboscis back and forth in opposing directions; this movement has been termed by several authors as "antiparallel motion of the proboscis." This saw-like movement is often performed at short intervals followed by intermittent uptake of the blood meal. Penetration of the host skin by the moth's barbed proboscis can be quite painful, and the resulting wound(s) are large in diameter when compared to the wound of a mosquito bite or bee sting. Since the description of the first blood feeding *Calyptra* species, males of nine additional *Calyptra* species have been observed piercing mammalian skin and feeding on blood under both laboratory and natural conditions.

Calyptra species are distributed throughout the Old World, but blood-feeding species have primarily been recorded from tropical and subtropical South and Southeast Asia. Recently, the first record of a species in the genus feeding on mammalian blood was reported from a temperate region in Far Eastern Russia (Table 7).

Blood feeding in these moths is considered to be facultative and they have been recorded feeding on a broad range of hosts such as cattle, deer, tapirs,

Skin-Piercing and Blood-Feeding Moths, *Calyptra* spp. (Lepidoptera: Noctuidae: Calpinae), Figure 48 **(a) Scanning electron microscope (SEM) image of *Calyptra thalictri* (Borkhausen) proboscis: *TH* = tearing hooks; *EB* = erectile barbs; *DG* = dorsal galeal cross linkage; *SS* = sensilla styloconica (terminology follows Büttiker et al. (1996)); (b) *Oraesia rectistria* Guenée piercing plum (Godavari, Nepal); (c) image of *Calyptra thalictri* (Borkhausen) feeding on human thumb.**

and zebu. Occasionally elephants and humans are attacked; female *Calyptra* adults have not been documented to feed on blood. It has been hypothesized that the skin piercing and blood feeding habit in these moths evolved from the fruit-piercing habit, a likely scenario given fruit-piercing and blood-feeding moths share the proboscis and behavioral modifications observed in both feeding types. In both cases, the male moths appear to be in search of sugars, proteins, and salts in order to increase longevity. It is possible that the occurrence of blood feeding in these moths is dependent on the availability of fruit hosts; thus, when the typical fruit hosts are unavailable, the moths seek out mammalian hosts to obtain the nutrients essential to survival. It is known that many fruit-piercing *Calyptra* species and those of related genera are of great economic importance in many countries, but their potential as vectors of human or animal disease remains unknown.

An alternative hypothesis regarding the evolution of feeding in *Calyptra* has been proposed and suggests the skin-piercing and blood feeding behavior is derived from other animal-associated feeding behaviors such as dung, urine, or tear feeding. Although one *Calyptra* species, *C. minuticornis* (Guenée), has been recorded feeding on tears, this evolutionary trajectory is an unlikely one given the proboscis structures of fruit piercers and blood feeders are not homologous with those of tear-feeding moths, and such lachrophagous moths do not pierce fruit. This hypothesis is also problematic given the shared behavioral modifications found in both fruit piercing and blood feeding moths. The actual piercing of fruits or mammalian skin is restricted to a small group of taxonomically associated genera of Noctuidae,

Skin-Piercing and Blood-Feeding Moths, *Calyptra* spp. (Lepidoptera: Noctuidae: Calpinae), Table 7
Summary of feeding behaviors for species recorded as blood feeders in the genus *Calyptra* (after Bänziger (1989), Zaspel et al. (2007))

Species	Location	Blood feeding habit	Fruit piercer	Mammalian hosts
C. bicolor	Nepal	Natural conditions	Yes	Zebu, humans
C. eustrigata	Thailand, Malaysia	Natural conditions	Yes	Tapir, rhinoceros, zebu, deer, antelope, Indian elephant, water buffalo
C. fasciata	N Thailand, NW India	Natural conditions	Yes	Indian elephant, pig, mule, zebu
C. fletcheri	China, Tibet	Laboratory conditions	Yes	Humans
C. minuticornis	Thailand, Malaysia	Natural conditions	Yes	Indian elephant, mule
C. ophideroides	NW India	Natural conditions	Yes	Zebu, humans
C. orthograpta	N Thailand	Natural conditions	Yes	Indian elephant
C. parva	N Thailand	Natural conditions	Yes	Horse, humans
C. pseudobicolor	Nepal	Natural conditions	Yes	Zebu, humans
C. thalictri	Russia	Experimental and semi-natural conditions	Yes	Human

whereas animal-associated feeding behaviors, including the imbibing of blood droplets found on the bodies of mammals, are widespread within Lepidoptera.

Skipper butterflies, family Hesperiidae, include about 4,100 species from all faunal regions; most are Neotropical, with 2,338 species. The actual world fauna probably exceeds 4,500 species. Seven skipper subfamilies are recognized: Megathyminae, Coeliadinae, Pyrrhopyginae, Pyrginae, Trapezitinae, Heteropterinae, and Hesperiinae. The family is in the superfamily Papilionoidea (series Hesperiiformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adult small to medium size (16–82 mm wingspan); antennae with clubs mostly elongated and hooked distally (club more compact in Megathyminae). Wings mostly triangular with somewhat acute forewing apexes; hindwings mostly rounded (rarely with tails); body robust. Maculation is primarily subdued shades of brown, often with various pale or hyaline spotting; rarely very colorful. Adults are diurnal, usually with very rapid flight, but a few tropical species are crepuscular. Larvae are leafrollers or borers, and typically have a large head capsule followed by a narrow prothorax (or "neck"). Host plants are primarily grasses (Gramineae) and other monocots, but some other hosts are also utilized; the primitive Nearctic Megathyminae are borers in Agavaceae. A few economic species are known, particularly on rice (Fig. 49).

Skipper Flies

Members of the family Piophilidae (order Diptera).

► Flies

Slavery

A phenomenon among ants wherein slave-making ants capture larvae and pupae of another ant species and take them (the future slaves) to their nest where they are raised and become part of the slave-making ant colony, carrying out their normal functions but for the benefit of the slave-making ant species.

Sleeping Sickness or African Trypanosomiasis

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Sleeping sickness is a vector-borne parasitic disease of humans in sub-Saharan Africa. The parasites causing the disease are transmitted to humans principally by the bite of tsetse fly, *Glossina* spp. (Diptera: Glossinidae). The parasites may be acquired by the flies from either humans or animals. The parasites are in the genus *Trypanosoma* (flagellated protozoa in the family Trypanosomatidae), and there are two forms (species or subspecies, depending on the author). *Trypanosoma gambiense* or *T. brucei gambiense* is found in central and western Africa. It is named after the country of Gambia in western Africa. *Trypanosoma rhodesiense* or *T. brucei rhodesiense* is found is southern and eastern Africa. It is named after the former country of Rhodesia, now Zimbabwe, in eastern Africa. Not only are the two trypanosome forms separated geographically (Fig. 50), but they differ in their hosts and in symptoms of infection. Morphologically, however, they are indistinguishable.

Trypanosoma gambiense or West African trypanosomiasis is the more common of the two diseases, representing over 90% of the known cases in humans. It also tends to cause a chronic infection, and a person can be infected for months or years without seeing symptom expression. However, once the disease is expressed, the disease is far advanced, and the nervous system is adversely affected. Humans are the only important reservoir for this disease. Tsetse of the *palpalis* group are the vectors, often *Glossina palpalis*, *G. tachinoides*, and *G. fuscipes*. These flies inhabit riverine areas and attack people when they collect water, wash clothing or bathe in the rivers, or collect firewood in these areas.

Trypanosoma rhodesiense or East African trypanosomiasis is much less frequent in

Sleeping Sickness or African Trypanosomiasis, Figure 50 **The distribution of sleeping sickness in Africa. The *shaded area* represents the regions generally affected. Areas west (*left*) of the *broken line* are affected by the West African form, and areas east (*right*) of the *line* are affected by the East African form.**

humans, but occurs in an acute form, with symptoms expressed in weeks or months. As in the case of the *gambiense* form, it affects the central nervous system but, of course, the disease progresses more rapidly. Tsetse of the *morsitans* group are the principal vectors, including *G. morsitans*, *G. pallidipes*, and *G. swynnertoni*. Cattle and wild animals are the principal reservoir of *rhodesiense*. Among the wild animals serving as hosts for East African trypanosomiasis are antelopes (bushbuck, duiker, impala, hartebeest, situtunga, wildebeest), buffalo, bushpig, elephant, giraffe, hyena, lion, warthog, and zebra.

Sleeping sickness occurs only in sub-Saharan Africa in regions where there are tsetse flies that can transmit the disease. For reasons that are not yet understood, there are many regions where tsetse flies are found, but sleeping sickness is not. Only certain species transmit the disease.

They are mainly found in vegetation by rivers and lakes, in forests, and in the savannah, but the different species have different habitat preferences.

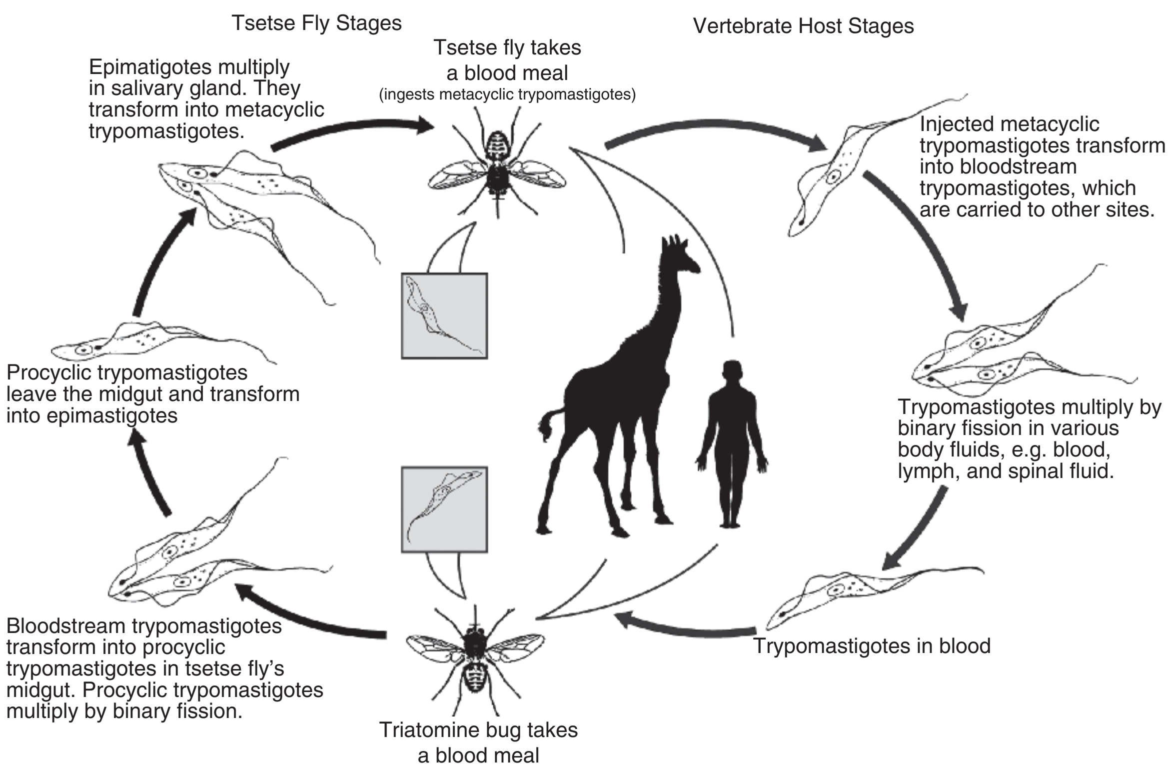
When the disease occurs in animals it is called nagana instead of sleeping sickness. Unlike the human form of the disease, which is not found everywhere tsetse flies occur, nagana occurs throughout the range of tsetse flies. Nagana is much more common than sleeping sickness, but sleeping sickness occurs frequently even today. The disease in domestic animals, and particularly the effects on cattle, has been a major obstacle to the economic development of rural central and southern Africa. It is estimated that three million cattle die annually due to this disease. For thousands of years, the ability of tsetse to transmit trypanosomes has denied the people of central and southern Africa the use of large domestic animals such as oxen and horses in their agriculture. Also, it has led to shortage of animal protein in the diet of many Africans. Offsetting this, perhaps, is the benefit of tsetse-borne disease in preventing the southward migration of Arab invaders because their horses and camels were susceptible. Also, the presence of tsetse-borne diseases probably has helped preserve the natural environment of Africa, particularly the rich wildlife. There is also evidence that some other flies play a minor role in mechanical transmission of the protozoan. Flies in the families Tabanidae and Muscidae also may transmit the disease to animals, and perhaps to humans, though this is of minor importance compared to tsetse transmission.

Typically, 40,000–50,000 cases are reported annually in humans, but this is likely a serious underestimate of the total number of people affected. It is more commonly a problem where public health services are inadequate, in rural habitats and among poor people, and in these situations accurate reporting is infrequent. Rural populations usually depend on agriculture, fishing, animal husbandry or hunting, and in these pursuits they are often exposed to the bite of the tsetse fly and therefore to the disease. Displacement of people following war or famine can exacerbate the problem. Sometimes the trypanosomes cross the placenta and infect the fetus, resulting in mother-to-child infection. Blood transfusions can be a source of the disease.

A tsetse fly bite is often painful and can develop into a red sore, called a chancre. Upon transmission of the disease by the bite of a fly, the trypanosomes multiply in the subcutaneous tissues, blood and lymph of the host. This first stage of the disease is known as the hemolymphatic phase. Associated with this phase are periods of fever and sweating, headache, swelling of the lymph nodes, joint pain and itching. With time, the typanosomes cross the blood-brain barrier and infect the central nervous system. This second stage, or neurological phase, has associated with it confusion, mood swings, sensory disturbances, weakness and poor coordination. As the “sleeping sickness” designation suggests, another symptom of the disease is disturbance of sleep. Ultimately, without treatment, sleeping sickness often leads to coma or convulsions, and death. The long asymptomatic first stage of the West African form of the disease (Fig. 50), and the generalized symptoms that occur when any ailment is noticed, make diagnosis difficult. Serological and cerebro-spinal tests usually are required. The drugs used to treat the disease during the first stage of the disease are not too toxic, easy to administer, and fairly effective. Unfortunately, if early diagnosis is not made, the drugs used to treat the second stage are toxic and difficult to administer.

Development of this trypanosome is similar but not the same as that of *Trypanosoma cruzi*, the causative agent of Chagas disease or American trypanosomiasis. Trypomastigotes (one major form of the trypanosome) circulate in the blood and the tsetse fly becomes infected with bloodstream trypomastigotes when taking a blood meal on an infected mammalian host. In the fly’s midgut, the parasites transform into procyclic trypomastigotes, multiply by binary fission, and leave the midgut. Eventually they migrate to the proboscis and attach to the epithelium of the salivary glands where they transform into epimastigotes (the other major form of the trypanosome). The epimastigotes continue multiplication by binary fission. The cycle in the fly takes approximately 3 weeks to progress, and then the trypanosomes transform back to trypomastigotes; at this point they are called metacyclic trypomastigotes and are infective to humans and animals. Once infected, the fly remains infective during its entire 6- to 12-month life span. An infected tsetse fly injects metacyclic trypomastigotes into skin tissue when taking a blood meal, and the parasites enter the host's lymphatic system and pass into the blood. There, they transform into bloodstream trypomastigotes and are carried to other sites throughout the body, reach other blood fluids (e.g., lymph, spinal fluid), and continue the replication by binary fission (Fig. 51).

Prevention and control of the disease tends to focus on elimination of the vector, tsetse flies. Clearing of brush, which favors persistence of flies by providing them cover, is an important management technique. The flies do not disperse long distances, so it is possible to create barriers around inhabited areas by removing such cover. Land used for crop culture or grazed periodically by livestock similarly is not very suitable for survival of tsetse. Insecticide application, both ground and aerial applications, has long been used for tsetse suppression. Area-wide management approaches can be implemented using release of sterile insects, but presently is too costly. Use of traps (blue or black cloth sprayed with insecticide, or cattle sprayed with insecticides) has had some success, as has traps baited with chemical attractants. Care should be taken to avoid being bitten. Bed netting and thick, long-sleeved clothing are helpful. Avoidance of brushy



Sleeping Sickness or African Trypanosomiasis, Figure 51 **The sleeping sickness disease cycle in tsetse flies and their hosts (adapted from CDC).**

habitats is helpful. Vaccines and preventative drugs are not available. It also is desirable to screen communities for occurrence of sleeping sickness to identify foci of disease outbreak and to apply curative medications to affected individuals. Certain breeds of cattle such as N'dama are tolerant of trypanosome infection, so this is an active area of research.

There are other forms of trypanosomiasis in Africa and elsewhere. For example, the aforementioned African sleeping sickness is perhaps better called African human trypanosomiasis to differentiate it from African animal trypanosomiasis (nagana). This latter disease is basically the same as the tsetse fly-transmitted disease transmitted to humans, but is caused by other trypanosomes such as *Trypanosoma congolense*, *T. suis*, *T. simiae*, *T. uniforme* and *T. vivax* in addition to *T. brucei*.

Slug Caterpillar Moths (Lepidoptera: Limacodidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Slug caterpillar moths, family Limacodidae, total 1,104 known species worldwide, the largest family of Cossoidea, mostly tropical and especially biodiverse in the Oriental tropics; likely world total is near 1,600 species or more. There is no established subfamily classification thus far. The family is in the superfamily Cossoidea (series Limacodiformes) in the section Cossina, subsection Cossina, of the division Ditrysia. Adults small to medium size (9–80 mm wingspan) (typically 20–30 mm), with head small and relatively rough-scaled; haustellum and maxillary palpi vestigial or reduced; labial palpi short; antennae short, usually bipectinate in males (typically becoming filiform near apex). Body robust. Wings usually quadrate and rounded, although some with forewings more pointed and elongated; hindwings usually ovoid. Maculation mostly various shades of brown, but some are colorful (rarely hyaline or with hyaline patches or spots), with few markings but for many with diagonal lines, various markings (some with bright green patches); hindwings usually unicolorous to match forewings or lighter (rarely hyaline). Adults perhaps only nocturnal; many with unique resting postures. Larvae slug-like (often colorfully marked over green base color) and mostly polyphagous leaf feeders, with vestigial prolegs and usually an extensive array of poisonous stinging spines dorsally. Large numbers of host plants utilized. Few species are economic, other than medically as stinging caterpillars, but palm defoliators can be a problem in the tropics (Fig. 52).

Small Fruit Pests and Their Management

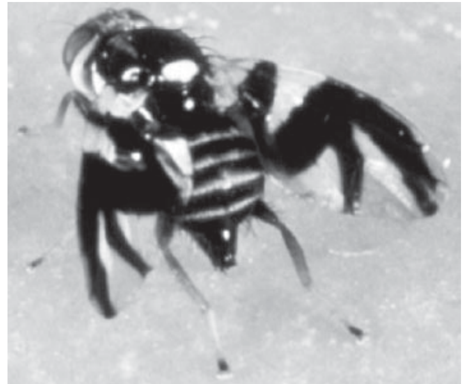
OSCAR E. LIBURD, ERIN M. SARZYNSKI
University of Florida, Gainesville, FL, USA

In the United States, the production of small fruit is becoming increasingly important as growers diversify from traditional staple crops to specialty fruits. Blueberries, cranberries, strawberries, and grapes comprise the major small fruit crops with combined annual sales exceeding $3 billion dollars. Despite these figures, further growth and development of small fruit industries will depend on producers' ability to develop effective pest management programs that specifically target key pests within these systems. The passage of the 1996 Food Quality Protection Act (FQPA) and public concern over food safety, as well as pressure from environmentalists, are forcing producers and pest management specialists to develop programs aimed at reducing pesticide residues in food and improving agricultural worker safety.

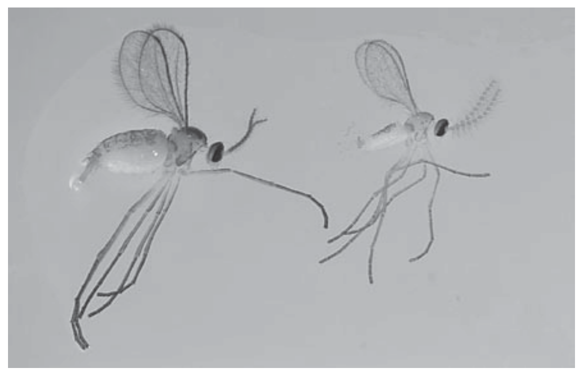
The goal of this section is to provide biological information on some of the major pests within small fruit systems in the United States. It is difficult to cover all of the economic pests that affect small fruit crops in a single section; therefore, a special effort has been made to highlight key insect pests that cause serious economic damage within the various small fruit systems. We attempted to provide up-to-date information on distribution, biology, and damage symptoms and focused our management efforts on effective monitoring and cultural techniques. A special effort was made to provide useful IPM strategies that can be adopted to minimize the use of pesticides. The information that is provided can be used as a basis to provide growers, consultants, and pest management specialists' options for managing key pests in these systems. Although there is substantial information in the literature on the use of reduced-risk pesticides, we did not make any spray recommendations because pesticide information changes frequently as more research becomes available.

Blueberries

In the USA, commercial blueberries are grown on approximately 109,000 acres of land with a total market value of 411 million USD. Michigan leads the US in producing over 40% of the northern highbush blueberries, *Vaccinium corymbosum* L., while Maine produces more than 90% of the lowbush blueberries, *V. agustifolium* Aiton. Rabbiteye blueberries, *V. ashei* Reade, are grown mostly in the southeastern United States, with the highest production coming from Georgia. The recently developed southern highbush blueberries, *V. corymbosum* X *V. darrowi* Camp are grown primarily in Florida, although Georgia and some areas in the western US, including Oregon and California also produce small quantities of southern highbush blueberries. Blueberries are a rich source of antioxidants as well as other nutrients that are associated with lowering the risk of cardiovascular diseases and cancer. Blueberries are attacked by several pests including blueberry maggot, *Rhagoletis mendax* Curran, cranberry fruitworm, *Acrobasis vaccinii* Riley, blueberry gall midge, *Dasineura oxycoccana* (Johnson) and flower thrips, *Frankliniella* spp.



Small Fruit Pests and Their Management, Figure 53 Adult blueberry maggot.



Small Fruit Pests and Their Management, Figure 54 Blueberry gall midge female (*left*) and male (*right*).

Pests of Blueberries, *Vaccinium* spp. (Family Ericaceae)

Blueberry Maggot, *Rhagoletis mendax* Curran (Diptera: Tephritidae)

Distribution

Blueberry maggot, *Rhagoletis mendax* Curran, is an important pest of commercially grown blueberries, *Vaccinium* L. spp., in the eastern and Midwestern United States. Only one generation per year has been reported throughout its distribution. Temperature, soil type, moisture and the presence of wild host plants may affect rate of emergence. Deerberry, *V. stamineum* L., and huckleberries, *Gaylussacia* Humboldt, Bonpland, and *Kunth* spp., have been identified as principal host species in the southeast (Fig. 53).

Biology

Adults emerge from overwintering puparia when berries begin to ripen, and flies will continue to emerge until all cultivars have fully ripened. Adults are black with a white spot on the thorax and are approximately 3–4 mm in length. The abdomen of females is black and pointed with four white cross bands. Males are slightly smaller than females and have only three white cross bands on their abdomen. Both males and females have a characteristic F-shaped marking on their wings. Mature females oviposit eggs singly into maturing berries. The larva is a creamy white, legless maggot approximately 4–6 mm in length. Larval development requires 18–20 days, at which time mature larvae drop to the ground to pupate in the soil. Puparia are smooth brown colored capsules and usually are located about 2–3 cm below ground level.

Damage

Larvae feed on the internal tissues of the fruit causing major destruction of the tissues. There is a low tolerance for maggots in fruit, and *R. mendax* infestations may render shipments of blueberries unmarketable.

IPM Strategies. Blueberry maggot can be controlled effectively with insecticides if applications are properly timed. Three principle types of traps should be considered when monitoring blueberry maggot: (i) yellow sticky boards, (ii) green sticky spheres and (iii) sticky red spheres. Baiting traps with ammonium acetate can increase monitoring efficiency. In highbush blueberries, a minimum of two sticky boards or spheres is needed for every two hectares (about 5 acres). One trap should be placed near (10–20 m) the border of the planting adjacent to wild host plants and the other trap should be placed in the center of the two-hectare block. Yellow sticky boards should be hung 15 cm (6 in.) above the bush and positioned in a "V" orientation with the sticky surface facing downward. Traps should be monitored weekly and recoated or replaced after 3 weeks of exposure to maintain efficiency. Spraying for blueberry maggot should commence when two or more flies are found on any one trap during a sampling period, or when the total number of flies over all traps in a field equals or exceeds five in 1 week. In the field, *Daichasma alloeum*, an opiine parasitoid, is known to attack third instar blueberry maggot larvae.

Cranberry Fruitworm, *Acrobasis vaccinii* Riley (Lepidoptera: Pyralidae)

Distribution

Cranberry fruitworm is a pest of *Vaccinium* spp. throughout the eastern United States and Canada, from Nova Scotia southward to Florida. Typically, cranberry fruitworm is a univoltine pest, although a second generation is possible under favorable climatic conditions.

Biology

Cranberry fruitworm adults are brownish-gray moths with a blend of light and dark coloration. Adult wingspan is approximately 18 mm, with females having a slightly larger and more orange-colored abdomen. Adult moths are nocturnal, with female activity preceding that of males at dusk/after sunset. Mated females lay eggs near the calyx-cup of expanding cranberries and blueberries. Females often lay eggs in berries located near bog or planting edges. Cranberry fruitworm eggs are white and slightly elliptical, approximately 1 mm in diameter. Newly hatched larvae exit the fruit near the oviposition site and crawl over the berry surface before reentering the same berry at either the stem end or the calyx to begin feeding. Mature larvae are pale green with a darkened head capsule, approximately 15 mm in length. Larvae pupate in hibernacula composed of sand, leaves and debris, and emerge as adults the following spring.

Damage

Damage caused by cranberry fruitworm is characterized by internal feeding. Larvae consume the pulp of approximately 5–8 berries, webbing berries together at their point of contact. Infested berries may exhibit premature color change, and larval frass often becomes entangled in the webbed cluster. Early instar larvae sometimes construct a silken enclosure over the entry site. Webbed fruit containing frass is a characteristic of *A. vaccinii* damage that is useful for differentiating between damage caused by cherry fruitworm and sparganothis fruitworm.

IPM Strategies

Current IPM strategies employ the use of pheromone-baited, (*E,Z*)-8,10-pentadecadien-1-ol and (*E*)-9-pentadecen-1-ol acetate, winged traps to monitor male *A. vaccinii* activity. Traps are available commercially, although their effectiveness may depend on several factors, including height with respect to host plant and geographic position within a bog or planting. Traps placed in adjacent habitats or within close proximity to blueberry or cranberry fields may provide additional information regarding male moth flight throughout the season. Monitoring for cranberry fruitworm also can be accomplished by examining individual clusters or plants for the presence of eggs. This strategy requires the aid of a hand lens, and since infestations of cranberry fruitworm may be aggregated, an accurate assessment may require a large sample size. Monitoring tactics will be useful for predicting peak oviposition and for timing insecticide applications. One cultural technique for managing cranberry fruitworm in cranberries involves late-water flooding because hibernacula cannot survive in water exceeding 16°C for more than 2 weeks.

Blueberry Gall Midge, *Dasineura oxycoccana* (Johnson) (Diptera: Cecidomyiidae)

Distribution

Blueberry gall midge is distributed throughout the eastern, mid-western and north western United States. In the south, blueberry gall midge infests rabbiteye and southern highbush blueberries (Table 8).

Biology

Blueberry gall midges are small insects, approximately 2 mm in size with long, slender legs, delicate wings (with microtrichia) and globular antennae. Female gall midges are slightly larger than males and have a distinctively orange-colored abdomen. A single female is capable of ovipositing more than 20 eggs into the developing buds. Eggs hatch within 2–3 days, and the emerging larvae develop through three or four instars that are characterized by color: transparent (first instar), white (second instar), and orange (third instar), respectively. Larvae drop to the ground and pupate in the upper layers of the soil. There are several generations per year. Climatic conditions and latitude influence the number of generations within a particular region.

Damage

The larvae of blueberry gall midge feed within the buds, which ultimately kill the developing tissues and terminates growth of the affected shoot. Vegetative buds also may be affected after fruits are harvested. Curled, cupped leaves characterize blueberry gall midge damage in a blueberry planting. In general, blueberry gall midge prefers young shoots rather than older growth. The injury is often misdiagnosed as frost damage. In blueberries post-harvest injury may limit flowering potential for subsequent seasons.

IPM Strategies

Monitoring for blueberry gull midge can be accomplished by destructively sampling floral and vegetative buds during and after bud swell, when scales have begun to separate. A dissecting microscope is necessary to view eggs and early larval instars. In blueberries, applications of reduced-risk insecticides may be most effective if targeted during the egg-hatching stage of the first generation. Cultural control practices include the use of bed sanding and alteration in pruning and fertilization practices.

Cranberries

Cranberries are produced mainly in Wisconsin, Massachusetts and New Jersey. In 2001, the US produced 500 million pounds of cranberries valued at $115 million dollars. Wisconsin leads the country in producing 60% of the nation's cranberries, followed by Massachusetts and New Jersey, which produced 142 and 57 million pounds, respectively. Cranberries are a rich source of vitamins, potassium and fiber, and have been reported to play a significant role in lowering the incidence of cystitis and other urinary tract infections. Recent studies also have indicated that cranberries are a good source of antioxidants. Like other plants belonging to the genus *Vaccinium*, cranberries are susceptible to several pests including Sparganothis fruitworm, *Sparganothis sulfureana* (Clemens) Riley, black-headed fireworm, *Rhopobota naevena* (Hübner) and cranberry fruitworm, *Acrobasis vaccinii* Riley (discussed under blueberry section).

Pests of Cranberries, *Vaccinium macrocarpon* Aiton (family Ericaceae)

Sparganothis fruitworm, *Sparganothis sulfureana* (Clemens) (Lepidoptera: Tortricidae)

Distribution

Sparganothis fruitworm is a major pest of cranberries throughout the eastern United States and Wisconsin. This species is not known to affect production of *Vaccinium* spp. on the west coast of the United States. Sparganothis fruitworm also has been reported on strawberry (Table 9).

Biology

Sparganothis fruitworm has no approved common name. Adults are approximately 15 mm in length and are characterized by having yellowish wings with a distinctly brownish "X" marking on the dorsal surface. Larvae have a yellow-green body with paired white spots on the dorsal surface and a yellow head. Sparganothis fruitworm has two generations per year. The first generation larvae are indirect pests, feeding on young foliage and webbing together terminal vine tips. Second generation larvae feed internally, causing direct damage to the fruit. Sparganothis fruitworm overwinter as larvae.

Damage

Fruit entry sites are generally larger and more tattered compared with cranberry fruitworm. Direct injury result from internal feeding and consumption of fruit pulp, with no evidence of frass inside affected berries.

IPM Strategies

Sparganothis fruitworm may be difficult to manage due to organophosphate resistance. There may be some promise for mating disruption with sprayable micro-encapsulated pheromones. The pheromone (E)-11-tetradecenyl acetate (E11–14: Ac) has been known to significantly reduce mating among virgin females in cranberry plots.

[a]also infest blueberries
[b]also infest strawberries

affects grasses that are common to many cranberry bogs.

Biology

Adult moths are approximately 9 mm in length and silvery, with light brown coloration on the outer edge of the forewing. Small black dots also may be visible on the outer margin of the forewing, although adults lose their coloration soon after emerging. Females lay eggs randomly within the bog floor. Eggs (0.5 mm) appear white when laid and attain a pinkish color when mature prior to hatching. Larvae have a dark brown head and cream-colored abdomen with fine hairs. Girdler larvae are concealed largely in the leaf litter on the bog floor and feed on the bark and internal vascular system of low-lying cranberry vines. Mature larva is approximately 13 mm in length. Prior to pupation, larva prepares a cocoon made from leaf litter for overwintering in the soil. Pupation occurs in the spring and there is one generation per year.

Damage

Larval feeding results in "girdled" or completely severed vines, which interrupts water and nutrient transfer in affected plants. Damage symptoms (including foliage browning) may appear in the late fall, although more extensive damage may not be visible until the spring. The occasional appearance of many dead or dying uprights in late summer and early fall could be a sign of girdler damage. Damage may be more abundant in bogs with accumulated trash.

IPM Strategies

Commercially available pheromone traps are useful for monitoring adult populations. There are some indications that certain plant species, including foxtail, *Alopecurus pratensis* L., can be used as monitoring tools in cranberry bogs. Cultural control practices include sanding and flooding. Parasitic wasps, spiders, and ground beetles may offer some degree of control in some areas.

Blackheaded Fireworm, *Rhopobota naevena* (Hübner) (Lepidoptera: Tortricidae)

Distribution

Blackheaded fireworm is a major pest of cranberry production in North America.

Biology

Adults are darkly colored small moths, approximately 7 mm, with light and dark brown-banded forewings. Mature larvae have shiny black heads with greenish-yellow abdomens and measure approximately 8 mm in length. Young larvae burrow into the green tissue of developing leaves eventually moving to the growing tips. Larvae often tunnel into swollen buds and web terminal leaves together with silk. Larvae feed for about 3–5 weeks, during which time a single larva can construct more than five silken tents. Blackheaded fireworm overwinters in the egg stage on the underside of cranberry leaves. Overwintering eggs are yellow, disc-shaped, and approximately 0.5 mm in length. There are two or three generations per year. First generation egg hatch begins in the spring. Pupation occurs either within tents or in the trash layer on the bog floor. Females lay eggs on the underside of cranberry leaves in the late spring/early summer. Development of the second generation proceeds similarly to the first except that second generation larvae cause direct damage to blossoms and berries. In addition, second generation adults fly in mid/late summer. A third generation is possible under favorable conditions.

Damage

Damage symptoms caused by first generation larvae appear similar to leafminer damage. First generation larvae also mine terminal buds, which may reduce fruit set. Second generation larvae cause direct damage to the flowers and fruit, often hollowing the fruit. Affected bogs exhibit a scorched appearance.

IPM Strategies

Monitoring for larvae often is conducted by viewing runner tips or sweepnet sampling. Particular attention should be paid to areas of previous infestation and bed edges. Pheromone traps are commercially available for monitoring adults. Regional recommendations for trap maintenance and spacing may vary.

Grapes

Among the small fruit crops, grapes have the highest market value in the US, averaging more than 2 billion dollars in annual sales. Grapes are produced on almost a million acres of land in the US. About 85% of the grapes produced are processed for wine production. A small amount of grapes is dried for raisins, or processed for jams and jellies, and less than 10% are used for juice production.

California leads the US in grape production, generating more than 90% of total sales, followed by Washington and New York, which produce 4 and 2%, respectively. Most American grape cultivars are hybrids of native American species and European grapes, *Vitis vinifera* L. Hybridization combines the excellent wine quality of European grapes with the insect and disease resistance qualities of the wild American grape species. American hybrids were used during the latter part of the nineteenth century to combat a major pest, grape phylloxera, *Daktulosphaira vitifoliae* (Fitch). A few European cultivars are grown in the colder regions of the American Muscadine grapes, *Vitis rotundifolia* Michx., are grown on small acreage in the southeastern regions of the USA. Muscadine grapes have a long history in commercial and backyard culture in eastern USA and were the first American grape to be cultivated. Muscadine grapes usually are sold in groceries as fresh pack. Like other small fruits, grapes are susceptible to many insect and disease pests. The glassy-winged sharpshooter, *Homalodisca coagulata* (Say), recently has become established in California and is a major threat to the state wine industry because it vectors the bacterium *Xylella fastidiosa*, which causes Pierce's disease in grapes.

Pests of Grapes, *Vitis* spp. (Family Vitaceae)

Grape Berry Moth, *Endopiza vitana* Clemens (Lepidoptera: Tortricidae)

Distribution

Grape berry moth is a key pest of grapes throughout the United States and Canada east of the Rocky Mountains. Prior to grape cultivation in this region, the grape berry moth infested wild grapes.

Biology

Adults are brown moths with grayish markings, with a 9–12 mm wingspan. There are two or three generations per year. First generation adults emerge from pupation in late spring. Females lay eggs singly on buds or stems, while the later generation(s) lay eggs directly on the fruit. Eggs, which are approximately 0.7 mm, must be viewed using a hand lens. Eggs hatch into creamy white larvae within a week in most regions. Larvae have a brown head and dark thoracic shield. The abdomen changes color from white to green to purple as the larvae mature. Full grown larvae measure about 10 mm in length. Larvae generally construct cocoons from leaves and leaf litter, although some larvae pupate within the fruit cluster in which they once fed. Pupae are light brown to green in color and are 5 mm long.

Damage

First generation larvae feed on tender stems, blossom buds, and berries. Later generations cause direct damage to the fruit, often boring into several grape berries at their point of contact and webbing the cluster together. Up to seven berries may be damaged by a single larva.

IPM Strategies

Pheromone lures are available commercially for monitoring the emergence of male moths within vineyards and in adjacent locations. These pheromone baited traps are useful for properly timing insecticide applications where grape berry moth is an annual pest. Cultural control methods include removing infested clusters, generally when infestations are mild. Leaf litter containing cocoons can be destroyed after harvest. In the spring, applying a layer of compact soil on top of the leaf litter may reduce adult emergence.

Grape Root Borer, *Vitacea polistiformes* (Harris) (Lepidoptera: Sesiidae)

Distribution

The grape root borer is a major pest of grapes in the south eastern United States. The life cycle of grape root borer requires 2–3 years in states north of Georgia. However, in Florida the lifecycle could be completed 1 year (Fig. 55).

Biology

Adults are dark brown with thin yellow bands across the abdomen and resemble paper wasps. The forewings are dark brown, while the hind wings are transparent. Adult moths are daytime fliers and live for approximately 7 days. Females lay up to 500 dark brown eggs in clusters on the soil surface, on grape leaves, or on nearby weeds. Eggs hatch in about 2 weeks, and first instar larvae drop to the ground and tunnel into vine roots. Larvae are cream colored with a brown head. Studies suggest that only 3% of neonate larvae survive threats of parasitism, predation and desiccation. However, once larvae become established in the vine roots, mortality is very low. Mature larvae can be up to 40 mm in length. Second year larvae leave the vine roots to pupate in cocoons near the soil surface. The pupal stage lasts approximately 35–40 days.

Small Fruit Pests and Their Management, Figure 55 Grape root borer.

Damage

Grape root borer damage is often difficult to diagnose since the damaging larvae are hidden within the vine roots. However, evidence such as protruding pupal skins left by emerging adults may indicate that an infestation is present. Larval feeding results in reduced vine vigor and a reduction in grape yield. Only two or three larvae are necessary to destroy an entire plant.

IPM Strategies

Cultural methods for control of grape root borer include mounding soil under vines just after pupation in order to reduce adult emergence. Proper weed management is also important for reducing potential egg laying sites and to increase larval mortality due to desiccation. Two species of *Heterorhabditis* nematodes have shown promise as biological control agents against grape root borer larvae. Pheromone-baited traps are recommended for monitoring adult moths. These traps should be placed about 100 m apart inside the vineyard and along adjacent woodland boundaries. Monitoring information may be useful for timing insecticide applications, although contact insecticides are ineffective once larvae reach the root system.

Glassy-Winged Sharpshooter, *Homalodisca coagulata* (Say) (Hemiptera: Cicadellidae)

Distribution

The glassy-winged sharpshooter, *Homalodisca coagulata* (Say), is native to the southeastern

United States. Glassy-winged sharpshooter recently has become established in California where it vectors the bacterium *Xylella fastidiosa*, which causes Pierce's disease in grapes.

Biology

Adults measure up to 2 cm in length and have large membranous wings with red markings. There are distinguishing small yellow dots on the head and thorax. The glassy-winged sharpshooter overwinters as an adult and emerges under favorable climatic conditions. Generally, there are two generations per year in semi-tropical climates. Females lay eggs in groups of 10–20 on the underside of leaves, just under the epidermis. After oviposition, females protect their eggs with "brochosomes," which are white hydrophobic particles produced in specialized locations within the Malphigian tubules.

Damage

The glassy-winged sharpshooter feeds on vines, not leaves. Early symptoms of Pierce's disease include wilting, the appearance of water loss, which is caused by bacterial growth that blocks the flow of xylem in affected plants. Subsequent damage includes discolored leaf margins, shriveled fruit, leaf drop, and irregular maturation of new canes. Several other sucking insects may transmit the *X. fastidiosa* bacterium, including the blue-green leafhopper, *Graphocephala atropunctata* (Signoret), although the common grape leafhoppers (discussed later) are not known to be vectors.

IPM Strategies

Host plant resistance methods, which focus on planting vines resistant to *X. fastidiosa* may reduce the incidence of Pierce's disease. In general, muscadine grapes are resistant to *X. fastidiosa*, which may be responsible for the absence of Pierce's disease in some places, including Florida.

Grape Leafhoppers, *Erythroneura* spp. (Hemiptera: Cicadellidae)

Distribution

There are several species of Cicadellidae that are referred to as grape leafhoppers. In general, members of the genus *Erythroneura* cause the most serious damage to grapes. The grape leafhopper, *Erythroneura comes* (Say), is the most abundant species in the northeastern United States. In Florida, *E. vulneurata* is the most important species, while *E. elegantula* and the variegated leafhopper, *E. variabilis*, occur in California. These species are also believed to vector Pierce's disease (Table 10).

Biology

Leafhoppers of the genus *Erythroneura* overwinter as adults, emerging from nearby hibernation sites when temperatures exceed 16°C. Adults are approximately 3 mm in length and are pale yellow in the beginning of the season. As the season progresses, adults obtain a deeper color, often with distinct markings or spot. Eggs are laid singly on the underside of the leaf just below the epidermis. Nymphs hatch within 7–10 days. Newly hatched nymphs are nearly transparent and have distinct red eyes. There are five nymphal instars, and with each molt thorax markings and wing pads become more prominent. Both nymphs and adults are very active.

Damage

Adults and nymphs bore small holes into the underside of leaves and extract cell sap and chlorophyll, generally when plant nutrients are

[a]also infest raspberries and strawberries
[b]also infest blueberries

abundant. Affected leaves have a mottled appearance and may lose their color. Severe injury to the leaf tissue may result in leaf drop and reduced fruit quality. Excreta (honeydew) from leafhoppers may accumulate on the foliage and berries making them susceptible to fungal attack, particularly sooty molds.

IPM Strategies

Monitoring strategies for leafhoppers include the use of yellow sticky boards or counting the number of nymphs and adults relative to the number of leaves. Removal of alternate host plants and weed management in areas adjacent to vineyards may reduce food sources and potential overwintering sites. Coverage on the undersides of leaves is important when insecticide treatments are warranted for leafhopper control.

Grape Leaffolder, *Desmia funeralis* (Hübner) (Lepidoptera: Pyralidae)

Distribution

The grape leaffolder is a common pest of grapes throughout the United States. It is native to eastern North America but it is now distributed from southern Canada to northern Mexico. Although damage is typically minor, outbreaks of grape leaffolder have been occurred occasionally in both California and Florida. There are several generations per year in the southeastern United States and California, although damage appears to be most problematic during the second and third generations.

Biology

Adult moths are nearly black and have slightly iridescent wings. Wingspan varies from 2 to 2.5 cm. There are two white, oval-shaped spots on the forewings of both sexes. Males have a white band on the hindwings, while a similar band may be partitioned into two spots in females. Mated females lay elliptical-shaped eggs singly on the underside of leaves, often near the veins. Emerging larvae feed on the leaves of grapevines. At maturity, larvae are 15–20 mm long and nearly transparent; larvae also may appear green as a result of consuming leaf material. The head of the larva is light brown and the abdominal segments have fine yellow hairs. If larvae are disturbed, they wriggle from their silken enclosure and drop to the ground. Pupation generally occurs within the leaf-roll.

Damage

Larvae feed for about 2 weeks before rolling the edge of a leaf to complete development. The leaf folds are constructed with silk threads. Rolled leaves have their undersides exposed, and often the upper surface is skeletonized. Third generation larvae may completely defoliate a vineyard, resulting in sun-scorched berries. In some instances, larvae may feed directly on the berries.

IPM Strategies

In general, populations of grape leaffolder are balanced by the presence of several larval parasites, including *Bracon cushmani* (Muesebeck). However, growers could monitor vineyards with a history of leaffolder outbreaks. Adult moths can be monitored with tent-shaped traps baited with terpinyl acetate or by using blacklight traps. If insecticide treatment becomes necessary, sprays are generally most effective against early instars.

Strawberries

In the USA, California is the largest producer of strawberries, generating more than 50% of the nation's strawberries on over 25,000 acres of land. Florida ranks second in the country in terms of quantity of strawberries produced, followed by Oregon and the state of Washington. During 2001, the total value of strawberries produced in the USA exceeded $1 billion dollars. In the south, strawberries are grown as an annual crop and are cultivated between October and May. In the northeast, strawberries are grown as a perennial crop. Some of the cultivars commonly grown in the north include Kent, Annapolis and Honeoye. In the south and western US, Camarosa, Sweet Charlie, Chandler, and Aromas are fairly common cultivars. Each variety has its own unique characteristics with distinct advantages and disadvantages. Strawberries are a rich source of vitamin C and folic acid. They are relatively low in calories and some varieties are rich in antioxidants. Strawberries are susceptible to several mite and insect pests including the two-spotted spider mite, *Tetranychus urticae* Koch, plant bugs belonging to the genus *Lygus*, tarnished plant bug, *Lygus lineolaris* (Palisot de Beauvois), in the east, and the western plant bug, *L. hesperus* Knight. The strawberry clipper, *Anthonomus signatus* (Say), once was considered a major pest of strawberries, but recent reports have indicated that the floral buds removed early in the season by strawberry clipper are compensated with more vigorous bud growth later in the season, resulting in larger more dense fruit.

Pests of Strawberries, *Fragaria* spp. (Family Rosaceae)

Twospotted Spider Mite, *Tetranychus urticae* Koch (Acari: Tetranychidae)

Distribution

The two-spotted spider mite is distributed widely across North America, and is known to feed on more than 180 species of plants in both greenhouse and outdoor environments. The two-spotted spider mite occurs year-round in the greenhouse, but its presence in the field requires warm temperatures (Fig. 56).

Small Fruit Pests and Their Management, Figure 56 **Twospotted spider mite.**

Biology

The two-spotted spider mite develops through five phases: egg, larvae, proto-nymph, deuto-nymph and adult. The larva can be distinguished from the other stages because it has only six legs and is the size of the egg. The protonymph and deutonymph resemble the adult. Adults are approximately 0.5 mm long and range in color from light green to dark red, usually with two dark spots on the dorsal surface of the abdomen. Adults overwinter under vegetative cover, and mated females begin feeding and laying eggs when temperatures increase. Maturity from egg to adult requires at least 5 days, but may approach 1 month, depending on environmental conditions. Dispersal of two-spotted spider mites can occur by either ambulatory or aerial means. The vast majority of dispersal takes place aerially due to the small size of mites and the amount of time it would take for a spider mite to travel from one plant to another. There are several generations per year.

Damage

Two-spotted spider mite feeds on the underside of strawberry leaves by inserting their mouthparts into the leaf cells and extracting cellular fluid from the plant. The result is chlorosis, which leads to a decrease in photosynthetic activity by the plant and a subsequent reduction in fruit yield. Infested leaves are often mottled brown and the leaf surfaces may be covered with fine webbing. Mite colonies tend to be localized rather than evenly distributed and are more abundant when the weather is dry.

IPM Strategies

Sampling for two-spotted spider mite can be accomplished by collecting leaves from the field and counting the number of mites on individual leaves, generally with the aid of a microscope. Heavy infestations can be treated with reduced-risk miticide. An alternative to treatment with miticides is the inoculative release of predatory mites, primarily in the family Phytoseiidae (Fig. 58). Monitoring for the persistence of Phytoseiidae mites in the fields should be conducted in conjunction with two-spotted spider mite sampling.

Strawberry Sap Beetle, *Stelidota geminata* (Say) (Coleoptera: Nitidulidae)

Distribution

There are several species of sap beetles that affect strawberries throughout the United States, including the strawberry sap beetle, *Stelidota geminata* (Say). Other sap beetles, including the picnic beetle, *Glischrochilus quadrisignatus* (Say), and the dusky sap beetle, *Carpophilus lugubris* Murray, also may be problematic in many areas.

Biology

Adult beetles are brown and somewhat mottled, approximately 3 mm in length with capitate antennae. The elytra are shortened, leaving the terminal abdominal segments exposed. Larvae range in color from white (early instar) to pale yellow (mature) and have a light brown head. The body is elongate and the mouthparts are exposed. Larval development is much shorter compared with the adult lifestage. *Stelidota geminata* pupae are tan colored prior to adult emergence and are about 4 mm in length. Adults emerge in the spring from decaying vegetation and mate and lay eggs near decomposing plant material. Larvae develop in decomposing material in or near the soil before pupating. The cycle from egg to adult takes about 30–35 days.

Damage

The sap beetle is also a contaminant of strawberries, which may cause large batches of fruit to be rejected by processors. In some cases the adults bore into the strawberry fruit, rendering it unmarketable.

IPM Strategies

The sap beetle may be monitored with traps baited with synthetic volatile compounds. Since the beetles are attracted to ripe fruits, insecticide treatments are usually not recommended. One cultural tactic is to harvest berries before they become over-ripe. In addition, damaged, decaying or diseased fruit should be removed from the field.

Strawberry Bud Weevil (Clipper), *Anthonomus signatus* (Say) (Coleoptera: Curculionidae)

Distribution

Strawberry bud weevil is a pest of several small fruits in the northeastern United States and Canada, including strawberries, blueberries, and brambles. This species often is called the "strawberry clipper" because clipped buds are characteristic damage resulting from weevil infestation (Table 11).

Biology

Strawberry bud weevil overwinters as an adult, emerging from protected areas such as mulch and fence lines when temperatures become favorable. Adults are approximately 3 mm in length. They are reddish brown beetles with a pronounced snout. Mated females lay eggs singly inside flower buds and then partially clip the blossom below the bud. The infested bud may remain on the plant or drop to the ground, where egg and larval development occurs. Eggs hatch within 1 week. The larvae are white and develop within the bud, reaching maturity after 3–4 weeks. Adults emerge in early to mid-summer, depending on region.

Damage

The major damage caused by strawberry bud weevil occurs during egg lay, as infested buds wilt and fail to produce fruit. Prior to egg lay, adults also may feed on pollen from unopened buds. Brownish-purple holes in the sepals may indicate pollen feeding, although this type of damage does not necessarily disrupt normal fruit development.

IPM Strategies

Monitoring tactics for strawberry bud weevil should focus on counting the number of clipped buds in a particular area. One method involves placing a 30 × 60-cm frame over plants

Small Fruit Pests and Their Management, Table 11 Selected list of arthropods that affect strawberry production in the United States

Common name	Scientific name	Order	Family
Strawberry spider mite	*Tetranychus turkestani* Ugarov & Nikolski	Acari	Tetranychidae
Two-spotted spider mite[a,b]	*Tetranychus urticae* Koch	Acari	Tetranychidae

[a]also infest brambles
[b]also infest grapes
[c]also infest blueberries and grapes

and counting the number of clipped buds. Growers should pay particular attention to rows located near potential overwintering sites. Insecticide applications may be warranted if the number of clipped buds exceeds 13 per sampling area (30 × 60 cm). Sampling should continue after insecticide applications are made in order to assess the need for further applications.

Tarnished Plant Bug, *Lygus lineolaris* (Palisot de Beauvois) (Hemiptera: Miridae)

Distribution

Tarnished plant bug feeds on wild and cultivated plants throughout North America, although it is a pest primarily in temperate regions. Regarding small fruit production, tarnished plant bug often affects strawberries and brambles (raspberry and blackberry) (Fig. 57).

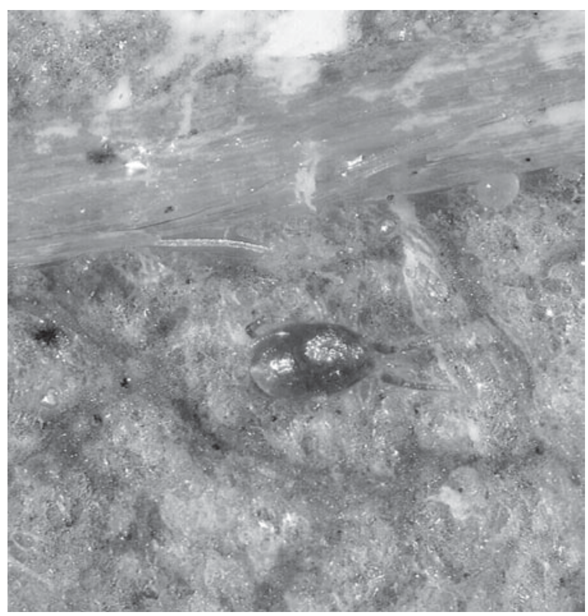
Small Fruit Pests and Their Management, Figure 57 **Tarnished plant bug.**

Biology

Tarnished plant bug adults exhibit a greenish-brown coloration that is mottled with red. Adults are approximately 6 mm in length and are identified by a characteristic yellow triangle at the junction of the wings anteriorly. Tarnished plant bugs overwinter as adults under bark, leaves, and other ground covers that offer protection. Adults become active during the blossoming period of fruit production and feed on nutritive plant juices. Females lay 1 mm long, cream-colored eggs in the plant tissue, either directly on the fruit crop or within adjacent ground cover. There are five nymphal stages, characterized by a progressive color change from green to brown. The entire lifecycle requires 25–40 days, yielding a varying number of generations, depending on seasonal weather conditions.

Damage

Fruit affected by tarnished plant bug feeding exhibits "catfacing," which is the result of tissue development around a centralized wound. Damage caused by egg lay may cause more intense fruit distortion and may be accompanied by one or more blemishes (scabs). The severity of damage resulting from tarnished plant bug injury may vary with cultivars.



Small Fruit Pests and Their Management, Figure 58 ***Phytoseiulus persimilis*, a predatory mite.**

IPM Strategies

There are several techniques that can be used for monitoring tarnished plant bug populations. Direct plant examinations or visual inspections, sticky traps, sweep sampling, and fruit injury counts are only some of the techniques used for monitoring tarnished plant bug activity in the field. Any one of these tactics may be preferred in one setting over another. Sweep netting is a simple way to sample for nymphs in nearby vegetation. Visual examination is a direct method for visualizing insect activity, although adults may fly if disturbed, and this method may vary considerably with weather conditions. Ground cover management, including mowing and tilling, may be useful for reducing migrating tarnished plant bug populations.

Brambles

Brambles are defined as plants belonging to the genus *Rubus* and include blackberries and raspberries. Tayberries are brambles resulting from a cross between blackberry and raspberry. Blackberries and raspberries are the two most common bramble crops grown in the US. In 2001, more than 6,000 acres of blackberries were produced in the US with an estimated value exceeding $14 million dollars. Oregon leads the country in blackberry production with more than 90% of the US sales. Among the brambles, raspberries are cultivated on the largest acreage. The three most commonly types of raspberry grown in the US are red, black and purple. In 2001, approximately 16,000 acres of raspberries were produced in the US with more than 50% of the production coming from the state of Washington. Brambles are susceptible to several key pests including raspberry cane borer, *Oberea bimaculata* (Olivier), rednecked cane borer, *Agrilus ruficollis* (F.), and blackberry psyllid, *Trioza tripunctata* (Fitch).

Pests of Raspberries and Blackberries (Brambles), *Rubus* spp. (Family Rosaceae)

Raspberry Cane Borer, *Oberea bimaculara* (Olivier) (Coleoptera: Cerambicidae)

Distribution

The raspberry cane borer is native to North America and it is found throughout the northeastern United States and Canada (Table 12).

Biology

The posterior region of the head (pro-thorax) is bright yellow with two or three black dots. Raspberry cane borer requires a 2-year cycle to complete its development. Females lays eggs on the canes and then girdle a hole approximately 6 mm in diameter around the eggs. After eggs hatch, larvae bore further into the cane to overwinter into the soil. During the following season, larvae continue to bore into the canes until they reach the raspberry crown. During the second spring mature larvae continue to feed, eventually pupating in the hollow surface of the cane. Adults begin to emerge in early summer and produce eggs shortly after.

Damage

Heavy infestation results in wilted shoots and toppled canes.

IPM Strategies

Canes should be examined weekly for hollow stems and signs of wilting. One cultural technique, which may reduce total infestation of raspberry cane borer, involves the removal of hollow canes and wilted shoots that show signs of injury. After canes are removed, end surfaces should be re-inspected to ensure that no hollow surfaces remain in the existing canes.

Eaton A (1994) Raspberry cane borer, small fruit pest. Extension fact sheet #53, Cooperative Extension Unit. University of New Hampshire, Durham, New Hampshire

Raspberry Fruitworm, *Byturus unicolor* (Say) (Coleoptera: Byturidae)

Distribution

Raspberry fruitworm is distributed throughout the eastern United States wherever raspberries are grown.

Biology

Adult beetles are yellowish brown, hairy and about 8 mm long. Adults lay grayish-white eggs on swollen, unopened blossom buds, which may be deposited at the base of the developing fruit. Eggs hatch into larvae within a few days, and the emerging larvae feed on the developing fruit for 5–6 weeks. Larvae pupate in the soil inside of a cocoon. Raspberry fruitworm overwinters as an adult, and emerges the following year when blossoms begin to develop.

Damage

Raspberry fruitworm larvae feed on raspberry receptacles, causing berries to dislodge from the plant stems. In some cases, larvae feed on internal tissues of immature berries. Adults feed on blossom and foliage but rarely cause significant damage. High populations of adult fruitworm may result in characteristic longitudinal holes in the foliage.

IPM Strategies

Collecting and inspecting known numbers of blossoms and looking for eggs can be used as a strategy for monitoring populations of raspberry fruitworm. Developing berries also should be examined for larvae. Cultural strategies include cultivating the soil to bury raspberry fruitworm pupae and exposing pupae to natural predators. Infested plant debris also should be removed from the soil. The use of some selected reduced-risk insecticides also may play a role in regulating raspberry fruitworm populations.

Occasional Pests of Small Fruits

Japanese Beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae)

Distribution

The Japanese beetle is native to Japan and was first detected in the United States in New Jersey in 1916. Since then, the Japanese beetle has migrated southward into Alabama and Georgia. Specimens also have been collected in Florida, although the Japanese beetle is not considered a pest in that region. High populations of Japanese beetles have been recorded in Michigan and Ohio, whereas isolated populations have been detected in some western states (Table 13).

Biology

Japanese beetle adults are metallic green with an amber hue on their forewings. Adults are about 10 mm long and 7 mm wide with characteristic rows of hair along each side of the abdomen. Adults are active by day and spend the nighttime hours within tunnels in the soil. Within 10 days of emergence females begin to lay eggs in the soil of short grasses and continue to lay eggs for several weeks. Larvae (grubs) are usually cream colored just after hatching. Larvae develop through three instars and turn darker with age as they mature. During the winter, larvae move downward into the soil to hibernate when temperatures are cool. After hibernation, grubs tunnel up through the soil to feed on grasses to complete their development. There is usually one generation per year.

Damage

Adult beetles are generalist feeders that skeletonize the leaves of more than 400 broadleaf plants. Feeding damage is characterized by brown lacy leaves. However, adults also may attack flower buds and fruit, including blueberries and grapes. When populations are high, the adult becomes a contaminant in the harvest of blueberries and grapes, thus interfering with the marketability of the fruit. Larvae generally are not injurious to fruit crops but their existence in the ground cover serves as inoculum for next year's adult population.

IPM Strategies

The strategies for controlling adults and grubs are quite different. Traps baited with a combination of sex and aggregation pheromones are available commercially for monitoring adult populations of Japanese beetle. However, traps may attract adults from adjacent areas, which may increase the potential for damage to fruit crops. When chemical control is warranted, several applications of insecticide may be necessary to provide adequate control since adults continue to emerge all season long. In the past, grubs have been controlled using the bacterial milky diseases *Bacillus popilliae* Dutky and *B. lentimorbus* Dutky. This method has been relatively successful in the eastern United States. Recently, certain species of entomophagous nematodes have been shown to be effective in suppressing larval populations.

Flower Thrips, *Frankliniella* spp. (Thysanoptera: Thripidae)

Distribution

There are several species of flower thrips that affect small fruit production throughout the United States. The eastern flower thrips, *Frankliniella tritici* (Fitch), is found east of the Rocky Mountains, and western flower thrips, *F. occidentalis* (Pergande), occurs throughout the United States and Canada. In the northeast, the blueberry thrips *F. vaccinii* Morgan and *Catinathrips kainos* O' Neil are minor pests in lowbush and highbush blueberries, causing leaf distortion and discoloration in small isolated patches in fields. In Florida, a species of flower thrips, *F. bispinosa* (Morgan), locally called Florida flower thrips, causes significant damage to southern highbush and rabbiteye blueberries. *Frankliniella bispinosa* also has been detected as far north as Georgia (Fig. 59).

Biology

In the absence of microscopic examination, flower thrips species are difficult to distinguish. Members of the genus *Frankliniella* are approximately 1–1.3 mm in length and yellow to brown in color, often

Small Fruit Pests and Their Management, Figure 59 ***Frankliniella bispinosa* thrips.**

with gray blotching across the abdomen. Males are generally smaller and paler than females. Eggs are cylindrical and are laid within the plant tissue, making them difficult to see. Thrips development progresses through several nymphal instars (latter stages sometimes are referred to as prepupae and pupae), each of which resembles the adult morph without wings. Adults and nymphs have rasping mouthparts. Most flower thrips migrate over long distances and are known to have an extensive host range.

Damage

Thrips are capable of causing damage in at least two different stages of fruit development. During the blooming period, thrips feed within the flowers by inserting their mouthparts into developing tissue and remove fluids. The resulting effect can be either aborted or distorted fruits. Thrips also may feed on pollen, causing additional floral abortion. Thrips also may feed on foliage, removing cell sap from plant tissues. If populations of thrips are high during the fruiting period, significant damage to the fruit can be observed, particularly in areas where the fruits are touching or closely clustered. This may result in silvery blemishes resembling a halo. Some species of thrips may be of particular concern for their potential to vector various plant viruses.

IPM Strategies

Because thrips are very mobile, their management can be very difficult. There are several methods available for monitoring flower thrips populations, including the use of sticky traps (white or blue), tapping infested flowers over a hard surface, and dipping infested flowers into alcohol. Grower preference and crop specifics may dictate which monitoring method works best in a particular area. It is also helpful to know which species is being targeted. Several predatory insects may be successful for suppressing flower thrips populations, including the minute pirate bug, *Orius insidiosus* (Say). The fungal pathogen *Beauveria bassiana* has shown potential for control of *F. occidentalis*, and may be a potential agent for control of other thrips species in the future. Cultural methods for control of thrips species include elimination of alternate hosts near the main crop, particularly if the blooming periods overlap.

Small Green Stink Bug, *Piezodorus guildinii* (Westwood) (Hemiptera: Heteroptera: Pentatomidae)

ANTÔNIO R. PANIZZI
Embrapa, Londrina, Brazil

The small green stink bug, *Piezodorus guildinii* (Westwood), is a Neotropical pentatomid found from the southern U.S. to Argentina. It first was described from the island of St. Vincent, and frequently has been reported from Central and South

America. It is a major pest of soybean in South America. In Brazil, this stink bug was seldom found on soybean until the early 1970s. Subsequently, it has become more common, ranging from Rio Grande do Sul (32° S latitude) to Piau (5° S latitude). With the expansion of soybean production to the central, west, and northeast regions of the country, *P. guildinii* is, perhaps, the most important pest of soybean in Brazil.

The list of food plants includes some economically important plants in addition to soybean, mostly legumes such as common bean, pea, and alfalfa. It is reported occasionally on sunflower, cotton, and guava, but it is not believed to be a serious pest of these crops. Native host plants include species of indigo legumes, *Indigofera* spp., in the southern U.S., Colombia, and Brazil. It also feeds on legumes of *Sesbania* and on *Crotalaria*.

Eggs are blackish and laid in two parallel rows. First, second, third, fourth, and fifth instars are 1.30, 2.25, 2.58, 4.60, and 7.87 mm long, respectively. Adults are light green to yellowish, with a red-band at the base of the scutellum, particularly on females (Fig. 60).

Small Green Stink Bug, *Piezodorus guildinii* (Westwood) (Hemiptera: Heteroptera: Pentatomidae), Figure 60 Adult of small green stink bug.

The number of egg masses per female will vary from approximately 3 on soybean up to 37 in some indigo species. Total number of eggs per female will vary from approximately 28 on soybean to approximately 200 on *Indigofera hirsuta* to approximately 500 on *I. truxillensis*. Adults will have a total longevity of approximately 50 days on soybean (mean of female and male) up to approximately 90 days on some of the indigo legumes. Despite its relatively low performance on soybean compared to native legumes, *P. guildinii* is highly detrimental to this crop, as noted previously.

Piezodorus guildinii, like most of the phytophagous pentatomids associated with soybean, feeds primarily on pods. The nature and extent of the damage to this crop is similar to that reported for southern green stink bug, *Nezara viridula*. *Piezodorus guildinii* usually is the first species to appear in soybean fields during flowering or even earlier. Apparently, *P. guildinii* is better adapted to feeding on flowering plants than other pentatomid species. However, it does have to feed on reproductive structures to thrive.

Chemical insecticides, such as monocrotophos and endosulfan, are the major weapons used to control *P. guildinii*. Natural enemies include several species of egg parasitoids such as *Telenomus mormideae* Lima, *Telenomus* sp., *Trissolcus basalis* (Wollaston), *T. scuticarinatus* Lima, *Ooencyrtus submetallicus* (Howard), and *Ooencyrtus* sp. Nymphs and adults of the pentatomid *Tynacantha marginata* Dallas were reported as predators of fifth instars, and adults are reported to be a substantial part of the diet of some birds in Argentina.

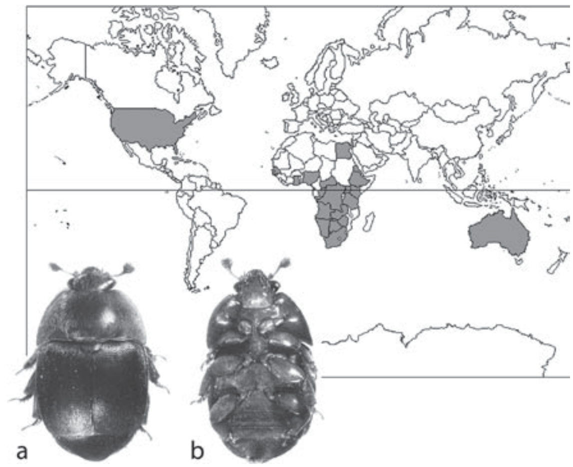
Small Hive Beetle, *Aethina tumida* Murray (Nitidulidae: Coleoptera)

Jamie Ellis[1], Amanda Ellis[2]
[1]University of Florida, Gainesville, FL, USA
[2]Florida Department of Agriculture and Consumer Services, Division of Plant Industry, Gainesville, FL, USA

The small hive beetle, *Aethina tumida* Murray, is native to sub-Saharan Africa where it is an occasional pest in colonies of African subspecies of western honey bees (Hymenoptera: Apidae, *Apis mellifera* L.). However, the beetle has been found outside of its native range where it can cause considerable damage to colonies of European subspecies of honey bees. Because of its spread, the SHB is studied increasingly, both for its economic importance and biological significance (Fig. 61).

The small hive beetle was confirmed in the southeastern USA in 1998 in a commercial apiary in Florida, but previously unidentified specimens indicate its presence in the USA since at least 1996. The small hive beetle initially occurred in port cities such as Charleston, South Carolina, and Savannah, Georgia, as well as parts of Florida. However, it has spread throughout the entire eastern half of the US and is now reported in western states.

Small hive beetles were found in Australia in the early 2000s. They initially were found in Sydney and Brisbane; both are port cities. From there, small hive beetles have spread in Australia, being firmly established there. The small hive beetle was found in Portugal, but it was eradicated quickly after its detection.



Small Hive Beetle, *Aethina tumida* Murray (Nitidulidae: Coleoptera), Figure 61 **An adult small hive beetle, viewed dorsally (a) and ventrally (b) (photo by James Ellis, University of Florida), and its worldwide distribution (from Ellis and Munn (2005) Bee World 86:88–101).**

Description

Newly emerged small hive beetles are light brown, becoming progressively darker (almost black) as their exoskeleton hardens. These color changes may occur in the pupal cell before the adult emerges. Adult female (5.7 ± 0.02 mm) small hive beetles are generally longer than males (5.5 ± 0.01 mm) but both are nearly identical in width (about 3.2 mm). Adult females (14.2 ± 0.2 mg) are also heavier than males (12.3 ± 0.2 mg) and occur in greater proportions of the population. Naturally occurring small hive beetles can vary greatly in size, possibly depending on diet, climate, etc.

Small hive beetle eggs are 1.4 × 0.26 mm (l × w) and pearly white in appearance. Newly emerged small hive beetle larvae have relatively large heads and numerous protuberances covering their bodies. Larval growth rate varies depending on diet, but the majority mature in 10–14 days. Upon full maturation, larvae will have reached a length and width of 9.5 mm and 1.6 mm respectively. Early-stage pupae of small hive beetles are pearly white, having characteristic projections on the thorax and abdomen. Later-stage pupae darken as their exoskeleton develops and hardens.

Life Cycle

Although not fully known, small hive beetle biology is becoming better understood. Upon emerging from the ground (where they pupate), adult small hive beetles search for honey bee colonies, probably identifying the host colony by a suite of olfactory cues. Studies have shown that small hive beetles fly before or just after dusk and that odors from adult bees and various hive products (honey, pollen) are attractive to flying small hive beetles. Some studies have suggested that small hive beetles also may find host colonies by detecting honey bee alarm pheromone. Additionally, small hive beetles carry a symbiotic yeast that produces honey bee alarm pheromone when deposited on pollen reserves in the hive.

Upon locating and entering the host colony, adult small hive beetles seek out cracks and crevices where they hide from bee aggression. Remarkably, honey bees station guards around the cracks where small hive beetles hide. The "prison" guards keep the small hive beetles confined to the cracks and out of the brood combs where there is an ample supply of honey, pollen, and brood on which small hive beetles reproduce. Small hive beetles do not starve in these prisons as they are able to solicit food trophallactically from their bee captors. In this behavior, small hive beetles use their antennae to rub the bees' mandibles and induce the bees to regurgitate. Small hive beetles then feed on the regurgitated substance.

Mating behavior of small hive beetles (including whether female small hive beetles mate once or multiple times) is not understood, but adult small hive beetles do not appear to be sexually mature until about 1 week post-emergence from the soil. If allowed to reproduce, female small hive beetles will oviposit directly onto food sources such as pollen or brood combs. Alternatively, female small hive beetles may deposit irregular masses of eggs in crevices or cavities away from the bees as female ovipositors are long and flexible, being perfectly designed to lay eggs in tiny, concealed places. A female small hive beetle may lay 1,000 eggs in her lifetime, although data suggests that the number of eggs produced in one female's lifetime might be upwards of 2,000. The majority of these eggs hatch within 3 days; however, some eggs are still viable and hatch after 5 days. Humidity appears to be a crucial factor influencing hatch rates as small hive beetle eggs are prone to desiccation if exposed to circulating air and relative humidity below 50%.

Newly hatched larvae immediately begin feeding on whatever food source is available, including honey, pollen, and bee brood, yet they have demonstrated a preference for bee brood. Maturation time for larvae is generally 10–14 days although some may feed longer than a month. Once the larvae finish feeding, a "wandering" phase is initiated where larvae leave the food source and migrate out of the colony to find suitable soil in which to pupate. It is believed that the bulk of larvae do this at night in the cover of darkness.

Larvae in the wandering stage may wander great distances from the hive to find suitable soil. Despite this, most larvae pupate within 90 cm of the hive. Nearly 80% of the larvae burrow down into the soil less than 10 cm from the soil surface but generally not more than 20 cm. Once larvae cease burrowing, they construct a smooth-walled, earthen cell in which they pupate. The period of time spent in the ground pupating can vary greatly depending on factors such as soil temperature, etc. However, the majority of adults emerge after being in the soil 3–4 weeks. Upon adult emergence, the entire life cycle begins again. The turnover rate from egg to adult can be as little as 4–6 weeks; consequently, there may be as many as six generations in a 12-month period under moderate climatic conditions.

Damage

In its native range, the small hive beetle regularly occurs in honey bee colonies but it does not cause damage in strong, healthy ones. In the USA and Australia though, small hive beetle damage in European colonies follows a characteristic pattern: (i) adult invasion into colonies; (ii) population build-up of small hive beetles; (iii) reproduction of small hive beetles; (iv) significant damage to brood, pollen, and honey stores by feeding small hive beetle larvae; (v) mass exodus of larvae from the colony; (vi) pupation in the soil; and (vii) emergence as adults and subsequent re-infestation of colonies. There is fermentation of hive products (particularly honey) associated with feeding larvae. This likely occurs due to specific yeasts associated with the small hive beetle. Honey damaged by small hive beetles is rendered foul and unfit for human consumption. Colonies heavily infested with adult small hive beetles may abscond (entirely leave the nest) although the number of adults needed to elicit this behavior often must be high (>1,000 small hive beetle adults per colony).

Small hive beetle damage to living colonies is not the only loss experienced by beekeepers. Adult and larval small hive beetles can be a significant problem in unprocessed honey crops stored in the honey house. As a result, beekeepers realize the necessity of extracting honey quickly and moving the equipment out of honey houses to discourage the ensuing build-up of small hive beetle larvae. Further, stored supers of honey or supers containing pollen residues are prime targets for small hive beetle reproduction and subsequent damage.

Despite the fact that small hive beetles may cause considerable damage in bee colonies in the USA, they increasingly are considered a secondary pest of bee colonies, much like the greater (*Galleria mellonella* Linnaeus) and lesser (*Achroia grisella* Fabricius) wax moths. Colonies hosting other bee diseases/pests are more likely to suffer small hive beetle damage than are healthy colonies. It appears that small hive beetles rarely kill a colony. They usually complete the job started by another colony malady, whether disease/pathogen or management-related.

Control

Since the introduction of small hive beetles into the United States, little progress toward developing chemical control methods has been made. As such, more attention has focused on cultural, biological, and genetic controls. Cultural/mechanical controls result from a change in practice with the intention of limiting, but not eradicating, a pest. Practices such as removing honey, bits of comb, and cappings from around the honey house will minimize foodstuffs to which small hive beetles may be attracted. It is also important to extract supers of honey quickly to reduce the damage that small hive beetle adults and larvae do to standing, unprotected crops. Reducing the relative humidity to 50% in honey houses and other places where honey is stored inhibits small hive beetle eggs from hatching. In the apiary, one should eliminate, requeen, or strengthen weak colonies to reduce colony stress and to make the colony better able to deal with small hive beetles. One should avoid other conditions that might lead to colony stress such as brood diseases, mite problems, wax moth activity, failing queens, excessive swarming and over-supering.

Two effective in-hive trapping devices have been developed for small hive beetle control. The first, the Hood beetle trap, fits in a standard hive frame. It can be filled with apple cider vinegar to attract and drown adult small hive beetles. A second trap, the West beetle trap, is designed to rest on the bottom board of a colony. It is covered with a lid containing small holes through which small hive beetles can move but through which bees cannot follow. The idea is that small hive beetles run from bee aggression through the holes in the lid of the trap, and into a tray filled with vegetable oil. The small hive beetle then becomes coated with oil and presumably suffocates.

Other control measures are being developed. First, a symbiotic yeast associated with the small hive beetle has been discovered. This yeast, when mixed with pollen, attracts other small hive beetles to weakened colonies. Researchers are taking advantage of this relationship and are developing traps using the yeast mixed with pollen as bait for adult small hive beetles. Secondly, two species of soil-dwelling nematodes have demonstrated activity against pupating small hive beetles. Finally, researchers have shown that some honey bee colonies are able to detect and remove brood that has been oviposited on by small hive beetles. This behavior, called hygienic behavior, can be selected for in-breeding programs and can help reduce small hive beetle problems. Research in these areas, as well as in others, is ongoing.

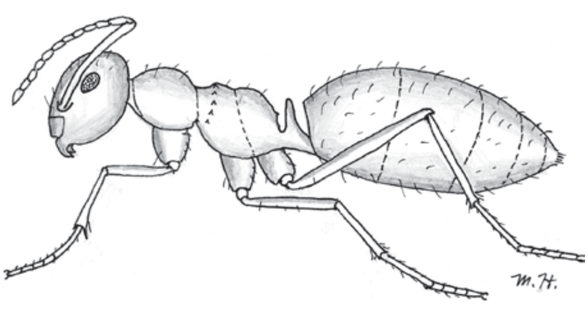
Small Honey Ant, *Prenolepis imparis* (Say) (Hymenoptera: Formicidae)

MARK HEADINGS
The Ohio State University Agricultural Technical Institute, Wooster, OH, USA

The small honey ant, *Prenolepis imparis*, is also sometimes referred to as the false or winter honey ant. The term "false honey ant" is used to distinguish it from the true honey ants, and the term "winter honey ant" describes its characteristic of remaining active even during cold weather. This ant species is reported to be widely found in areas across the continental USA.

Description

The worker ant is approximately 3 mm in length and has a light to dark brown color and the queen is approximately 7 mm in length. When the ant becomes filled with food, however, it may appear larger due to enlargement of the gaster (abdomen). Other identifying characteristics of the ant are: (i) the scape (basal segment) of the 12-segmented antennae is longer than the ant head, (ii) the thorax is hour-glass shaped, (iii) there is only one node on the petiole, (iv) the abdomen is triangular in shape and wider than the head when viewed from above, (v) there is a small tight circle of hairs on the tip of the abdomen, (vi) the ant appears rather shiny, and (vii) it has no foul odor when crushed (Fig. 62). Ants are social insects and therefore share food with other members of the colony. This species has a large abdomen relative to overall body size, which thereby accommodates carrying a larger amount of food per foraging trip. Replete ants serve as honey containers, which may comprise up to 80% of the workers prior to aestivation; however, it was observed that by end of summer



Small Honey Ant, *Prenolepis imparis* (Say) (Hymenoptera: Formicidae), Figure 62 **Small honey ant, *Prenolepis imparis* (Say).**

in Missouri, numbers had fallen to about 67%. This drop occurred during the period when workers were not foraging and larvae were being fed. During this sequence in the life cycle of the small honey ant, eggs are laid around mid-July, larvae pupate around mid-August and pupae emerge around mid-September. Length of development time from egg to adult may, however, be dependent on temperature. New male and female ants produced are kept in the nest over winter until their nuptial flights in early April. During the winter months no brood is retained in the nests.

Behavior

Small honey ant, *P. imparis*, is a cold-temperate ant species. It initiates ground surface activity (foraging) when temperatures reach just above freezing and discontinue such activity at about 20°C. The optimal humidity for ground surface activity ranges from 80 to 100%. In fact, this ant does not hibernate during the cold season of the year, as many ant species do, although, during the warmer season of the year, it may exhibit aestivation for a period of 1–2 months in areas such as Ohio and up to 7–8 months in climatic conditions of Florida. In Missouri, *P. imparis* was primarily active above-ground during the day in early March due to optimum temperatures occurring at midday, whereas, in early April the ants were primarily nocturnal due to elevated daytime temperatures. Ants, being social insects, exhibit behaviors that are designed to benefit the entire colony, whether it be gathering food, caring for immature members, or defending the colony and its food sources. Ant species vary in the intensity of their defensive behavior. Workers in the genus *Myrmecia*, for example, defend only the colony nest area. In contrast, workers of *P. imparis* have been observed defending rotting fruit as far as 1.5 m from the nest entrances. This is expressed by exhibiting aggressiveness towards other insects approaching the food source and by also emitting a highly repellent chemical from the posterior end of the abdomen. An extreme example is the case of wood ants, *Formica rufa*, which travel on pathways 200 m in length leading to trees where they forage and aggressively protect their food sources from other insects.

Colonies

It has been observed in one study in Florida that the number of ants per colony ranged from 600 to 10,300, and nesting sites were generally found in soil in open shaded areas. The typical nesting site has a small mound surrounding the single nest entrance which leads to a vertical tunnel extending to depths of 2.4–3.6 m (where $n = 8$ and mean = 2.83 m) with horizontal chambers positioned at intervals along the tunnel. Nest tunnels are thought to be only about one-third or less as deep in more northern states such as Ohio and Missouri. Likewise, the upper nest chambers may only be a few cm below the surface of the ground compared to 60 cm in Florida. It is suggested that soil type and temperature could be factors related to chamber depth and distribution. However, the small honey ant may also be found nesting in or around homes, especially during the colder season of the year. Winged males and females typically begin their mating flights during the first warm days of spring, in April or May, in more northern states. This is earlier than many other ant species, which are just completing their winter dormancy by that time. Most mating likely occurs on the surface of the ground. Following mating, the inseminated queen breaks off her wings and then attempts to establish a new colony in the soil. Twenty nests of *P. imparis* were excavated in Missouri and no queens were seen in three nests, one queen in each of 15 nests and two queens in each of two nests. Eight nests examined in northern Florida revealed that two nests had one queen each and the rest were polygynous, with up to six queens per nest (mean = 4.14). It has been suggested that in Florida, worker ants may live for 2 years or more and that a colony may continue to function for over 9 years.

Nutrition Sources

During aestivation, honey from replete workers is also used for larval development. It has been observed in Florida that brood rearing during aestivation is highly dependent upon large amounts of fat and other nutrients stored in the replete workers. The weight of corpulent (obese) workers ranged up to 8 mg (average of 5.4 mg) and the weight of foragers was 2.0–2.2 mg. Elsewhere the mean dry weight of *P. imparis* has been recorded as being 0.7 mg (where $n = 20$), with substantial within-colony variation. Emergence from aestivation seems to coincide with time of fruit maturation in Missouri. The small honey ant is in great need of nutrition at that time and readily feeds upon fruit available. In general, this species feeds upon sweet substances from certain honeydew-producing insects (aphids, scales, and treehoppers; order Hemiptera), extrafloral nectar produced by plants, and upon tender plant tissues such as flower buds. It has been reported, however, that in baiting trials, *P. imparis* demonstrated a preference for protein-fat food (tuna over sugar baits). They have been observed to feed upon certain other insects as well as dead earthworms. In addition, these ants may be found feeding upon sweetened foods and beverages in house kitchens where ant foraging traffic appears to flow along trails as a result of laying down scent markers (pheromones) as they travel.

This species may be considered a nuisance when it is active in or around homes, especially when feeding on fruits, baked goods, meats, and sugar products. They have also been known to cause some plant damage as a result of chewing into soft tissues of certain flower buds to feed upon sugar sweetened plant sap. In such cases, the use of an insecticide may be warranted.

Small Rice Stink Bug, *Oebalus poecilus* (Dallas) (Hemiptera: Heteroptera: Pentatomidae)

ANTÔNIO R. PANIZZI
Embrapa, Londrina, Brazil

The small rice stink bug, *Oebalus poecilus* (Dallas), also known as *Solubea poecila* (Dallas), is perhaps the most important pest of rice in South America. Although showing preference for Gramineae such as rice, barley, oat, corn and wheat, it also is associated with soybean, cotton, and guava. There are about 42 species of host plants for this pest within the state of Rio Grande do Sul, Brazil.

Adults are rust to black dorsally, with yellowish spots; the venter usually is darker in females than males. Males are 6.9–8.3 mm long and females are 7.4–9.5 mm long. The small rice stink bug has distinctive morphs that distinguish non-diapausing and diapausing adults. The adult key characters are the pronotal shape and color of the body (Fig. 63). In the non-diapausing summer morph, the lateral angles of the pronotum are spinose and the predominant dorsal

Small Rice Stink Bug, *Oebalus poecilus* (Dallas) (Hemiptera: Heteroptera: Pentatomidae), Figure 63 **Small rice stink bug.**

coloration is dark brown, almost black; in the overwintering diapausing morph, the lateral angles are rounded and the predominant dorsal coloration is light brown.

Despite the importance of *O. poecilus* as a pest, little has been published on its biology. The egg color changed due to the embryonic development, which allowed the age of the egg to be estimated. *Oebalus poecilus* is reared successfully in the laboratory using panicles of the weed *Polygonum punctatum*.

Nymphs and adults fed on the developing grains of rice, and the nature and extent of damage depend on the stage of grain development at the time of attack. Florets fed upon during early endosperm formation (milk stage) resulted in either empty glumes or severely atrophied kernels. Feeding during later stages of endosperm development (dough and hard stages) resulted in a chalky discoloration around the feeding site. Rice with this damage, known as "pecky rice," is weakened structurally and often breaks under mechanical stress during milling. Furthermore, the pecky rice that escapes breakage is of inferior quality as a finished product because of the discoloration. Other types of damage include withering of young plants, reduction of tillers, and grain emptiness due to feeding activity.

In spite of being a major pest, no effective method to manage *O. poecilus* on rice fields has been developed. However, a pest management strategy for *O. poecilus* in southern Brazil based on planting time has been recommended. This method consists of delaying and restricting the time of rice planting. Planting the crop in the first half of December results in a synchrony between the pest and the crop because the developing grain is available in March when bugs entering the adult stage are diapausing morphs that migrate to hibernating sites instead of remaining in the crop. The result is that damage is considerably reduced.

Natural enemies of *O. poecilus* include the egg parasitoid *Telenomus mormideae* Lima, and the nymph and adult parasite *Beskia cornuta* Brauer & Bergenstan (Diptera: Tachinidae).

Small RNA Viruses of Invertebrates

PAUL D. SCOTTI[1], PETER D. CHRISTIAN[2]
[1]The Horticulture and Food Research Institute of New Zealand Mt. Albert Research Centre, Auckland, New Zealand
[2]National Institute for Biological Standards and Control, Potters Bar, Hertfordshire, UK

Baculoviruses are the best-known viruses associated with insects. They have large, rod-shaped particles that measure around 30–60 nm by 250–300 nm which contain double-stranded DNA genomes. Baculovirus particles are most often embedded in large proteinaceous occlusion bodies that usually measure between 0.5 and 2 μm and thus are visible by light microscopy. However, during the last 30–40 years a large number of non-occluded, small (25–40 nm in diameter), icosahedral viruses have been reported in a variety of insects and other invertebrates. With their small size, spherical appearance, and genomes comprised of RNA, they have frequently received the general epithet picornaviruses. This name derives from the combination of terms pico (=small) + RNA + viruses. However, to avoid confusion with the recognized taxonomic group of vertebrate viruses known as the Picornaviridae, the insect viruses are best referred to by the more general term small RNA viruses (SRVs). Wherever possible we have used the terminology and nomenclature recognized by the International Committee for Taxonomy of Viruses (ICTV) in their VIIth report.

There are three recognized families of invertebrate SRVs: Nodaviridae, Tetraviridae and Dicistroviridae (previously termed the "cricket paralysis-like viruses"). In addition, there is an emerging grouping of picorna-like viruses that show superficial similarity to the Picornaviridae. The basic characteristics of these four groups are presented below. Moreover, while a large number of SRVs still remain unclassified and show no affinities with other recognized groups of viruses, we also provide a brief description of some of the more novel virus-types to be found among this more ad hoc assemblage. In the final sections of this chapter, we also provide a brief summary of the general pathology of insect SRVs and of their potential for use as biocontrol agents and biopesticides.

Nodaviridae

This is a unique and well-studied group with virus representatives from both vertebrate and invertebrate hosts. The members of the family from the genus *Alphanodavirus* generally infect insects while those from the genus *Betanodavirus* are those isolated from fish species. The nodavirus genome is comprised of two separate single-stranded RNAs: RNA1 (approximately 3,100 nucleotides long) and RNA2 (approximately 1,400 nucleotides long). The 30 nm diameter virus particles are primarily assembled from a single protein of 40,000–45,000 molecular weight (MW) whose precursor is coded by RNA2. The protein(s) that form the structural shell (the capsid) which surrounds the viral nucleic acid generally are referred to as the capsid proteins. The type virus of the family, Nodamura virus (NV), was isolated from *Culex* mosquitoes but is able to replicate in other invertebrate hosts (e.g., *Galleria melonella* larvae and honey bees, *Apis mellifera*) as well as in suckling mice. There are also nodavirus isolates from Lepidoptera (Boolara virus (BoV) from the hepialid, *Oncopera inticoides* and gypsy moth virus from *Lymantria ninayi*), and from Coleoptera (black beetle virus (BBV) from *Heteronychus arator;* Flock House virus (FHV) and Manawatu virus (MwV) from *Costelytra zealandica*). Surprisingly, FHV has been shown to replicate and assemble infectious virus particles in some plants, although these infections only occur if the viral genome is introduced directly into the plant cells (by a process known as transfection). Some of the alphanodaviruses (e.g., FHV, BBV) generate extraordinarily large yields (milligram quantities of virus) during laboratory infections of two *Drosophila* cell lines (i.e., Schneider's Line 1 and Line 2 cells). They also are capable of establishing persistent infections in these cell lines under certain conditions and one nodavirus, New Zealand virus (NZV; also known as *Drosophila* line 1 virus, DLV) is most likely to have resulted from a chance laboratory infection of this continuously cultured cell line.

Tetraviridae

Tetraviruses have been isolated so far only from, or shown to infect, Lepidoptera, mainly saturniid, limacodid and noctuid moths. The particles of tetraviruses are relatively large (38–40 nm in diameter) and exhibit a lower density than most of the other SRVs of insects (i.e., approximately 1.30 g/ml in caesium chloride cf. 1.34–1.43 g/ml for the dicistroviruses and picorna-like viruses). The group name is derived from the unusual $T = 4$ (tetra) symmetry of their particles which contrasts to the $T = 1$ or $T = 3$ symmetry common to most other small RNA viruses. The major tetravirus capsid protein is large, around 60,000 MW, although a minor protein of 7,000–8,000 MW can also be present in some types. The tetraviruses are divided into two genera: Betatetravirus (the *Nudaurelia* β-like viruses) and Omegatetravirus (the *Nudaurelia* ω-like viruses), although the majority of isolates have yet to be assigned to either group. Members of both genera contain a major single-stranded RNA approximately 5,300–6,500 nucleotides long. However, Omegatetraviruses also contain a second, smaller strand of RNA approximately 2,500 nucleotides long that has been shown to code for the capsid protein. The betatetraviruses *Darna trima* virus (DtV) and *Setothosea asigna* virus (SaV) (*Thosea asigna* virus) have been successfully used in biological control programs directed against their primary limacodid hosts, which are pests of oil palms. Field trials with an Omegatetravirus, *Heliothis armigera* stunt virus (HaSV), have indicated that it has potential for the control of the cotton bollworm (*Helicoverpa armigera*) even though no natural epizootic of the virus has been recorded.

Picorna-Like Viruses

The vertebrate Picornaviridae include such well-known members as poliovirus, hepatitis A virus (HAV) and foot-and-mouth disease virus (FMDV), as well as the plethora of viruses whose infections result in the common cold (rhinoviruses). Although the derivation of the family name simply alludes to being small RNA viruses, the true picornaviruses all have three major capsid proteins which encase a ssRNA genome around 7,500 nucleotides long. Many picornaviruses also have a fourth, internal capsid protein. During infection, the genomic RNA is translated to produce a single, long polypeptide (greater than 200,000 MW). This is cleaved to produce the various non-structural proteins (involved in RNA replication and protein processing) observed during the replication cycle as well as the capsid proteins which eventually are assembled into mature virions which contain the RNA genome.

Although a number of the invertebrate small RNA viruses are remarkably similar to picornaviruses with respect to their particle diameters, densities and protein compositions, it is at the molecular level of the genome where important differences have recently become apparent. Thus, while these recent genomic studies have produced evidence that some insect SRVs produce a single polypeptide from the genomic RNA and have their genomes organized like the picornaviruses with their structural proteins at the 5′ end of the genome, the specific arrangement of the capsid proteins is more like the discistroviruses (see below). Three viruses have, to date, been found to have such characteristics, namely Infectious flacherie virus (IFV) of silkworms, sacbrood virus (SBV) of honeybees and *Perina nuda* picorna-like virus (PnPV) from the ficus transparent wing moth, *Perina nuda*.

Other picorna-like SRVs are either insufficiently characterized or, like the type member, Cricket paralysis virus (CrPV), have been shown to have a genome structure and replication characteristics that warrant them being placed in a separate group, the so-called Cricket paralysis-like viruses or Dicistroviridae.

Dicistroviridae (Cricket Paralysis-Like Viruses)

A number of other insect SRVs originally isolated in the 1960s and 1970s, such as CrPV, *Drosophila* C virus (DCV) and IFV, also were thought to be picornaviruses since they produced large precursor polypeptides which were then post-translationally cleaved to produce three major capsid proteins and the non-structural proteins. However, there were a number of discrepancies which suggested that these well-studied insect viruses, as well as others, represented a novel category of SRVs. The proteins observed during infection, for example, were produced in unequal amounts, i.e., some were present at significant molar excess whereas equivalent amounts would be expected from the true picornavirus strategy. Also, partial sequence analysis indicated that the 3′ end of the genome (where picornaviruses code for the non-structural proteins) appeared to be directing the synthesis of the virus capsid proteins. The sequencing and analyses of the complete genomes of DCV and several other viruses, including CrPV, has since revealed that these viruses actually translate their RNA in two separate parts in stark contrast to the true picornaviruses. The existence of two separate cistrons (or Open-Reading Frames, ORFs) is the derivation of the name, Dicistroviridae. Interestingly, these viruses also use a novel method of translating the polyprotein; the more 3′ of the two ORFs has dispensed with the initiation codon used for starting the translation, of virtually every other eukaryotic protein. Other confirmed dicistroviruses are the lepidopteran *Plautia stali* intestine virus (PSIV); several viruses isolated from hemipterans (*Triatoma* virus, TrV; *Rhopalosiphum padi* virus, RhPV; Himetobi P virus, HiPV); and the hymenopteran isolates Acute bee paralysis virus (ABPV) and Black queen cell virus (BQCV). As more viruses are sequenced, the Dicistroviridae will undoubtedly accumulate more members. Recently, a virus that infects penaid shrimp (Taura syndrome virus) has been found to have all of the characteristics of a discistrovirus, demonstrating that these viruses are not restricted to the Insecta.

Unclassified Viruses

Most of the insect SRVs isolated to date remain unclassified. These include observations made of presumably RNA-containing virus-like particles in insect extracts examined by electron microscopy or crystalline arrays noted in thin sections. There are also virus isolates which are reasonably well characterized biophysically but which still defy classification because they do not easily fit into pre-established taxonomic categories. Some have unique features, like the lemon-shaped particles of Chronic bee paralysis virus (CBPV) and *Drosophila* RS virus or the knobbed capsid structure of kelp fly virus (KFV). At present, there is insufficient data to confidently classify these viruses. Other unclassified examples include the icosahedral *Acyrthosiphum pisum* virus, which produces a single major capsid protein and several smaller capsid proteins from an array of overlapping ORFs, and Bee virus X and Bee virus Y that have only single capsid proteins of around 50,000 MW.

Pathology of SRVs

Despite the size of their single-stranded RNA genomes, which comprise only about 3–15 genes, SRVs often are capable of rapidly killing or severely debilitating their host. In other instances the SRVs appear to be benign, existing as latent or unapparent infections in their hosts who show no obvious symptoms of infection. Thus, the presence of SRVs may remain undetected for years until their hosts display obvious symptoms which in many instances seem to be associated with increased stress in the host. For example, during studies on the Australian field cricket, *Teleogryllus commodus*, in the 1960s, apparently healthy young crickets were collected and brought into the laboratory. Subsequently, in these large overcrowded laboratory colonies some crickets became paralyzed and died. The paralytic disease, which spread rapidly and devastated the colony, was found to be caused by the now well-known Cricket paralysis virus.

Similar outbreaks of other virus diseases in laboratory colonies of insects are not unheard of even in the best-maintained rearing facilities. However, the symptoms of disease often are difficult to define. They may range from reduced longevity of the host insect (*Drosophila* A virus and *Drosophila* C virus), general lethargy (*Setothosea asigna* virus), through to the more obvious symptoms of paralytic disease (CrPV and Aphid lethal paralysis virus) and inability to molt or developmental stunting (*Helicoverpa armigera* stunt virus). Many insect SRVs are readily transmitted from individual to individual but many also are transmitted through the germ-line to the progeny of infected individuals. In the latter case, surface sterilization of eggs using low concentrations of hypochlorite often can eliminate the offending SRV but re-infection from laboratory sources can occur readily.

Potential for Insect SRVs as Biocontrol Agents and Biopesticides

SRVs replicate in the cytoplasm of infected cells and may produce on the order of 250,000–1 million particles within each infected cell during their 12–24 h replication cycle. Thus, their capacity to increase in number and spread to uninfected individuals is enormous. This, coupled with the often severe pathological effects of infection, makes them candidates for use as biological control agents or biopesticides of insect pests. There are several examples of their successful use in the field. In the 1960s in Uganda, the lasciocampid moth *Gonometa podocarpi* was a serious pest of pine plantations. Some larval cadavers were found to contain a small RNA virus and a crude extract of these, applied in areas where no diseased larvae had been detected, resulted in effective control of the pest. Other examples are in the Indonesian states of Sabah and Sarawak in the early 1970s with the control of *Darna trima*, a pest of oil palms and in the 1990s with *Epicerura perigrisea*, a lepidopteran defoliator of two economically important tree species in the Ivory Coast.

There has been some reluctance to seriously consider the insect SRVs as biocontrol agents/biopesticides primarily because of similarities to the vertebrate picornaviruses. Safety testing, as with any biological agent, would be required. Host range considerations also would be important since some of the SRVs can affect a wide range of insect hosts. CrPV, for example, has been shown to multiply in a large number of species from five different insect orders (Lepidoptera, Orthoptera, Diptera, Hymenoptera and Heteroptera) and arguably has the widest host range of all known viruses. Some SRVs (e.g., the tetraviruses) have a highly restricted host range and may infect only a few lepidopteran species. Others, like kelp fly virus (KFV), may infect only a few species but from different orders (Diptera and Lepidoptera). The SRVs are particularly attractive control agents for pests where no baculoviruses are available.

The host range of any SRV contemplated as a biological control agent would require specific tests with reference to the ecological considerations of the areas in which their use was contemplated. The use of selective application strategies or baits may be advantageous. Economic concerns may limit commercial production of SRVs although large quantities, in some cases, can be produced directly in insect hosts or in available insect cell lines. However, local cottage industry production and application as in the cases in Uganda, Sabah and Sarawak, and the Ivory Coast may be the most feasible alternative in many situations.

Smirnoff, Vladimir A.

Vladimir Smirnoff was born on 1 September, 1917 in St. Petersburg, Russia, and he completed a degree at the Forest Institute of the Soviet Union and then attained his Ph.D. from the Forestry Academy. Early in his career he became interested in forest pests. He left the USSR near the end of World War II and became a research entomologist with INRA in Morocco, studying scale insects of palms. He completed another Ph.D. at the Sorbonne in France.

In 1957, Smirnoff moved to Quebec, Canada, and became an insect pathologist with the Canadian Forest Service. This led to important work on several insect pathogens of forest insects, and he became a leading voice for biological control in Canada. He is best known for his effective and pioneering work on the use of the bacterium *Bacillus thuringiensis* for control of spruce budworm outbreaks. This led to general use of *B. thuringiensis* for control of lepidopterous pests in forests and agriculture.

Smirnoff earned many recognitions, including the Parizeau Award of the French Canadian Association for the Advancement of Science, a medal from the Chemical Institute of Canada, and an award of merit from the Quebec Order of Engineers. He was a prolific publisher, authoring more than 300 publications. He retired in 1984 and died on 1 November, 2000.

Smith, John Bernhardt

John B. Smith was born at New York City, New York, USA, on November 21, 1858. Though admitted to the bar in 1879, after practicing for a few years he abandoned the legal profession to pursue a career in entomology. He had many interests and proficiencies, and became known as both an economic entomologist and a taxonomist. The members of the Brooklyn Entomological Society were likely responsible for switching Smith from a legal to an entomological career. Initially he worked for the United States Department of Agriculture, but in 1886 he became assistant curator in entomology at the U.S. National Museum. There he published some excellent works including "Monograph of the Sphingidae of America North of Mexico," "A preliminary catalogue of the Arctiidae of temperate North America," "A revision of the lepidopterous family Saturniidae," and "Contributions toward a monograph of the family Noctuidae." In addition to this work on Lepidoptera he also studied Coleoptera while at the Museum, and in 1889 moved to Rutgers University. In 1894 he became state entomologist for New Jersey. Though taxonomy was Smith's first interest, he applied his considerable energy and enthusiasm to solving the state's pest problems, and so became involved in insecticide studies aimed at vegetable, fruit, shade tree, livestock and medical pests. A particular success was demonstration of the effectiveness of fish-oil soap for suppression of San Jose scale. However, he is best known for the development of mosquito management techniques for the New Jersey salt marshes, which emphasized ditching and draining. His vision of ridding New Jersey of salt marsh breeding mosquitoes was met with ridicule by the state legislature, but Smith was both intelligent and persistent, so he persevered and eventually the legislature appropriated funds to support this project. One of the important concepts that he promoted was that mosquitoes did not honor municipal boundaries, and that mosquito control had to be handled on a large geographic scale. Smith's approach was quite effective at reducing salt marsh mosquitoes, and eventually became adopted all along the Atlantic coast of the United States. Smith authored more than 600 titles, including several important books, including "Mosquitoes occurring within New Jersey, their habits, life history, etc.," "Catalogue of the Lepidopterous superfamily Noctuidae found in boreal America," "Explanation of terms used in entomology," and "Economic Entomology." Smith belonged to many societies, often serving in a leadership role, and was a fellow of the American Association for the Advancement of Sciences, and the New York Academy of Sciences. He died March 12, 1912.

Smith, Harry Scott

Harry Smith was born at Aurora, Nebraska, on November 29, 1883. He obtained his A.B. (1907) and M.S. (1908) degrees from the University of Nebraska. From 1909 to 1913 he worked for the United States Bureau of Entomology, studying natural enemies of important pests. In 1913 Smith was appointed superintendent of the California State Insectary in Sacramento, and in 1923 was transferred to the University of California at Riverside where he was put in charge of the Department of Biological Control. He remained in this capacity until his retirement in 1951, and did much to foster implementation of biological control in California and the western United States. Smith was largely responsible for the large-scale use of the coccinellid *Cryptolaemus moutrouzieri* for citrus mealybug suppression, and the wasp *Macrocentrus ancylivorus* for Oriental fruit moth suppression. He also pioneered the use of biological suppression of Klamath weed with insect herbivores. Smith was elected president of the American Association of Economic Entomologists, and received an honorary doctorate from the University of Nebraska. He died at Riverside on November 28, 1957.

Smith, Ray F.

Ray Smith was born at Los Angeles, California, USA, on January 20, 1919. He received all his degrees at the University of California-Berkeley. He joined the faculty there in 1946, and became Department Chairman in 1959. Smith authored over 300 publications, and championed the ecological approach to pest management, and the minimization of pesticides in agricultural ecosystems through integration of pesticides with other approaches to pest suppression. A paper he co-authored on integrated control was cited as one of the most important publications on crop protection, and Smith is considered by some to be the "father of pest management." Among his many honors and awards are the C.W. Woodworth Award, Fellow and President of the Entomological Society of America, and member of the National Academy of Sciences. He also was co-recipient of the 1977 World Peace Prize. He died August 23, 1999, in Lafayette, California.

Snakeflies (Raphidioptera)

LIONEL STANGE
Florida Department of Consumer and Agricultural Services, Division of Plant Industry, Gainesville, FL, USA

The Raphidioptera, or snakeflies, are virtually restricted to the Holarctic region. They are easily identified by their general appearance, have an elongate head and prothorax, with the legs arising posteriorly (Fig. 64). The females have a long ovipositor. There are two families which have similar biologies. The larvae usually live in the crevices in the bark of trees or shrubs, or in the superficial stratum of the soil around the roots of shrubs. The pupae are strange in that they can move about in their environment. Most of the taxonomy is based on the male and female terminalia.

The family Inocelliidae is a small family of about 20 species in about five genera. They differ from the Raphidiidae in lacking ocelli. Two genera occur in the New World, *Negha* Navás (also in Spain) and the endemic *Indianoinocellia* Aspöck & Aspöck.

The family Raphidiidae consists of about 168 species in 26 genera. The majority of genera and species are found in the Palaearctic Region. There are only two genera found in North America, *Alena* Navás, which is the southernmost occurring genus in the world with two species living in the pine forests of Oaxaca,

Snakeflies (Raphidioptera), Figure 64 **A snakefly, *Agulla bicolor* (Albarda) (Raphidioptera: Raphidiidae) (photo L. Buss).**

Mexico, and *Agulla* Navás which is restricted to the western half of North America. Larvae of *Alena* were found under pine bark.

Snodgrass, Robert Evans

Robert Snodgrass was born at St. Louis, Missouri, on July 5, 1875. His family relocated to Kansas and then California, and Robert entered Stanford University in 1895. He majored in zoology, and due to his interest in birds he was encouraged by V.L. Kellogg, the entomology instructor, to study bird lice. This culminated in two publications on louse morphology. He accepted a teaching position at Washington State University when he graduated in 1901, but his practical jokes were not fully appreciated and he returned to Stanford. There he caused problems by stripping the mulberry trees to feed his silkworms, so he moved on to San Francisco and eventually Washington, DC, where he commenced work for the Bureau of Entomology. Not satisfied with that employment, Snodgrass moved to New York to study art. He work in entomology off and on for brief periods, then settled in with the Bureau of Entomology in 1917 and taught entomology at the University of Maryland from 1924 to 1947. Snodgrass authored over 80 publications, but is best known for his expertise in morphology, exemplified by his books: "Anatomy and physiology of the honeybee" (1925), "The principles of insect morphology" (1935), and "Textbook of arthropod anatomy" (1952). After nearly 70 years, his "principles" book remains the definitive work on the subject. He died in Washington, DC, on September 4, 1962.

Snout Butterflies (Lepidoptera: Libytheidae)

JOHN B. HEPPNER

Florida State Collection of Arthropods, Gainesville, FL, USA

Snout butterflies, family Libytheidae (also called beaks), are a small family of only 12 species but with at least one species in each faunal region. Alternate classifications, either as a separate family, or as a subfamily within Nymphalidae, continue to plague specialist views on the group, but the family basically represents the lineage to Nymphalidae and are very unique if included within the latter family. The family is in the superfamily Papilionoidea (series Papilioniformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium size (25–55 mm wingspan), with very long porrect labial palpi; forelegs somewhat reduced and not used for walking. Wings triangular, typically with a falcate forewing apex, often somewhat truncated; hindwing relatively rounded with emarginate

Snout Butterflies (Lepidoptera: Libytheidae), Figure 65 Example of snout butterflies (Libytheidae), *Libytheana bachmanii* (Kirtland) from Pennsylvania, USA.

margin. Maculation mostly shades of brown with orange or red suffusion and some light and dark spotting. Adults are diurnal. Larvae are leaf feeders. Host plants are in Ulmaceae (Fig. 65).

Snout Moths (Lepidoptera: Pyralidae)

John B. Heppner

Florida State Collection of Arthropods, Gainesville, FL, USA

Snout moths, family Pyralidae, comprise the third largest family of Lepidoptera, with about 16,500 described species, but a probable fauna of at least 25,000 species worldwide. There are 19 subfamilies in the classification, divided into two groups: group Crambinina, with 14 subfamilies (Crambinae, Schoenobiinae, Cybalomiinae, Linostinae, Scopariinae, Musotiminae, Midilinae, Nymphulinae, Odontiinae, Noordinae, Wurthiinae, Evergestinae, Glaphyriinae, and Pyraustinae), and group Pyralinina, with five subfamilies (Pyralinae, Chrysauginae, Galleriinae, Epipaschiinae, and Phycitinae). The group names are sometimes elevated to separate families, as was already done over 100 years ago, but they can equally be maintained within the single family Pyralidae as has long been the practice. By far the largest subfamily is the Pyraustinae, with about 7,500 species worldwide. The family is in the superfamily Pyraloidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to large (6–95 mm wingspan), with head mostly rather smooth-scaled; haustellum scaled; labial palpi usually porrect and prominent; maxillary palpi 4-segmented (rarely 2- to 3-segmented). Wing shape (Fig. 66) usually has rather elongated and pointed forewings. Maculation extremely varied, often subdued and with various markings, but also many very colorful species; hindwings usually unicolorous and pale. Adults mostly nocturnal, but some are crepuscular and a few are diurnal. Larvae are mostly leafrollers or leaf webbers, but many are borers, root feeders, detritus feeders (including stored products pests), and a few are leafminers, plus rare myrmecophilous species, and even some aquatic groups making cases (Nymphulinae). Host plants are in a large number of plant families. A large number of economic species are in this family, including pests on virtually all crops and forest trees. Most Crambinae and Schoenobiinae larvae feed on grasses, including crops such as rice and other grains. Pyralinae and Phycitinae include a number of stored products pests, now mostly worldwide in distribution due to their association with dry stored foods. Galleriinae have beehive pests.

Snow Pool Mosquitoes

These are *Aedes* mosquitoes that breed early in the spring in pools of water formed from melting snow. In the northernmost northern hemisphere they breed in tremendous numbers, causing great suffering to animals such as caribou that have little option but to try to get away from these blood sucking insects.

► Mosquitoes

Snow, Francis Huntington

Francis Snow was born at Fitchburg, Massachusetts, on June 29, 1840. He was an industrious young man from the start, and in the course of his life developed an astounding number of interests and competencies, among them ornithology, botany, geology, paleontology, mineralogy, and entomology. Professionally, he was at various times a minister, teacher, and chancellor of the University of Kansas. He grew up in the exciting days just before the American Civil War, and the antislavery views of his father strongly influenced young Francis Snow. He excelled at Williams College, from which he graduated in 1862, and was most interested in natural history. He taught high school briefly, then entered Andover Theological Seminary. An avowed pacifist, he assisted chaplains and aided the wounded during the war. In 1866 Snow moved to Kansas to accept a professorship in mathematics and natural science. Snow quickly gained a reputation for being a knowledgeable, sincere, and patient teacher, greatly admired by the students at the University of Kansas. Snow was quite impressed with the grasshoppers in Kansas; at times they were so numerous that the train could not move because the crushed bodies of the grasshoppers prevented traction of the wheels on the tracks. A swing of an insect net would collect up to 190 grasshoppers. However, Snow was interested in everything, and he and his students collected insects, birds, plants, minerals and other elements of natural history earnestly, an activity that would eventually result in a fine museum. Williams College bestowed on Snow an honorary Ph.D. in 1881. In 1882 he was named State entomologist, and in 1885 the legislature named the Snow Hall of Natural History in his honor. In 1890 he accepted the position as chancellor. Though Snow was a collector, he was not a taxonomist. He devoted much of his energies to economic entomology, a fact that encouraged the practical farmers of Kansas to support him as chancellor. As chancellor he strengthened the faculty of both science and humanities. In 1889 Snow's son died an accidental death, and in the wake of this unfortunate event Snow suffered nervous disorders. He never completely recovered, and he died on September 20, 1907, while visiting Wisconsin (Fig. 67).

Snow Scorpionflies

Members of the family Boreidae (order Mecoptera).

► Scorpionflies

Soaps as Insecticides

REBECCA BALDWIN
University of Florida, Gainesville, FL, USA

Soaps were used as insecticides in Europe as long ago as 1787, and there are several thousand references in the literature on the use of soaps as insecticides. Prior to 1900, fish or whale oil soaps were the most commonly used insecticidal soaps. Soaps have changed a lot since then, yet they still prove to be an effective control of certain insect pests. Currently, numerous soap salts are registered as insecticides with the US Environmental Protection Agency (EPA). There are three documented active ingredients of soluble soap salts: sodium, ammonium and potassium. It is principally potassium salts that are used as insecticides, acaricides, herbicides, and algaecides.

Because of their chemical structure, soap salts precipitate out of hard water, resulting in an insoluble residue known as soap scum. To combat this, synthetic soap substitutes, or detergents, are available as cleaning products. Detergents share the cleansing and emulsifying properties of soap, and they are not separately listed as pesticides by the EPA.

Toxicity of Soaps

Soaps are salts of fatty acids. Fatty acids are long hydrocarbon chains that are naturally derived from plant oils and animal tallow. Plants and animals have differing amounts and combinations of fatty acids. For example, caprylic, capric, lauric and myristic acids are all constituents of coconut oil. Some plant oils have a large proportion of one fatty acid. Peanut oil is 51% oleic acid, coconut oil is 48% lauric acid, while palm oil is 47% palmitic acid. Corn, sunflower and safflower oil are made mainly of linoleic acid. Animal fat such as lard contains 44% oleic acid, while beef tallow is 44% linoleic acid. Tallow also contains 29% palmitic and 19% stearic acid. These insoluble fatty oils are distilled or pressed from their source and are exposed to a metal radical or organic base to produce soap.

Not all commercially available insecticidal soaps are pure fatty acid salts; some contain other active ingredients such as pyrethrum or neem. These combination insecticidal soaps must be registered for each active ingredient. The majority of the registered fatty acid salts include C_8–C_{18} potassium laurate, potassium myristate, potassium oleate, and potassium ricinoleate. These salts may be used singly or as mixtures because the EPA considers all potassium fatty acid salts to be the same active ingredient. Potassium fatty acid salts are generally recognized as safe by the Food and Drug Administration (FDA), and the EPA has exempted them from tolerance levels for all raw agricultural commodities. These soft soaps, such as oleic acid, have an oral LD_{50} of 74,000 mg/kg which places them in the lowest toxicity category, Category IV. These potassium fatty acid salts also have low to very low dermal toxicity, and may cause mild irritation if applied directly to the eyes. These salts have a half-life of less than a day and are readily broken down by soil microbes. While they may cause vomiting if ingested, these fatty acids pose no known health risks and are not toxic to birds.

Chemical Structure of Fatty Acids

Fatty acids are carboxylic acids. They are made of long unbranched hydrocarbon chains ending with a carboxyl group. Most naturally occurring fatty acids contain an even number of carbons in their chain, with C_{16} and C_{18} being the most common. These chains are building blocks for more complex fatty acids that are used as energy stores in many organisms. Fatty acids may be saturated or unsaturated, with unsaturated fatty acids being the most abundant in living organisms.

Shorter fatty acid chains are water soluble but become less so as the chain lengthens. The longer chains are viscous and form a gel in water. To increase solubility of fatty acids, a cation in the form of a mineral salt, potassium, sodium, or ammonium, must be added (e.g., potassium caprylate CH_3–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–COO–K^+). The addition of the salt causes hydrolysis of the carboxyl end of the fatty acid, resulting in a bond with the salt. This formation of the fatty acid chain and mineral salt is commonly called a fatty acid salt or soap salt.

Chemical Structure of Potassium Fatty Acid Salts

The fatty acids that are most commonly used in soap production are saturated, straight chain, monocarboxylic groups with even numbered carbon members. After the fatty acid is saponified with potassium hydroxide, a potassium fatty acid salt is precipitated. In some studies, the toxicity of the saturated fatty acids increases as the chain length increases peaking at C_{10} and then decreases until another peak at both the saturated and unsaturated C_{18} chains (Table 14).

The carboxyl end of the potassium soap salt is hydrophilic and carries a negative charge. The soap has a pH of 10 and is generally used as a cleaner. When in water, the negatively charged hydrophilic ends of the soap salts repel each other forming a spherical structure called a micelle. Non-polar soil or oil particles become suspended in the micelle and are held in solution. This action is known as surface active, or surfactant. Although the mode of action is unclear when used as an insecticide, fatty acids and their salts have been shown to have insecticidal properties.

Insecticidal Uses of Potassium Fatty Acid Salts

As noted previously, there is documented use of soaps as insecticides from as early as 1787. From the 1880s through the early 1900s, cottonseed oil soaps and fish oil soaps were used to control scale insects. In 1925, research documented that between 90 and 99% of *Anuraphis sanburni* Gill, black chrysanthemum aphid, were killed with caproic, capric, and lauric fatty acid sprays. Myristic acid, however, demonstrated significantly less toxicity. It was noted that soap salts, potassium, sodium, and ammonium, required higher concentrations to meet the same mortality as the fatty acids plus additives. It was later shown that fatty acid salts could produce mortality rates as high or higher than the fatty acids alone. Researchers noted that aphid exposure to the soap salts resulted in paralysis, with the dead insects remaining attached to the plant by their inserted mouthparts. After comparing fatty acids to fatty acid salts, the authors

Soaps as Insecticides, Table 14 **Common potassium salts**

Technical name	Structural name	Chemical formula	Molecular weight
K^+ caprylate	Octanoic acid	$C_8H_{15}KO_2$	182
K^+capryate	Decanoic acid	$C_{10}H_{19}KO_2$	210
K^+ laurate	Dodecanoic acid	$C_{12}H_{23}KO_2$	238
K^+ myristate	Tetradecanoic acid	$C_{14}H_{27}KO_2$	266
K^+ palmitate	Hexadecanoic acid	$C_{16}H_{31}KO_2$	294
K^+ stearate	Octadecanoic acid	$C_{18}H_{35}KO_2$	322
K^+ oleate	9-Octadecanoic acid	$C_{18}H_{33}KO_2$	320
K^+ ricinoleate	Ricinoleic acid	$C_{18}H_{33}KO_3$	336

All examples are saturated except for K^+ oleate (unsaturated) and K^+ ricinoleate (unsaturated alcohol) surmised that the free fatty acids were the toxic agents and were absorbed through the insect membranes and tracheae. Other studies on sodium and potassium soap salts from an assortment of animal and plant sources produced various levels of mortality to the Japanese beetle, *Popillia japonica* Newman. The highest mortalities were found from palm oil, beef tallow, and coconut oil (65–85% mortality).

In 1930, the efficacy of resin fish oil soap (6%) and a commercial soap, Crystal Cocoa (2%), on the harlequin bugs, *Murgantia histrionica* (Hahn), Colorado potato beetle, *Leptinotarsa decemlineata* (Say), and an aphid species was tested by dipping or spraying the insects. The investigator theorized that the soap solution covered the spiracles with a film that blocked the air supply to the insects. In order to test this hypothesis, *Murgantia histrionica* (Hahn) were submerged in water for 25 min. All insects fully recovered and had no ill effects from the submersion treatment. In comparison, after a five second soap exposure, 92% of the insects were killed. To further investigate the hypothesis, India ink, as a dye marker, was added to the soap solution to visualize the penetration of the soap solution into the insect. Insects that died after soap exposure had ink that penetrated deep into the thoracic spiracles. Thus, the investigator concluded that soap did not cause mortality by blockage.

One of the most thorough studies of fatty acids and their soaps was conducted in 1935 in New York. Instead of evaluating commercial soaps, this study evaluated fatty acids and their potassium salts against the rose aphid, *Macrosiphum rosae* L., and the bean aphid, *Aphis rumicus* L. Because fatty acids have low solubility in water, sulphonated cod oil was added to the solution as an emulsifier. Aphids exposed to cod oil (0.5%) alone resulted in 9% mortality. Aphids exposed to capric acid (0.17%) and cod oil (0.5%) or lauric acid (0.17%) and cod oil (0.5%) resulted in the highest mortality at 45% and 42% respectively; however, there was some phytotoxicity. The fatty acids that were the most toxic to the insects, lauric and capric acids, also caused plant injury to tomato, *Lycopersicon esculentum* Mill.; tobacco, *Nicotiana tabacum* L.; potato, *Solanum tuberosum* L.; bean, *Phaseolus vulgaris* L.; cabbage, *Brassica oleracea* L.; and nasturtium, *Tropaeolum minus* L. Aphids exposed to 0.5% potassium oleate and 0.5% potassium laurate resulted in 89 and 67% mortality, respectively. The authors also compared potassium oleate with sodium oleate at concentrations from 0.125 to 1%. Mortality of 98% was reached with concentrations ≥0.5%. The order of toxicity of the potassium soaps at 0.5%: oleate > laurate > caprate > caprylate > myristate > palmitiae. There was no significant mortality of aphids exposed to potassium caproate and potassium stearate when compared to controls.

Other research used various solvents, including kerosenes, mineral oils, hexane, pentane, and others, to trace penetration of substances into the nervous system of mosquito larvae. Detergents including Tergitol #7, and a fatty acid, oleic acid, were introduced into the respiratory siphon. None of the detergents migrated to the nervous tissue of the insect. The oleic acid had good diffusion into the tracheae but had less, or erratic, penetration into the nervous tissue.

The creation of the Environmental Protection Agency in 1970 prompted new research on soaps as insecticides. After an application of a 0.1% coconut oil soap spray, *Aphis gossypii* Glover was reduced by 79% and *A. spiraecola* Pagenstecher by 72% on roadside plantings in California. One study found that 1% solutions of C_{10} capric and $C_{18:1}$ oleic acid were most effective on balsam woolly aphid, *Adelges piceae* (Ratzburg). To increase solubility of the fatty acids, 0.1% Tween, a non-ionic surfactant, was added to the solutions. In this case, the potassium soaps performed better than the fatty acids alone.

Interestingly, some research demonstrated that immersions of yellow mealworm (*Tenebrio molitor* L.) pupae in 5% solutions of oleic acid, linoleic acid, potassium oleate, and potassium linoleate caused early death. The growth inhibition resulting from the treatment was described as "juvenile hormone-like." In 1979, Ivory® dishwashing liquid (Proctor and Gamble, Cincinnati, OH), Acco Highway Plant Spray® soap (38.5% coconut oil soap) (Acme Chemical Co., Blue Bell, PA), Shaklee's Basic® laundry bar soap (Shaklee, Pleasantville, CA) and Tide® detergent (Proctor and Gamble, Cincinnati, OH) were tested on the thrips *Heliothrips haemorrhoidalis* (Bouche); mites, *Panonychus citri* (McGregor); psyllids, *Psylla uncatoides* (Ferris and Klyver); and aphids, *Myzus persicae* (Sulzer), *Aphis citricola* (van der Goot), and *A. fabae* in the home landscape. Ivory® dishwashing liquid at 1–2% provided the most consistent results. It was noted that soaps do not provide any residual activity and must be applied often.

The majority of the early studies involving the use of fatty acids and their salts as insecticides used them against soft-bodied insects. However, a few studies tested soaps on hard-bodied insects such as harlequin bugs, Colorado potato beetles and Japanese beetles. More recently, when soaps were used as a contact insecticide by splashing, a 0.5% solution of the Chandrika® or Surf® soaps achieved 100% mortality of crickets, and a 2% solution achieved 100% mortality in cockroaches. The authors theorized that the soaps cause spiracle blockage, and they noted that a soap-water spray may prove a safe and economical solution to insect pests. For all cockroach stages, exposure to concentrations of 3% soap solution resulted in 100% mortality within 72 h. The researcher suggested that the mode of action was asphyxiation due to spiracle or tracheae blockage. In another study, American, *Periplaneta americana*, and German, *Blattella germanica*, cockroaches were exposed by 30 s immersion to even-numbered fatty acid salts, C_8–C_{18}. A 2% solution of potassium oleate (C_{18}) was the most toxic to both German (LC_{50} = 0.36%) and American (LC_{50} = 0.17%) cockroaches.

Potential Mode of Action of Potassium Fatty Acid Salts

The traditional explanations for the mode of action of soaps are cuticle disruption and spiracle blockage, but there is a third possibility. In contrast to this uncertainty, everyone agrees that fatty acids and their salts are contact-only insecticides and that they provide no residual activity.

Cuticle Disruption

It is sometimes stated that the mode of action of insecticidal soaps is dehydration after contact. The fatty acid purportedly penetrates the cuticle and disrupts the cellular integrity, causing leakage and collapse. The Olympic® Horticultural Products Insecticidal Soap 49.52 CF label states that the mode of action is a disruption of the outer waxy layer that causes damage to the cuticle.

Spiracle Blockage and Asphyxiation

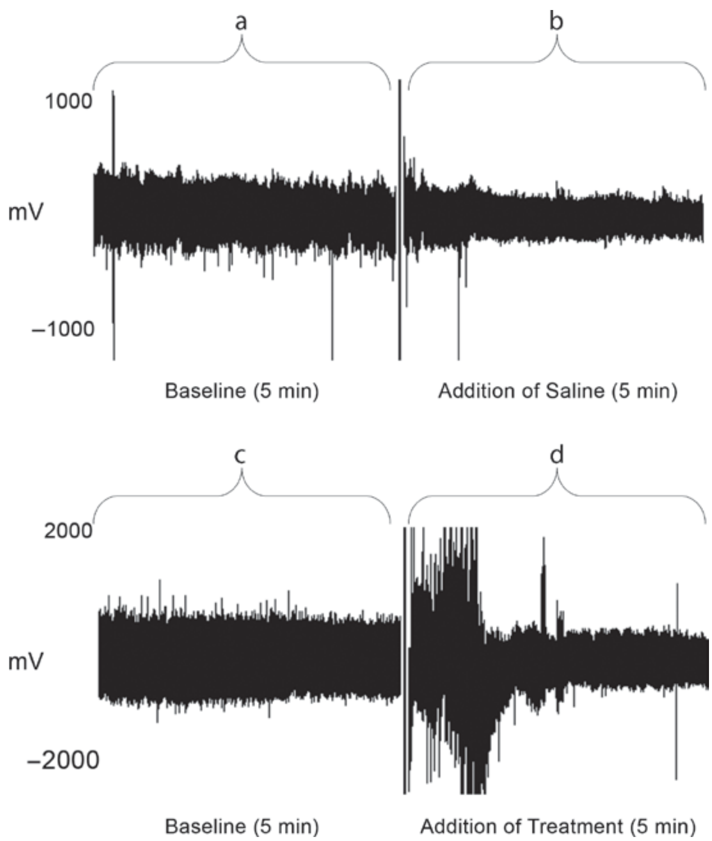
The majority of researchers believe that blockage of the spiracles or tracheae is the source of mortality in insects. This theory seems plausible because soap is able to enter and may be actively pumped in through the respiratory system of the insect. Water has a high surface tension so cannot enter the tracheal system of insects. When the surface tension is reduced to half of that of water by an emulsion, the solution may enter the tracheae. A soap solution would be an example of this. Once inside, the liquid can spread along the walls of the tracheal tubes. Rapid paralysis occurs after soap solutions enter the tracheal system. This has been attributed to hemolytic action.

Neurotoxins

It has also been suggested that soaps act as nerve toxicants. Supporting this hypothesis is the rapid paralysis and death of the insect after contacting soap solutions. Asphyxiation and dehydration could not account for the almost immediate response of insects to soap treatments; these modes of action would not result in such rapid death. Neurophysiological recordings of cockroaches exposed to soaps (Fig. 68) support the hypothesis that the soaps act, at least partially, via a neurological mode of action.

The Future of Soaps for Pest Control

Soap solutions, due to their low mammalian toxicity, have potential for use as a pest management option in sensitive environments such as occupied hospital rooms, in classrooms with children, and in daycare centers while children are present. Dishwashing liquid and household cleaners are readily available and are common



Soaps as Insecticides, Figure 68 **Spontaneous electrical activity from representative *Periplaneta americana* neural preparations were recorded with a threshold of 500 baseline counts per minute. Baseline electrical activity from an untreated neural preparation in physiological saline is seen in (a). After a 5 min recording, a saline control (1 ml) was added to the neural preparation as seen in (b). Baseline electrical activity in physiological saline was recorded in a separate neural preparation (c) before the addition of potassium laurate (1 ml at 0.75%) in physiological saline (d). As seen, the addition of the potassium laurate caused an increase in electrical activity followed by a quieting of spontaneous electrical activity. The decrease in electrical activity corresponded with paralysis, without recovery, of the specimen. (From R. Baldwin, unpublished Ph.D. Dissertation, University of Florida.)**

items already found in these environments and in the home (Table 15). Many different brands and formulations provide rapid knock-down and kill ants, cockroaches and other insects effectively. Not only are soaps effective against different stages of the insect, but there is little if any recovery of insects after the initial knock-down. Soaps are inexpensive and concentrations of soap needed to knockdown or kill pest cockroaches are very low. This results in not only an effective, but also and economic pest management option.

Soaps also have a place for plant feeding insect management. Commercial products developed for use on plants generally are safe to use. Some people like to make their own soap sprays from household soaps and detergents, and certain brands of hand soaps and liquid dishwashing detergents can be effective for this purpose. They are also substantially less expensive. However, there is increased risk of plant injury with these products, as they are not designed for use on plants. Dry dish soaps and all clothes-washing detergents are likely too harsh to be used on plants safely. Regardless of the product selected, soap and detergent sprays are always applied diluted with water, typically at a concentration of around 2–3%. A test area should be sprayed with the soap solution to test for phytotoxicity before making a full application.

Social Insect Pheromones

ROBERT K. VANDER MEER, CATHERINE A. PRESTON
United States Department of Agriculture,
Agricultural Research Service, Gainesville,
FL, USA

Social insects are unique in that they have overlapping generations in which adult workers (normally sterile) assist their mother in rearing sisters and brothers. In addition, there are reproductive and non-reproductive castes constituting a division of labor. Our discussion of social insect pheromones will be restricted to the social Hymenoptera (Formicidae, ants; Apidae, bees; Vespidae, wasps) and Isoptera (Termitidae, termites), although there are examples of social thrips and cockroaches.

Regardless of the size of the social insect colony, which can range from tens of individuals to millions, social interactions are required for effective food retrieval, brood and queen care, regulation of caste (sexuals/workers), recognition and exclusion of non-nestmates, and other tasks. There are several sensory mechanisms available to social insects for communication, e.g., tactile and vibratory, however, chemical communication has evolved to a high level of complexity in these insects.

There are advantages to the use of chemical signals as a means of information transfer. The chemicals are relatively small, volatile structures that are energetically inexpensive to biosynthesize and easy to release into the surrounding airspace. In addition, because the signal is detected through space by the sense of smell, it is functional under various environmental conditions. Some disadvantages are that it is difficult to direct the signal at a single recipient unless detection is through direct contact. Also, once released, the signal cannot be changed rapidly or in some cases the signal dissipates before the information has been transferred to all intended recipients. Specific terminology has been developed to define chemical interactions between organisms. We will restrict ourselves to intraspecific chemical communication.

Pheromones are chemicals released by an individual that have an effect on members of the same species. The word pheromone is derived from the Greek "pheran" meaning to transfer and "horman" meaning to excite. There are two pheromone subcategories, (i) releaser pheromones and produce an immediate response in the recipient individual, e.g., a male moth orienting toward the sex pheromone released by the female moth; and (ii) primer pheromones and perception triggers the initiation of a complex physiological response that is not immediately observable. Both pheromone types are extremely important in maintaining colony social structure.

Unlike hormones, pheromones must be secreted outside the insect's body via exocrine glands. It is a testament to the importance of pheromones to the success of social insects that they have evolved a very diverse repertoire of exocrine glandsand over 70, with 45, 21, 14, and 11 in ants, bees, wasps, and termites, respectively. Some of these glands function to produce wax, other types of building materials, or defensive compounds; however, many exocrine glands have become specialized for the production of pheromones that play major roles in communication and the maintenance of colony social structure. Pheromone-producing glands can be found anywhere on the social insect and from the pretarsal glands of bees to the frontal and labial glands of termites. In addition, the ovipositor of solitary insects evolved into the sting in the aculeate Hymenoptera, bees, wasps, and ants. Most important for this discussion is that the accessory glands associated with the ovipositor evolved into the Dufour's and poison glands. Both of these glands have become very important in pheromone communication in social insects.

The pheromone products have diverse uses among social insects. Recruitment pheromones help guide workers to food materials and in a different context can lead the entire colony to new nesting sites. When a worker ant, wasp, bee, or termite detects an intruder it will release an alarm pheromone that acts to excite and attract nearby workers, which then respond aggressively toward the intruder. Other compounds act as sex pheromones, queen recognition pheromones, territory markers, and brood pheromones, among others. Additional layers of complexity are added because pheromone structure and function varies within the morphological/functional caste system in social insects. Not only is there variability between queens and workers different, but also between the different worker castes as well. Sometimes, a single chemical plays different pheromonal roles, depending on the caste releasing it and the context of the situation. With such a plethora of glandular sources and elicited behaviors there appears to be no pattern in pheromone chemical structure or the glandular source relative to behavior elicited. To illustrate the unpredictability of glandular source versus function, trail pheromones in ants have been reported from the Dufour's gland, venom gland, hindgut, pygidial gland, Pavan's gland, and the postpygidial gland. Thus, the glandular source of a pheromone that elicits a particular biological behavior must be determined through bioassay.

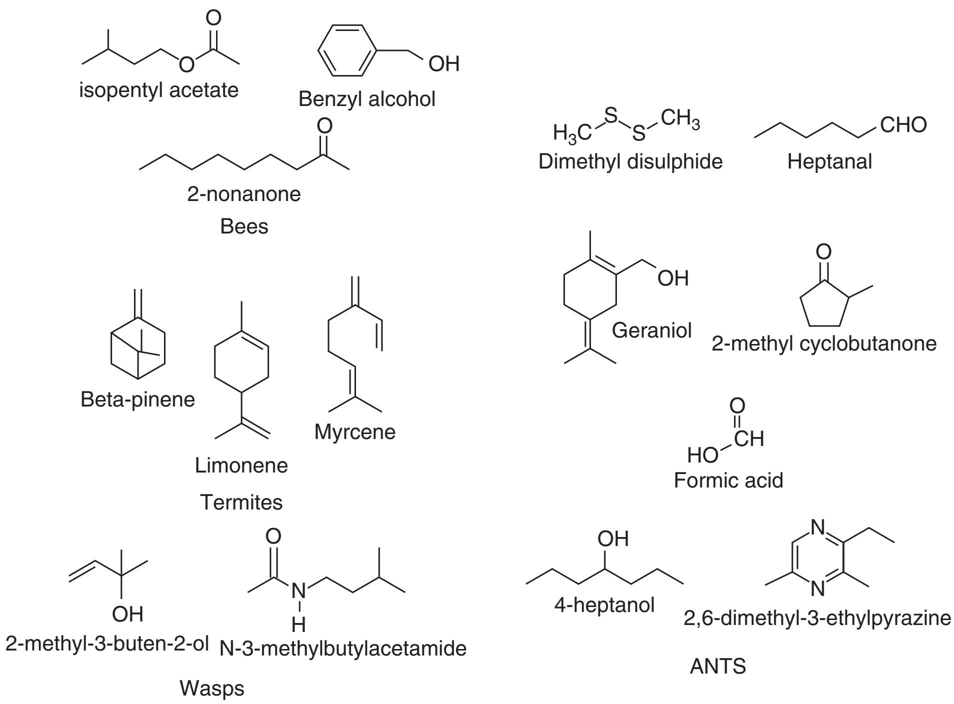
Pheromone Glands

Pheromone-producing glands are specialized for the distribution of their secretory products. Besides the biosynthesis of the active pheromone components, the glands must be able to regulate the release of the secretion. The mechanisms of release are not well understood; however, glands that have reservoirs may have specialized musculature at the reservoir opening that controls the release of the gland contents. Interestingly, the act of opening the mandibles initiates the release of alarm pheromones from mandibular glands of some ant species. Where there is no reservoir, glandular products may be released directly to the outside as they are produced. Release may be continuous or synthesis and release could be triggered by exogenous stimuli.

The chemistry of social insect pheromones is very diverse. Releaser pheromones elicit an immediate response in the recipient and are generally detected by the antennae in the air and therefore must be volatile. Primer pheromones elicit physiological change and may or may not be volatile, because they can be distributed to colony members by grooming and/or trophallaxis (passage of regurgitated material from one individual to another). We will briefly go through the major pheromone behavioral categories and their associated chemistry.

Alarm Pheromones

Alarm pheromones represent an important evolutionary development for eusocial insects because they enable colony worker resources to be focused at specific colony needs, e.g., nest or food defense. The alarm signals only act to alert other members of the colony. If the alerted workers subsequently find an intruder they will likely respond aggressively by attacking. If they find food they may be stimulated to ingest the food. So, while the alarm reaction is usually associated with defensive behavior, it is subsequent stimuli that often dictate what happens next. The release of alarm pheromones may be initiated by the physical disturbance of an individual worker or by the chemical recognition of an intruder. Once the alarm response is initiated, its release may be "telegraphed" to other nearby workers. This helps explain anecdotal accounts that hundreds of nestmate bees or wasps respond to the accidental disturbance of a single bee or wasp. Similarly with fire ants, people report that worker ants will sneak up their leg, then when in position all of them will sting in unison. Actually the ants simply go undetected for a period of time, until a movement disturbs one ant that then releases an alarm pheromone, quickly activating nestmates in the area. While the mandibular gland is the most common source of alarm pheromones they have also been reported from the pygidial gland, Dufour's gland, Koschevnikov's gland (associated with the sting apparatus of bees), and other glands (Fig. 69).



Social Insect Pheromones, Figure 69 **Representative alarm pheromones identified from bees, termites, wasps and ants, illustrating the diversity of structural types.**

There are many reported behaviors associated with alarm pheromones. In ants for example, attraction to the alarm pheromone source, increased speed of movement, frenzied running, aggression, raised head and more have all been reported as alarm behaviors. More complicating is that the context in which the alarm pheromone is released can affect worker response, e.g., colony disturbance, an encountered intruder, age of the colony, etc. Consequently, it is important for the researcher to clearly define the alarm behavior being investigated.

The requirement for a quick response to the alarm pheromone, as well as for its rapid dissipation after the perceived need has passed suggests that alarm pheromones should be small volatile compounds. While in some instances only one component is reported, e.g., 2-methyl-3-buten-2-ol for the hornet (*Vespa crabro*), it is expected that many more potentially active compounds will be isolated and identified. For example, initially only isopentyl acetate was isolated from Koschevnikov's gland in honey bees (alarm pheromone source); however, subsequent analysis has identified at least 22 additional compounds. Many ant alarm pheromones have been isolated and identified. Considering the necessity that alarm pheromones must be highly volatile, the variety of structural types pays homage to the biosynthetic versatility of the social insects and ants in particular.

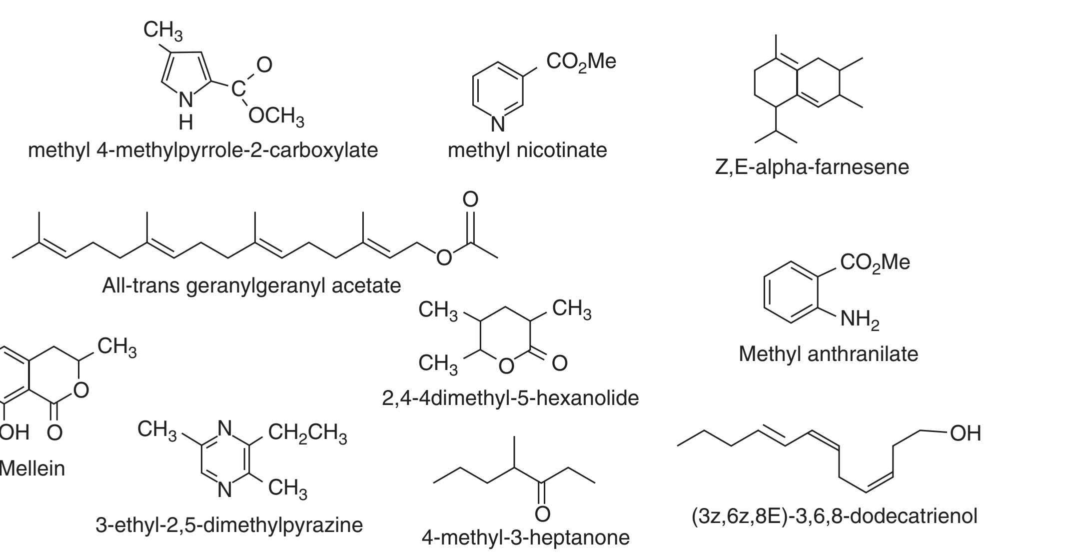
Future work in this area should focus on the precise definition of the alarm behavior, development of a behavior-specific bioassay, and then the bioassay-driven isolation of the active compounds.

Recruitment Pheromones

Recruitment pheromones are compounds involved in bringing colony workers to a particular location where they are needed. An ant trail between the colony's nest to a dead insect or other food material is a familiar sight to most people. The trail is the end result of a complex process; but since it is easily observed this pheromone system is sometimes referred to as the trail pheromone. Nestmates may be recruited to gather food resources, or to defend their territory against invasion, or recruitment pheromones may be used to guide the migration of the colony to a better nest site (Fig. 70).

The terrestrial ants, of necessity, have evolved a wide variety of recruitment mechanisms and glandular sources of recruitment pheromones. In ants the Dufour's gland, poison gland, the pygidial glands, and sternal glands, hindgut, and rectal gland have been reported as sources of recruitment pheromones. Pheromones from these sources can be readily envisioned being deposited on a solid substrate. Similarly the sternal gland is used in several genera of termites as a source of trail pheromones. Thus far this gland is the only known source of termite trail pheromones. The flying social insects also have a need to recruit a worker force to food supplies and/or to guide colony members to new nesting sites and hence recruitment pheromones can also play a role. Social wasps do not commonly recruit to food sources but do recruit to new nest sites. During this process workers drag their gasters on a substrate to deposit sternal gland secretions, which then guides the migrating colony to a new nest site. Stingless meliponine bees deposit mandibular gland products at intervals on the ground while the Nasanov gland in honeybees is a source of marking pheromones. Most investigations of recruitment pheromones have focused on ants, primarily because they form readily observed trails on the surface and bioassays have been relatively easy to develop.

The red imported fire ant, *Solenopsis invicta*, is a good model to illustrate the behavioral components of the recruitment process. The process begins when a foraging scout worker discovers a food source too large for it to carry back to the colony. During the foraging process the scout keeps track of its position relative to a light source (sun, street light, etc.) and is able to navigate pretty much straight back to the colony. As it makes its way back, it periodically deposits minute amounts of Dufour's gland products to the substrate. The Dufour's gland is attached to the base of the sting apparatus and the products exit through the sting. Thus, in this case, the sting is periodically extended to touch the substrate. When the scout returns to the nest Dufour's gland products are used to attract other workers toward the scout and activate them to follow the very weak initial trail. The attracted and activated workers detect and respond to the trail by following it to the food source. The movement back



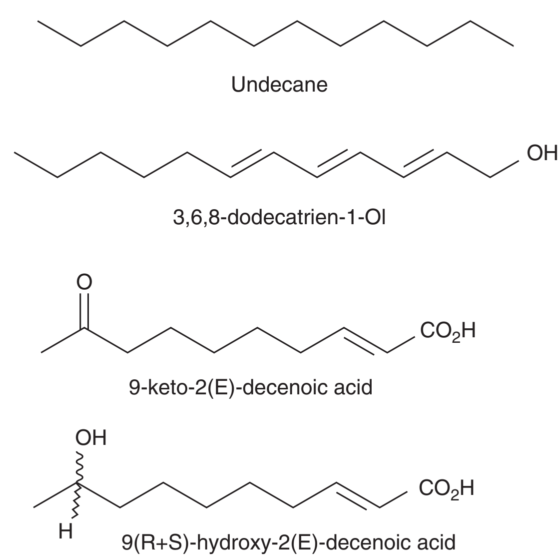
Social Insect Pheromones, Figure 70 Representative recruitment pheromone structures illustrating the diversity of structural types.

and forth along the trail is called orientation. The newly recruited workers ingest some food, stimulating them to reinforce the trail with additional recruitment pheromone as they return to the nest. More workers are recruited until the food source is covered with fire ants and additional workers cannot get to the food and do not reinforce the trail. As the food source diminishes fewer workers reinforce the trail and because of its volatility, the concentration of the deposited recruitment pheromone weakens until the food is gone and the trail evaporates completely. The recruitment process can be broken down into several sub-categories. (i) Initial trail laying by the scout ant; (ii) attraction of additional workers to the scout ant; (iii) activation (induction) of the workers to follow the trail; (iv) trail orientation. Separate behavioral bioassays were developed for each of the categories and used to guide the isolation of the responsible pheromone components. Z,E-α -farnesene appears to be solely responsible for orientation, but does not attract worker fire ants. A mixture of Z,E-α-farnesene and a bicyclic homofarnesene account for 100% of the Dufour's gland activity in an olfactometer (attraction) bioassay. Remarkably, when this mixture is presented to foraging ants as a trail they do not orient along the artificial trail! This illustrates that the workers first need to be activated or put into a more alert state. In some ant species the scout worker will physically agitate perspective recruits, whereas the fire ant can do the same job with Dufour's gland products. This activation requires virtually a reconstitution of the complete chemical profile of the Dufour's gland.

The fire ant provides one example; however, in some ant species the scout attracts and escorts a single nestmate back to the food source and in others the scout physically activates nestmates who are then able to independently follow the trail. Social insects occupy virtually all ecological niches and have evolved a myriad of mechanisms to accomplish tasks such as recruitment to bring nestmates to a point in space where extra legs and mandibles are needed. The chemistry of many recruitment pheromones has been determined.

Sex Pheromones

Sex pheromones are substances that are emitted by males or females that function to attract the opposite sex for the purpose of mating. Most commonly the female attracts the male(s) to her. There are many examples among solitary insects, especially lepidopteran species, of both the associated behaviors and the chemistry of the pheromones involved. However, few sex pheromones have been reported in social insects, probably because of the difficulty in developing appropriate bioassays. Most social insects, including the terrestrial variety (ants and termites), mate during "mating flights." The mating flights are usually triggered by specific environmental conditions, so laboratory assays are difficult to establish and observations of the natural phenomenon have been rare. For example, the red imported fire ant, Solenopsis invicta, may send off hundreds of thousands of male and female winged sexuals, with males taking flight approximately 30 min before the females. The males and females find each other, presumably through sex pheromones, and mate about 100–200 m in the air, then the females come down to attempt to start a colony (Fig. 71). No one has



Social Insect Pheromones, Figure 71 The structures of known social insect sex pheromones.

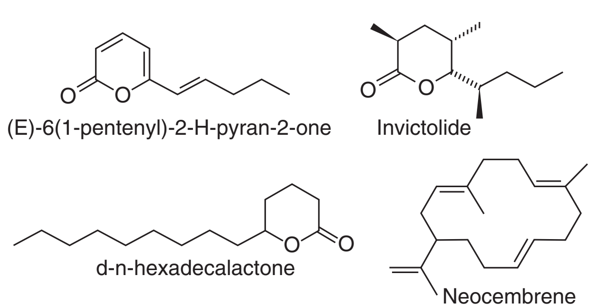
yet seen a mating pair of fire ants and no one has been able to get them to mate successfully in the laboratory!

The honey bee "queen substance" produced by the mandibular glands is used in the context of an established colony to control the production of female sexuals. These same glandular products are used by virgin queens to attract male drones for mating. While there are many compounds produced by the mandibular glands, only two compounds appear to play a sex pheromone role: (E)-9-oxodec-2-enoic acid and (E)-9-hydroxydec-2-enoic acid. The other two examples of sex pheromones in social insects are also pheromones that have different behavioral effects depending on the context of their use. In termites 3,6,8-dodecatrien-1-ol is a trail pheromone, but has also been implicated as a sexual attractant for two termite species: *Pseudacanthotermes spiniger* and *Reticulitermes santonensis*. The one and only sex pheromone from an ant species was isolated from Formica lugubris. The pheromone undecane was isolated from the mandibular glands and accounted for 100% of the sex pheromone bioassay activity. This compound is also used by workers as an alarm pheromone.

Queen Pheromones

Queen recognition pheromones or more simply "queen pheromones" are exocrine gland products released by the queen that usually attract workers to her, eliciting care and protection. Most queens of social insects have the ability to attract workers, so the behavior is well documented. Again, various glands serve as sources for the queen pheromone, from the mandibular glands in the head of honey bees to the poison sac in the abdomen of fire ants. The queen benefits from the attention of the workers, and the workers may also use the pheromone signal to gain information about the queen. For example, the release of poison sac contents is directly linked to queen egg laying, thus workers may be able to assess the fecundity of their queen based on the amount of pheromone released into the colony (Fig. 72).

The chemistry of these pheromone systems has been elucidated in only a few systems. In the fire ant *Solenopsis invicta* the source of attractant pheromones was found to be the queen's poison sac. Two lactones have been identified as the active pheromones. The pharoah's ant, *Monomorium pharaonis*, produces a macrocyclic compound, cembrene A, in its Dufour's gland that elicits worker attraction. Ejection of the sting and possible deposition of Dufour's gland products on the eggs has also been reported for this species. The honey bee queen pheromone is produced by the mandibular gland and has turned out to be a very complex mixture of compounds that by themselves are only slightly active but when taken together act as synergists, reproducing the activity from the mandibular gland itself. Unusual for pheromones, most of the compounds are found in tens of μgs. In spite of the large quantity of pheromones produced, the synergistic effects of the components complicated the isolation of the active compounds. No queen pheromones have been isolated and identified yet from termite species. Only one compound, δ -n-hexadecalactone, has been isolated as a queen pheromone from a wasp species. It was isolated from head extracts and affect worker behavior.



Social Insect Pheromones, Figure 72 The structures of queen recognition pheromones.

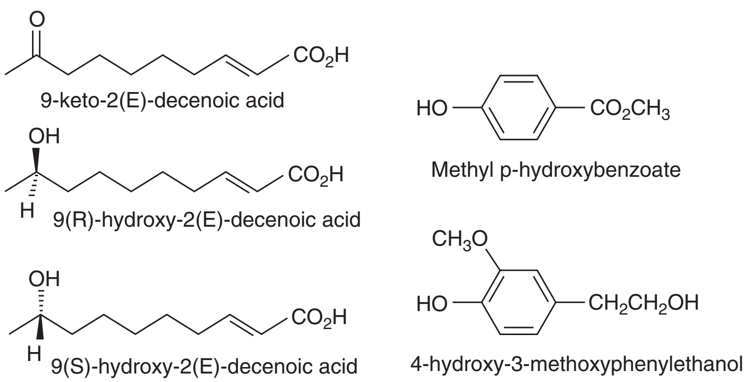
Releaser and Primer Pheromones

As mentioned earlier there are two broad categories of pheromones, releaser and primer pheromones. The above discussion centers around releaser pheromones whose detection yields an immediate observable behavioral change. Thus, bioassay development is easier and results can be obtained quickly. This area of social insect pheromone communication has foraged ahead rapidly, while primer pheromones have lagged far behind. This is because they trigger the initiation of complex physiological responses that are not immediately observable. It may take days or more to obtain results. Bioassays have been developed that demonstrate the existence of primer pheromones, but the chemistry has not been forthcoming, except for the honey bee (Fig. 73).

The honey bee, *Apis mellifera*, is one of the most extensively studied social insects, in part because of its economic importance and the ready availability of colonies. Interestingly, the queen's mandibular pheromone blend of five components acts as both releaser and primer pheromones. The blend attracts workers to the queen as in "queen recognition" and therefore has releaser pheromone effects. It acts as a primer pheromone by inhibiting queen rearing by workers. Additionally, it retards the build up of juvenile hormone titer in worker bees, which effectively acts to slow the developmental progression of workers from brood tending to foraging. These effects clearly represent changes in the physiology of honey bee workers.

Most, if not all, social insect primer pheromones are produced by the queen and function in some way to prevent reproductive competition. Another example comes from the fire ant. The fire ant queen has been demonstrated to produce several primer pheromones that function to: (i) inhibit ovary development in female sexuals; (ii) suppress egg production by mature queens in polygyne colonies; (iii) inhibit the production of female sexuals; (iv) regulate nestmate recognition sensitivity, such that newly mated queens are executed by workers. Unfortunately, the structures of these interesting primer pheromones are still unknown.

We have discussed the main behavioral categories of pheromones in social insects; however, there are other categories, such as territorial marking and brood pheromones, a discussion of which can be found in the references. In addition, there are nestmate recognition cues that are on the surface of individuals that allow members of one colony to distinguish members of another colony of the same species. While the effect is conspecific, the behavioral response is different for nestmate and non-nestmate; acceptance or attack, respectively. Nestmate recognition cues may be acquired from the environment, inherited, or derived from a combination of the two sources. Thus, nestmate recognition cues do not quite fit into the realm of pheromones.



Social Insect Pheromones, Figure 73 **The five components that constitute the queen produced honey bee primer pheromone.**

We have demonstrated the complexity of social insect pheromones and their sources, associated behaviors, and chemistry and hope that readers will be stimulated to delve deeper into the literature to further uncover the beauty and intricacies of this fascinating subject.

Sociality of Insects

GARD W. OTIS
University of Guelph, Guelph, ON, Canada

The social insects represent a major evolutionary success story. Their cooperative nest-building, prey capture, and recruitment for food have captured the attention and fueled the imaginations of humans. This cooperation also has contributed to the numerical abundance and ecological dominance of social insects in many habitats. For example, in tropical forests and savannahs, ants and termites outweigh the impressive and very conspicuous mammalian fauna. In all but the coldest environments, ants are the predominant predators of other insects, and they are also major dispersers of seeds of numerous plant species. Social bees pollinate a large proportion of the flora throughout the world, both because they are abundant and because many of them have efficient recruitment tactics such as the remarkably complex dance language of honey bees. Termites are the primary decomposers of wood and other materials containing cellulose in the tropics. Termites and ants together move more soil than earthworms in all tropical habitats, and even in temperate regions, have a major role in mixing nutrients in the soil and creating topsoil. From these examples, it is evident that the social insects figure prominently in nutrient cycles and energy flow in the biosphere.

The majority of all insects are solitary. For solitary species, the most social point in their life cycle is often the interaction between mates, after which females go about their business of reproduction without cooperating with other members of their species. Parasitic wasps lay eggs in their hosts, grasshoppers oviposit in the soil, and butterflies seek out larval host plants on which to lay their eggs. The common thread among these diverse solitary groups of insects is that their offspring develop into adults without interaction with their mothers.

Eusocial Insects

At the other extreme are the eusocial insects. Eusociality is a term that refers to a set of three very specific criteria: overlap of generations (i.e., mothers live sufficiently long to interact with their adult offspring); cooperative brood care (i.e., females provide some care to offspring that are not their own, and individual larvae are provisioned by more than one female); reproductive division of labor (i.e., some individuals of a group leave behind more offspring than others).

Most of the insects we think of as highly social and honey bees, yellowjacket wasps and hornets, ants, and termites and meet the criteria of eusociality. In fact, most eusocial species belong to the order Hymenoptera, with all the species of ants (about 9,000 species), about ten percent of bees (more than 2,000 species), and some wasps (about 1,000 species) being eusocial. The other main group of eusocial insects contains the termites, order Isoptera, with all 2,200 species being eusocial. There are only a handful of other eusocial organisms by the above set of criteria: a bark beetle in Australia, various gall-forming aphids and thrips, sponge-inhabiting snapping shrimp, and naked mole rats in Africa.

Between the extremes of solitary and eusocial insects are numerous species in many different taxa that exhibit some, but not all, of the criteria for eusociality. These insect species often are described by the nonspecific term, presocial. Because eusociality evolved from presocial societies, considerable attention has been directed at presocial insects in an attempt to elucidate those factors that favor the evolution of more complex social systems. Presociality can be further divided into parasociality and subsociality. The definitions and examples of these two major categories of subsocial species will be discussed here, and their central role in the evolution of sociality will be considered later in this article.

Parasocial Insects

Parasocial species are those in which the colonies are comprised of individuals of the same generation, and are usually groups of sisters that nest together. Thus, in parasociality, the first criterion of eusociality (overlap in generations) is not met. For example, females of the carpenter bee (*Xylocopa virginica*), that is common over much of eastern North America, construct galleries in wood. The young adult bees emerge after their mother has died and often they remain in the gallery in a communal society over winter. Once spring arrives, they disperse and initiate nests individually. Although the offspring share the nest for a period of time, there is little or no cooperation between individuals. In some parasocial colonies (e.g., some neotropical orchid bees, *Euglossa* spp.), although all adult females have developed ovaries and apparently are equally capable of laying eggs (i.e., no reproductive division of labor), there are more adult bees than cells with larvae being provisioned at any point in time. This is suggestive of cooperative brood care. There also may be some slight specialization in nest guarding, but overall cooperation in such parasocial bee societies usually is rudimentary. Tropical parasocial spiders (e.g., *Anelosimus eximus*, *Agelena consociata*) are able to construct huge webs in clearings and thereby encounter more and larger prey than their solitary relatives can. Within their societies, these spiders exhibit a variety of relatively complex behaviors, but they lack reproductive division of labor.

Subsocial Insects

The other broad category of presociality is subsociality. Subsocial insects are those in which females show extended care of their offspring that enhances offspring survival. The specific selective forces that favor subsociality vary widely, but generally are linked to either very harsh conditions or very favorable but ephemeral conditions. The European rove beetle, *Bledius spectabilis*, provides an example of a species that lives under extremely unfavorable conditions. Adult females construct vertical burrows in tidal mudflats. After feeding on algae on the mud at low tide, the beetles retreat to their burrows and plug the entrances. Without the adult beetle present when the burrows are submerged at high tide, the younger immatures are unable to maintain the tunnels and they die from lack of oxygen. At the opposite extreme, burying beetles (*Nicrophorus* spp.) reproduce on small rodents that represent abundant, high quality, ephemeral resources. In order to reproduce successfully they must find, then defend, a dead rodent from potential competitors such as fly larvae, fungi and bacteria, and even other *Nicrophorus* beetles. Consequently, a reproductive pair of beetles usually fights other *Nicrophorus* to gain control of the rodent, after which they shave it and treat it with mandibular secretions. The female, and sometimes the male, remain with the larvae, protecting and even directly feeding them, until they pupate in the soil. At that time, the continued presence of the adults cannot enhance offspring survival, and the beetle(s) disperse to seek new cadavers upon which they can reproduce.

The evolutionary "breakthrough" that enabled some presocial species to evolve more complex eusocial societies is reproductive division of labor. In most cases, that translates into morphologically distinct queen and worker castes, with queens doing most or all of the reproduction. "On the Origin of Species", Darwin wrote that the sterile workers and soldiers of social insects presented "one special difficulty, which at first appeared to me insuperable, and actually fatal to my whole theory." Why should some individuals "give up" their own reproduction in order to assist the queen of their colony? The evolution of sterile individuals seems contrary to the principles of natural selection, in which those individuals with the highest fitness as measured by number of offspring contribute most to succeeding generations. Darwin believed he solved this puzzle by treating the colony as the unit of selection. If specialization into distinct worker and soldier castes enhances colony survival and functioning, then the colony will be able to invest greater energy into the rearing of reproductives (new gynes [potential queens] and males) and as a result will experience enhanced reproductive success. As a consequence, colonies could evolve various specializations of queens, workers, and soldiers that contribute to colony-level fitness. This view of social insect colonies probably helped to usher in the early-1900s view of social insect societies as "superorganisms," in which colonies were seen to have attributes or abilities that were distinct from the sum of the behaviors of the individuals that comprise those colonies.

In 1964, W.D. Hamilton III proposed a different view of sociality based on kinship. He pointed out that in the Hymenoptera (bees, wasps and ants), males arise from unfertilized eggs. A consequence of this is that all sperm from a single male are identical. Female nestmates (sisters) that have the same father share three quarters of their genes in common, more than they share with their own offspring (one half). Hamilton pointed out that in hymenopteran colonies in which the queen has mated only once, it is genetically beneficial for females to remain in their nest to cooperate in rearing sisters rather than to risk leaving to start a new nest and raise daughters with which she would be less closely related and would share fewer genes. Hamilton extended his theory of "inclusive fitness" to all kin, both direct offspring and others that share some genes through shared ancestry (e.g., sisters, cousins, etc.).

Hamilton's theory of inclusive fitness ushered in a new wave of research on the role of kinship (i.e., the proportion of genes shared through common ancestry) on social systems, a field termed "sociobiology." One of the first steps was to determine whether organisms could recognize kin. Now, four decades later, there is ample evidence that within all the taxa of social insects, kin recognition abilities have been demonstrated. Recognition is mediated by chemical "signatures," both intrinsic, or genetically determined, and environmentally influenced, on the surface of the insect that are learned by nestmates. But simply having the ability to recognize kin does not mean that social insects also choose to direct aid towards individuals that are more closely related to them. Again, after numerous contributions from many researchers, the evidence has mounted that proves that, in most cases, social insects can act in ways to enhance their inclusive fitness. A classic demonstration of the operation of kin recognition comes from "worker policing" in honey bees. Worker bees have the ability to lay unfertilized eggs that develop into males, but when the queen is present in a normally functioning colony, worker-laid eggs usually are cannibalized by other workers. One can predict mathematically that it is in the workers' best interests to attempt to reproduce, because they are more closely related to their own sons (relatedness = 1/2) than to their brothers (i.e., queen-derived unfertilized eggs; r = 1/4). However, because queens naturally mate with about ten males, when a worker in the colony encounters a worker-laid egg, roughly nine times out of ten it will share only 1/8 of its genes with it as a result of common ancestry. When faced with eggs laid by workers (the majority of which are related by 1/8) and queen-laid male eggs (r = 1/4), it is in the best interests of worker bees to destroy the eggs laid by other workers. In fact, when tested empirically, it was found that after 24 h all worker-laid eggs had disappeared from colonies, whereas approximately 50% of queen-laid male eggs remained. As another example, paper wasps (*Polistes* spp.) have been shown to preferentially join with nestmates (e.g., sisters) rather than non-nestmates when more than one foundress wasp cooperate to initiate nests in spring.

On the surface it seemed that W.D. Hamilton had discovered the major factor leading to insect sociality, namely the genetic asymmetry resulting from the haplodiploid sex determination system (females diploid, males haploid) of Hymenoptera. The simple fact that females could gain more inclusive fitness by staying in their nest to cooperate in rearing sisters rather than leaving to initiate new nests to rear daughters seemed to answer the question. However, several pieces of information suggest that the situation is not so simple. As early as 1976, Robert Trivers and Hope Hare pointed out that the inclusive fitness gained by rearing their sisters (r = 3/4) is lost in rearing brothers (r = 1/4) rather than sons (r = 1/2) if colonies rear equal numbers of queens and males. Secondly, there are many haplodiploid taxa that have failed to evolve eusociality. Even most taxa in which offspring are produced clonally by their mothers, so that sisters and brothers share all of their genes in common, are not eusocial. Thirdly, the termites are an extremely diverse and successful group of insects, but their males derive from fertilized eggs and there is no genetic asymmetry between daughters and sisters, or sons and brothers. Although Hamilton's ideas have dramatically changed the perspective of biologists with respect to the concept of fitness and the role of kin in animal sociality, other considerations have eliminated the 3/4 relatedness hypothesis as the sole factor favoring the evolution of sociality.

In place of a unifying theory, most scientists now recognize that each taxonomic group of insects has its own set of conditions that have influenced the evolution of sociality. As an example, paper wasp (*Polistes*) larvae have the ability to eat proteinaceous prey, while adults with the narrow petiole connecting their head and thorax to the abdomen are restricted to a liquid diet. In times of inclement weather and the ensuing food shortages that regularly occur early in the nesting cycle, the adults solicit and receive food from the larvae to prevent their own starvation. While this behavior allows the queens and their brood to survive into warmer, less threatening times of year, it results in the offspring produced early in the nesting cycle receiving suboptimal nutrition. It has been suggested that these nutritionally compromised adults gain higher inclusive fitness by remaining on their natal nest rather than initiating new nests on their own. In the case of sweat bees (family Halictidae) that nest in aggregations in soil, brood parasitism often is reduced by sharing of the nest with another female. When either of the females is away foraging, the other is usually in the nest defending it from intruders. This mutualism enhances the overall reproductive success of both females and has played a significant role in the repeated evolution of sociality in sweat bees. In termites, symbiotic gut microorganisms are passed between colony members. When nymphs molt, they must become re-inoculated with these symbionts from their nestmates. The exchange of these symbionts has undoubtedly been a factor in the evolution of termites from their closest relatives, the cockroaches. However, Hamilton's work made it clear that no matter what the specific set of circumstances surrounding a particular taxonomic group, loss of reproductive capacity will not evolve unless the interactions involve related individuals (i.e., kin).

Bernard Crespi has examined in detail the life history traits of the less typical eusocial organisms, as a way to elucidate the suite of traits that are most likely to enable eusociality to evolve. He has suggested that three conditions are necessary for the evolution of eusociality: coincidence of food and shelter, strong selection pressure for defense of nests, and the ability to defend nests. In this context, the occurrence of the sting in Hymenoptera probably has played a large role in the evolution of sociality in bees, wasps, and ants. Crespi suggests that additional eusocial insect taxa may be found among long-lived bark beetles that have substantial cohabitation of adults and their offspring, book lice (order Psocoptera) and webspinners (order Embiidina) that occupy long-lived webs, and other gall-inhabiting taxa.

Because evolution cannot be viewed directly, we must infer the evolutionary pathways to eusociality followed by various groups of social insects. In the past, this was achieved by logical reconstruction of the stepwise changes that could have led to eusociality using the biologies of living species. An excellent example involves the evolution of sociality in wasps. Howard Evans used the comparative approach to relate social systems of various wasp species to each other. He developed a widely accepted framework, from solitary species to primitive mother-offspring (subsocial) associations, to more complex subsociality, and finally eusociality with reproductive division of labor as seen in temperate hornets and yellowjackets (subfamily Vespinae). With the advent of cladistic methods to construct phylogenies (evolutionary histories), and statistical analyses that allow the certainty of those phylogenies to be tested, we have made important advances in the understanding of the evolution of sociality. Returning to wasp evolution, by "mapping" behavioral states onto the phylogeny of the subfamilies of vespid wasps, it has been discovered that the most basal wasp subfamily in the phylogeny that exhibits sociality contains only parasocial associations of sisters, not subsocial mother-daughter associations. The sweat bees provide another example of the approach of combining phylogenetic analyses with behavioral data. It has long been recognized that parasocial associations of females have been involved in the repeated evolution (and loss) of eusociality within the family. By mapping states of sociality onto phylogenies, it is possible to identify those species for which further study will best illuminate the factors affecting the evolution of sociality, by finding closely related species that differ in their degree of social complexity. In a similar way, this approach of combining behavioral traits with phylogenies has enhanced our understanding of the evolution of sociality in termites.

The superorganism concept was mentioned earlier. Early in the twentieth century, the concept that insect colonies were analogous to whole organisms complete with "germ plasm" (queens and males) and "soma" (workers and soldiers) gained enormous popularity. Despite the importance of the superorganism concept as a paradigm for studying the biology of social insects for a significant period of time, it had largely disappeared by the 1960s. As ethological approaches to the study of animal behavior gained in force, so too did the application of the scientific method to field studies. Modern scientists entered an era of hypothesis formulation and testing. While the superorganism concept provided interesting analogies to other organisms, it failed to provide concrete hypotheses that could be tested empirically. Interestingly, the concept has seen a revival since the development of powerful personal computers. Researchers can quantify simple rules of behavior by observing individual insects, then combine them through computer simulations to recreate behavioral patterns of self-organized behavior with remarkable accuracy. This approach has been used to model, among other behaviors, pattern formation on honey bee combs, nest construction by termites, and army ant raids.

The study of insect sociality has led to many profound discoveries about insects. Some areas of research that should provide new insights in the future include the study of molecular and genetic changes that occur as complex societies evolve, the specific conditions that favor sociality, the relative importance of parasocial and subsocial routes to eusociality, more complex integration of systems of self-organized behavior, and enhanced understanding of the role of social insects in ecosystem functioning.

Soil Fumigation

JOSEPH W. NOLING
University of Florida, Lake Alfred, FL, USA

Soil fumigation is a preplant chemical treatment of soil, using a pesticide product that converts to form a volatile gas. The gas is able to diffuse through open pore space throughout the soil to provide soil-borne pest and disease control. All of the fumigants are phytotoxic to plants and the fumigant gases must dissipate from soil, usually from a few days to a month, before seeding or transplanting can occur without risk of crop injury. They are used globally on a wide range of annual and perennial crops, and can be used alone or in combination to control a wide range of soil inhabiting pest species including insects, nematodes, fungi, and weeds. Because of their wide range ofpesticidal activity, they are often called "multipurpose" or "broad-spectrum" fumigants.

Fumigants are commonly used in high value cropping systems to protect investment in crops where pest pressure is so high that it would be technically or economically unfeasible to grow a crop without the use of fumigant. As such, preplant soil fumigants have had a profound influence on production agriculture, and have catalyzed the worldwide development of many different high-value cropping systems. In some cases, fumigants have been adopted almost to the exclusion of all other soil pest management strategies because of their superior broad-spectrum pest control efficacy and consistent enhancement of crop growth, development, yield, and quality.

Historical Background

Discovered in 1869, the first fumigant pesticide to become available for agricultural use was carbon bisulfide. Because of its flammability, high rates of application, cost, and pest control inconsistency, carbon bisulfide was never extensively used in agriculture. In 1919, soil treatment with chloropicrin was demonstrated to provide excellent control of the root-knot nematode (*Meloidogyne* spp.), while in other studies, use of chloropicrin was shown to cure problems of "soil sickness" that restored the soil to a higher productivity than could be obtained from years of crop rotation or fallow. After considerable delay, chloropicrin was commercially introduced in the USA as a soil fumigant in 1937. It was first used on a limited basis by nurserymen and greenhouse operators as a substitute for soil steaming. In 1943, D-D (1,3-dichloropropene, 1,2,-dichloropropane and related C3 hydrocarbons) was shown in field trials to be an effective nematicide. By 1945, Shell Chemical Corporation had developed specialized field application equipment for D-D, including a tractor-drawn cart, complete with applicator, shanks, pumps, and tank for the fumigant, and even offered the first custom soil fumigation service. As a result, D-D was commercially introduced in 1945 as the first really effective and inexpensive soil fumigant for general field use.

In 1945, after demonstrating excellent control of root-knot nematode, ethylene dibromide (EDB) was commercially introduced by Dow Chemical Company as a low cost fumigant. Within a few years, the use of D-D and EDB increased tremendously due to the dramatic improvements in plant growth that were often observed following their use. Because use of these soil fumigants made the difference between an excellent yield and no yield, many growers adopted soil fumigation as a general practice. By 1949, soil fumigation with D-D and EDB has expanded to such an extent in many areas of the west and southeast, that the first mass production of field application equipment was undertaken.

Methyl bromide was first reported to be effective as a soil fumigant in 1940. In 1953, the synergistic effect of methyl bromide-chloropicrin mixtures for improved disease control was reported in California. Because specialized equipment required for methyl bromide field application was expensive, it was not extensively used, being employed only by large farming enterprises.

Soil fumigation in the USA really began in earnest during the early 1950s with in-furrow applications of D-D and EDB to control nematodes that became economic problems in re-cropped fields. In 1954, DBCP (1,2-dibromo-3-chloropropane) was determined to be a highly effective nematicide. Sodium methyldithiocarbamate (metam sodium) was introduced about 1956 and methyl isothiocyanate (MITC) mixed with D-D and released as DD-MENCS about 1960. By the mid 1960s, soil fumigation had become a common practice for controlling nematode and disease pests. In 1965, an integrated approach to soil pest management was introduced which combined broad spectrum soil fumigation using methyl bromide and chloropicrin with plastic film mulch to cover a raised plant bed for crop production. Soil fumigation with methyl bromide was quickly adopted and for over 40 years, preplant soil fumigation with methyl bromide and chloropicrin has been the principal fumigant used for soil-borne pest and disease control for many fruit and vegetable crops around the world.

As indicated previously, many different soil fumigant compounds have been field evaluated for soil-borne pest and disease control. Six soil fumigants have been used at one time or another for crop production including methyl bromide-chloropicrin; DD-MENCS (chlorinated C3 hydrocarbons (80% D-D) + 20% methyl isothiocyanate [Vorlex]); sodium methyl dithiocarbamate (Vapam); 1,3-d (1,3-dichloropropenes [D-D, Telone]); EDB (ethylene dibromide) (Dowfume, Soilfume, W85); and DBCP (1,2-dibromo-3-chloropropane [Nemagon, Fumazone]). Unfortunately, many of these fumigants have been found to leave toxic residues in the soil and/or pose potentially serious risks to humans and/or to the environment. For example, in 1977, a high incidence of male sterility was reported among workers at the Occidental Petroleum plant in Lathrop, California, USA, where DBCP was manufactured. In May 1979, DBCP was discovered in groundwater in California, and was shortly thereafter withdrawn from most of the global marketplace. In 1984, EDB was similarly banned for environmental contamination. In 1990, 1,3-d was restricted from use in California due to potentially harmful air quality concerns resulting from high soil emissions during spring fumigations. It was restored for use in 1994 after improved application and soil containment methods were tested and implemented. Most recently, methyl bromide was implicated as a significant contributor to ozone depletion. In 1993, it was mandated for phase-out of production and use by January 1, 2005, in developed countries and a phase-out deadline of 2015 in developing countries. Recent actions by state and federal regulatory agencies suggest that additional restrictions, including buffer zones that will restrict places of fumigant use, and added forms of personal protective equipment worn by field workers, will serve to limit use of any of the remaining fumigants in the USA, and perhaps elsewhere.

Fumigant Spectrum of Activity

Since their introduction to agriculture, many different soil fumigants have been evaluated in field research trials to characterize pest control efficacy and crop yield response. The results from many of these research trials have provided the basis for overall generalization of pesticidal activity for the various fumigant chemicals. In general, this research has repeatedly demonstrated methyl bromide or methyl iodide to be very effective against a wide range of soil-borne pests including nematodes, diseases, and weeds. Chloropicrin has proved very effective against diseases but seldom nematodes or weeds. Although with some suppression, bacterial pathogens have not been satisfactorily controlled by any of the soil fumigants. Historically, most of the research conducted to evaluate 1,3-dichloropropene (Telone™; Dow AgroSciences) has repeatedly demonstrated consistently effective nematode control with little or no control provided for soil-borne disease or weeds. Metam sodium, metam potassium, and dazomet are all non-selective preplant soil fumigants which provide measures of fungicidal, herbicidal, insecticidal, and nematicidal activity. Pest control efficacy of metam sodium and metam potassium have proved inconsistent, performing good to excellent in some trials, while poor in others. Field research continues to evaluate modification of rate, placement, and improved application technology to resolve problems of fumigant inconsistency with these compounds.

Because of their target pest specificity, many of the soil fumigants are formulated together or co-applied to increase their overall level and spectrum of pest control. For example, chloropicrin is used both as a stand-alone soil fumigant, as a chemical warning agent in formulation with methyl bromide, and in formulation with 1,3-d to increase its disease control effectiveness. Examples of co-formulated or sequential application include 1,3-dichloropropene plus chloropicrin formulated together as Telone C17 or Telone C35, or sequential applications involving a broadcast application of 1,3-dichloropropene, followed later by chloropicrin and/or metam sodium in separate soil applications. Given the general lack of herbicidal activity associated with many of the fumigants, separate application of one or more herbicides may be required to achieve effective weed control (Table 16).

Physical and Chemical Properties

After application to soil, the fumigants penetrate into the soil and quickly become partitioned in liquid, gas, and adsorbed soil phases. Initially, and immediately after soil injection, fumigant movement in soil is driven by density and pressure gradients from a narrow, linear band of concentrate product deposited directly below the chisel path. As the fumigant's partial pressure falls, soil movement via mass flow becomes less important than by simple gas diffusion processes. Fumigant persistence, volatility, and degradation are influenced by many factors, including chemical properties, soil properties, and environmental conditions. A listing of the physical and chemical properties of the primary soil fumigants is provided (Table 17).

Volatilization continues as long as the fumigant remains in soil and upward movement of the fumigant occurs as long as a concentration difference exists between the soil surface and soil atmosphere. Henry's Law Constant characterizes the equilibrium distribution of dilute concentrations of volatile, soluble chemicals between gas and liquid phases, and is used to describe the mobility potential of volatile organic compounds through soil as a gas. High soil mobility in soil is due to vapor diffusion, large Henry's constant and low soil sorption. Vapor pressure is a measure of the tendency of a fumigant compound to change into the gaseous or vapor state. The temperature at which the vapor pressure at the surface of a liquid becomes equal to the pressure exerted by the surroundings is called the boiling point of the liquid. The lower the boiling point, the more volatile the fumigant compound. Hot and dry soil conditions favor more rapid escape of fumigants like methyl bromide, methyl iodide, and chloropicrin, particularly within surface soil horizons.

Methyl bromide is a colorless, odorless, liquid under certain conditions of pressure and temperature. At temperatures below the boiling point of 3.6°C, or within the confines of a pressurized cylinder, methyl bromide exists as a liquid. At temperatures typical of field application (26–32°C), methyl bromides rapidly volatilizes to a gas once

Soil Fumigation, Table 16 Generalized summary of the effectiveness of various soil fumigants for nematode, soil-borne disease, and weed control (L = liquid; G = Microgranule)

Fumigant	Nematode	Disease	Weed
Methyl bromide (L)	Excellent	Excellent	Good to excellent
Chloropicrin (L)	None to poor	Excellent	None to poor
Methyl iodide (L)	Good to excellent	Good to excellent	Good to excellent
Metam sodium (L)	Poor to excellent	Poor to good	Poor to good
Dazomet (G)	Poor to good	Poor to good	Poor to good
1,3 Dichloropropene (Telone II) (L)	Good to excellent	None to poor	Poor
1,3 Dichloropropene + chloropicrin (17%) (Telone C17) (L)	Good to excellent	Good	Poor
1,3 Dichloropropene + chloropicrin (35%) (Telone C35) (L)	Good to excellent	Good to excellent	Poor
Metam potassium (L)	Poor to good	Poor to good	Poor to good

Soil Fumigation, Table 17 **Physical and chemical properties of various soil fumigants (physical state: L = liquid; G = Microgranule)**

Fumigant compound and physical state	Boiling point (°C)	Molecular weight	Density (g cm^{-3})	Vapor pressure (mmHg)	Henry's constant	Specific gravity	Soil degradation half-life (d)	Solubility (mg L^{-1})
1,3-Dichloropropene (L)	120	111	1.22	28	0.06	1.218	3–5	2,250
Chloropicrin (L)	112.4	164	1.69	18	0.07	1.692	1–2	2,270
Methyl bromide (L)	3.6	95	1.73	1,420	0.25	1.732	12–20	13,400
Methyl iodide (L)	42	142	2.28	400	0.22		20–40	14,200
Metam sodium (L)	112	129	1.21	0.4	0.01		25 min	578,290
Metam potassium (L)	114	145	1.27	24				
Dazomet (MG)	–	284		–	–	–		30
Methyl isothiocyanate	112	73	1.05	20	0.01	–	4–5	89,400

released from the pressurized cylinder into the ambient pressure of air or soil. With such a high vapor pressure (1,420 mmHg), methyl bromide is capable of very high mobility through open air passages among soil particles. Water may effectively block efficient diffusion in soil. Without impediment, methyl bromide can quickly move to the soil surface and escape into the atmosphere. With such rapid soil diffusion, some form of containment is usually necessary to hold highly volatile gases like methyl bromide, chloropicrin, and methyl iodide in soil for sufficient time and concentration to achieve satisfactory pest and disease control. Factors which affect containment include use of plastic mulch, thickness and permeability properties of the mulch, soil injection depth, soil bulk density, and soil water content.

Chloropicrin is a small, colorless, single-carbon molecule (mw 164.4) with a moderate vapor pressure (18.3 mmHg) and high boiling point (112°C). Chloropicrin diffuses readily through soil, but the diffusion and dissipation process is slower than that of methyl bromide. Chloropicrin is also a strong lacrimator (tear producer), which makes it useful as a warning agent to field workers if it escapes from the soil. Released to the atmosphere, chloropicrin photodegrades at a half-life of 20 days. Like chloropicrin, 1,3-d has an intermediate vapor pressure of 28 mmHg and water solubility of 2,250 mg/L. In general, the entire soil fumigant process for 1,3-d (volatilization, diffusion, dissipation) is about three to five times slower than that of methyl bromide, and all phases of the process can be significantly delayed by rainfall or irrigation events that saturate soil air spaces with water. Under conditions of low soil temperature and/or high soil moisture, outward diffusive movement is retarded and soil dissipation is protracted if soils remain cold and wet. In some instances, it may be necessary to disturb the soil to encourage soil fumes of 1,3-d to escape before transplanting or seeding.

Dazomet is a granular product that must be mixed mechanically with the soil and activated with water to release the bioactive degradation product, MITC. Metam sodium and metam potassium are both very water soluble compounds with low vapor pressure. Both become activated in water and also quickly degrade to MITC at rates determined by soil moisture and temperature conditions. Metam sodium and metam potassium differ from other soil fumigants like 1,3-d, methyl iodide, methyl bromide, and chloropicrin that principally move through open air passages within soil. Both metam compounds are not as volatile and move in the soil profile with soil moisture. In general, movement in soil is most efficient in the water phase than gas phase.

Mode of Action and Lethal Dose

Fumigant mode of action refers to the lethal action of a chemical on specific and vital life processes of an organism. For example, a broad-spectrum fumigant can penetrate the body wall of a nematode directly and does not have to be eaten to be effective. Once inside the body cavity of the nematode, different internal organs are affected since they are bathed by body fluids containing the fumigant compound. Metam sodium and potassium are very soluble compounds which become activated in water. The fumigants and their products interfere with many different vital processes, including enzymatic, nervous, and respiratory systems. Death of the nematode is rapid under these conditions, and development of tolerant or resistant populations to the chemical are unlikely because so many integral bodily functions are simultaneously affected. In general, fumigant concentration in internal body fluid frequently reaches equilibrium with soil concentrations within about 30 min to 4 h. In some cases fumigant concentration may accumulate to much greater levels within the nematode than in soil.

In general, the lethal effect of a fumigant is determined by two components. The first is concentration (C) of the fumigant in soil air or soil solution, usually expressed as parts per million (PPM). The second is the length of time (T) the pest organism is exposed, expressed in minutes, hours or days. The level of pest control is then related to dosage, the amount of fumigant pesticide placed in the environment of the soil-borne pest for a known length of exposure time (concentration X time). Total exposure is the sum of CT products. Computed in this way, the cumulative dosage or concentration-time index (CT), is often used as a criterion with which to evaluate the effectiveness of soil fumigation. For most organisms, there is a concentration level below which kill is not obtained regardless of the length of exposure. For most nematodes, long exposures to low concentrations of fumigant nematicides above the minimum concentration appears to be more effective than short exposures to higher concentration.

Fumigants move through soil air, dissolve in the soil water and kill in the soil water. Fumigants are volatile substances and change into gases upon injection into the soil as liquids. The vapors can only move through the continuous soil air space. Pest and disease organisms normally exist within surface films of water surrounding soil particle grains. Even as fumigants move through open air passages, fumigant molecules dissolve into these surface water films and establish a dynamic equilibrium, moving back and forth from the air to the water phase as the fumigant diffuses through the soil mass. That portion of the fumigant dissolved in the soil water establishes the concentrations responsible for the kill of most soil-borne organisms.

In practice, fumigants are commonly injected through a series of uniformly spaced shanks into soil. As the liquid volatilizes, gases begin moving in mass flow, diffusing outward in all directions from the point of injection. Because diffusion is greater in air above the soil surface, upward mass flow and diffusion is usually greater than downward movement, and much of the gas may escape the soil and enter the atmosphere. As the fumigant front moves through soil, gaseous molecules are adsorbed to soil particle surfaces, redissolve into soil solution, and fill empty air spaces between soil particles. Maximum fumigant concentration decreases as do the sums of CT products with distance from the point of injection. Eventually, with time and distance, concentrations fall below an immediate killing level. The number of pests or disease propagules killed by fumigant treatment within these areas depends on the number of CT units which develop within the fumigant treated zone. The relationship between fumigant application rate and pest control efficacy is therefore not only a measure of fumigant toxicity but chemical dispersion as well. If dispersal is good, increases in fumigant application rates will result in higher CT values and provide control to a greater soil volume. If dispersal is poor, increases in application rates will not provide control to a larger soil volume. Reducing volatilization losses from soil is an effective way in which to increase CT values and improve fumigant pest control efficacy. It is for this reason that water seals and impermeable plastic mulches are used to increase fumigant diffusion resistance near the soil surface. This serves to promote both downward diffusion of the fumigant and to enhance residence time and gas phase persistence in soil.

Factors Affecting Efficacy

Various edaphic, environmental, biological, and cultural factors are known to directly influence fumigant treatment performance and consistency. Regardless of application method, fumigant efficacy is highly dependent upon dosage, uniform delivery, and soil distribution. Prevailing soil and climatic conditions are also very important determinants of gas phase movement in soil, and thus pest control efficacy and crop response.

Soil Moisture

Once injected into soil and at temperatures above 15°C, most fumigants vaporize readily into a gas and diffuse through open soil pore space. Soil moisture content is important in this regard, primarily as it relates to the availability of continuous pore space. Soils that are too moist inhibit extensive diffusion through soil. Fumigants can move as much as 10,000–30,000 times faster in soil air than they do in the soil water. Soils that are too dry promote the rapid escape of gases from soil into the atmosphere. As a soil changes from dry to field capacity, the amount of fumigant in the soil water increases and the amount in the soil air decreases. In the case of a saturated or wet soil, the fumigant will not move through the soil as a gas. Soils with a high water table effectively block downward diffusion and limit depth of pest control. In general, good fumigation conditions exist when the soil can be compressed in the palm of a hand to form a ball that breaks apart with slight finger pressure. If the soil ball does not break apart easily, it is likely too wet for fumigant treatment.

Some fumigants, like 1,3-d, are more vulnerable to high soil moisture conditions. As a soil-injected liquid, 1,3-d slowly volatilizes into a gas that then moves through unrestricted air space. It is the unrestricted movement of 1,3-d through soil air spaces three dimensionally that defines treated soil volume and the overall zone of pest control. Any soil zone in which water fills open pore spaces between soil particles, or where soil particles are compressed and closely compacted, will inhibit 1,3-D diffusion. High levels of rainfall or irrigation can thus potentially reduce 1,3-d treatment efficacy by filling open pore air space before, during, or even after fumigation has been completed. This reduced efficacy can occur via containment (trapping the liquid, preventing further volatilization, movement and degrading the product via hydrolysis), or by inhibiting unrestricted movement from the chisel stream flow of injected product. Because of its differences in vapor pressure compared to other fumigants, 1,3-d requires much more consideration of appropriate soil preparation and moisture condition to ensure satisfactory performance in the field.

Soil Temperature

Temperature is also important as it relates to soil moisture, because it directly influences the fumigant vaporization rate in soil. As temperature increases, so then does the vaporization rate of the fumigant. The importance of soil moisture and temperature to product efficacy cannot be overemphasized. For example, when applied to dry, sandy soil under conditions of high air and soil temperatures, substantial losses of fumigants from soil can occur. A change in soil temperature also changes the solubility of the soil fumigants in air and water. More fumigant is dissolved in the soil water at 4°C than at 26°C; the solubility of a fumigant in the water increases at lower temperatures, whereas the percent of the fumigant in soil air decreases. The decrease in the amount of fumigant in the soil air occurs because the cold soil results in slower movement of the fumigant s compared with warm soil. It is important, therefore, that appropriate conditions of soil moisture, temperature, and land preparation are present at the time of fumigation to optimize outward diffusion and soil retention of any soil fumigant. In general, moist (not wet) soils of a temperature between 15 and 26°C are usually considered ideal for soil fumigation.

Soil Texture

The ability of a fumigant to move throughout the soil profile, and therefore its efficacy, also varies with soil type. Diffusion of a fumigant through fine textured soils such as silt or clay is a slower and much more difficult process than diffusion through a coarse textured soil like sand. As a result, a clay or silty loam soil should be quite dry prior to treatment, whereas a very sandy soil can be quite wet. Any soil condition that restricts fumigant diffusion or favors rapid escape will affect the overall performance of soil fumigation.

Plow, rip or otherwise till the soil to the depth to which effective treatment is required. The soil should be worked until free of clods or large lumps. Residue from previous crops should be worked into the soil to allow for decomposition prior to fumigation. Soil moisture should be adequate for seed germination. Coarse textured soils can be fumigated with higher moisture content than fine textured soils. For best results, soil should be kept moist for at least 4 days prior to treatment. Do not fumigate if the soil temperature is below 10°C. For best results, fumigate when soil temperature is 15–26°C at a depth of 15 cm.

Compaction, Clods, Organic Matter

After the fumigant is injected into the soil, it vaporizes and a portion of it moves upward. As it approaches the soil surface, it tends to move more rapidly because of the drier conditions and increased porosity. If the surface is sealed by compaction or with some type of sealing device, loss through the surface will be reduced. A clod represents two problems in control. A compacted soil clod will not allow the fumigant to penetrate and control the organisms within the clod, and the soil surface is very difficult to seal if there are large clods on the surface. Organic matter in the soil also affects the mobility of the fumigant in the soil. Soil fumigants are readily absorbed by organic matter. Also, undecayed plant remains can foul application equipment and puncture plastic film. If possible, organic matter should be allowed to decay before application. Fumigant rates should be increased where soils contain large amounts of organic matter. Weed control is greatly influenced by soil conditions. Soil too wet, too dry or cloddy will reduce the level of control achieved.

The presence of a compacted zone, hard pan, or traffic layer can impede downward diffusion and overall performance of fumigant treatment. As the soil becomes more and more compacted, the particles make physical contact, and the water films bridge over resulting in an impermeable condition. Thus, compacted soil layers cannot be effectively penetrated with fumigants. However, this same principle can be utilized to hold fumigants in the soil by compaction of soil particles near the surface, providing a type of seal by closing off the soil air spaces. To resolve problems of compaction, deep tillage is recommended.

Phytotoxicity

All of the fumigants, including the gas and water phases of these fumigants, are toxic to plants. Soil dissipation and the persistence of toxic residues are strongly influenced by environmental conditions. Any change in soil condition that promotes a cooling and/or wetter soil condition will typically delay dissipation of a fumigant compound. As a result, soil applications must always be made well in advance of a seeding or planting date to ensure sufficient time for dissipation of fumigant residues from soil. The problem is usually most severe with fumigants of low vapor pressure, where longer term planning horizons must be adopted to avoid problems of phytoxicity or to avoid long unscheduled delays in planting after the plants have arrived from the nursery. Growers that use fumigants, typically adopt planning horizons that consider beginning field preparation and soil application 2–3 weeks earlier than normal to avoid problems of potential phytotoxicity that may result from use of impermeable mulches, or unexpected cold fronts or storm(s) producing abundant rainfall.

Fumigant Containment

Historically, most of the field research conducted to evaluate the use of soil fumigation has repeatedly demonstrated effective soil-borne pest and disease control when applications were made under optimal soil conditions, uniformly applied at the appropriate dosage and depth, and using containment systems that prevented rapid escape of gases from soil. Any system designed to provide containment of fumigant gases must first insure immediate closure and seal of chisel traces as they are produced behind the tractor moving across the field. Left undisturbed, the chisel traces act as chimney vents for volatilizing fumigant gases. This can be accomplished with press wheels behind the chisel or chisel injections immediately in front of bed forming equipment. The treated field area may also be rolled to compact surface soil, so as to increase soil density and reduce air passage size and volume. Irrigation is also often applied over the top of the treated area or rolled surface to form a surface water seal to further inhibit fumigant outgassing from soil. In some instances, repeated irrigations may be necessary to manage fumigant containment and offsite movement of fumigant gases.

After a fumigant is applied, the treated soil may also be tarped with a plastic polyethylene mulch to provide an additional measure of fumigant containment to soil. The plastic mulches, often a prerequisite for fumigant use, are not only a barrier in themselves but act as a condensation surface for the formation of water droplets that redeposit to soil as a water layer, adding another barrier to soil volatilization loss. There are a range of different mulches which can be used to reduce fumigant emissions from soil. Low density polyethylene (LDPE) or high density polyethylene (HDPE) tarps have been extensively used in combination with soil fumigation as a soil covering to reduce fumigant emissions from soil. Unfortunately, the barrier properties of LDPE and HDPE to fumigant gases are quite poor and, depending on the fumigant, much of it may quickly escape the soil. In general, the permeability of plastic mulch to a fumigant gas is directly related to its thickness, density, and chemical composition. Significant resistance to fumigant outgassing has been achieved with use of virtually impermeable mulch films (VIF). VIF mulches are typically manufactured as multi-layer films composed of barrier polymers such as ethylene vinyl alcohol (EVOH) or polyamide (nylon) sandwiched between other polymer layers (typically LDPE) or have metalized coatings to reduce the amount of fumigant that can move through the film and into the atmosphere.

Compared to LDPE, certain VIF films are over 20,000 times less permeable to fumigant compounds and, as a result, significantly increase the residence time of fumigants in soil. Because of their excellent barrier properties, fumigant application rates can often be reduced as much as 50% without loss of pest control activity or crop yield. The mulch, although not completely impervious to fumigant gases, reduces the dissipation rate of gases into the air that increases the overall efficacy of the treatment by subjecting soil pests to greater cumulative dosages levels of the fumigant.

Due to increased environmental and regulatory scrutiny, use of VIF or high barrier plastic mulch films are likely to become mandated for use of any soil fumigant in the future. Use of these more gas-retentive mulches will, however, require changes in field application and soil injection equipment to insure accurate and uniform dispensing of such reduced volumes and application rates of the fumigants. These required changes include reduced rate flow meters, smaller delivery tubing size, installation of sight gauges to monitor flow uniformity among chisel streams, and installation of low pressure gauges upstream of flow divider to monitor and insure adequate system back pressure.

Field Application Equipment

Soil fumigants are applied using several methods. Liquid fumigants can be applied by directly injecting them into the soil using shanks or chisels, and in some cases by injection into the irrigation system (chemigation). Fumigants are formulated and applied to soil in a number of ways. The portion of the field that is fumigated can also vary. For example, in the production of some crops, the entire field is treated, and this represents an overall or broadcast treatment. In other situations, fumigants are only applied in the plant row or raised plant bed. In this situation, only a portion of the field is treated and this is termed a strip, band, or in-row treatment. Most liquid fumigants with high vapor pressure are shanked or knifed into the soil. Narrow knifelike shanks are tractor-drawn through the soil at the required depth to inject the fumigant into soil. Metal delivery tubes attached to the trailing edges of the shanks provide the conduit for injection to soil. Delivery tubes release the fumigant in the bottom of the furrow made when pulling the shank thorough the soil. Fumigant flow rate to the soil shanks is regulated using various combinations of pressure, metering valves, nozzle orifices, shank spacing, and speed of travel.

Metam sodium, metam potassium, and emulsified concentrate formulations of 1,3-dichloropropene, chloropicrin, and methyl iodide can also be metered into irrigation systems and applied through a low volume trickle or drip irrigation system. Metam sodium and potassium have also been broadcast applied by overhead sprinklers. The other fumigants are liquids with high vapor pressure, so they are usually stored and applied as liquids (under pressure) and begin to vaporize shortly after injection in the soil. It may also be applied to field or row crops during preplant stages via chemigation, soil broadcast treatment, soil band treatment, soil-incorporated treatment, and soil-injection treatment. Chemigation is the most common method of application for some fumigants like metam sodium or metam potassium.

Because of the slow diffusion of MITC as a gas and high affinity for the water phase, continuous delivery in irrigation water following premixing has generally resulted in more uniform soil distribution with enhanced nematode control and crop yield when compared with conventional chisel injection methods. The proximity of the plant to the drip tube has also been demonstrated to be very important in terms of defining pest control efficacy and plant growth response with a chemigated fumigant. Given the sandy nature of some soils, narrower bed widths, drip tubes with closer drip emitter spacing (likely in the range of 8–12 in.), and planting practices that place plants closer to the drip tube may need to be adopted to more effectively utilize the drip tape for chemigational purposes. Soils and grower production practices differ markedly, and these differences in soil type, compaction, and depth to restrictive layers can all affect water movement and the final distribution of chemicals. The presence of a shallow compacted traffic layer severely restricts downward penetration of drip water. In general, the average depth, width, and cross sectional area wetted by drip irrigation water increases with total water volume applied. For a given water volume, the use of two tapes per bed increases spatial distribution of irrigation water simply because of the spacing between drip tubes and the increased number of emission points along the bed.

As a microgranule formulation, dazomet is typically applied to the soil surface using a Gandy type drop spreader, and then watered into or mechanically incorporated into soil. New soil application technologies are capable of multiple operations, including drop spreading, rotovator incorporation via L-shaped tines, followed immediately by a power-driven roller to optimize containment of methyl isothiocyanate (MITC) gases after soil incorporation. Power rolling serves to compress, smooth, and seal the soil surface to minimize escape of MITC gases. After application, incorporation, and rolling, irrigation is applied to provide another form of surface water seal to escaping gases, as well as to convert (activate) dazomet to the bioactive compound, MITC. Because of typical tractor power requirements, incorporation depths are often limited to 15 cm or less. In general, biocidal activity derived from conversion of dazomet to MITC is directly related to Dazomet application rate and limited by incorporation depth. Dazomet's physical characteristics (ultra-fine powder) also impose application limitations because it is extremely corrosive to equipment, vulnerable to drift, and application equipment must be tightly sealed to limit spillage to areas of application.

Other fumigants, like methyl bromide, chloropicrin, and 1,3-dichloropropene, are premixed and sold in compressed gas cylinders. In most cases, these fumigants are shank-injected into the soil 20–60 cm deep using a positive pressure-closed system in which the fumigant cylinders are pressurized with nitrogen. With this system, an inert gas is used to propel liquid flow from the cylinder through the metering systems and through armored lines to the rear shanks or chisels, exiting through a steel delivery tube welded to the back side of the shank or chisel. Deep placement is not only a requirement of the fumigant label but is essential for prolonged fumigant retention in soil. In general, the closer to the soil surface a fumigant is applied, the faster the outgassing or escape from soil and, in general, the poorer the pest control response. A plastic, polyethylene tarp may be laid down over the soil immediately behind the shanks of the injection equipment to provide a diffusion barrier for containment of the fumigant.

Application

As indicated previously, an inert gas (nitrogen) is used to maintain constant pressure to the fumigant cylinder to ensure a constant flow of the fumigant from the cylinder to the metering device during fumigant application. In-line valves downstream of the fumigant cylinder are then used to actually control the delivery rate of the fumigant to and through the flow meter. The sole function of the meter is to act as a simple gauge to indicate the percentage of maximum flow (0–100%) discharging from the meter. Many factors affect the actual flow rate of a liquid through the flow meter. For example, all soil fumigants have different densities (specific weights) and are heavier than water. In general, the denser a liquid, the higher its specific gravity, and the more slowly it will flow through a flow meter compared to water. Because of these differences in specific gravity, the actual capacity of the flow meter will change, and thus must be corrected to insure application accuracy with the different fumigants. Miscalibration of the flow meter and determination of field application rate are two of the most common causes of fumigation failure. Other causes of inconsistency are due to inappropriate soil conditions, application procedures, or equipment. In general, uniform delivery and distribution among soil chisels can only be achieved with proper fumigant metering, delivery tube sizing, and maintenance of manifold back-pressure at the flow divider.

Risks to Environment and Human Health

A considerable amount of research has been conducted to evaluate food and worker safety and risks to the environment. For example, the results of numerous plant metabolism studies generally confirm that there is no reason to expect unhealthful residues in or on any raw agricultural commodity when any of the fumigant compounds are applied as a preplant soil treatment according to label directions. As a result, none of the fumigants have required the establishment of food tolerances for US federal pesticide registration. There are, however, other key concerns that have been consistently expressed by state and federal regulatory agencies. These concerns generally involve both dermal and inhalation exposure by field workers. Also, those people in the general population living and working in close proximity to fumigant treated fields are susceptible to inhalation exposure.

Methyl bromide is colorless, tasteless, and odorless except at extremely high concentrations. Because methyl bromide is a gas at room temperature, respiratory problems through inhalation are the most common and serious injury. Methyl bromide is poorly absorbed through the skin, although direct contact with the liquid phase of methyl bromide can cause skin blisters and diffuse through the skin to enter the circulatory system. In the body, it may cause severe lung irritation and cumulative damage to the heart, kidneys, and nervous system. Accidental overexposure to methyl bromide may result in acute (short term) or chronic (long term) poisoning.

Chloropicrin is a colorless oily liquid, alternatively identified as tear gas. Concentrations of 0.1 ppm or greater generally result in painful irritation to the eyes in three to 30 s. Since chloropicrin causes so much irritation of the eyes and upper respiratory tract, exposed individuals are unlikely to inhale a quantity of fumigant capable of damaging the lungs. Methyl bromide is not so irritating to the nose, eyes, throat, and bronchi, but causes serious injury to the cells lining the fine air sacs of the lung. The onset of symptoms of methyl bromide poisoning may be delayed several hours or days following exposure. Thus, it is more likely than other fumigants to induce pulmonary edema (fluids in lungs), a major cause of death from overexposure. In practical terms, mixtures with chloropicrin are always used in commercial agriculture to minimize the insidious effects of methyl bromide.

For both metam sodium and potassium, the principal routes of entry include skin and eye contact and inhalation. In general, the principal signs of dermal exposure include moderate to severe skin irritation depending on solution concentration and length of exposure. As with all MITC-generating fumigants, overexposure to MITC may cause irritation of mucous membranes of the lungs, bronchitis or pneumonia or other symptoms of respiratory distress. Because of this, various types of eye, skin and respiratory protection may be required for field workers.

All of the fumigants continue to be closely scrutinized by local, state and federal regulatory agencies for worker safety and risk of exposure. Following application, many of these fumigants can volatilize into the atmosphere and be transported off-site. This can lead to inhalation hazards and exposures to the fumigants in the general public and to workers following application. New rules and regulations governing use of fumigants within the USA continue to change. Currently, the US EPA is considering new requirements for personal protective equipment to mitigate possible contact and inhalation exposures. These new changes may require field workers to wear NIOSH-approved respirators, and to mitigate dermal exposures, workers may be required to wear adequate protective clothing, which, dependent upon the fumigant, may include coveralls, impervious gloves, boots, face sealing goggles, and/or other protective headgear.

Soil Mites (Acari: Oribatida and Others)

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Soil is a complex of living and non-living components which are present in different combinations. Small arthropods, including several groups of mites, contribute to the humus fraction and permit complexes of soil organisms to exist. Even though the role of mites in soil mixing may be small in comparison with that of larger invertebrates such as earthworms, insects, crustaceans and millipedes, mites exercise an important function in mineral turnover, vegetation succession and as decomposers of organic matter. Densities of 50,000–250,000 or more mites per square meter may be found in the upper layers of soil. Dozens of species may be found in a small area when soil is rich in organic material such as decaying vegetation, dung or animal remains. In combination with microflora, which the mites may disperse, soil mites help in decomposing organic matter which they cannot digest. Much of the work on soil mite taxonomy, biology and ecology, including their role in nutrient cycling and fertility-humification processes, has been carried out in Europe.

Mites in the Suborder Oribatida (=Cryptostigmata), also called moss mites or beetle mites (Figs. 74–75), are distinctive soil mites, ranging in size from 200 to 1,400 μm. They are common in soils that are relatively undisturbed and have a high organic content. Some species of Oribatida may be found on the trunks of trees or on low-growing vegetation. Oribatida species can even be found associated with roots of plants very deep in the soil. There are an estimated 150 families in the Oribatida in 10,000 species in 1,100 genera. The name “beetle mites” is a result of the fact that many have hard, dark brown exoskeletons and somewhat resemble miniature beetles. The term moss mites is due to the fact that they are often found in mosses.

A summary of their biology is as follows: Sperm transfer is indirect, and mating takes place when males deposit spermatophores that are taken up by the female (indirect sperm transfer). Spermatophores are stalked and often deposited in groups. Many are destroyed by being eaten. Copulation has never been observed in oribatids and parthenogenesis (reproduction without mating) is known in some families. Females typically deposit one to twelve eggs at a time. After mating, females deposit oval eggs singly or in small clumps in old exuviae, the axils of moss bracts, under detritus, and in the soil pores. Often the female retains a number of eggs until all are mature and she deposits them at once. There is a prelarva, larva, three nymphal stages and the adult. The length of time to reach adulthood depends on temperature, but is relatively slower than that of other mite suborders; smaller oribatid species have a shorter development time and life span than larger species. Rate of development also is influenced by whether the diet is adequate and whether the mites are crowded. In general, small species may have several generations a year (compared to one generation a week for the two-spotted spider mite, a plant-feeding pest in the suborder Prostigmata). Larger species may have one generation per year and some oribatid species may require several years to complete their life cycle in cool climates.

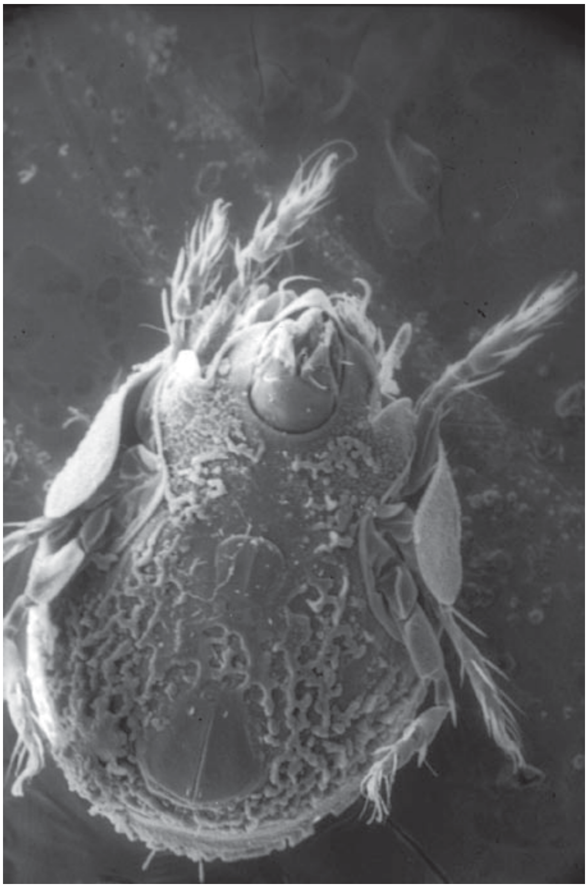
Soil Mites (Acari: Oribatida and Others), Figure 75 **A soil-swelling oribatid mite, *Haplophorella cucullata* (Ewing), side view (photo by Roy Norton, SUNY, Syracuse).**



Soil Mites (Acari: Oribatida and Others), Figure 76 **A soil-dwelling oribatid mite, *Ceratozetoidea pteromorphae*, viewed from below.**

Oribatids chose optimal temperatures (or at least avoid unfavorable temperatures). Humidity requirements are species specific; some are able to survive for days at low relative humidities while others need higher relative humidities to survive. Salinity and soil pH are important; soils rich in organic matter have a high pH.

Oribatid mites are microphytophages, feeding on pollen, small pieces of algae, lichens, highly decomposed humus, and fungal hyphae. They can also be macrophytophagous, feeding on dead plant tissues, parenchyma of needles, or directly on dead wood. Some are nonspecialized, feeding on leaf tissue and on fungal mycelia. The larger species are generally macrophytophagous or nonspecialized and thus play the main role in litter decomposition. Some oribatids prefer animal food and can be maintained on cricket powder in the laboratory. Some oribatids feed on the numerous nematodes in the soil. Laboratory rearing of some species can be accomplished with dried mushrooms, chopped lichens, decomposing leaves, or an artificial diet of dextrose and casein or brewer's yeast.

Only a few soil mite species have a direct role in altering soil morphology. Most exercise indirect effects through stimulation of microbial activity and distribution of spores. Pesticides can have a negative effect on nutrient cycling by permitting energy to remain bound up in undecomposed plant debris. Pesticides can positively affect nutrient cycling by killing predators of saprophagous arthropods, thus releasing detritus-feeding populations.

Species in the Oribatida are thought to be especially important decomposers of plant debris. On mulched plots, they make up 60% of the total arthropod species, compared to 8.5% on mowed or fallow plots. Distribution of microarthropods is irregular under annual crops, in part due to the effects of cultivation. Fewer mites are found in grasslands than in forest communities. Microarthropod distribution is influenced by water, pore space, oxygen saturation deficits, temperature variations, ground cover, fungi, flooding, cropping, cultivation, organic matter, disturbance, soil compaction, soil type and texture, predation, and feeding habits.

Oribatida serve as food for centipedes, symphyla, diplurans, spiders, pseudoscorpions, opilionids, ground beetles, and ants. The Oribatida also are fed on by beetles in the families Pselaphidae and Ptiliidae. Some birds, salamanders, frogs, skinks and other small lizards also may feed on oribatid mites. Oribatid mites may function as vectors of anoplocephaline tapeworms; moss mites are intermediate hosts for the transmission of cysticercoids of these tapeworms and 12 families, 25 genera and 32 species are confirmed vectors.

Mites other than species in the Oribatida also are found in the soil; Actinedida, Gamasida and Acaridida are present, although are not as numerous. Much remains to be learned about the role of the Oribatida, and other mite groups, in soil biology and ecology.

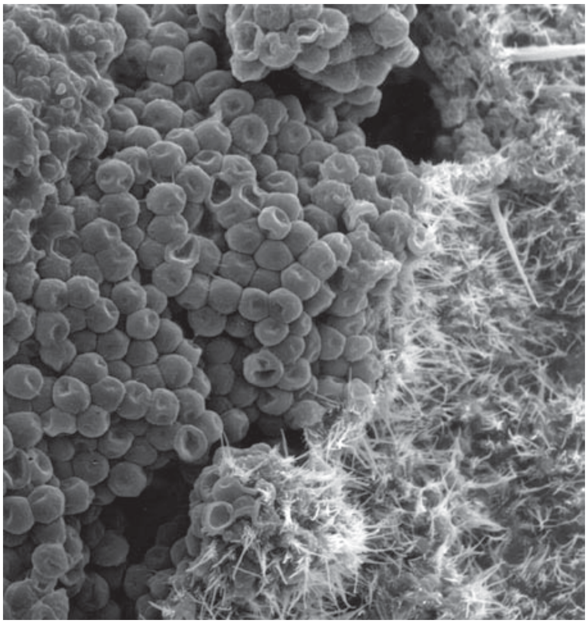
Sorosporella

DRION G. BOUICAS
University of Florida, Gainesville, FL, USA

Sorosporella was first described from a coleopteran, *Cleonus punctiventris*, in 1886 by Krassilstschik, and then 2 years later from a lepidopteran by Sorokin. Krassilstschik named the fungus *Tarichium uvella*, while Sorokin called it *Sorosporella agrotidis*. In 1889, Giard suggested that these two genera were the same and combined the two names into *Sorosporella* uvella. Speare, in the early 1900s, wrote the only detailed descriptions of Sorosporella to date; included were his observations on phagocytosis of the hyphal bodies by hemocytes in cutworms, which constitute one of the first reports of cellular defense response in insects invaded by a fungal pathogen.

Sorosporella exists endogenously as globose, brick-red, thick-wall chlamydospores (Fig. 77) which are 6–10 μm in diameter. These structures form within the insect hemocoel from the yeast-like vegetative hyphal bodies and cohere into solid masses that, at maturity, may become dry and powdery, and then separate. *Sorosporella* germinates on water or various types of media. On Sabouraud maltose agar, the germinating chlamydospores produce a white mycelial mat with a synnematous-type growth sometimes evident. The mycelia generate conidiophores and phialides, which produce hyaline, ellipsoidal conidia approximately 1–1.5 μm in diameter. This conidial stage is known as the alternate state of *Sorosporella* and was identified as Syngliocladium. This is not a teleomorph-anamorph association since both genera represent asexual states. The laboratory-produced conidia were infectious to several different insects, but *Sorosporella-Syngliocladium* has never been seriously targeted as a biocontrol agent, especially in comparison to other more promising Hyphomycetes.



Sorosporella, Figure 77 **Scanning electron micrograph of chlamydospores produced in mole crickets infected with *Sorosporella*. The cuticle of the mole cricket has been peeled away exposing internal chlamydospores.**

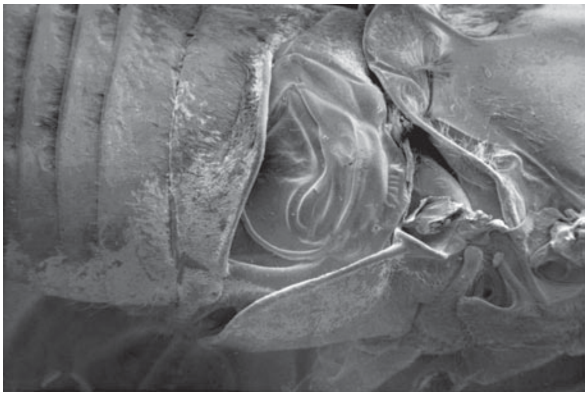
Sound Production in the Cicadoidea

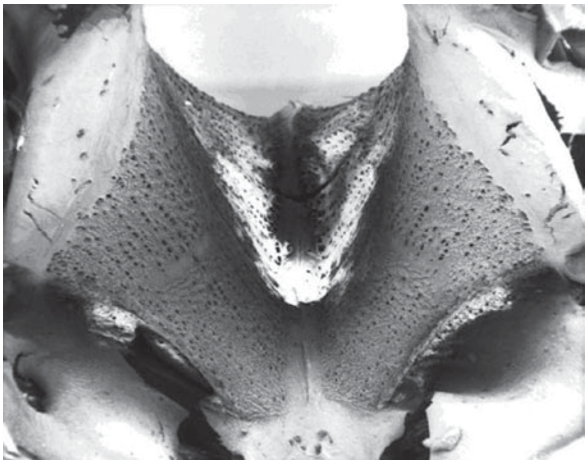
ALLEN SANBORN
Barry University, Miami Shores, FL, USA

One of the characteristic sounds of summer is the calling of cicadas. The sounds cicadas produce are used in the attraction of mates, courtship, and as an alarm to startle potential predators. These sounds can be as intense as 109 dB at 50 cm, and choruses can be heard for more than a mile. Each species has a unique calling song and there are significant differences between the frequency and temporal patterns of species that share the same environment. Cicadas use three main mechanisms to produce sound.

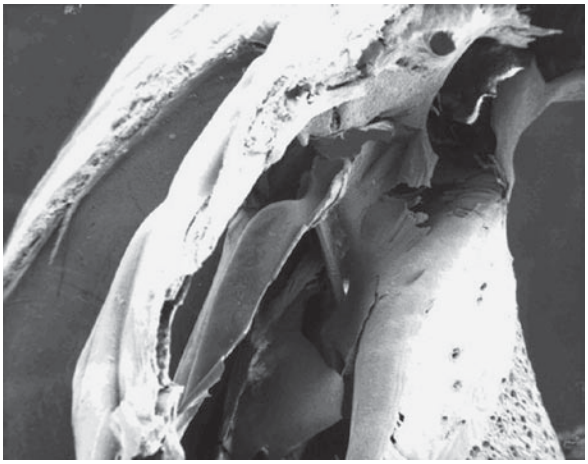


Sound Production in the Cicadoidea, Figure 78 **Right timbal of *Beameria venosa* (Uhler). The operculum can be seen extending under the ventral surface of the abdomen. The wings have been removed for clarity.**

The primary sound production mechanism in cicadas is the timbal organ (Fig. 78). The timbal is a chitinous membrane located on the dorso-lateral surface of the first abdominal segment of most male cicadas. The timbal contains a flattened area, termed the timbal plate, and several ribs that help to strengthen the timbal. The timbal produces sound pulses when it is deformed by a timbal muscle. The timbal muscles are located within the abdomen attached to a support structure (the chitinous V) on the ventral side and is attached dorsally to the timbal plate by an apodeme. To produce sound, the timbal muscle contracts, pulling on the timbal. Eventually the muscle force is sufficient to buckle the timbal plate and continued muscle force leads to buckling of the timbal ribs. Sound pulses are produced when the timbal plate and ribs buckle. In addition, some timbals will produce sound when they return to their resting position as the timbal muscle relaxes. Rebound of the buckled timbal to a resting state is facilitated by the rubber-like protein resilin that is incorporated into the timbal. The rate of timbal muscle contraction determines the sound pulse repetition rate for each species. The frequency of the sound that is produced by a particular species is primarily determined by the resonance of the timbal organ. There is a good inverse correlation between body size and the frequency of the song produced in cicadas, where larger species have lower frequency calls. However, there are several body structures that can alter the frequency of the sound produced (Figs. 79 and 80).



Sound Production in the Cicadoidea, Figure 79 **Timbal muscles of *Tibicen winnemanna* (Davis). The ventral attachment is to the chitinous V in the lower center of the micrograph.**



Sound Production in the Cicadoidea, Figure 80 **The timbal is attached to the timbal muscle by an apodeme. A timbal cover can be seen lying over the surface of the timbal.**

Multiple accessory structures have been shown to affect the sound produced by the timbal organs. The timbal covers protect the timbals from damage in members of the Family Cicadidae but they also can act as resonating structures to increase the amplitude of the cicada call. The opercula are plate-like structures on the ventral surface of the abdomen that can also resonate or modify the frequency of the timbal. The abdominal air sacs transform the abdomen into an amplifier to increase the intensity of the call. The tympana are thin membranes at the base of the dorsal abdomen that can dampen the sound produced and also act as the main site of sound radiation so cicadas radiate sound through their eardrums. The timbal tensor muscle acts to put tension on the timbal that increases the amplitude of the emitted sound. The dorsal and ventral abdominal muscles act to elevate and depress the abdomen. The changes in abdominal position can bring the abdomen into resonance with the timbals and also produces frequency and amplitude modulations in more complex calls.

Stridulation is a second method of sound production in cicadas. A stridulatory apparatus has been described in various cicada genera from around the world. A typical stridulatory apparatus is composed of a file and scraper similar to the system found in crickets, grasshoppers, and some heteropterans. The cicada stridulatory apparatus is normally found associated with the tegmina and the mesonotum. However, one stridulatory apparatus has been described as a modification of the genitalia, although it has not been seen being used in the field. Stridulation is used primarily as a secondary acoustic system in cicadas. The stridulating cicadas that have been studied use stridulation in addition to the timbal call. In addition, stridulation has permitted some females to respond to male timbal calls (Fig. 81).

A final method of sound production in cicadas is crepitation. The North American genera *Platypedia* and *Neoplatypedia* have replaced timbal songs with crepitation but other genera use crepitation in addition to timbal song production. A crepitating cicada will snap the wings together or

Sound Production in the Cicadoidea, Figure 81 The mesonotal stridulatory apparatus of *Tettigades undata* Torres.

bang the wings on vegetation to produce a sound pulse. Individual sound pulses are produced when the wings are snapped against the body. There does not appear to be a cost in terms of the sound intensity to the cicadas that use a crepitation signal. It has been found that a crepitating species does not differ from the expected sound intensity based on the relationship between body size and timbal song intensity. A benefit to crepitation appears to be the two-way communication between males and females that it permits. The two-way communication between males and females in crepitating and stridulating species can ensure proper species identification when it comes to selecting a mate.

It should be noted that the mechanisms described above are used by members of the family Cicadidae. The primitive Tettigarctidae of Australia have been shown to communicate through vibrational rather than acoustic signals.

Southern Bacterial Wilt

This bacterial disease is more of a problem where insects or other wound-producing organisms occur.

► Transmission of Plant Diseases by Insects

Southern Blotting

A technique developed by E. M. Southern for transferring DNA fragments isolated electrophoretically in an agarose gel to a nitrocellulose filter paper sheet by capillary action. The DNA fragment of interest is then probed with a radioactive nucleic acid probe that is complementary to the fragment of interest. The position on the filter is determined by autoradiography. The related techniques for RNA and proteins have been dubbed “Northern” and “Western” blots, respectively.

Southern Chinch Bug, *Blissus insularis* Barber (Hemiptera: Blissidae)

This is an important pest of southern turf, particularly St. Augustinegrass.

Southern Green Stink Bug, *Nezara viridula* (L.) (Hemiptera: Heteroptera: Pentatomidae)

ANTÔNIO R. PANIZZI
Embrapa, Londrina, Brazil

The southern green stink bug, *Nezara viridula* (L.), has a worldwide distribution, occurring throughout the tropical and subtropical regions of Europe, Asia, Africa, and the Americas. To this distribution should be added California in the United States and some areas in South America, wherein the bug is expanding its distribution, in particular in Paraguay, south Argentina, and central-west toward the north-east of Brazil. The expansion in South America is the result of increased acreage for soybean production.

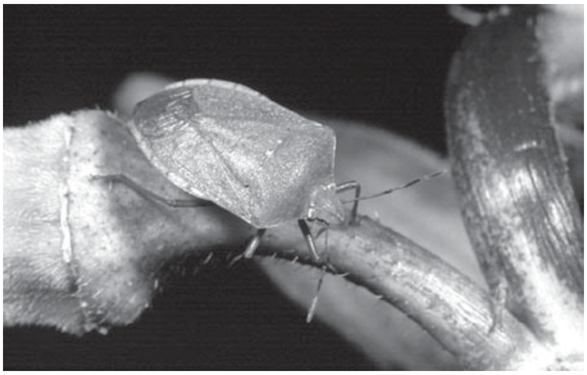
Nezara viridula is highly polyphagous, and more than 150 species of plants of over 40 families have been recorded as hosts. Despite its polyphagy, this stink bug shows preference for leguminous and brassicaceous plants.

This bug completes several generations per year, depending on the favorability of the environment. For instance, in the United States, adults leave overwintering shelters during spring and begin feeding and ovipositing in clover, small grains, early spring vegetables, corn, tobacco, and weed hosts, where they complete the first generation. A second generation is completed on leguminous weeds, vegetables and row crops, cruciferous, and okra, which are typical midsummer hosts. Third generation adults move into soybean where they complete the fourth and fifth generations. Another example of host plant sequence for *N. viridula* was studied in Paraná state, southern Brazil. The bug concentrates on soybean during the summer, which is very abundant at this time; two to three generations are completed on this crop. During fall, adults move to wild hosts, which include the star bristle, *Acanthospermum hispidum*, and the castor bean, *Ricinus communis*, where they feed but do not reproduce. They also move to wild legumes, such as the beggar weed, *Desmodium tortuosum* and *Crotalaria* spp., where they feed and reproduce, with its resulting offspring completing a fourth generation. During late fall and early winter, *N. viridula* completes a fifth generation on radish, *Raphanus raphanistrum*, and mustards, *Brassica* spp. During winter, it may feed but will not reproduce on wheat, *Triticum aestivum*. During spring, a sixth generation is completed on Siberian motherwort, *Leonurus sibiricus*. Many other cases of *N. viridula* host plant sequences have been studied elsewhere, indicating the importance of knowing these sequences to manage this pest species better. Both pods and seeds of legumes generally provide a suitable food source for nymphs, whereas survival is poor on leaves and stems.

Adults are (Fig. 82) green and 12 mm long. Eggs are firmly glued together in rows within compact polygonal clusters. At the time of deposition, eggs are cream colored, turning pinkish or reddish as development progresses. Nymphs in the early instars are strongly gregarious, and this behavior tends to disappear as the nymphs grow older.

Significant reductions in seed yield, quality, and germination can result from feeding by this pest; damaged seeds can have an increased incidence of pathogenic organisms. The feeding punctures (flanges) on seeds cause minute darkish spots, and generally chalky-appearing air spaces are produced when the cell contents are withdrawn.

The effects of *N. viridula* on corn are more severe on younger plants, and yield reductions are



Southern Green Stink Bug, *Nezara viridula* (L.) (Hemiptera: Heteroptera: Pentatomidae), Figure 82 **Adult southern green stink bug.**

attributed to total ear loss rather than reduction in kernel weight. On tomato, its feeding is associated mostly with reduced quality of the fruit. *N. viridula* also can attack nut crops. It is one of the most damaging pests of macadamia, causing nut abortion in small nuts and quality damage in larger nuts in the trees or on the ground. In recent years, *N. viridula* has been reported as a pest of flue-cured tobacco. Both adults and nymphs extract plant fluids from younger tender growth, causing the leaves to wilt and flop over due to loss of turgor pressure.

Several tactics have been studied and implemented to manage *N. viridula* attacking many crops. The use of chemical control still is the major tool used by growers, but many other tactics within the context of cultural practices and biological control have been investigated and used. For chemical control, chlorinated hydrocarbon, organophosphates and organochlorophosphate insecticides, such as methyl parathion, monocrotophos, trichlorphon, dimethoate, and endosulfan have been recommended. Some of these insecticides are recommended to control *N. viridula* on soybean using reduced dosages mixed with sodium chloride, which increase their efficacy. Also, the use of a natural insecticide, such as an extract of neem seed, has been reported to decrease the scars on pecan nuts caused by *N. viridula* feeding.

Trap cropping has been utilized to suppress *N. viridula* and other pentatomid species on soybean. It takes advantage of the fact that stink bugs colonize soybeans during the pod-set and pod-filling stages of plant development. Thus, early maturing or early planted soybeans are highly attractive to stink bugs and can be used to exploit this behavioral response by attracting large populations of the bugs into small areas containing these trap crops (usually less than 10% of the total area). The concentration of ovipositing females and the subsequent nymphal population can be controlled effectively with insecticides before the next generation of adults disperses to the surrounding fields. The key to success of this cultural practice is to control nymphs before they become adults and disperse to adjacent fields. If insecticide controls are not timed properly, then this management strategy is useless and, in fact, actually intensifies the stink bug problem in the main crop. Inoculative releases of the egg parasitoid Trissolcus basalis (Wollaston) (Hymenoptera: Scelionidae) in early-maturing soybean, used as trap crops, caused a reduction and delay in the population peak of this stink bug.

Some progress has been made in the development of host plant resistance to *N. viridula* feeding on some crops. But, so far, cultivars with variable levels of resistance have been little used, mainly because the potential production of these cultivars is usually lower than other commercial cultivars.

Nezara viridula is attacked by numerous natural enemies including parasitoids, predators, and entomopathogens. As many as 57 parasitoid species are recorded for *N. viridula*. The most important of these are the egg parasitoid *Trissolcus basalis* (Wollaston) and, in the New World, the adult parasitoid *Trichopoda pennipes* (F.) in North America, and *Trichopoda nitens* (Blanchard) in South America.

Several arthropod predators have been reported to feed on *N. viridula*. There is a complex of nonspecific predators, and the fire ant, *Solenopsis invicta* Buren, is mentioned as an effective predator of eggs and early instars in the United States.

Soybean Aphid, *Aphis glycines* Matsumura (Hemiptera: Aphididae)

DAVID W. RAGSDALE
University of Minnesota, St. Paul, MN, USA

This insect is native to Asia where it is only an occasional pest of soybean, *Glycine max* (L.) Merr. In addition to cultivated soybean, *A. glycines* has been collected from wild relatives of cultivated soybean, e.g., *Glycine soja* Sieb. & Zucc. In North America, soybean aphid was first found in the summer of 2000 nearly simultaneously in ten north central states. By 2007, soybean aphid was reported from 22 states and 3 Canadian provinces. Economic infestations of soybean aphid have occurred primarily in the north central USA and Canada. It appears that high summer temperatures are limiting the expansion of the soybean aphid's range to the south with only occasional records of soybean aphids collected from soybean in Mississippi and Georgia.

It is likely that soybean aphid was present in the USA prior to 2000, but until populations reached damaging levels, it went unnoticed. Interestingly, soybean aphid was also discovered infesting soybean in Australia in the 1999–2000 growing season. Since 2000 there has been little research published regarding soybean aphid in Australia, suggesting that its pest status is more limited in Australia. However, in North America soybean aphid has become one of the most serious pests of soybean, capable of causing annual yield losses in excess of $100 million.

Life History of Soybean Aphid

In temperate parts of Asia, soybean aphid has a heteroecious and holocyclic life cycle, meaning that it alternates between an asexual form of reproduction (parthenogenesis) in the summer and sexual reproduction in the fall, and it uses two unrelated host plants during its seasonal cycle. Sexual reproduction occurs in the fall when winged sexual forms (gynoparae and androparae) fly from soybean (secondary host) to a woody perennial, in this case buckthorn, *Rhamnus* spp. (primary host) where mating occurs and overwintering eggs are laid. Beginning in the spring through late summer, reproduction is by parthenogenic, viviparous females. In Asia, soybean aphid uses *R. davurica* Pallus and *R. japonica* Maxim as primary hosts. In early spring, females hatch from overwintering eggs and several parthenogenic generations are completed on the primary host. During late spring winged forms are produced and soybean aphid migrates from the primary host to the secondary host, which in North America is restricted to soybean.

In the USA, neither of the recorded primary hosts is present, but an invasive buckthorn species from Europe, *R. cathartica* L., common buckthorn, is widespread in the north central US and Canada. Soybean aphid uses *R. cathartica* as its principal primary host in North America. Another native species of *Rhamnus*, alderleaf buckthorn, *R. alnifolia* L'Hér, can also serve as a primary host for soybean aphid, but its distribution is far less extensive than *R. cathartica*. It is noteworthy that an exotic aphid from Asia survives in North America by using a primary host introduced from northern Europe and a secondary host (soybean) from Asia. There are no other members of the genus *Glycines* native or introduced to North America except soybean. In the laboratory, soybean aphid will accept and reproduce on red clover, *Trifolium pratense* L., but soybean aphid has only rarely been observed colonizing this plant in the field. In other parts of the world other secondary hosts of soybean aphid include kudzu, *Pueraria thunbergiana* (Sieb. & Zucc.) Benth., tropical kudzu, *P. phaseoloides* (Roxb.) Benth., *Desmodium intortum* (P. Mill.) Urban, and scarlet runner bean, *Phaseolus coccineus* L. (= *multiflorus*).

Aphis glycines is a small yellow aphid similar in size to a closely related species, *A. gossyppii*, the cotton or melon aphid. Winged morphs are required to distinguish *A. glycines* from other *Aphis* spp. On *R. cathartica*, the buckthorn aphid, *A. nasturtii* Kaltenbach, coexists with soybean aphid. There are several unique characteristics used to distinguish between winged morphs of *A. nasturtii* and *A. glycines* including the following characters unique to soybean aphid: pale cauda, a sclerotized patch on the abdomen at the base of the dark cornicles, and antennal segment IV without rhinaria.

Damage to Soybean

In North America, *A. glycines* begins colonizing soybean as soon as the crop emerges (late May to early June). During the vegetative growth stage, soybean aphid colonies are typically found on the growing point including the stem, petioles and the partially expanded trifolioates. In North America it is uncommon to find soybean aphid colonies tended by ants, but in China and Japan ant-tended aphid colonies are common. Multiple studies conducted in North America and Asia show that aphid colonization of young vegetative plants rarely results in a yield loss. Yield loss is mostly attributed to heavy aphid infestation during reproductive plant growth stages. In response to high aphid density during the beginning of the reproductive growth stage, R1 (first flower) through R5 (pod elongation and beginning seed set) plants often abort pods. Once pods abort, yield potential is substantially reduced so, even if aphids were controlled following pod abscission and plants remained aphid-free the remainder of the season, a significant yield loss would still occur. Yield losses in excess of 50% have been reported during aphid outbreaks.

Once soybeans reach terminal height aphids are no longer found on the upper portion of the plant. Aphids move lower in the canopy and can be found on secondary growing points (lateral shoots), expanding pods, and on mature leaves. Aphids found on fully expanded mature leaves are often smaller and are pale white. These "white dwarfs" are less fecund and shorter lived than the large pale green soybean aphids found on the growing points. As the plant enters R6 (pod filling) these mature leaves become an excellent resource equal in quality to the growing point during vegetative growth as photosynthate stored in mature leaves is mobilized for pod filling.

Environmental conditions that favor soybean aphid development are cool temperatures ranging from 20 to 28°C, low humidity which suppresses entomopathogenic fungi, and lower than average rainfall because heavy rainfall can dislodge soybean aphid from the growing points. The optimal temperature for growth and reproduction is 28°C and in laboratory studies under optimal conditions, population doubling times are as low as 1.3 days. In the field doubling times of 2.4 days have been measured but average doubling time during reproductive growth stage R1 to R5 in a 6-state study over 19 locations was 6.8 days. During a growing season as many as 18 generations can occur.

Currently, in North America soybean aphid is not commonly found in the southern soybean production areas. It is unknown why this is the case, whether it is a lack of overwintering hosts since *R. cathartica* is not present in the deep south, or if high summer temperatures are detrimental to soybean aphid population growth. Soybean aphid is known from subtropical areas of Asia, so there may be biotypes adapted to the warm humid conditions of the south central US and soybean aphid may continue to expand its range in the future.

Natural Enemies

As an exotic invasive insect, soybean aphid arrived in North America without its full complement of natural enemies. Since 2000, numerous native predators and fungal pathogens have been documented as being important mortality factors of soybean aphid. Predators such as *Orius insidiosus* (Say), insidious flower bug (Hemiptera: Anthocoridae), and several species of ladybird beetles are recognized as key predators of soybean aphid. One predator in particular, the exotic multi-colored Asian ladybird beetle, *Harmonia axyridis* (Pallas), has proven to be an important predator of soybean aphid. Throughout North America, one guild of natural enemies that is largely missing is the parasitoids (Hymenoptera). Only rarely are parasitized soybean aphids observed in North America, but in Asia parasitoids appear to be the principal natural enemy guild keeping soybean aphid populations under control. It is not uncommon to find more than 40% of soybean aphids parasitized in China.

Management

Soybean aphid is currently the most damaging insect pest of soybean in the north central region. Tens of millions of acres of soybean have been treated with insecticide since 2001, costing producers more than a billion dollars in lost yield and additional production costs.

Economic Threshold and Economic Injury Level

An economic threshold (ET) has been developed that is applicable for the entire north central region. The current ET is 250 aphids per plant when more than 80% of the plants are aphid infested. The ET assumes the aphid population is doubling in less than 7 days, and the corresponding economic injury level is 674 aphids per plant. The ET is valid from plant growth stage R1 through R5. An ET during growth stage R6 (full-size green seed) is not yet available, but the limited number of replicated trials where aphid populations peaked during R6 suggests the ET during R6 will be substantially higher. Soybean aphid populations often naturally decline during late R6, due in part to environmental cues (shortened day length and lower nighttime temperatures) resulting in development of sexual morphs. Sexual morphs begin leaving soybean and migrate back to buckthorn where a fertilized female will deposit overwintering eggs on the primary host instead of producing live young.

Sampling

One of the key elements of any IPM program is an effective sampling program. Counting aphids on a per plant basis is time consuming and tedious, often taking more than 1 h to sample a single field. Using whole plant counts for the ET requires a minimum of 30 plants per field to make a treatment decision. To reduce sampling time and to encourage adoption of an ET for making treatment decisions, a bionomial sequential sampling plan (presence or absence) was developed. This binomial sampling plan termed "Speed Scouting" allows a producer to make a treatment decision faster and is as accurate as whole plant counting. Speed Scouting uses a tally threshold of 40, so if a plant has 40 or more soybean aphids it is tallied as "infested." It is important to note that the Speed Scouting tally threshold of 40 is not a lower economic threshold. If you took every plant that exceeded the tally threshold of 40 and took the time to count every aphid, the average aphid density per plant would be 250. Speed Scouting is most effective when aphid populations are very low or when aphid populations are high, and a decision to treat or to leave the field untreated can be made by sampling as few as 11 plants and requires <15 min to make a treatment decision. In validation studies, 79% of the time Speed Scouting made the correct "treat" decision compared to whole plant sampling using the ET of 250 aphids per plant. In the remaining 21% of the cases, Speed Scouting and whole plant counts did not arrive at the same decision, and Speed Scouting was always more conservative, i.e., arriving at a "treat" decision when in fact the aphid population was lower than 250 aphids per plant. To overcome this bias, a "treat" decision via Speed Scouting needs to be confirmed by a second sample taken 3–4 days later, to assure that the aphid population is indeed increasing.

Biological Control

A classical biological control program began in 2001 with the first collection of parasitic hymenoptera from China, followed by subsequent collection in different regions of China, and in Japan and Korea. In 2007, host range testing was completed for one parasitic wasp, *Binodoxys communis* (Galan) (Hymenoptera: Braconidae), and this parasitoid was released in at least five midwestern states in the summer of 2007. Whether this classical biological control program will succeed in permanently reducing soybean aphid densities below damaging levels is yet to be determined.

Insecticides

The most common foliar-applied insecticides used to control soybean aphid are the pyrethroids. However, if twospotted spider mites, *Tetranychus urticae* Koch, are also found, the organophosphate insecticide clorpyriphos is recommended instead of pyrethroids because the latter tends to flare twospotted spider mites under drought conditions. Insecticide application for soybean aphid is most typically applied to full canopy soybeans. Application of insecticide by airplane is as effective as application by ground equipment, but application costs are typically double of that by grower-owned, tractor-drawn spray equipment. Using ground equipment in full canopy soybeans causes mechanical damage to soybean and research shows that such losses often exceed 1 bu/ac (67 kg/ha).

Insecticides in a new chemical group, the neonicotinoids, are being used more frequently to control soybean aphid. As foliar-applied materials, the neonicotinoids are highly effective. Neonicotinoids are also used as seed treatments for use at planting. Efficacy of seed treatments is relatively short lived with mortality no different from untreated controls by 35 days after planting (V3 to V5). Although aphids do colonize young vegetative soybean, it isn't until much later in the growing season that aphids build to damaging densities that exceed the ET and long after seed treatments remain effective. The inability to predict when and where soybean aphid will reach damaging densities, coupled with the ability of young vegetative plants to withstand substantial aphid feeding without a concomitant yield loss, all suggest that seed treatment is a poor method of aphid control.

Host Plant Resistance

Soon after the discovery of the soybean aphid, aphid resistant soybean cultivars were identified. The cultivars Dowling and Jackson (Maturity Group VII and VIII, respectively) were shown to be nearly immune to soybean aphids in greenhouse and field cage studies which suggested antibiosis as the mechanism of resistance. However, these maturity groups can only be grown in the southern-most soybean production area in the US where soybean aphid has not yet been found. Markers for the soybean aphid resistance gene, *RagI*, were identified through conventional breeding. *RagI* was transferred into cultivars typically grown in the north central region (Maturity Group III and 0). However, in the summer of 2006, even before these resistant cultivars were released to the public, a variant of soybean aphid that overcomes *RagI* mediated resistance was discovered in Ohio. Release of cultivars with only a single gene for soybean aphid resistance would appear to be only a short term benefit and, if widely planted, soybean aphid biotypes that overcome *RagI* mediated host plant resistance are already present in the population.

Altogether, soybean aphid represents a major constraint to profitable soybean production in the north central USA and Canada. Long term strategies of host plant resistance and biological control offer promise but until those tactics are widely available growers must rely on sampling, economic thresholds and conventional means of crop protection.

► Small Fruit Pests and their Management

Sparkling Archaic Sun Moths (Lepidoptera: Eriocraniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Sparkling archaic sun moths, family Eriocraniidae, are a Holarctic family of 25 species, of which about half the species are in Europe and half in North America. The family, plus the related Acanthopteroctetidae, are the only members of the superfamily Eriocranioidea, which form the infraorder Dacnonypha of the suborder Glossata. Adults small (6–13 mm wingspan), with roughened head scaling; haustellum reduced; mandibles present but vestigial (haustellum absent); labial palpi 3-segmented; maxillary palpi 5-segmented and folded. Maculation rather colorful with various iridescent spots of gold on darker forewings. Adults are diurnally active. Hosts are mostly in Betulaceae and Fagaceae, and the egg is inserted by the female into tender host leaves in early spring, whereupon the young larvae feed before the leaves turn hard. Larvae are leafminers with serpentine mines that become blotch mines as the larvae grow.

Spatulate

Broad at the tip and narrow at the base. The tip is flattened or sometimes recessed and spoon-like.

Spear-Winged Flies

Members of the family Lonchopteridae (order Diptera).

► Flies

Specialist

Insect occupying a narrow niche, or consuming a narrow range of food.

Speciation Processes Among Insects

ANTHONY ROSSI
University of North Florida, Jacksonville, FL, USA

The development of molecular genetics has led to a renewed attempt to define the concept of the species. Originally, "species" was defined by Ernst Mayr as an interbreeding group of organisms (= population) that is reproductively isolated from other such groups (typically referred to as the biological species concept or BSC). However, the increasing frequency of reported viable hybrids produced by crosses of "parental species" in natural systems (often recognized as distinct species until molecular analyses revealed that they are intermediate crosses of various degrees between the parentals and/or hybrids), suggests that Mayr's definition was inadequate. As a result, other species concepts were developed such as the phylogenetic species concept (PSC), which identifies species (and other taxonomic categories) based on the presence of shared derived characters. In other words, taxa that share recently derived morphological or genetic characters are assumed to be more closely related than lineages that do not share these derived traits. While this definition circumvented the reproductive isolation requirement imposed by the BSC, it has its own unique set of problems. For instance, the phylogenetic (i.e., evolutionary) relationships inferred from a cladistic analysis can be affected by the choice of characters used in the assessment (this is also true for studies that rely on the use of shared derived genetic sequences).

Regardless of the functional definition of the term, the evolution of new species is traditionally believed to occur through allopatry or, less frequently, through the more controversial pathway of sympatry. Allopatric speciation, which involves a geographic separation and isolation of segments of a formerly contiguous population, is firmly established as the primary mechanism by which new species evolve. Sympatric speciation also predicts the development of new species under certain restrictive conditions, but this mechanism does not require speciating subpopulations to be geographically isolated from one another. It is precisely this lack of geographic isolation that has rendered sympatric speciation so contentious because, without spatial isolation among speciating subpopulations, it is difficult to imagine a scenario in which interbreeding (i.e., gene flow) among diverging groups can be greatly reduced or eliminated (a requirement for speciation).

Insects in general, and phytophagous insects in particular, provide some of the strongest evidence for the sympatric pathway of speciation. Several recent studies have found evidence suggesting that host range expansion by phytophagous insects may result in the development of new species without geographical isolation of host-specific subpopulations. The tenability of this mechanism is directly tied to the problem of fitness trade-offs and potential gene flow among diverging subpopulations. According to the generalized model, females mistakenly oviposit on an atypical (i.e., outside its normal host range) plant species and, if progeny survive on this novel host (to which they are, by definition, non-adapted), temporal or seasonal differences in host plant phenology may effectively isolate this subpopulation from conspecifics on the natal host species. However, for this scenario to be feasible, insects from the atypical host species must show a high degree of fidelity for this novel host even though they are likely to suffer decreased survival, fitness and performance compared to insects from the original host.

How can such a paradox be resolved? Many phytophagous insects are specialists on one or a few hosts and they often exhibit host-specific assortative mating. Although the reasons for this behavior are unclear, plant-feeding insects, especially endophages such as leafminers or gallers, may become chemically marked by the host plant during development. As adults, they may rely on these chemical cues when searching for mates and/or oviposition sites. Additionally, host-specific mating behavior may simply provide the most reliable source for locating a potential mate, a likely possibility if the host shift is to a plant with a different phenology than the ancestral host species. For instance, in one of the best-documented cases of nascent speciation, host-associated races of the apple maggot fly (*Rhagoletis pomonella*) complex, undergo courtship and mating on their individual host plants, often on the fruits. This is also true for the tephritid sawfly (*Eurosta solidagginis*), which consists of two host-associated races that attack the goldenrods, *Solidago altissima* and *S. gigantea*, in which mating and oviposition occur on the natal host plant. Mating of the soapberry bug, *Jadera haematoloma*, which has expanded its host range to include several introduced species, is also limited to the host plant.

Host-specific associative mating is likely to result in reduced gene flow between subpopulations or races that utilize different host species if insect development time is variable and host fidelity among subpopulations is high. For example, spring-summer gall persistence (measured as LD_{90} and correlated with larval development time) of host-associated populations of the gall midge, *Asphondylia borrichiae*, which galls the terminals of three plants in the aster family, ranges from approximately 29 days on *Iva imbricata* to 70 days on *Borrichia frutescens*. Since these midges only live for a couple of days as adults after emergence from the gall, it is very likely that host shifts have resulted in semi-isolated subpopulations of *A. borrichiae* because adults may be limited to mating with conspecifics from the same host species owing to different host-specific emergence times. Host-associated populations of *A. borrichiae* also exhibit a high degree of host fidelity (at the level of plant genus). Midges that emerged from sea oxeye daisy (*Borrichia frutescens*) attacked the natal host approximately 97% of the time, whereas midges that emerged from the other two hosts (*Iva* spp.) attacked these hosts exclusively. Similar allochronic isolation owing to variable host plant phenology occurs among host-specific races of *R. pomonella* that feed on the fruits of several plants including blueberry, domestic apple and hawthorn. Prior to pupation, larvae emerge from the fruit of the host plant and drop to the ground where they pupate in the soil. Larvae from blueberry pupate 1–2 weeks earlier than those from apple and approximately 4 weeks earlier than those from hawthorn. Synchronization of adult eclosion also mirrors differences in host-specific fruit phenology; adults from the blueberry race eclose first, followed by those from apple and hawthorn, respectively. Gene flow among the ancestral host, hawthorn, and the derived host, domestic apple, has been estimated at 4–6% per generation.

Moreover, larvae that find themselves on a novel host plant may experience reduced levels of attack by natural enemies such as parasitoids. For the apple maggot fly, which has apparently expanded its host range numerous times from its ancestral host, hawthorn (*Crataegus* spp.), including expansion to the commercially important domestic apple (*Malus pumila*) introduced from Europe, both interspecific competition and parasitism are greatly reduced on the derived host. Asphondylia borrichiae also appears to experience lower levels of parasitism on two species of *Iva* compared midges on *B. frutescens*. Indeed, reduced levels of parasitism and/or competition on derived hosts may offset lower rates of survival and fitness on sub-optimal hosts, thereby aiding the establishment and maintenance of host-choice polymorphisms.

Although phytophagous insects provide some of the best evidence for the sympatric pathway of speciation, it does not appear to be limited to herbivorous insects. For instance, the predatory lacewings *Chrysoperla carnea* and *C. downesi*, which differ in color, are believed to have originated in sympatry relatively recently. Most likely a color polymorphism arose in the ancestral population, which lead to habitat-specific assortative mating among subpopulations. *Chrysoperla carnea* is light green-brown and prefers deciduous woodlands, while *C. downesi* is dark green and prefers coniferous forests. Differences in habitat-specific survivorship/fitness and habitat preference has favored fixation of different color morphs and asynchronous breeding seasons among the subpopulations that would eventually become *C. carnea* and *C. downesi*.

While phytophagous insects provide model systems for investigating sympatric speciation, some plant-feeding insect guilds such as leafminers and gallers, which are intimately associated with their hosts, may possess characteristics that facilitate the formation of host-associated races or species in sympatry including: (i) sessile larvae that are restricted to feed on the host plant selected by the ovipositing female; (ii) endophagous larvae that feed exclusively within the tissue of the host plant; (iii) significant host-specific variation in larval survival and performance (including differential attack by natural enemies); (iv) differences in host plant phenology (and host-specific insect development) that result in allochronic isolation of host-specific subpopulations (i.e., plant-mediated reduction in gene flow); and (v) host fidelity of ovipositing females. While many biologists still harbor doubts about sympatric speciation, several recent studies provided strong evidence for this evolutionary pathway. After all, Charles Darwin clearly stated in Chap. 4 of his magnum opus, "On the Origin of Species": "I can see no means to agree…that migration and isolation are necessary elements for the formation of new species."

Species

Populations with individuals that are similar in structure and behavior, and capable of mating and producing fertile offspring.

► Speciation Processes Among Insects

Species Areas-Relationship

The concept that the number of herbivore species associated with a plant is positively related to the area occupied by the plant. This is an outgrowth of island biogeography theory, in which larger islands support larger faunas; alternative explanations include the length of time a plant has been available for colonization (with more insects accumulating over time) and habitat heterogeneity (with plants living over a wider range being exposed to greater environmental and faunistic diversity).

Species Complex

A group of closely related species, or a species that appears to be variable, and is thought to consist of more than one undefined species.

Species Concepts

MARC BRANHAM
University of Florida, Gainesville, FL, USA

Species concepts are not new to biology. Biologists today are using more species concepts than ever before, concepts which convey how they think about and define species. The notion of species is central to biology in that it provides a formal connection between biological research and the organisms being studied. This connection is in no way trivial and needs to be made in a careful and systematic manner. With an increasing number of species concepts to choose from, opinions differ about the importance of the various processes which shape species and how species should be diagnosed. Much debate has also focused on the applicability and limitations of these various concepts. Obviously, species concepts vary greatly depending on their purpose.

Theoretical Versus Operational Species Concepts

Species concepts can generally be divided into two main categories on the basis of whether they are theoretical (process-oriented) or operational (descriptive) concepts.

Theoretical Species Concepts

These focus on defining what a species is as it relates to our understanding of evolutionary processes. The focus of this type of concept is the process of evolution within species. This concept usually incorporates processes related to reproduction, competition and distribution. A common criticism of these concepts is that because the mode of reproduction (e.g., sexual vs. asexual) is so narrowly defined, the concept is not widely applicable to other organisms (see below.) In addition, a great deal of information about specific biological process remains unknown for most taxa.

Operational Species Concepts

These focus on specific criteria used to identify species. These concepts serve the practical purpose of diagnosing species based on specific criteria. A common criticism of this type of concept is that it is so narrowly restricted to specific measurable features that its implementation could subdivide species. Even though theoretical concepts are often impractical for application to most taxa, they provide information about processes that shape species. Even though operational concepts prove practical for identifying species, they usually do not provide much insight into how species are formed and maintained. Theoretical and operational species concepts can correspond, but they do not always.

Species Concepts in Use Today

Some 22 different species concepts have been identified as being in use in the modern literature on species. These 22 species concepts vary considerably in their focus, depth and applicability to various taxa. While many of these concepts have not been widely adopted or discussed, several are routinely juxtaposed in discussions of species concepts (Table 18).

Biological Species Concept [sensu Mayr and Ashlock] – (theoretical) "A species is a group of interbreeding natural populations that is reproductively isolated from other such groups." The use of this concept requires knowledge of population distributions in time and space. Criticisms of this concept include:

1. Excludes uniparental species.
2. Indiscriminate use of a reproductive isolation criterion.
3. Its relational nature: *A* is a species in relation to *B* and *C* because it is reproductively isolated from them.

Evolutionary Species Concept [sensu Wiley and Mayden] – (theoretical) "… an entity composed of organisms which maintains its identity from other such entities through time and over space, and which has its own independent evolutionary fate and historical tendencies." It has been proposed

Species Concepts, Table 18 Species concepts proposed by various authors (after Mayden, 1997)

Successional Species Concept

that this species concept could possibly accommodate all known types of biological diversity. As such, it is important as a theoretical species concept for structuring ideas about species. Criticisms include:

1. It is not as helpful in the operational or practical sense.
2. It cannot be used to identify species.

Phylogenetic Species Concept [sensu Wheeler and Platnick] – (operational) "…the smallest aggregation of (sexual) populations or (asexual) lineages diagnosable by a unique combination of character states." Phylogenetic species are basal taxonomic units that can be broadly compared. This concept is also operational, i.e., can be applied to diagnosing species, even from dead museum specimens labeled with little more than date and locality information. Criticisms include:

1. Could potentially over-estimate species diversity if the characters of choice do not accurately diagnose real "species."

Recognition Species Concept [sensu Paterson] – (theoretical) "A species is then most inclusive population of individual, biparental organisms which share a common fertilization system." This concept emphasizes mating adaptations that become fixed in the population; individuals "recognize" certain characteristics of suitable mates. Criticisms include:

1. Impossible to apply without knowledge of the specific mate recognition system of the organism.
2. Excludes uniparental species.

Issues of Special Concern to Entomologists

There are several issues that might be of concern to entomologists when choosing a species concept. Parthenogenesis is known to occur in a variety of insect orders. This asexual form of reproduction occurs persistently in clonal populations or in alternating generations in other populations. While it is generally agreed that populations of persistent clonal organisms appear to constitute a unique species, it is appropriate to distinguish them as such by using a species concept that accommodates uniparental organisms. However, some authors recommend that when a parthenogenetic lineage is derived from a known bisexual species, it should not be designated as a new species, but as a parthenogenetic form of the original species.

In many insect groups, specimens can be readily identified to species on the basis of the morphological variation associated with the male reproductive organ, the aedeagus. However, not all groups possess enough variation in this structure to prove useful for delineation. Because some insect groups are host specific they may be very diverse yet morphologically indistinguishable from other closely related taxa. Modern molecular methods are showing promise in identifying genetic sequence variation in addition to traditional morphological suites of characters. Currently there is much debate about which molecular marker is the most informative at the level of species and how much variation needs to be present to justify raising a population to species status.

The Importance of Selecting Appropriate Species Concepts

The importance of species concepts directly relates not only to processes associated with speciation but also to studies of conservation biology, the Endangered Species Act and the current biodiversity crisis. Identifying species requires an operational concept, which once selected will affect the accuracy of the total estimated number of species for a particular region, or the planet. It is also important for biologists to explicitly state which species concept they have adopted for a particular study, as the concept conveys the particular view of species used as well as the particular assumptions associated with it.

Species Diversity

An index of community diversity that considers both species richness and the relative abundance of species.

Species Inquirenda

A questionable species; there is some doubt about its status.

Species Novum

A species that is about to be described in the accompanying text; a species new to science.

Species Odor

The odor associated with the body of social insects It is unique to a species, though it may be a component of the colony odor.

Species Richness

The number of species present in an assemblage, community, or other defined ecological unit.

Specific Name

The name applied to a species, accompanying the genus name; the second portion of the scientific name. It must be an original combination, and must agree grammatically with the generic name according to Latin grammar.

Sperm Precedence

In insects with multiple matings, the sperm of the last male to copulate with the female is most likely to father the offspring. The last sperm to be stored in the spermatheca are the first to be released.

Spermatheca

A small cuticular storage chamber that stores sperm and is associated with the median oviduct of females. Impregnated females can store sperm for weeks, months or even years depending on the species, and release sperm as an egg passes through the oviduct, resulting in fertilization (Fig. 83).

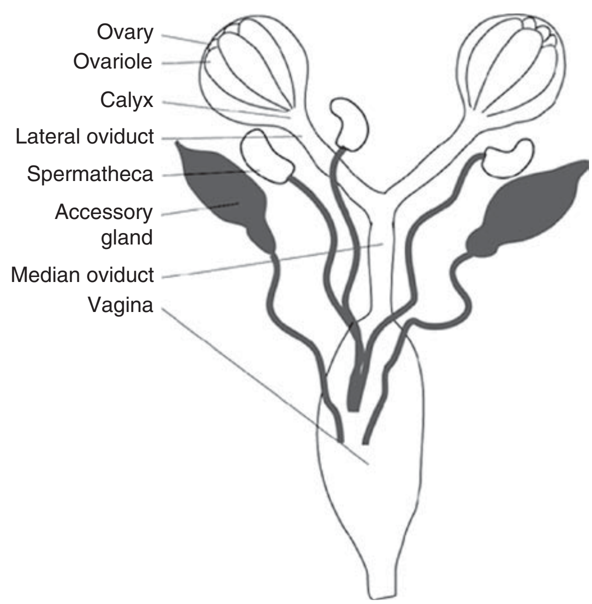
Spermatid (pl., spermatozoa)

A germ cell in the testis that eventually becomes sperm. Developmentally, the spermatid develops from the spermatocytes by mitosis, and mature into sperm.

Spermatocyte

A cell in the testis that divides, eventually forming the sperm. Developmentally, spermatocytes occur in multicellular cysts created by mitosis of spermatogonia, and develop into spermatids.

► Reproduction
► Endocrine Regulation of Reproduction



Spermatheca, Figure 83 **Diagram of the female reproductive system, as found in *Rhagoletis* (Diptera) (adapted from Chapman, The insects: structure and function).**

Spermatogenesis

The production of sperm cells in the testis.

► Sterile Insect Technique

► Reproduction

Spermatogonia

Cells developing in the testis and forming spermatocytes mitotically. The first step in the production of sperm.

► Reproduction

► Endocrine Regulation of Reproduction

Spermatophore

A covering or capsule around the sperm.

Spermatophylax

A portion of the spermatophore that does not include the sperm. It is produced by the male and consumed by the female after copulation as a nutritive supplement.

► Nuptial Gift

► Cannibalism

► Mormon Cricket

Sphaeritidae

A family of beetles (order Coleoptera). They commonly are known as false clown beetles.

► Beetles

Sphaeroceridae

A family of flies (order Diptera). They commonly are known as small dung flies.

► Flies

Sphaeropsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or Psocids

Sphecidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Sphecology

The scientific study of wasps.

Sphecophile

An organism that spends part of its live cycle in wasp colonies.

Spherulocyte

A type of hemocyte of intermediate size.

► Hemocytes of Insects: Their Morphology and Function

Sphindidae

A family of beetles (order Coleoptera). They commonly are known as dry-fungus beetles.

► Beetles

Sphragis

ANDREI SOURAKOV
University of Florida, Gainesville, FL, USA

In many species, mating is preceded by complex courtship rituals, in which females have a choice of mate. However, the male sometimes places a plug or "chastity belt" on the female after mating, limiting her ability to choose other mates. This structure is called a sphragis, from the Greek word for "seal." These sphragis devices can range from a simple plug secreted by a male into female's mating tube at the end of copulation, to elaborate shell-shaped structures attached to the outside of the female's abdomen that prevent the male's claspers from holding onto the female and positioning his genitalia for mating.

In African *Acraea* butterflies, a male can grab a flying female in the air and take her down onto the ground to mate with her. Other males might later attempt a similar strategy with the same female, but they will not be able to attach themselves to the female's abdomen, whose mating tube is blocked by a waxy plug, and pairing will not take place. In the Holarctic genus of primitive tailless swallowtail butterflies, *Parnassius*, the sphragis is external and gives a strong visual cue to an approaching male that the female has been mated. One large species of these butterflies, *Parnassius clodius*, can be observed in the mountains of northern California in late summer. By making the sphragis so noticeable to other males, the successful male not only protects the female from subsequent intercourse by means of a physical barrier, but saves her and his competitors a great deal of energy that would be lost in the redundant hopeless sexual pursuit. Research has shown that males of *Parnassius* invest up to 10% of their body weight during mating by transferring not only sperm into the female, but also nutrients used for building the egg mass.

Spicula, Spicule, or Spiculum

Any small, pointed or needle-like process or spine.

Spider Behavior and Value in Agricultural Landcapes

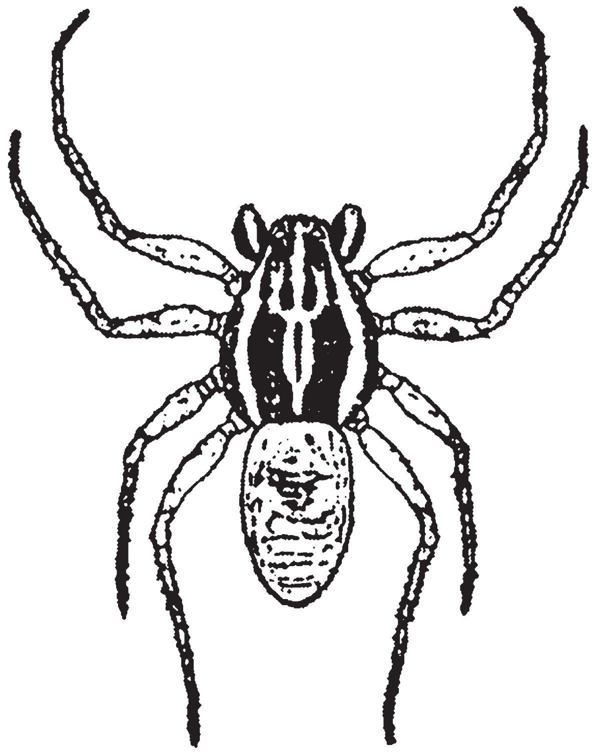
DIVINA AMALIN
USDA, APHIS, Miami, FL, USA

Spiders are one of the largest groups of predatory organisms in the animal kingdom with more than 39,000 species distributed over 108 families worldwide. They are so diverse they are found almost everywhere on earth, from arctic islands to dry desert regions. They are particularly abundant in areas of rich vegetation. It is no exaggeration to say that spiders have conquered all possible ecological niches on land.

Even though spiders are found in abundance all over the world, they have not been fully used in pest management programs. The widespread, undeserved reputation of spiders as being dangerous to people and their animals is one reason why they are not given proper credit as important natural pest control agents. With the exception of one group under the family *Uloboridae*, all spiders have poison glands. However, not all spiders have venom of medical importance to humans. There are many more useful spider species than harmful ones. Of over 39,000 known species, only about 160 are considered to be of any medical hazard to humans. The venom produced by spiders is intended to affect insects and the effect of the venom on humans is usually only slight. Spider venom was not designed to kill humans. Human death by spider venom is an unfortunate reaction, much the same as adverse human reaction to some wasp and bee stings.

Some of the most well known spider species in the world that can cause medical problems when they bite include black widow spiders in the genus *Latrodectus* (Theridiidae). Species of *Latrodectus* can be found throughout the world. The venom is considered a neurotoxin and can cause systemic pain. Recluse spiders in the genus *Loxosceles* (Sicariidae) are distributed worldwide, but most species are found in tropical regions or regions with relatively high humidity. Bites of these spiders cause necrotic lesions surrounding the bite site. Yellow sac spiders in the genus *Cheiracanthium* (Miturgidae) are found worldwide and some species are particularly common in homes. Bites from species of *Cheiracanthium* can be painful and can result in minor necrotic lesions. Banana spiders in the genus *Phoneutria* (Ctenidae) are found in Central and South America. These spiders can be aggressive and their venom is neurotoxic, causing similar symptoms as a black widow bite. The Sydney funnel web spider, *Atrax robustus* is found in Australia. This notorious spider is aggressive and has dangerous venom that can and has caused deaths in humans. Reliable information about spiders with venom of medical importance can be found at http://spiders.ucr.edu/dermatol.html.

Most of the dangerous spiders are shy and only become aggressive and bite when provoked. Overall, spiders receive an undeserved reputation for causing bites. Generally, they are friends of farmers, not foes to be avoided or eliminated.



Spider Behaviour and Value in Agricultural Landcapes, Figure 84 **Beneficial spider, *Lycosa pseudoannulata*.**

Importance of Spiders in Agriculture

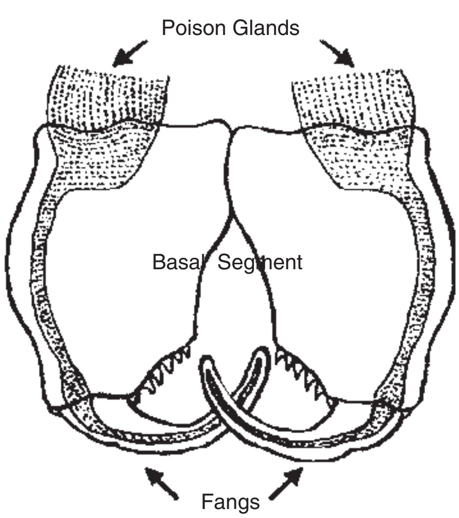
In reality, spiders are a component of the natural enemy complex in nearly all agricultural landscapes. To date, over 300 studies on spiders in different agricultural crops are documented. In general, spiders are extremely beneficial because they are important predators of pests such as thrips, caterpillars, aphids, plant bugs, leafhoppers, flies, and other arthropod pests in home gardens and crop fields. Spiders, along with other predators, are important in agriculture because they regulate and balance arthropod pest populations. They are beneficial in keeping insect populations in check, which far outweighs the hazard posed by the few spiders that occasionally bite humans and pets.

The importance of spiders as pest control agents (Fig. 84) is not a recent discovery. Several ancient books in agriculture mention their importance. In China, the use of spiders for pest control dates back 2,000 years and even today, many elderly people in Chinese villages consider the number of spiders in a field as a measure of its potential agricultural productivity. The scientific literature amply demonstrates the biological control potential of spiders. A classic example of a successful biological control system using spiders was reported on rice. A wolf spider, *Pardosa pseudoannulata* (Lycosidae), successfully controlled the brown planthopper, *Nilaparvata lugens*, which is the major pest of rice in Southeast Asia. In Britain, comb-footed spiders (Theridiidae) and dwarf spiders (Linyphiidae) suppress orchard mites. In Australia, another species of small theridiid, *Achaearanea veruculata*, successfully controls the tortricid moth. A study in an unsprayed peach orchard in the Niagara Peninsula of Canada shows another species of theridiid, *Theridion murarium* and a species of Philodromidae crab spider *Philodromus praelustris*, regulate the density of phytophagous mites.

Feeding Behavior

Great differences exist among spiders concerning the ways in which they capture their prey. While some spiders stalk their prey and others ambush it, most spiders trap their prey by snares and a few live by eating the prey captured by other spiders (these are called kleptoparasites). Spiders paralyze their prey by injecting poison secreted by a pair of venom glands in the chelicerae (front jaws). The ducts from these glands open on each side through a minute pore located near the tip of the fang (Fig. 85).

Prey catching strategies have been thoroughly studied in web-building spiders. For instance, the sheet web spider (family Agelenidae) hides in its funnel-shaped web and rushes out only when the prey has been trapped in the web. Members of the family Linyphiidae construct a horizontal sheet web with vertical threads that serve as trapping lines for insects. Once the prey is trapped by the threads, the spider shakes the web until the victim falls onto the sheet, then bites through the web and pulls down the victim. Some web-building spiders (e.g., theridiids) produce threads with glue droplets that trap and glue insects to the broken threads. The insects become progressively more entangled while attempting to escape. The alerted spider quickly climbs down and throws more sticky threads over the victims before biting them. Some orb weaving spiders bite prey caught in the web, then wrap the prey in silk; others throw silk over the prey first to subdue it, then bite through the silken shroud.



Spider Behaviour and Value in Agricultural Landcapes, Figure 85 **Front jaws (chelicerae of spider).**

The wandering spiders do not rely on snares. Most locate and overpower their prey directly. Among the more familiar examples of wandering spiders are the wolf spiders (Lycosidae), the jumping spiders (Salticidae), most of the crab spiders (Thomisidae), and the two-clawed foliage spiders (Clubionidae, Anyphaenidae). These spiders run in search of their prey and pounce upon it when an opportunity arises. Wandering spiders, exemplified by lycosids or wolf spiders, actively hunt for their prey. Wandering spiders spend some of their time stationary adopting a sit and wait strategy. Wandering spiders catch their prey in a different manner than web-builders. First, they locate the prey. Then they turn toward the victim and grasp it with the tips of the front legs, pulling it to the chelicerae and then biting (venom injection). Next, they release their grasp with the legs and hold the prey with the chelicerae instead, fastening some silk thread over the immobilized victim, and then commence feeding. Wandering spiders may locate their prey either by visual cues or by vibration, depending on the species. Classical examples of visually guided predators are the jumping spiders. They have highly developed main eyes that can analyze shapes, and can even recognize motionless prey. Spiders with poor eyesight, like the clubionids and related species, rely on the vibration of the substrate, or immediate contact with a victim to elicit direct catching movements.

Three species of sac spiders, *Chiracanthium inclusum* (Clubionidae), *Hibana velox* (Anyphaenidae), and *Trachelas volutus* (Corrinnidae), belong to the wandering spider group. Studies show they do not capture prey in webs, but actively hunt their prey, usually at night. During the day, they hide in tubular silken capsules that they construct, which give them the common name sac spiders. They are important in agriculture because they feed on the larvae and prepupae stages of citrus leafminer (*Phyllocnistis citrella* Stainton), one of the major pests of citrus. These spiders belong to the group of spiders with poor vision and they are nocturnally active hunters. Their prey capture depends greatly on substrate vibration. They detect their prey through the vibration of the substrate where the prey is concealed. Movement of citrus leafminer larvae and prepupae creates vibrations on the leaf substrate, which serves as a cue for the spiders to locate the positions of the prey. The prey capture sequence for these three species of spiders follows a similar pattern. During the searching period, the spider moves around and then stops for a while to locate sources of vibration. Once the spider touches the prey with its legs, the spider turns rapidly toward the prey and grasps it.

Two methods of prey attack are exhibited by the three species of sac spiders. In one method, the spider punctures the mine, immobilizes the larva then it bites and sucks the larval body fluid. In the second behavioral pattern, the spider makes a slit on the mine, and then pulls the larva or prepupa out of the mine using its forelegs. The first gentle touch of the forelegs quickly changes into a powerful grip aided by the special hairs on the spider's forelegs. For *Cuppiennius*, another genus of wandering spider, the forelegs are able to improve their secure hold by means of the adhesive hairs or scopulae on the tarsi. This may also be true for *Chiracanthium inclusum*, *Hibana velox*, and *Trachelas volutus* since these species possess tarsal scopulae and dense claw tufts. After securing a hold, the prey is pulled quickly toward the spider's body, then the chelicerae of their fangs move apart and are inserted rapidly into the nearest part of the victim's body. Immediately after the bite, the tips of the legs release their grip and the prey is held in the air only with the chelicerae, thereby minimizing any danger to the spider from the prey. This is advantageous because the victim has no contact with the substrate and therefore cannot apply any direct force to free itself. Only after the prey has become immobilized by the venom does actual feeding (the chewing and the exuding of digestive juice) begin.

Studies show that *Chiracanthium inclusum*, *Hibana velox*, and *Trachelas volutus* start to feed on citrus leafminer larvae at their first nymphal stage. This is not surprising, since spiders in general, after their first nymphal molt, are self-sufficient. At this stage, they have developed their sensory hairs, their legs are equipped with the typical claws, the eyes have the bulging lenses, and the mouthparts are already differentiated for hunting and feeding. The percent of citrus leafminer consumption for all the species of hunting spiders varies among the different nymphal stages and the adult stage. Consumption increases as they develop to later nymphal stages, especially for *H. velox*. Consumption peaks at the third nymphal stage for all of the species, halfway to the adult stage. For all of the species, feeding slows down and sometimes stops for 1 or 2 days before molting and then resumes right after molting. Most spiders that are preparing to molt withdraw into their retreat for several days and stop feeding. This phenomenon occurs naturally in all spiders.

Conservation

The diversity and voracious appetite of spiders in almost all agricultural systems suggests the importance of spiders as predators of insect pests and other arthropods. Thus, they should be considered as an important component of integrated pest control programs. Conservation and augmentation of spiders in fields is a simple and efficient method of pest control. There are several ways to conserve and augment the populations of spiders in the field. One way is to avoid the use of harmful pesticides. Studies show that there are more spiders and fewer insect pests in unsprayed fields than in sprayed ones. Another way is to manipulate their habitat by providing natural mulches (ground cover), which serve as refuge areas for spider breeding or by naturally increasing habitat diversity in the field. A more diverse agroecosystem in terms of habitat structure results in increased environmental opportunities for biological control agents like spiders, and consequently improved biological control. One way to enrich the vegetation structure of cropping systems is through weed management. The impact of weed diversity in the form of weed borders, alternate rows, or by providing weeds in certain periods of the crop growth is important in keeping the populations of the existing beneficial natural control agents, including spiders.

Spiders (Arachnida: Araneae)

PAULA E. CUSHING
Denver Museum of Nature & Science, Denver, CO, USA

Spiders differ from insects, crustaceans and other members of the phylum Arthropoda by having two body parts rather than the three of insects and crustaceans, and the multiple body parts of other arthropods. They also completely lack antennae, the only arthropod group to lack these sensory organs. Spiders use structures called chelicerae in feeding rather than the mandibles found in other arthropod groups.

Evolution and Taxonomy

Spiders, in the order Araneae, share the class Arachnida with other organisms such as scorpions (order Scorpiones), pseudoscorpions (order Pseudoscorpiones), camel spiders (order Solifugae), vinegaroons (order Thelyphonida), tailless whipscorpions (order Amblypygi), daddy long-legs (order Opiliones), and mites and ticks (order Acari). All these arachnid groups are thought to have evolved from an ancestor similar to eurypterids (order Eurypterida). These marine chelicerates were common in the seas from 500 to 245 million years ago (Ordovician to the Permian). Some eurypterids grew to two meters long. These giant aquatic arthropods were formidable predators of the ancient seas and had similar morphological characteristics as extant scorpions. In fact, some of the earliest scorpion fossils resemble more recent eurypterid fossils. Scorpion fossils from the Silurian period probably were aquatic because gills are apparent on these fossils. The arachnids that evolved from a eurypterid-like ancestor moved from the marine environment to the terrestrial environment, but largely maintained their predatory nature.

The earliest fossil arachnids include certain scorpions that date back to the Silurian period between 440 and 410 million years ago. The earliest true spiders appear in the fossil record in the Devonian Period about 380 million years ago. Early terrestrial arthropods had certain adaptations that gave them an advantage in the transition from an aquatic to a terrestrial environment including jointed legs to support the body against the pull of gravity and an exoskeleton to protect them from the desiccating effects of the air. The respiratory structures of the early aquatic chelicerates were probably similar to the book gills found on horseshoe crabs. These book gills are, in turn, similar in structure to the internal book lungs of extant terrestrial arachnids. It is tempting to imagine that as the early chelicerates were making the evolutionary transition from an aquatic to a terrestrial existence, the external respiratory structures became internalized as the book lungs.

The order Araneae currently includes over 40,000 species. This number includes only those species known to science. New species are being discovered every year, and the true species diversity is probably closer to 80,000, according to Dr. Norman Platnick of the American Museum of Natural History. Spiders are found in 108 families and over 3,600 genera. Following is a current taxonomic classification system for spiders, and the currently accepted families. Detailed information about spider taxonomy can be found in The World Spider Catalog at http://research.amnh.org/entomology/spiders/catalog/INTRO1.html.

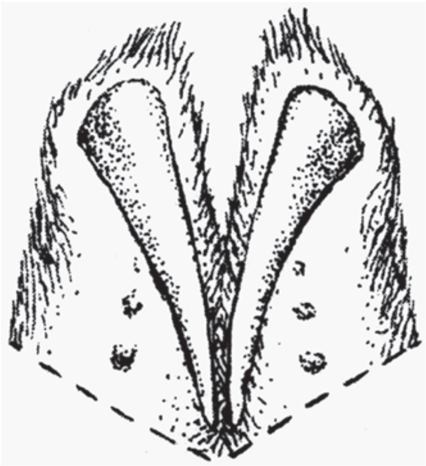
Spider Phylogeny

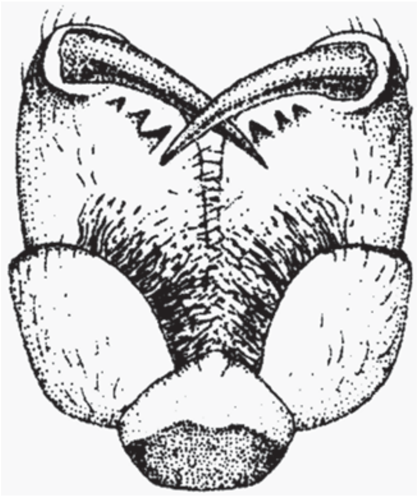
The order Araneae is considered a monophyletic lineage. Characters that unite spiders include venom glands in the chelicerae, male pedipalpi modified for sperm storage, and abdominal silk glands. The suborder Mesothelae is considered a plesiomorphic lineage. Liphistiids are the only spiders that have a segmented abdomen, a character that has been lost in all more recently evolved lineages. Liphistiids also have four distinct pairs of spinnerets instead of the three pairs found in all other spiders. This suborder contains only the single family Liphistiidae, species of which are found only in China, Japan, southeast Asia, and Sumatra.

The suborder Opisthothelae contain all remaining spider families which are divided into two infraorders: the Mygalomorphae and the Araneomorphae. In North America, the mygalomorphs are commonly called tarantulas and, elsewhere, are referred to as baboon spiders. This infraorder includes the quintessential large, hairy pet store spiders. The mygalomorphs are united as a single lineage based largely on spinneret and male genitalic characters. They have only two functional pairs of spinnerets and the bulb of the male pedipalp is fused in most families of mygalomorphs. Most mygalomorphs also are characterized as having paraxial chelicerae that are positioned more or less parallel to one another like the tongs of a garden rake (Fig. 86) These robust spiders also are characterized as having two pairs of book lungs. They also lack a key character present in the infraorder Araneomorphae, the piriform silk gland. Piriform glands allow araneomorphs to cement their silk to a substrate. Piriform silk has enabled araneomorphs to substantially diversify their use of silk, including in the construction of elaborate prey capture webs.

The infraorder Araneomorphae contains the majority of spider species worldwide. This infraorder is sometimes referred to as the "true" spiders even though liphistiids and mygalo-

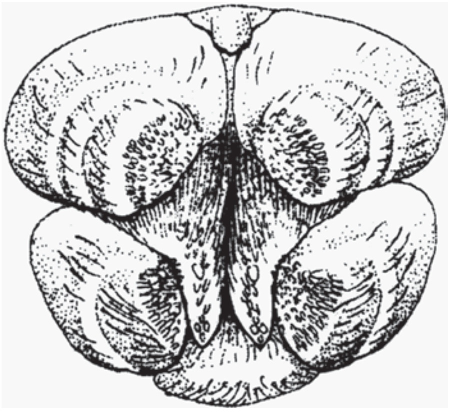


Spiders (Arachnida: Araneae), **Figure 86** **Chelicerae of a spider in the infraorder Mygalomorphae (drawing by Eric Parrish, University of Colorado).**



Spiders (Arachnida: Araneae), **Figure 87** **Chelicerae of a spider in the infraorder Araneomorphae (drawing by Eric Parrish, University of Colorado).**

morphs are as true as they come! This infraorder contains the best known and most familiar spiders, such as the orb weavers in the family Araneidae, the wolf spiders in the family Lycosidae, the jumping spiders in the family Salticidae, and the crab spiders in the family Thomisidae. Araneomorphs typically have opposing chelicerae that move somewhat like the blades of scissors (Fig. 87), and they typically have either one pair of book lungs or lack book lungs altogether. They also have three pairs of spinnerets, although some families of araneomorphs have a residual pair of anterior spinnerets that has evolved into a flattened spinning plate called the cribellum. Ecribellate spiders have a non-functional structure called the colulus (see "Silk production" section for information on the cribellum and its function; Figs. 88 and 89).



Spiders (Arachnida: Araneae), **Figure 88** **Spinnerets of a spider. The colulus is the nipple-shaped structure anterior to the spinnerets (drawing by Eric Parrish, University of Colorado).**

The majority of araneomorph spiders are further divided into two groups known as the Haplogynae and Entelegynae. In the haplogyne araneomorphs, the terminal part of the female's genitalia – that portion that opens to the outside – serves as both a copulatory duct and a fertilization duct. In other words, the external portion of the genitalia connects directly with the seminal receptacles, or spermathecae. Haplogyne females have no complex sclerotized structures associated with their genital opening. The entelegyne spiders, on the other hand, have females with very complex structures associated with their genital openings. These sclerotized structures are collectively referred to as the epigynum. In the entelegyne spiders, side ducts lead from the fertilization duct to the spermathecae. Sixteen families make up the Haplogynae branch of araneomorph spiders and 71 families make up the Entelegynae branch. Three araneomorph families – the Hypochilidae, the Gradungulidae, and the Austrochilidae – are not considered either haplogynes or entelegynes. Hypochilidae form a sister group to all the other Araneomorphae taxa. The hypochilids, like the Mesothelae and Mygalomorphae, are considered a more "primitive" (i.e., earlier evolved) group. Remnants of abdominal segmentation are present in hypochilids and hypochilids have a cribellum (see "Silk production" section). The Gradungulidae and Austrochilidae together form a sister group to the entelegyne/haplogyne branch of the evolutionary tree. The species in these two families are found primarily in South America and Australia, probably due to a Gondwana distribution.

Arachnid Characteristics

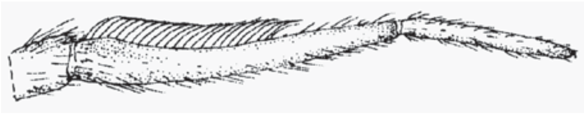
Most arachnids share certain characteristics including: (i) a body divided into two parts, the cephalothorax or prosoma and the abdomen or opisthosoma; (ii) no antennae; (iii) chelicerae; (iv) a unique pair of appendages in the front of their bodies called pedipalps involved in feeding and/or mating; (v) four pairs of walking legs; (vi) external digestion; (vii) indirect sperm transfer; (viii) elaborate courtship behaviors; and (ix) a strict predatory lifestyle. However, not all arachnids share all these characteristics. For example, the cephalothorax and abdomen of opilionids and acarines have become fused giving them the appearance of having only a single body part rather than the two characteristic of the other arachnid groups. Some species in these two orders also differ in having direct sperm transfer. Opilionid males have a penis that delivers the sperm directly into the female's body. Some opilionids can digest solid particulate food and, therefore, do not rely solely on pre-digested, or externally digested, material. Opilionids and acarines also differ in that neither group is a strict predator. Opilionids are, for the most part, scavengers, whereas acarines can be predators, ectoparasites, or plant feeders.

Silk Production

Silk is characteristic of all spiders. Spider silk emerges from structures at the posterior end of the spider's abdomen called spinnerets. The proteinaceous material is produced in silk glands in the abdomen. As the silk protein is exuded through the tiny opening of the silk spigot on the surface of the spinneret, most of the water is re-absorbed. The protein configuration completes its transformation from liquid to solid as the droplet of silk is stretched or put under tension. This can occur as the spider pulls the silk out of the spinnerets with a rear leg, or as the spider attaches the droplet to the substrate and walks away – these movements create enough tension to change the protein structure from liquid to solid.

Most spiders have three pairs of spinnerets – the anterior, the median, and the posterior pairs. However, it is thought that ancestral spiders had four pairs: an anterior lateral pair, an anterior median pair, a median pair, and a posterior pair. Spiders in the suborder Mesothelae still have four pairs of spinnerets, but one pair (the anterior median) is nonfunctional and residual. Many mygalomorph spiders have only two pairs of functional spinnerets having lost the anterior pairs (i.e., the pairs closest to the cephalothorax). Among araneomorph spiders, most species have three pairs of functional spinnerets. The anterior median pair has been lost and a rudimentary, non-functional structure called the colulus remains, positioned between the anterior lateral pair of spinnerets. Other species of araneomorphs, called cribellate spiders, have a flattened spinning plate, called the cribellum, positioned between the anterior lateral pair of spinnerets (Fig. 89). It is thought that the cribellum and the colulus are homologous structures and both are thought to be evolutionary derivatives of the anterior median pair of spinnerets. The cribellum is also thought to be an ancestral, or plesiomorphic, characteristic among the araneomorph spiders. The cribellum is covered with hundreds to thousands of individual silk spigots. In some cribellate species, the cribellum is divided into two small plates; in others, it is a single continuous plate. Cribellate spiders also have a specialized comb, called a calamistrum (Fig. 90), on the metatarsal segment of the last leg. The calamistrum is used to comb the cribellate silk out of the cribellum. Both cribellate and ecribellate spiders are found in the Haplogynae and in the Entelegynae. Therefore, it is currently thought that the cribellum is a polyphyletic characteristic.

Spiders (Arachnida: Araneae), Figure 89 Cribellum located anterior to the spinnerets (drawing by Eric Parrish, University of Colorado).



Spiders (Arachnida: Araneae), Figure 90 Calamistrum located on the metatarsal segment of the last leg of a cribellate spider. Used to comb the silk out of the cribellum (drawing by Eric Parrish, University of Colorado).

On the surface of each spinneret are different types of silk spigots each of which leads to a silk gland in the abdomen of the spider. Spiders can possess up to six different types of silk glands, each secreting a different kind of silk for different functions. These glands include ampullate glands, aciniform glands, tubuliform glands, piriform glands, aggregate glands, and flagelliform glands. Ampullate glands produce dragline silk and spider web frame threads. Draglines are continually produced by spiders as they move around in the environment and serve as safety lines. Aciniform glands produce the silk used to wrap prey as well as silk used by male spiders to construct sperm webs and silk used by females in constructing the outer walls of the silken egg sacs. Tubuliform glands are only found in female spiders and are also involved in the construction of the egg sacs. Piriform glands are used in the production of prey capture silk and in fastening silk lines to the substrate. Flagelliform and aggregate glands are found only in orb weaving spiders. Aggregate glands produce the glue that covers the prey capture silk of ecribellate spiders' webs. Flagelliform glands produce the axial thread of the sticky spiral. Adult male spiders lose their aggregate and flagelliform glands when they mature and, thus, lose the ability to build prey capture webs.

Spider silk is remarkable for its strength and elasticity. In terms of tensile strength, it is about as strong as the best steel. In terms of its tenacity and elasticity, dragline silk would have to be 80 km long before it broke under its own weight and it is more elastic than the stretchiest nylon. Many spiders recycle silk proteins by eating their webs. Scientists have radioactively labeled silk to determine how the silk proteins are used by such spiders. The results of these studies indicate that the silk proteins appear again as new silk in just 30 min;

spiders are clearly the masters of recycling. In World War II, spider silk was used for the cross hairs in gun sights because of its strength and durability. Natives of New Guinea used spider webs as fishing nets. The real Dr. Thomas Muffet of Little Miss Muffet fame was an actual practicing physician who had a fondness for spiders. One of Dr. Muffet's treatments for cuts or abrasions was to wrap the wound in fresh spider webs. Some spider silk has an acidic pH (around pH 4) and is, therefore, resistant to bacterial decomposition. Because of this, there seems to be some benefit to Dr. Muffet's treatment of wounds.

Spiders use silk for a variety of purposes. Dragline silk protects the spider walking around the habitat from plummeting to its death when a sudden gust of wind knocks it off a leaf; egg sac silk provides the spider eggs some protection from desiccation and from egg parasites and predators; non-sticky silk provides the framework for webs and serves to line burrows and retreats of non-web building spiders; sticky silk allows ecribellate web building spiders to capture prey by gluing the prey to the web; cribellate silk allows cribellate web building spiders to capture prey by tangling the hairs of the prey in the fine sheaths of silk combed from the cribellum by the calamistrum. Cribellate silk has also been found to be quite adhesive. Silk production is at the core of a spider's day-to-day existence.

Prey Capture

When spiders encounter prey, most either bite the prey, injecting it with venom and then wrap the prey in silk, or they wrap the prey to immobilize it and then inject the wrapped prey with venom. Whatever immobilization technique is used, venom plays a crucial role. Venom is produced by all families of spiders except those in the family Uloboridae. All other spiders have venom glands in the cephalothorax that are linked to the fangs by ducts running through the chelicerae. One of the common misconceptions about spiders is that the venom of spiders acts not only to immobilize the prey, but also to digest the prey. This is incorrect. The venom is not involved in digestion and contains only trace amounts of digestive enzymes if any at all.

Spider Venoms of Medical Importance

Another common misconception about spiders is that the venom of many spiders is harmful to humans. Of the over 40,000 species of described spiders worldwide, only 160 or fewer have venom harmful to humans, not even 1% of the species. In the United States, the most common spiders with venom of medical importance are the black widow species in the genus *Latrodectus* (family Theridiidae) and the recluse spiders in the genus *Loxosceles* (family Sicariidae). These spiders have proteinaceous toxins in their venom. Both black widows and recluse spiders are fairly timid and only bite when severely provoked. People get bitten by black widows primarily when they accidentally press down on a resting spider hidden beneath a stone, under a log, or under the seat of a privy in an outhouse. In areas where *Loxosceles* is common inside homes, people usually get bitten when the spider seeks shelter in clothing dropped on the floor. As a person puts on the clothing, the spider is threatened and may bite in defense.

The venom of black widows is neurotoxic and can cause severe systemic pain by disrupting the transmitter substances at the neural synapses. Toxicity of *Latrodectus* venom varies between different vertebrates. Rabbits and sheep, for example, are little affected by bites from black widows, whereas horses and camels are very susceptible to injections of the venom. The effect of black widow bites on humans varies between individuals depending on the amount of venom injected, and the age and health of the individual. Rarely do bites from black widows cause death, but they can cause severe abdominal pain, cramps, pain in the joints, and other systemic effects. Antivenin is now readily available in areas where black widows are common. However, because the antivenin is in horse serum and because many people have allergic reactions to the serum, other treatments may be attempted first to ease the pain caused by the bite. Injection of calcium salts may be beneficial. Treatment with pain medications may temporarily ease the symptoms as well, although administration of the antivenin is most effective.

Loxosceles (or recluse) venom is proteolytic and hemolytic, primarily affecting tissues at the bite site. A substance in the recluse venom triggers an immune response that causes the body to cut off blood supply to the affected area. This is what causes the lysis of the cells surrounding the bite site. Bites from these spiders can cause deep, ulcerous wounds that heal very slowly, sometimes taking up to 3 weeks. These lesions can become extensive. They are typically treated topically with corticosteroids. Antibiotics often are given to prevent secondary bacterial infection of the wound site. In extreme cases, surgical excision of necrotic tissue is necessary, often followed by skin grafts. Although antivenin is being developed, it is not yet readily available.

One of the more infamous spiders with medically significant venom is the Sydney funnel web spider, *Atrax robustus* (Mygalomorphae, family Hexathelidae). This spider is found only in Australia. The venom of male *A. robustus* acts upon neuromuscular endings, stimulating the release of acetylcholine, adrenaline and noradrenaline from the autonomic nervous system. Males are much more venomous than females and much more likely to be encountered. Females tend to remain in the funnel webs, whereas adult males are found wandering in search of females and may, in their wanderings, have a face-to-face encounter with a human. When only a little venom is injected, the bite site is very painful for hours to days but, otherwise, only mild reactions to the venom are evident. A more serious bite can result in nausea, vomiting, abdominal pain, arrhythmia and other systemic symptoms. In severe cases, confusion, coma and death by asphyxiation can result from an *A. robustus* bite. Antivenin is now readily available in areas of Australia where the Sydney funnel web spider is found. This antivenin is extremely effective.

Digestion of Prey

Once the prey has been immobilized using venom, the spider regurgitates digestive enzymes onto the prey through the mouth. The mouth is located between three plates situated on the ventral side of the cephalothorax: a central plate called the labium and two lateral plates called the endites. These enzymes that are regurgitated onto the prey break down, or pre-digest the body of the prey until the body has been completely liquefied. When a spider bites its prey, the fangs create holes in the exoskeleton of the prey that serve as entryways for the digestive enzymes. Some spiders create further holes in the body of the prey using teeth lining the fang furrows on the chelicerae. Spiders without such teeth on the chelicerae rely on the holes created by the fangs to digest and suck up the pre-digested prey. With these spiders, all that is left when they are done is the intact exoskeleton of the prey, a hollow husk of its former self.

A spider's stomach is the main organ used to imbibe the pre-digested food. The stomach is located in the dorsal portion of the cephalothorax. It is connected to the spider's exoskeleton by a series of muscle bands. The apodeme, or muscle attachment, of the dorsal band can be seen clearly on the cephalothorax of a tarantula as a median indentation, somewhat like a dimple. Circular muscle bands surround the stomach. When the muscle bands connecting the stomach to the body wall contract, the stomach lumen expands; when these muscles relax, the circular bands reduce the volume of the stomach. The spider's stomach thus acts as a pump, drawing fluid into the body when the long bands contract, or pumping fluid out of the stomach and either forward as regurgitant, or laterally and backward into the remaining tubes of the digestive system. The stomach of spiders, appropriately, is called a sucking stomach.

A spider cannot ingest solid particulate matter; it can only suck into its body pre-digested liquids. Setae are often found on the lateral borders of the endites and on the anterior border of the labium. These setae function to filter out particulate material. The pharynx is lined with downward pointing ridges that also act to filter out larger particles. These larger particles are spit out of the mouth by an anti-peristaltic stream of digestive fluid and are concentrated as a solid pellet, which is then cleared away from the mouthparts using the pedipalps. While feeding, the spider continually vomits digestive fluid and sucks up the resulting liquefied prey until all that is left is the empty exoskeleton, or bits of exoskeleton. When larger spiders feed on vertebrate prey, the pre-digestive process is readily apparent as the mouse or small bird becomes a glistening, liquefied ball of material. All that is left when a vertebrate is eaten is a collection of bones, cartilage, feathers and other indigestible material.

Extensions of the digestive system, called diverticula, extend out into all areas of the spider's body including the legs, the eyes and the abdomen. These extensions create an incredibly efficient and effective transport system for the pre-digested food. Partly because of these extensive diverticula and partly because of the low metabolism of spiders, these animals can go a very long time without eating. Pet tarantulas can be fed once a month or less and be perfectly content (or so it seems).

Excretion

The posterior portion of the digestive system ends in a stercoral pocket, or cloacal chamber. The excretory products of the main excretory organs, the Malpighian tubules, empty into this sac-like stercoral pocket. The main excretory products secreted by spiders are guanine, adenine, hypoxanthine and uric acid, all of which are largely insoluble in water. Therefore, spiders lose very little water through excretion. These excretory products are stored in the stercoral pocket until the pocket is periodically emptied and the material excreted through the anus. In some spiders, waste products from digestion are stored as crystals of guanine just below the transparent cuticle where they are seen as white markings on the abdomen.

Respiratory and Circulatory Systems

When talking about the circulatory system of spiders, it makes sense to talk about the respiratory system as well because the primary function of the circulatory system is oxygen transport. Oxygen enters the body of a spider through openings in the body called spiracles. For mygalomorph spiders, these spiracles lead to two pairs of book lungs. Araneomorph spiders have either one pair or no book lungs. The posterior pair of book lungs in most araneomorph spiders is thought to have evolved into a pair of tubular tracheae.

The spiracle opening into the book lung is a passive opening; in other words, it cannot be closed. The air flows between thin plates of tissue called lamellae. In between these lamellae are evaginations of the body cavity filled with hemolymph, or blood. Oxygen diffuses through the lamellae into the hemolymph. The tubular tracheae of spiders are similar to the tracheae of insects, except that insects have multiple spiracular openings into the tracheae, whereas spiders have either one or two spiracles opening into their tracheae. As with insect tracheae, spiders' tracheae branch into ever smaller tubes. Passive diffusion of oxygen into the hemolymph occurs across the tiny walls of the smallest tracheoles.

For both the book lungs and tracheae, oxygen enters the body passively with little help from muscular contractions. The tracheal system varies in different araneomorph families. In some, the tubes branch out only into the abdomen; in others, the tubes branch all over the spider's body including into the cephalothorax. In some very tiny spiders, they have lost the book lungs completely and rely on an extensive system of tracheal tubes to get their oxygen.

The hemolymph of spiders contains oxygen-carrying molecules called hemocyanin. This molecule functions very similarly to hemoglobin found in mammals. However, hemoglobin has iron atoms as part of its structure and is contained in blood cells, whereas spider hemocyanin has copper atoms and is not contained within blood cells. Whereas the iron atoms give mammalian blood its red color when it becomes oxygenated, the copper atoms gives spiders' blood a blue-green color. Hemocyanin is nearly as effective as hemoglobin in binding to oxygen molecules. The hemolymph of spiders also contains cells that are involved in blood clotting, wound healing, fighting off infections, and storing different types of compounds for transport throughout the body.

After the hemocyanin molecules pick up the oxygen from the book lungs and from the tracheae, this oxygenated blood is carried throughout the body. This transport is carried out via the circulatory system. As with all arthropods, spiders have an open circulatory system; the hemolymph bathes the internal organs and tissues and is not contained in blood vessels. Nevertheless, a circulatory pathway does exist. A spider's heart is located in the dorsal portion of the abdomen. As the heart muscle relaxes, holes in the sides of the heart, called ostia, open and the oxygenated blood is sucked into the heart. The heart then contracts, which causes the ostia to close and forces the blood anteriorly and posteriorly into a system of open-ended arteries. The oxygenated blood thus gets circulated throughout the body in a directional manner such that as the hemolymph loses its oxygen, it flows back toward the abdomen and the respiratory organs before returning to the heart. The circulation of the hemolymph follows a gradient of decreasing blood pressure. This carries the deoxygenated blood back to the abdomen and over the book lungs or tracheal.

In addition to its other functions, the hemolymph of spiders also serves another very important function. Spiders have both flexor and extensor muscles in all their leg joints except the femur-patella joint and the tibia-metatarsal joint, which both lack extensor muscles. Spiders extend their legs at these joints by increasing the blood pressure in their limbs. This increased pressure is caused by a contraction of muscles connecting the carapace (or top of the cephalothorax) with the sternum (or bottom plate of the cephalothorax) thus reducing the volume of the first body segment and increasing blood flow into the extremities. If spiders lose too much water, they can no longer increase hemolymph pressure sufficiently to extend the legs. Spiders caught inside homes away from any source of free water are often found with their legs curled up underneath them. If found in time, a droplet of water can revive such a hapless spider. Although spiders can survive long periods without food, most cannot survive long without some source of moisture.

Sensory Setae and Pits

Setae on a spider's body serve as mechanoreceptors, responding to touch, vibrations, air currents, and positions of the spider's joints. In some mygalomorph species, the setae on the abdomen also serve for defense. These setae are often barbed and, when provoked, the spider brushes them off using a rear leg. Some wandering spiders, such as mygalomorphs and jumping spiders, spiders that hunt without a web, have scopula and claw tufts on the tarsi and metatarsi (Fig. 91). These setae are more structural than sensory. They are very fine setal fringes that allow these spiders to climb and keep a foothold on very smooth surfaces. Any smooth surface is covered by a fine film of water. The thousands of small setae making up the claw tufts and scopula allow these spiders to walk across these surfaces surefootedly due to capillary forces.

Spiders (Arachnida: Araneae), Figure 91 Scopula and claw tufts of a mygalomorph spider (drawing by Eric Parrish, University of Colorado).

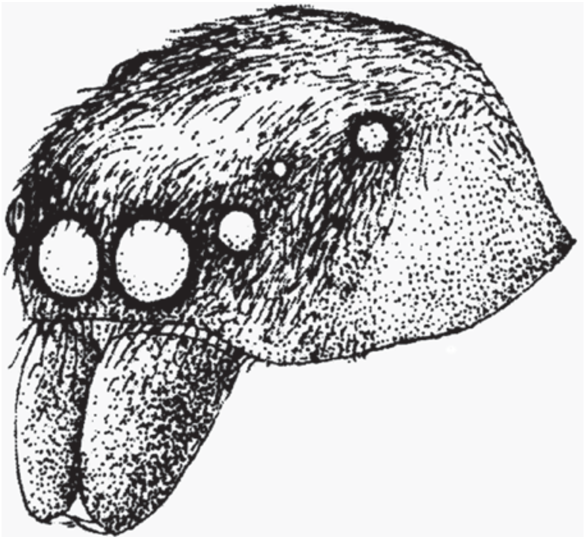
On the leg segments of spiders are long, fine hair-like sensillae called trichobothria. These sensillae are sunk into sockets with multiple dendritic nerve endings at the base. They are found on the legs and are extremely sensitive to air currents, even those produced by the wings of an insect flying nearby. They probably serve in localizing prey or enemies. Patterns of trichobothria are often diagnostic of certain families. Sensory structures called slit sense organs are located near the leg joints. These slits are also connected to dendrites. Clusters of slit sense organs are called lyriform organs because they look like a stringed instrument called a lyre. Slit sense organs, or slit sensilla, serve multiple functions. Some slit sensilla are sensitive to airborne sounds, some probably serve as gravity receptors, some respond to vibrations within a certain frequency, others respond to movements of the spider's own extremities.

Open-ended hair-like setae at the ends of the legs and pedipalps serve as taste receptors. Spiders will avoid pungent or acidic substances upon contact. An adult spider can have over 1,000 contact chemoreceptors, or taste hairs, on the tarsal segments of its legs. These contact chemoreceptors probably enable the spider to tell good-tasting prey from bad and enable males to detect female pheromones that may be deposited in their silk. It is clear that spiders can also respond to airborne odors or smells. It is thought that the "noses" of a spider are small, open pits on the dorsal side of each tarsus. These pits are called tarsal organs. Spiders use these tarsal organs to respond to airborne cues from prey and mates. Although the majority of spiders are solitary predators often living and hunting far away from conspecifics, when a female matures, males are able to quickly locate her. This localization is almost certainly done via airborne pheromones or chemical cues that females deposit either on the substrate or in their silk.

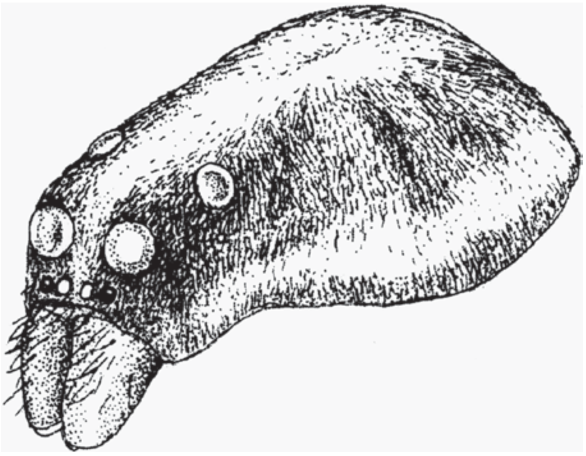
Vision

Most spiders have eight eyes arranged as two rows, although some families are characterized by spiders with only six or two eyes and some cave dwelling species have lost their eyes altogether. Often, the eye arrangement is diagnostic for a particular family. For example, jumping spiders (Salticidae) and wolf spiders (Lycosidae) can be identified to the family level solely by their eye pattern. The structure of a spider's eyes is similar to the ocelli of insects. Spiders have simple eyes with a single outer lens, an inner cellular vitreous body and a layer of visual and pigment cells which together make up the retina. For the vast majority of spiders, vision is not the primary sense they rely upon in their daily lives. Most spiders are nocturnal and, in the low light levels of the night, they rely primarily on tactile and chemical cues. Web building spiders, in particular, have what, by vertebrate standards, would be considered poor vision. They respond to changes in light intensity, or to changes in the polarization of incoming light, but probably cannot see fully formed images of objects. However, wandering spiders or cursorial hunters, such as wolf spiders, jumping spiders and crab spiders are much more reliant on vision both to catch prey and to court mates (Figs. 92 and 93).

Jumping spiders, in particular, have exceptional eyesight. They can probably see in color and can perceive images of objects 8–10 cm from them. A jumping spider will respond to movement of objects up to 40 cm away. These spiders are diurnal and can often be found hunting on the sides of houses, fences, barns or other structures. When a human moves close to a jumping spider, the spider often responds to the movement and orients its body in order to face the person. Their large main eyes, or anterior median eyes, and their



Spiders (Arachnida: Araneae), Figure 92 Eye pattern of a jumping spider in the family Salticidae (drawing by Eric Parrish, University of Colorado).



Spiders (Arachnida: Araneae), Figure 93 Eye pattern of a wolf spider in the family Lycosidae (drawing by Eric Parrish, University of Colorado).

responsiveness to the slightest movement give these spiders a very personable countenance (at least to arachnophiles). Salticids have elaborate courtship behaviors involving zigzag dances and specific movements of the front legs and pedipalps. The bright colors of many salticids probably serve a role in mate choice.

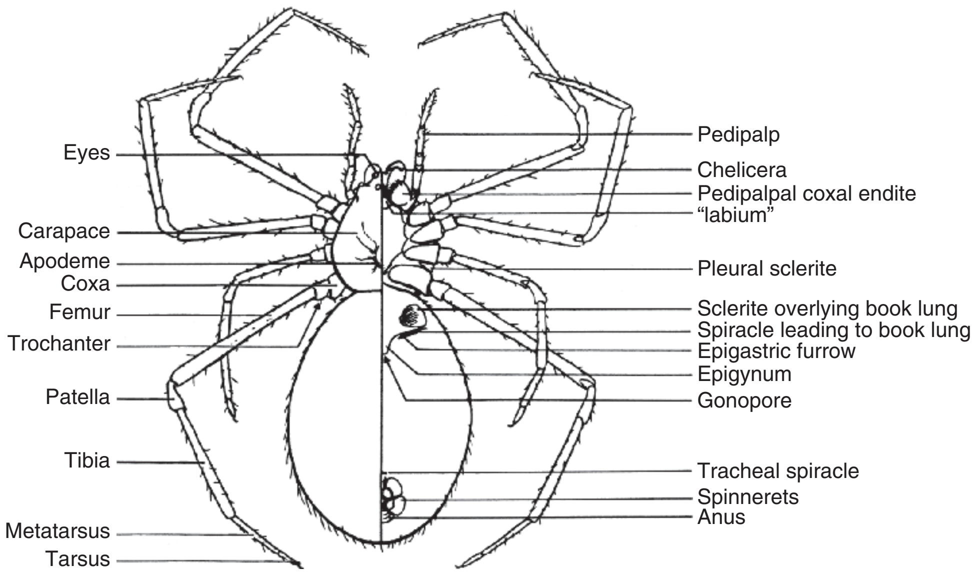
Wolf spiders also have keen vision. Most wolf spiders are crepuscular, or nocturnal. These spiders have a light-reflecting crystalline structure called a tapetum behind the retinal cells of the secondary eyes (secondary eyes include all eyes except the anterior median eyes). It is thought that the tapetum functions to gather incidental light in low light conditions. The tapetum also allows arachnologists to hunt wolf spiders at night using headlamps. The light from the headlamp reflects off the tapetum so spider hunters can find wolf spiders by their eyeshine. Diurnal hunters, such as salticids, lack tapeta. Wolf spiders also have keen vision and actively pursue their prey and their mates. They also have elaborate courtship behaviors involving visual signals. In addition, some wolf spiders incorporate vibratory cues in their courtship rituals by tapping their legs and pedipalps against the substrate.

Central Nervous System

Whereas insects have interconnected ganglia throughout their bodies, spiders have only two major ganglia. Both nerve centers are located in the cephalothorax: the supra- and the subesophageal ganglia. The subesophageal ganglion consists of nerves controlling the legs and pedipalps. A nerve bundle called the cauda equina arises from the subesophageal ganglion and enters the abdomen. The supraesophageal ganglion, located, as the name implies, above the spider's esophagus, includes the nerves to the chelicerae, the pharynx, the poison glands and the eyes. The supraesophageal ganglion is considered the spider's "brain." (Figure 94 shows an overview of a spider's body.)

Although some aspects of a spider's behavior are "pre-programmed" or instinctive, in many respects spiders show a wide range of behavioral plasticity in their response to environmental cues; spiders, in other words, can think. Perhaps they do not think in the way that humans define that term, but they certainly show more behavioral flexibility than one would expect of an animal showing purely instinctive responses to cues.

A good example of this behavioral plasticity is seen with the jumping spiders in the genus *Portia*



Spiders (Arachnida: Araneae), Figure 94 Composite drawing of a typical spider with principal body parts labeled. *Left half* is dorsal view; *right half* is ventral view.

found in New Zealand. Although most jumping spiders hunt primarily insects, *Portia* specializes in hunting other species of spiders as well as spider egg sacs and insects. *Portia*, as do all jumping spiders, has very keen vision. If it is stalking an insect, its behavioral hunting strategy is similar to that of any other jumping spider. Most insects that *Portia* hunts cannot fight back very effectively so the spider uses stealth, but not caution, in its hunt. However, if *Portia* is stalking another spider, the tables can turn quickly, and hunter can become hunted. *Portia*'s hunting strategy changes commensurate with the type of prey. If the prey is a web building spider, *Portia* will approach the web and pluck it to mimic an insect caught in the silk. If the web builder responds by approaching the vibrations, *Portia* pounces. However, if the web builder does not respond, or if the web builder is larger than *Portia*, the jumping spider will try different vibratory cues or different hunting tactics until its behavior is effective in luring the web builder close enough to kill. *Portia* is even known to detour around a particularly dangerous prey in order to approach from a direction from which *Portia* itself cannot be attacked. A spider's brain may only be the size of a pinhead, but the integration of electrical signals from the spider's appendages and eyes can result in extraordinarily complex behaviors (Figs. 95 and 96).

Sex Among the Spiders

The internal sexual organs of spiders, the testes and ovaries, are located in the abdomen. However, male spiders have no intromittent organs associated with the genital opening. As with most arachnids, spiders have indirect sperm transfer. With primitive groups of arachnids, such as scorpions, the male deposits a stalked sperm packet, or spermatophore, on the substrate and, using complex courtship behaviors, manipulates the female over the spermatophore. Male spiders have evolved a more direct strategy for ensuring that their spermatophore makes it into the female.

Male spiders can be distinguished from females by the shape of their pedipalps. Male spiders look like they are wearing boxing gloves on the end of their pedipalps. When a male spider matures, he builds a small platform of silk called a sperm web. In some groups, the sperm web consists of just a few lines of silk. Onto this sperm web,

the male deposits a droplet of sperm from his genital opening. He then presses a tube associated with the pedipalp called the embolus into this droplet of sperm and sucks the sperm into the bulb of the pedipalp where it is stored until the male mates. The pedipalps of entelegyne spiders are much more complex than those of haplogynes. However, mating in all groups of spiders requires the expulsion of the sperm stored in the pedipalp into the female's genital opening. In entelegyne spiders, complex structures on the male pedipalp correspond to structures located on the female's epigynum.

The majority of spiders are solitary predators and will opportunistically feed on whatever prey is available, even if the prey is of its own species. A male spider must, therefore, be cautious when approaching a female and must effectively communicate to her that he is a mate and not a meal. This is particularly important among web building spiders because there is often dramatic dimorphism between males and females with males being considerably smaller than their female conspecifics. When a male web building spider locates a female, probably via airborne pheromones, he sings a silk song to her communicating that he is a mate and not a hapless insect caught in the web. If the female is mature and is willing, she will respond to his vibrations in a species specific manner. If she is not responsive to mating, she may try to attack the male.

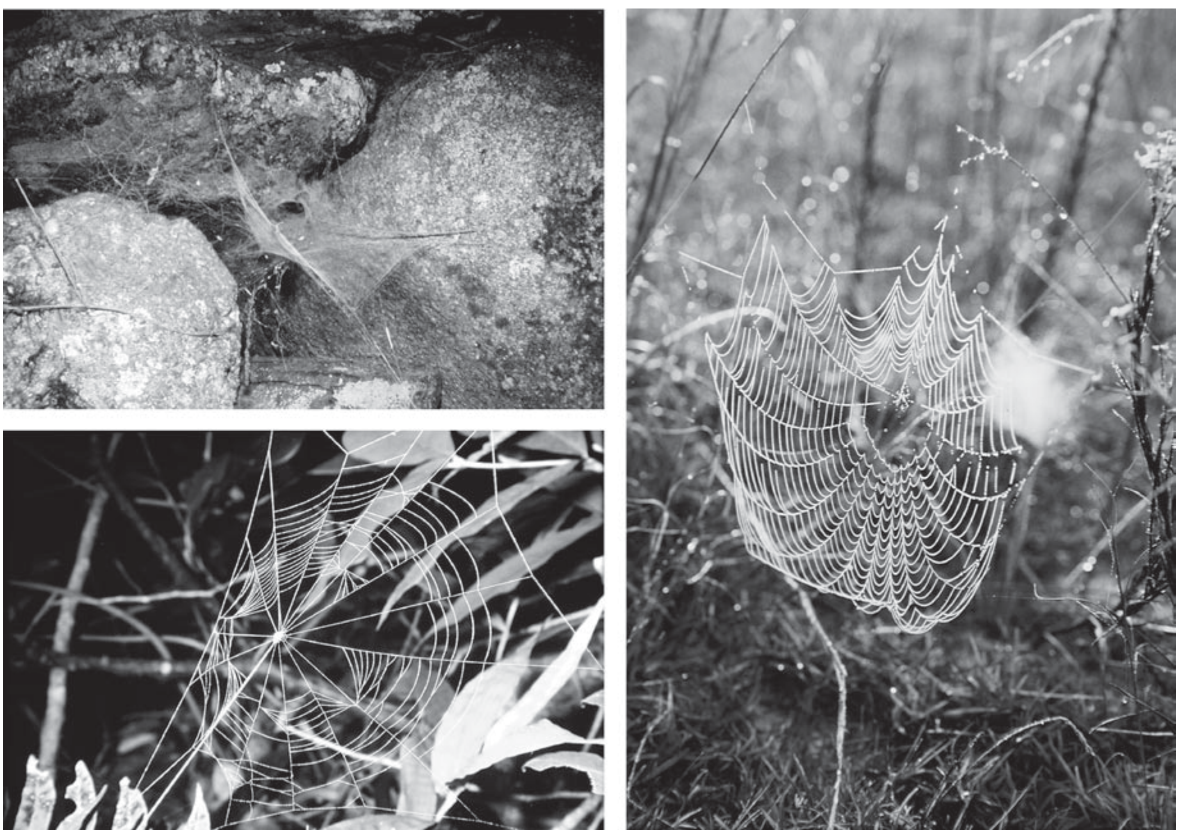
Male wandering spiders, such as wolf spiders or jumping spiders, dance for their lady loves. The courtship behaviors of male jumping spiders are particularly striking in that they often involve zigzag dances, and waving of the legs and pedipalps. Wolf spiders may add a vibratory component by tapping their pedipalps on the ground. Some male spiders have stridulatory structures on their bodies that are probably involved in courtship.

When a male's courtship behaviors have been accepted by a female, he will approach her cautiously and may stroke her. Finally, he will insert his embolus into her genital opening to inject the sperm. The female has seminal receptacles where the male's sperm is stored. Some females will mate multiple times with the same or with different males. In some species, depending on the location of the seminal receptacles in relation to the oviducts, the first male to mate with the female fertilizes most of her eggs, whereas in other species, the last male's sperm takes precedence. In some species, the male will deposit a mating plug into the female's genital opening in an attempt to prevent her from mating with other males. Sometimes, the mating plug is the broken tip of the male's embolus.

When male web building spiders mature, the silk glands responsible for creating prey capture silk become non-functional. In other words, the aggregate and flagelliform glands of male ecribellate spiders become non-functional and the glands associated with the cribellum of cribellate spiders become non-functional. When male web building spiders mature, they are no longer thinking about food, but only of true love. Partly as a consequence of this, male web building spiders have shorter life spans then their conspecific females. This difference in life span holds true for the majority of spiders including mygalomorphs (Fig. 97).

Brood Care, Hatching and Dispersal

Within a few weeks after copulating, female spiders are ready to lay their eggs. The stored sperm is released and fertilization occurs in the oviduct just prior to egg emergence from the genital opening. The female builds a silken egg sac to protect the eggs. In some spiders, the egg sac is an elaborate structure with thick walls of silk. However, some spiders, such as those in the daddy longlegs or cellar spiders family (Pholcidae) (which share a common name with the arachnids in the order Opiliones) attach the eggs together with just a few silk strands. Most females can produce multiple egg sacs, each containing from a few to over 1,000 eggs depending on the species. In many species, the female guards the



Spiders (Arachnida: Araneae), Figure 97 Some spider webs: funnel web (Agelenidae) (*upper left*), theridiosomatid web (Theridiosomatidae) (*lower left*), and orb web (Araneidae) (*right*) (photos by author).

egg sac against egg sac parasitoids and predators until hatching. Female spiders in the family Uloboridae, for instance, remain in contact with the suspended egg sac, brushing off any insect that might land or walk on it. Female wolf spiders (Lycosidae) attach the silken, disc-shaped egg sacs to their spinnerets and carry them around until the egg sacs hatch. Female fishing spiders (Pisauridae) carry their egg sacs in front, holding onto the silk with their chelicerae. Female jumping spiders (Salticidae) remain in silken retreats with their egg sacs until they have hatched.

Within a few weeks, the egg sacs hatch except in those species that overwinter. In some cases, as with wolf spiders, the mother assists her young by cutting a hole in the egg sac to facilitate emergence. In most cases, the offspring cut their own way out of the silken structure. After hatching, some females will continue to guard and care for their young. For example, upon hatching, wolf spiderlings crawl up onto their mother's back. Wolf spider females have specialized knobbed setae on the back of the abdomen to which the babies cling. The female carries her offspring on her back until the yolk supply from the egg stage is depleted and they are old enough to hunt for themselves. In a very few species, the mother actually provides food for her newly hatched offspring either in the form of prey the mother has killed, or in the form of regurgitated food.

After 1 or 2 weeks, the spiderlings of most species are ready to disperse. Ballooning is one common method of dispersal seen among araneomorph spiderlings. These spiderlings crawl to the top of a blade of grass, a twig, a branch or some other structure and release a strand of silk. Air currents catch the silk, often called gossamer, and lift the tiny spider up, up and away. Although some of these "flying spiders" may land only a meter or two away from the take-off point when their silk gets tangled in the branches of a nearby tree, others can travel truly extraordinary distances by this means of aerial dispersal. Some ballooning spiders have been found on ships far out at sea and have been collected from airplanes. Because of this ability to travel long distances by ballooning, spiders are often one of the first pioneer species to establish themselves on distant oceanic islands. However, lack of food and water probably makes life difficult if not impossible for these pioneer predators. In a few families of very tiny spiders, even the adults will sometimes move to a new habitat by means of ballooning. In other spider families, including some mygalomorphs, dispersal mechanisms are much more mundane. The spiderlings, when they are old enough to hunt, simply wander away from natal ground and establish themselves in a new area.

Spiderlings look much like the adult stages except that they are often paler and have no fully developed sexual organs. The complex structures of the male pedipalp do not appear until the final molt, nor do the structures associated with the female's epigynum. The palpal and epigynal characters are the structures used by arachnologists to identify spiders to species. Tiny spiders require about five molts to reach maturity, whereas larger species can require up to 10 molts. Araneomorph spiders do not undergo any further molts after reaching maturity; mygalomorph females, however, continue to molt all their lives. The molting process in spiders is similar to that in insects. As with insects, all chitinous structures, including such internal structures as the trachea, the book lungs and, with mygalomorph females, the linings of the seminal receptacles, are molted. For adult mygalomorph females, this means that any sperm stored in the seminal receptacles when they molt is lost and the female becomes newly virginal (the one group of animals that can actually regain its virginity!).

Most araneomorph spiders either drop down on a silken thread, or enter a silken retreat or burrow when they are getting ready to molt. Mygalomorphs turn over onto their backs prior to molting. Many a pet tarantula owner has thrown away their pet thinking it was dead when it was just getting ready to put on a new skin. As with all arthropods, molting is a dangerous time for the spider. The spider is vulnerable to predators during the molting process and just after completing the molt when the new exoskeleton is not completely sclerotized.

Most male spiders, araneomorphs and mygalomorphs, die shortly after maturation. In temperate regions, most species live only 1 or 2 years. The majority of adults die soon after the first hard frost. In tropical regions, lifespans can vary and there can be multiple generations of one species at any time. The longest lived spiders are some mygalomorph species that have recorded lifespans in the laboratory of up to 30 years for females and up to about 10 years for males. In temperate regions, some spiders overwinter in the egg sac stage, the development arrested until warmer temperatures in the spring. In other species, the spiderlings overwinter by seeking protection in warmer microhabitats in cracks, crevices, or in the leaf litter layer.

Spiders as Predators

Spiders are found in every terrestrial ecosystem on earth except Antarctica. Although a few spiders can obtain some nutritional value from pollen on occasion, all species of spiders, including the occasional pollen eater, are overwhelmingly predatory in their lifestyle. They are one of the top invertebrate predators in terrestrial communities. An arachnologist, William S. Bristowe, once estimated that a one acre field (0.4 hectare) in England could be home to over two million spiders. Although no volunteers have been found to empirically verify this extraordinary number, spiders are in high enough numbers to affect the populations of their prey species. Most spiders are generalist predators and, because of their euryphagous diet, have not been considered useful biocontrol agents in agroecosystems. However, more and more studies have indicated that spiders can, in fact, suppress pest populations. Exploring the usefulness of spiders as biocontrol agents in integrated pest management is a burgeoning field of research.

Spielman, Andrew

Spielman is recognized for his contributions to public health entomology. Born in 1930 in Brooklyn, New York, USA, he graduated from Colorado College in 1952 before enrolling at Johns Hopkins University where he received a Sc.D. in 1956 in pathobiology. While studying for his doctorate, Spielman worked with the Tennessee Valley Authority in Alabama as a malariologist, and after graduating worked for the U.S. Navy at Guantanamo Bay, Cuba. In 1959, he moved to Harvard University, eventually rising to become a professor of tropical public health in the department of immunology and infectious diseases. His areas of study included malaria, dengue, encephalitis, Lyme disease, West Nile virus, and babesiosis. He worked actively in both the USA and in Africa. Spielman made notable contributions by working in both the field and laboratory. He is probably best remembered for pioneering work on Lyme disease, and the role of deer ticks in transmitting this ailment to humans. He was a proponent of reducing the deer population as a way of managing the disease, but also developed methods to curtail infection in small rodents, and worked on development of a vaccine. Among his nearly 350 publications was a book coauthored with Michael D'Antonio, "Mosquito: a natural history of our most persistent and deadly foe." He died suddenly on December 20, 2006.

Spindle-Shaped

Elongate, cylindrical, thickened at the middle and tapering at the ends.

Spine

A large, stout seta or thorn-like process extending from the integument.

Spinose

Spined, spiny, covered with spines.

Spiny-Headed Worms

A phylum of invertebrates called Acanthocephala. They are usually slightly flattened, and bear an evertable proboscis with hooks or spines (hence the name spiny-headed worms) that are used to pierce and hold the gut wall of its host. They live in the intestinal tracts of vertebrates, but insects sometimes serve as intermediate hosts.

Spined Soldier Bug, *Podisus maculiventris* (Say) (Hemiptera: Pentatomidae, Asopinae)

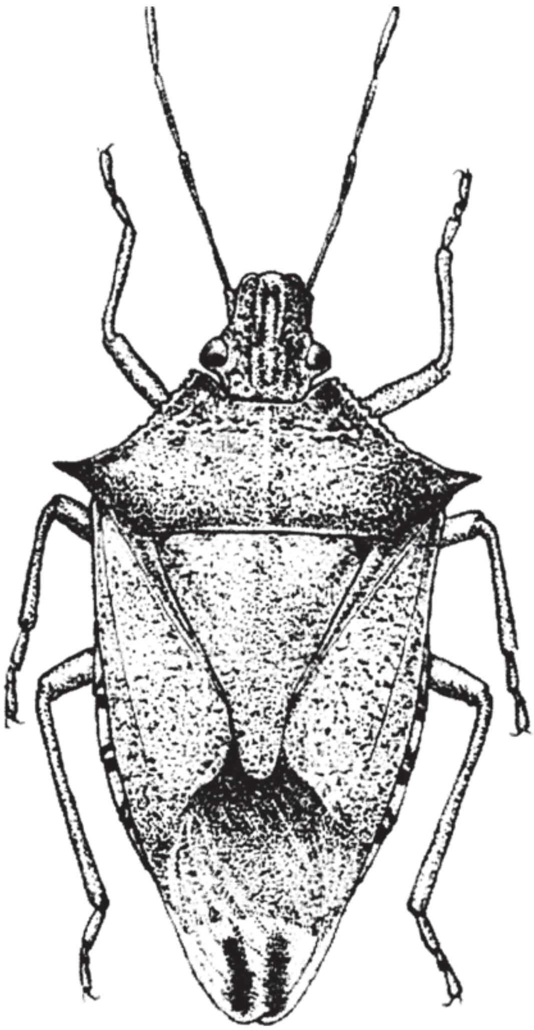
PATRICK DE CLERCQ
Ghent University, Ghent, Belgium

The spined soldier bug, *Podisus maculiventris*, is the most common predatory stink bug in North America. It is naturally distributed from Mexico, the Bahamas and parts of the West Indies into Canada. The insect occurs in a variety of natural and agricultural ecosystems, such as shrubs, woods, streambanks, orchards and several field crops.

Adult spined soldier bugs (Fig. 98) are pale brown to tan in color and are 10–14 mm long, with the females somewhat larger than the males. They are shield-shaped and have a prominent spine on each "shoulder." The adults have a distinct dark spot on the membranous tip of each forewing. The adults, as well as the nymphs, have a thickened rostrum or beak which they can extend fully forward to feed on prey, and which they keep folded under their body when not feeding. The females start ovipositing about 1 week after emerging and usually lay eggs throughout their entire lifetime. The adults are long-lived, with reported longevities ranging from 1 to 4 months under laboratory conditions. Fecundities measured in the laboratory range from 300 to over 1,000 eggs per female, mainly depending on the prey supplied.

The eggs are deposited in loose oval clusters, each containing on average 15–30 eggs. The eggs are about 1 mm in diameter and 1 mm long, are cream-colored to black in color and have a ring of about 15 long micropylar processes around the operculum on top. The duration of the egg stage is 5–8 days, depending on the temperature.

There are five nymphal instars. The nymphs are round to oval rather than shield-shaped. Young nymphs are red and black in color, whereas older nymphs are marked with black, red, yellow-orange and cream bands and patches. The wing pads become clearly visible from the fourth instar on. The length of the respective instars averages 1.3–1.5, 2.5–3, 3.5–4, 5–6, and 7–9 mm. First instars



Spined Soldier Bug, *Podisus maculiventris* (Say) (Hemiptera: Pentatomidae, Asopinae), Figure 98 ***Podisus maculiventris*.**

are highly gregarious and hardly move about. In later instars, the nymphs become progressively more solitary with each molt. First instars are not predaceous and usually only take up moisture, although they have been observed feeding on unhatched eggs from the same mass. The nymphs start actively searching for insect prey shortly after molting to the second instar. The nymphs (and adults) become cannibalistic when food is short. The nymphal stage requires 20–30 days for complete development, depending on the temperature and on the availability and quality of food.

Development from the egg to the adult stage typically takes 4–5 weeks at 20–25°C. A lower threshold temperature for immature development is approximately 12°C. In Canada and in central and northern parts of the United States, the spined soldier bug usually has 2–3 generations per year and hibernates as an adult from October to April. Overwintering takes place in litter, under tree bark, under stones, etc. In warmer climates, like in the southern United States, the insect is active all year.

Although in natural habitats it is primarily found in association with soft-bodied larvae of plant-feeding Lepidoptera, Coleoptera and Hymenoptera, the spined soldier bug is a strongly generalist predator, reportedly attacking more than 90 insect species from 8 orders. Nonetheless, there may be important differences in developmental and reproductive success depending on the prey species or stage supplied. The nymphs and the adults of the spined soldier bug have frequently been observed feeding on plant juices. This plant-feeding habit appears to be particularly important when prey is scarce. Plant-feeding primarily provides moisture, but it may also furnish certain nutrients to the bugs at critical times. Plant-feeding by spined soldier bugs has not been reported to cause plant damage.

Several studies have favorably assessed the predation capacity of the spined soldier bug on various insect pests, including the Colorado potato beetle, *Leptinotarsa decemlineata*, the Mexican bean beetle, *Epilachna varivestis*, the pine sawfly, *Diprion similis*, the fall webworm, *Hyphantria cunea*, the cotton leafworm, *Alabama argillacea*, the cotton bollworm, *Helicoverpa zea*, the tobacco budworm, *Heliothis virescens*, and the beet armyworm, *Spodoptera exigua*. From the 1930s up to the 1980s, numerous attempts have been made to introduce the spined soldier bug into different parts of Europe for the control of the Colorado potato beetle, but the predator never became established, probably because of its inability to overwinter. The predator has been used in augmentative biological control of leaf-feeding caterpillars (mainly belonging to Noctuidae) in

European and North American greenhouse crops. For augmentative releases, the nymphs are preferred to the adults, because the latter tend to fly quickly from the treated plots. Two releases of 0.5 fourth-instars per square meter in commercial glasshouses proved to be effective in keeping noctuid caterpillars in check on sweet peppers, eggplants and some ornamentals. Hot spots of aggregating caterpillars have been treated successfully at densities of 5–10 nymphs per square meter. In field crops in North America, natural populations of the spined soldier bug are often too low to effectively suppress outbreaks of pests like the Colorado potato beetle, particularly early in the season. Natural populations may be augmented by releasing laboratory-reared individuals. In small field plots, releases of about three second- to third-instars per potato plant reduced high densities of Colorado potato beetle eggs and larvae and provided good foliage protection. However, the cost of rearing and releasing the predator on a large scale may be prohibitive. Alternatively, a synthetic pheromone can be used to lure spined soldier bugs to target areas in early spring, as adults emerge from overwintering. The pheromone can also be employed to capture large numbers of predators that can be used to establish mass cultures.

Podisus maculiventris is easily reared in the laboratory on different factitious prey, including larvae of the yellow mealworm, *Tenebrio molitor*, and the greater wax moth, *Galleria mellonella*. Wax moth larvae appear to be a particularly good food, yielding good survival, rapid development and high fecundity. However, given the great voracity of the predator, extensive parallel cultures of prey insects are needed, rendering its mass production less economical. An artificial diet based on beef is available to support the production of consecutive generations of the bug, but development is somewhat prolonged and fecundity is about half of that obtained when wax moth larvae are the primary food.

Although the spined soldier bug has been commercially available in Europe and North America since the 1990s, wider adoption of this beneficial in augmentative biological control is hindered mainly by its high production cost. In Europe, there is also some concern that releases of this and other exotic generalist predators may have detrimental effects on nontarget, native fauna.

Spiny Shore Bugs

Members of the family Leptopodidae (order Hemiptera).

► Bugs

Sphingidae

A family of moths (order Lepidoptera). They commonly are known as sphinx, hawk or hummingbird moths, or hornworms.

► Hawk Moths
► Butterflies and Moths

Spinneret

A structure that produces silk in immature insects. The spinneret is often a finger-like structure.

Sphinx Moths

Some members of the family Sphingidae (order Lepidoptera).

► Hawk Moths
► Butterflies and Moths

Spider Beetles

Members of the family Ptinidae (order Coleoptera).

► Beetles

Spider Mites

Mites (Acari) in the family Tetranychidae are often called spider mites.

► Mites
► Acaricides or Miticides

Spider Wasps

Members of the family Pompilidae (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Spine-Tailed Earwigs

Members of the earwig family Forficulidae (order Dermaptera).

► Earwigs

Spinose Ear Tick, *Otobius megnini* (Duges) (Acari: Ixodidae)

This is a livestock pest in western North America.

► Ticks

Spiny Rat Lice

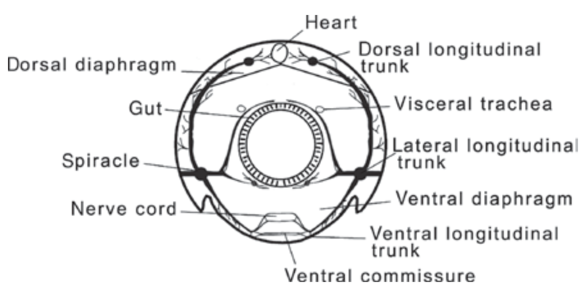
Members of the family Polyplacidae (order Phthiraptera).

► Chewing and Sucking Lice

Spiracle (pl., spiracles or spiraculae)

An external opening of the system of ducts (trachea) used to transfer atmospheric gases into, and out of, the body of arthropods. They are commonly found along each side of the body (Fig. 99).

► Tracheal System and Respiratory Gas Exchange



Spiracle (pl. Spiracles or Spiraculae), Figure 99 **Cross section of the abdomen of an insect, showing the principal trachea and tracheal connections (adapted from Chapman, The insects: structure and function).**

Spiracular Bristles

Bristles found in close proximity to a spiracle.

Spiracular Gill

A gill formed by an extension of a spiracle, or a plastron around a spiracle.

► Tracheal System and Respiratory Gas Exchange

Spiracular Plate

A plate found adjacent to or surrounding a spiracle.

Spirea Aphid, *Aphis spiraecola* Patch (Hemiptera: Aphididae)

This aphid affects citrus and other trees and shrubs.

► Citrus Pests and their Management

Spittlebugs (Hemiptera: Cercopoidea)

DANIEL C. PECK[1], VINTON THOMPSON[2]
[1]International Center for Tropical Agriculture, Cali, Colombia
[2]Roosevelt University, Chicago, IL, USA

The superfamily Cercopoidea belongs to the suborder Auchenorrhyncha of the order Hemiptera. It includes four taxa, the family Cercopidae, Aphrophoridae, Clastopteridae and Machaerotidae, which encompass the spittlebugs proper and the tube-dwelling machaerotids. Some taxonomists still include all four groups as subfamilies within the traditional unified family Cercopidae.

The Clastopteridae (about 85 described species in one genus) and Machaerotidae (about 105 species in 27 genera) are sister groups, limited to the New and Old World, respectively. The Machaerotidae are predominantly tropical, with a handful of temperate species in China and Japan. The Clastopteridae are abundant from Canada to Argentina, all in the single speciose genus *Clastoptera* (the status of an additional isolated Philippine genus is problematic). The Aphrophoridae (about 820 species in 150 genera) probably represent a polyphyletic group, in which the Cercopidae constitute one monophyletic branch. The Aphrophoridae are best represented in north temperate habitats, but also occur widely in the tropics. There are approximately 1,360 described species in the Cercopidae in 140 genera, and a recent revision lists 416 of those species distributed in the New World. This group is predominately tropical. Only two species, *Prosapia bicincta* and *P. ignipectus*, occur north of Mexico in the Americas, and only two genera, *Cercopis* and *Haematoloma*, occur in Europe.

Adult spittlebugs, known as froghoppers for their quick jumps and putative resemblance to tiny frogs, are named in parallel to other Auchenorrhyncha such as the leafhoppers, planthoppers and treehoppers. They are distinguished from these groups by 1 or 2 strong spines on the metatibia, a crown of spines at the distal end of the tibia, and nymphs that live in spittle masses or calcareous tubes filled with liquid.

Biology and Behavior

Nymphs and adults of the Cercopoidea have sucking mouthparts and feed on the xylem sap of host plants. Compared to phloem sap, xylem sap is a challenging food resource because it is normally under negative pressure and offers a very dilute source of organic nutrients. Special adaptations to this resource include a filter chamber shunt to manage high volumes of fluid and an inflated clypeus and reinforced apodemes to support the enlarged sucking muscles. Other consequences include a relatively long life cycle and unique defensive opportunities for the nymphs compared to phloem-feeding Auchenorrhyncha.

The Cercopoidea have five nymphal instars. Nymphs in the Clastopteridae, Aphrophoridae and Cercopidae construct spittle masses at their feeding sites and gain protection from desiccation and most natural enemies. The spittle is composed of bubbles added to excreted, attenuated xylem sap fortified with mucopolysaccharides that are secreted by the Malphigian tubules. Nymphs form the bubbles one-by-one with repeated thrusts of the tip of the abdomen out of the excreted liquid to pick up air in a special pocket formed by the ventral abdominal plates. The Clastoptera tend to have very aqueous spittle masses, while those of the Aphrophoridae are frothy and those of the Cercopidae intermediate. Typically there is a single nymph per spittle mass, but sometimes two or more nymphs cohabit one mass. On occasion, nymphs of two species share a common spittle mass. The widespread Neotropical aphrophorid species *Cephisus siccifolius* forms large communal spittle masses with dozens of nymphs. Machaerotid nymphs live in liquid-filled calcareous tubes constructed at the feeding site. They form a spittle mass, at the mouth of the tube, only in conjunction with the adult molt.

Adult spittlebugs do not make spittle masses. Like nymphs, they excrete large volumes of sap, but flick it away in small drops, so it does not accumulate. Large species may drip like faucets when actively feeding. In Africa, species of the aphrophorid genus *Ptyelus* drip so copiously that it appears to be raining beneath their dry season "raintree" hosts.

Adult Aphrophoridae, Clastopteridae and Machaerotidae depend on camouflage or disruptive coloration and jumping as defensive mechanisms. The Cercopidae exhibit a unique shared character, reflex bleeding. When threatened, adult Cercopidae emit odoriferous orange hemolymph from the tips of their feet, helping to repel attackers. This defense is accompanied by warning coloration in a large proportion of taxa. Many species exhibit striking red, yellow, orange or black markings, making them conspicuous in their natural surroundings.

Substrate communication plays an important role in courtship and other behaviors among adult Cercopoidea. Tymbals located on the first abdominal segment produce vibrations that are transmitted through the host plant. In the Cercopidae, male courtship calls vary in pulse structure (simple to compound), duration, peak frequency and pulse repetition frequency. A receptive female transmits her response via the substrate to guide males to copulation. There is also evidence for other classes of vibrational communication, such as distress calls.

Most temperate spittlebugs are univoltine. A few have two generations per year. Most tropical spittlebugs are multivoltine, with life cycles tied to seasonal rainfall patterns.

Ecology

Spittlebugs feed on an unusually wide range of plants. Very generally speaking, the Cercopidae tend to feed on herbaceous monocots, the Clastopteridae and Machaerotidae on flowering trees and shrubs, and the Aphrophoridae on conifers and herbaceous dicots. There are many exceptions to these generalizations, however, and some species feed on an extraordinarily wide range of hosts. Philaenus spumarius, the aphrophorid meadow spittlebug, may have more recorded hosts than any other phytophagous insect. Presumably, wide host range is a consequence of xylem feeding, xylem sap being chemically less defended and rather similar in composition across plant groups. Within this diversity of hosts, many spittlebugs have an affinity for nitrogen-fixing plants that may provide a richer and more constant source of xylem sap nutrition. The Cercopidae, for instance, have a predilection for plants that have associative nitrogen fixation through root zone bacteria, while many Aphrophoridae prefer legumes, and many Clastoptera prefer actinorhizal hosts. Other factors that influence host plant or feeding site selection include concentration of amino acids, tissue toughness, depth of xylem elements, presence of trichomes and growth habit or architecture.

Two species of the genus *Mahanarva* in Central America have aquatic nymphs that live in the flowers of Heliconia plants, the only known truly aquatic spittlebugs. Nymphs of several species of Aphrophoridae and Clastoptera as well as one machaerotid have associated Diptera (Drosophilidae: Cladochaeta, Leucophenga, Paraleucophenga) larvae that share their spittle masses. The precise nature of these associations, whether parasitic or commensal, is not fully understood.

In the temperate zone several aphrophorid species (primarily of the genera *Aphrophora* and *Peuceptyelus*) are serious pests of conifers. Philaenus spumarius is a pest of alfalfa and other legume forage crops, as well as strawberries. Clastoptera species attack cacao, pecans and citrus but are only rarely of serious concern. The cercopid species Haematoloma dorsatum is a pest of pines in Southern Europe and, as elaborated below, the grass-feeding Cercopidae as a group are serious pests in Latin America.

As xylem feeders, spittlebugs are infrequent disease vectors, but all tested species transmit the xylem-limited bacterium *Xylella fastidiosa*, which causes Pierce's disease of grape and diseases of several other plants. *Xylella fastidiosa* is a serious concern in California and other areas where this bacterium poses a threat to commercially important crops. Spittlebugs also transmit the bacterium that causes Sumatra disease of cloves and the mycoplasma that causes stunt disease of *Rubus*.

Grass-Feeding Neotropical Spittlebugs

As pests, the Neotropical grass-feeding spittlebugs of the cercopid subfamily Ischnorhininae are by far the most important Cercopoidea. This economically critical subset includes dozens of species from at least 11 genera (*Aeneolamia*, *Deois*, *Isozulia*, *Kanaima*, *Mahanarva*, *Maxantonia*, *Notozulia*, *Prosapia*, *Sphenorhina*, *Tunaima*, *Zulia*). These insects are destructive pests of forage grasses and sugar cane, and occasionally other cultivated graminoids, such as turfgrass and rice. The following sections relate specifically to this well-studied group.

Life Cycle

Eggs go through four generalized developmental stages, completing development in 2–3 weeks. In the case of diapause and quiescence, time to hatching can be prolonged up to 530 days. Although soil is the most common oviposition site, litter and plant stem surfaces are used by some species and favored in preference to soil by others.

The five nymphal instars can be reliably differentiated by morphological measurements, particularly the width of the head capsule. Recently emerged first instar nymphs usually establish spittle masses on roots at the soil surface or in cracks and pores of the upper layer of soil. While the nymphs of most species remain near the soil, others migrate upwards into leaf axils on more erect hosts. In sugar cane, for instance, *Aeneolamia postica* nymphs emerge from eggs in the soil and complete development on surface roots, while *Mahanarva andigena* nymphs emerge from eggs on litter or the base of old leaf sheaths and favor aerial spittle masses in leaf whorls. Development time varies with species and climate, ranging from 4 to 9 weeks. Duration of the adult phase ranges from 1 to 3 weeks.

Adults usually exhibit sexual dimorphism, with males smaller and often more brightly colored than females. Some species also exhibit multiple color forms within one or both sexes, while unrelated species often share common color patterns, complicating species identification. The styles, plates and aedeagus of the male genitalia are the most diagnostic taxonomic features.

Agricultural Ecology

Nymphs and adults of grass-feeding spittlebugs occur during the wet season. Most species pass the dry season as drought tolerant diapause eggs. Depending on species, habitat and duration of the wet season, they achieve 1–6 generations per year. In highly seasonal sites, the return of the wet season promotes synchronous hatching and damaging early season outbreaks. Population dynamics are characterized by high population fluctuations and population synchrony. In continuously humid sites, all life stages are present throughout the year, fluctuations and synchrony are reduced, and yield loss can be less severe.

The most widely reported natural enemies are fungal entomopathogens, predaceous larvae of the pan-Neotropical syrphid fly *Salpingogaster nigra* that attack nymphs in their spittle masses, parasitic nematodes (Mermithidae), and generalist robber flies (Asilidae). Egg parasites (Eulophidae, Mymaridae, Trichogrammatidae), parasitic flies (Pipunculidae) and parasitic mites (Erythraeidae) also have been reported.

Economic Impact

Grass-feeding spittlebugs are widely distributed in the Neotropics and are economically important in lowlands and highlands from the southeastern U.S. to northern Argentina. They attack all economically important genera of tropical forage grasses, particularly species of African origin. Adult feeding causes a phytotoxemia identified by a chlorosis that spreads from the feeding site. Nymphs cause damage similar to water stress, identified by browning spreading from the leaf tip. Severe outbreaks result in the yellowing off of the entire aboveground portion of the plant. This damage lowers forage production, quality, and palatability, reduces milk and beef production, inhibits the establishment and persistence of improved pastures, and increases soil degradation.

Pest Management

Management of spittlebugs in forage grasses and sugar cane is still haphazard, given the challenges posed by the diverse situations in which they occur. Due in part to incomplete information on the biology and habits of the specific pest species, there has been a tendency to overgeneralize the spittlebug/host/habitat interactions to the detriment of control efforts. In pastures, controlled grazing, effective fertilization, burning, host plant selection and diversification of forage species offer possibilities for control. A long-term breeding program is achieving successes for spittlebug resistance in *Brachiaria* grasses, the most widely planted forage grasses in South America and the most susceptible to spittlebug attack. In sugar cane, control measures include cultural control tactics and applications of commercial fungal entomopathogens. Management successes in both systems are limited by poorly developed IPM decision tools such as yield loss assessments, sampling schemes and thresholds, in addition to the fundamental challenges inherent to IPM in extensive and low value agroecosystems such as rangelands.

In systems with highly seasonal precipitation, the recommended management strategy is temporal and spatial identification of the early season nymph outbreaks to target control tactics that will suppress population development before the invasion of uninfested areas and the propagation of future generations. In less seasonal systems, the recommended management strategy will depend on cultural control techniques such as host plant selection and controlled grazing, and there will be more options for biological control.

► Piroplasmosis

Spongillaflies (Neuroptera: Sisyridae)

DAVID E. BOWLES
Texas Parks and Wildlife Department, Austin, TX, USA

The insect order Neuroptera is primarily a terrestrial group. Unique among the neuropterans, however, is the family Sisyridae that have aquatic larvae. The common name of this family is spongillaflies and is derived from the predaceous, and arguably parasitic, feeding of the larvae on freshwater sponges (Porifera: Spongillidae). Spongillafly larvae occur in various types of freshwater habitats including streams, lakes and impoundments. Comparatively little is known about the biology of sisyrids in relation to other aquatic insect groups largely due to their unique larval habitats and their relative rarity. The classification is as follows:

Order: Neuroptera
Suborder: Planipennia
Superfamily: Hemerobioidea
Family: Sisyridae

Taxonomy and Distribution

The known genera of spongillaflies include *Climacia*, *Sisyra*, *Sisyrina* and *Sisyborina*. The genus *Climacia* is distributed primarily in the New World tropics although three species are represented in temperate regions. The genera *Sisyrina* and *Sisyborina* consist of only three described species and is restricted to India and Asia, respectively. *Sisyra* occurs throughout the world from boreal to tropical environments. Only about 60 described species of spongillaflies among all genera occur worldwide.

Adult spongillaflies superficially resemble brown lacewings (Family Hemerobiidae). However, because of the branching pattern of the forewing venation, brown lacewings appear to have two radial sector veins while the spongillaflies have only one clearly defined radial sector vein. In addition, most of the coastal crossveins of brown lacewings are branched, but those of sisyrids are not branched. Most spongillaflies are uniformly brown in color, but some species in the genus *Climacia* have colorless wings marked with black and brown patches or streaks (Figs. 100–101).

Sisyrid larvae (Fig. 102) are robust, odd-looking insects having fairly long antennae, and slender legs each bearing a single tarsal claw. Their bodies bear numerous stout setae, and they are variably colored ranging from yellowish-brown to green. In addition, the second and third instar larvae bear two-or three segmented, transparent ventral gills that are folded beneath the abdominal segments. The mouthparts of larval spongillaflies are modified into elongate, unsegmented styles used for sucking fluids from their sponge hosts.

Natural History

Spongillafly larvae most often are found crawling about the surface of their host sponge, but occasionally they may be found within the cavities and recesses of the sponge. Several genera of freshwater sponge are parasitized by spongillaflies

Spongillaflies (Neuroptera: Sisyridae), Figure 100 ***Sisyra vicaria*** **(Walker). Female, lateral view.**

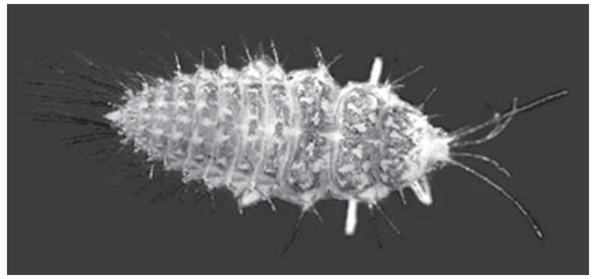
and all are widely distributed in North America. These genera include *Anheteroeyenia*, *Dosilia*, *Ephydatia*, *Eunapius*, *Heteromeyenia*, *Radiospongilla*, *Spongilla* and *Trochospongilla*. Some

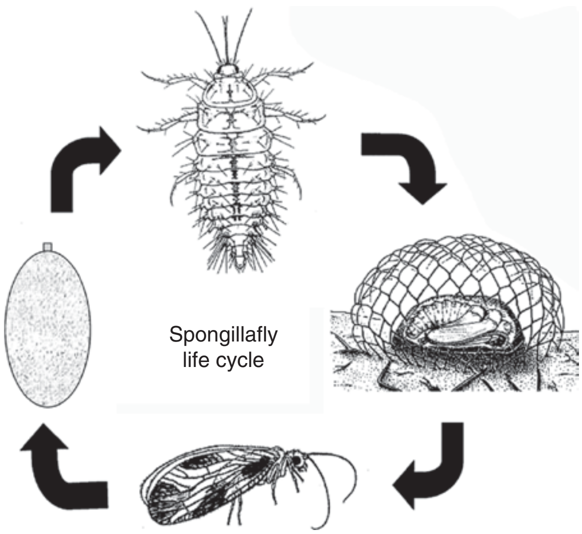


Spongillaflies (Neuroptera: Sisyridae), Figure 102 ***Climacia chapini*** **Parfin & Garneg. Larva, dorsal view.**

sponges do not form large, robust colonies and may appear only as a thin encrustation on woody debris or stones. The latter forms are more difficult to locate and collect than the former, but they still can support spongillaflies. Rarely, spongillaflies have been reported feeding on bryazoans and algae. Adult spongillaflies often can be found on flowering plants and other riparian vegetation during daylight. The feeding habits of adult spongillaflies are not well known, but they have been observed feeding on insect eggs, and nectar also may be a food source.

Spongillaflies have complete life cycles similar to that of other neuropterans. Female spongillaflies typically lay eggs in masses of 2–5 on emergent vegetation or other objects overhanging the water. The eggs are oval, whitish to yellowish in color, and covered with a web of white silk. The eggs hatch in about 1 week and the first instar larvae fall into the water and immediately proceed to search for a host sponge. First instar larvae "jump about" presumably to aid in their distribution. Jumping is accomplished by tucking the various appendages underneath the body and then rapidly straightening them out causing the body to lift off the substrate and move forward. Mature larvae swim in a vertical position and gain forward movement by snapping the body. There are three larval instars in the life cycle with the final instar larvae ranging from 4 to 8 mm in length (Fig. 103).

Prior to pupation, final instar larvae leave the water and climb onto objects along the bank such



Spongillaflies (Neuroptera: Sisyridae), Figure 103 **Generalized life cycle of a spongillafly. The pupal cocoon is cut-away to show the pupa inside. Illustrations are redrawn and modified from those of Brown (1952) and Pupedis (1987).**

as plants, tree limbs and other solid structures often some distance from the water. Pupae are housed in hemispherical, usually double-walled, silken cocoons. The inner wall of the pupal cocoon consists of tightly woven mesh and the outer wall is more loosely constructed.

Spongillafly larvae in North America occasionally are attacked by the parasitoid wasp *Sisyridivora cavigena* Gahan (Hymennoptera: Chalcidoidea: Pteromalidae). The female wasp pierces the pupal cocoon of the spongillafly using a long ovipositor, stings the pupa, and lays its eggs. In some instances, the female wasp may use a feeding tube constructed from their own ovipositors to feed on the body fluids of the host. The extent and effects of such parasitism on spongillafly populations are unknown.

Collecting Methods

Adult spongillaflies are strongly attracted to a variety of lights including incandescent, ultraviolet, and mercury-vapor. Such lights provide an excellent means by which to collect adult spongillaflies. Adult spongillaflies also can be collected by sweeping the vegetation bordering aquatic habitats. Larvae can be collected by hand from freshwater sponges, and by using a variety of benthic collecting devices and techniques such as kick-nets, Surber and Hess samplers, and Eckman and Ponar grabs.

Preservation

Larval and pupal spongillaflies ideally should be fixed in Kahle's solution (parts by volume: 15–95% ethyl alcohol, 6–10% formalin, 1-glacial acetic acid, 30-distilled water) for approximately 24-h when possible, and then permanently stored in 70% ethyl or isopropyl alcohol. However, 80% ethyl or isopropyl alcohol will serve this purpose satisfactorily when Kahle's solution is unavailable. Adult specimens ideally should be pinned or pointed, but preservation in 70% ethanol or isopropyl also is suitable.

Spore

A reproductive stage of fungi, usually somewhat resistant to adverse environmental conditions, that is capable of growing into a new organism.

Spotted Cucumber Beetle or Southern Corn Rootworm, *Diabrotica undecimpunctata* Mannerheim (Coleoptera: Chrysomelidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

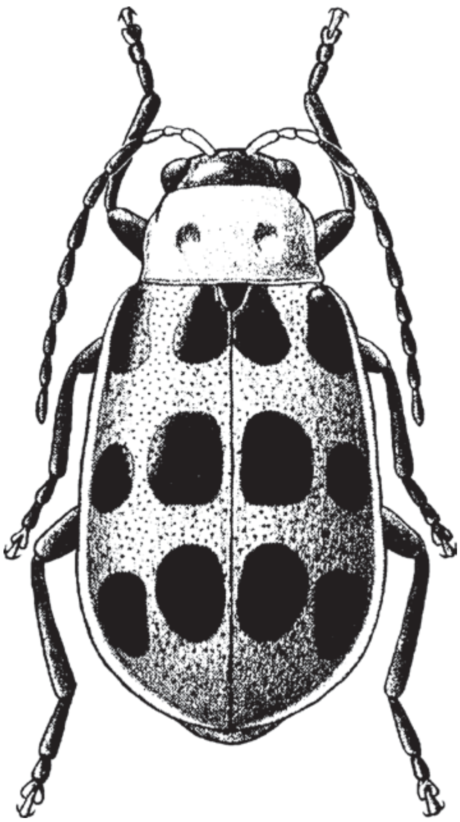
This species is found throughout the United States and southern Canada, although two races are recognized. In the Rocky Mountain region and westward a variant designated as *Diabrotica undecimpunctata undecimpunctata* Mannerheim is recognized, and called the western spotted cucumber beetle. The eastern form of the spotted cucumber beetle is found east of the Rocky Mountains, including eastern Canada as far west as Alberta, and is designated *Diabrotica undecimpunctata howardi* Barber. Spotted cucumber beetle is also found in Mexico, and consists mostly of the eastern race.

In the USA, spotted cucumber beetle is often found in the same areas occupied by other cucumber beetles. However, in the north the striped cucumber beetle, *Acalymma vittatum* (Fabricius), is dominant; in most southern areas spotted cucumber beetle is most abundant, and in the southernmost areas of Florida and Texas the banded cucumber beetle, *Diabrotica balteata* LeConte, predominates. Spotted cucumber beetle is highly dispersive, overwintering in southern states and dispersing northward annually.

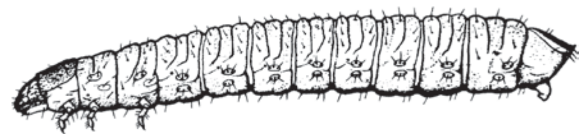
Life History

The spotted cucumber beetle normally completes its life cycle in 4–6 weeks. The number of generations per year seems to be unusually variable, possibly because there is no true diapause in these insects and they continue to reproduce as long as the weather allows, and because they annually re-invade northern areas. Often there are two generations per year, but a single generation is reported in Oregon, and three in Alabama and southern California. Because the generations overlap considerably, and adults can be found continuously during warm weather, field observations could lead to an underestimate of generation number. The adult is the overwintering stage. Overwintering beetles hide in plant debris and become active when the temperature reaches about 15–20°C. In the mild weather areas of the northwestern USA, aggregation of beetles in protected locations may occur during the winter, but this is the exception, not the rule, and beetles generally overwinter only in areas with mild winters, principally the southern states, dispersing northward annually. Northward dispersants in the spring can consist of a mixture of insects that had dispersed southward during the preceding autumn, and new adults produced at southern latitudes (Fig. 104).

Normally, about 40 eggs are produced at each oviposition. Beetles prefer coarse soil or soil with cracks to fine, smooth soil; they also prefer wet over dry soil for oviposition. A female will deposit, on average, six egg clusters during her life, for a total of 200–300 eggs. All values related to egg production are quite variable, with the values decreasing as the beetles progress from generation 1, to 2, to 3. The yellow egg is oval, and measures about 0.7 mm long and 0.5 mm wide. Egg incubation time varies with temperature, from as little as a week to up to a month. The three instars generally require about 7, 5, and 4 days, respectively, or about 14–24 days for complete larval development. The larva grows from about 1.8 mm long at hatching to about 12 mm long at maturity. Head capsule widths measure 0.3, 0.4, and 0.6 mm, respectively. The larva is yellowish white, with the head and the dorsal plate at the tip of the abdomen colored brown. The mature larva



Spotted Cucumber Beetle or Southern Corn Rootworm, *Diabrotica undecimpunctata* Mannerheim (Coleoptera: Chrysomelidae), Figure 104 Adult of spotted cucumber beetle or southern corn rootworm, *Diabrotica undecimpunctata* Mannerheim.



Spotted Cucumber Beetle or Southern Corn Rootworm, *Diabrotica undecimpunctata* Mannerheim (Coleoptera: Chrysomelidae), Figure 105 Mature larva of spotted cucumber beetle or southern corn rootworm, *Diabrotica undecimpunctata* Mannerheim.

constructs a small chamber in the soil and pupates within (Fig. 105).

The pupa is white initially, but turns yellow with age. It measures about 7.5 mm long and 4.5 mm wide. The tip of the abdomen bears a pair of stout spines, and smaller spines are found dorsally on the remaining abdominal segments. Duration of pupation is about 7 days, with a range of 4–10 days. After completion of the pupal period the beetle digs to the soil surface.

The adult is long-lived; 60 days is common during the summer but longevity is extended considerably, up to 200 days, during the winter. The adult is about 6–7.5 mm long. It is generally colored yellowish green with 12 black spots on the elytra and a black head. The western form of spotted cucumber beetle has black legs and abdomen, whereas the eastern form has a pale abdomen and the legs are at least partly pale. Adults usually do not begin oviposition until 2–3 weeks after emergence.

This insect has a very wide host range; more than 200 plants are known to be fed upon. Beetles fly considerable distances regularly in search of suitable food. Adults are especially fond of pollen and flower petals. Although the adult will feed on the flowers of almost any plant, they prefer cucurbits, legumes, tomato, ornamental plants, and fruit crops. Adults also feed readily on sweet substances, such as fruits and aphid honeydew, and the foliage of some plants. The larvae, however, are largely restricted to feeding on the roots of cucurbits, legumes, and grains (including corn) and grasses. Winter cover crops and weeds, especially broadleaf species, often are attractive to ovipositing females.

Several natural enemies of spotted cucumber beetles are known, the most important being *Celatoria diabroticae* (Shimer) (Diptera: Tachinidae). This fly deposits her larva within the abdomen of the adult beetle, which soon perishes. Cucumber beetles also are fed upon by many bird species and attacked by mermithid nematodes and the fungus *Beauveria*. The nematode *Howardula benigna* (Cobb) (Nematoda: Allantonematidae) can sometimes parasitize a high proportion of beetles. *Howardula*-infected female beetles have poorly developed ovaries.

Environmental conditions, and particularly soil moisture, have been implicated in the abundance of spotted cucumber beetle. High soil moisture is a requisite for larval survival. In dry years it is only the clay soils or low spots that successfully produce beetles, whereas during moist years sandy soils are more suitable.

Damage

Adults eat small holes in the leaves and flower petals of many plants. If provided a choice, vegetable crops rather than grain crops are usually attacked by adults. Fruit of smooth-skinned melons is susceptible to damage, especially before the skin hardens. In a study of adult feeding on seedlings of zucchini squash in Louisiana, densities of ten beetles per plant caused significant levels of plant mortality, but their effect diminished greatly once the seedlings attained the two or three leaf stage. While beetle damage may result in complete defoliation, sometimes the feeding is limited to the pollen or fruit. Because beetles often avoid heat, the shaded portions of the fruit may be especially damaged.

The beetles also transmit cucumber mosaic virus and muskmelon necrotic spot virus, and bacterial wilt of cucurbits and of corn. Transmission of cucurbit bacterial wilt by spotted cucumber beetles is a secondary, late-season spread, so these insects are considered to be less important vectors than striped cucumber beetles.

The larvae feed on the roots of plants and also bore into the base of the stems. Root pruning may result in only a discolored and stunted plant, whereas when larvae burrow into the stem they may cause the plant's death. Larval feeding may increase the incidence and severity of Fusarium wilt. Some injury to the surface, or rind, of fruit may occur as larvae burrow up from the soil and feed on fruit in contact with soil, and larvae are sometimes called "rindworms." Grain seedlings, particularly corn, are often damaged by larval feeding. Older plants are less susceptible to death following feeding.

Management

Planting time application of granular insecticides, applied in a band over the row, is often recommended for protection of plant roots if a field is expected to be heavily infested by larvae. Foliar and blossom injury is prevented by timely application of insecticides, especially to the seedling stage because they are more susceptible to injury. There is risk of foliar insecticides interfering with pollination in insect pollinated crops such as cucurbits, though this is not a consideration in wind pollinated crops such as corn. Insecticide applications made late in the day minimize damage to pollinators. Waiting at least 1 day after insecticide treatment before introducing beehives is also advisable. Control of beetles helps reduce spread of cucurbit wilt, but the concern over this disease diminishes as the plants mature.

Feeding stimulants and lures have considerable potential for increasing both the effectiveness and selectivity of insecticide applications. Cucurbitacins are arrestants and feeding stimulants for spotted cucumber beetle, although they have low volatility and therefore are not valuable as lures. Volatile components of blossoms, attractive to beetles, have been identified and evaluated as lures. Various mixtures attract beetles, but phenyl acetaldehyde was found to be more attractive to spotted cucumber beetle than to the other common squash blossom-infesting *Diabrotica* beetles. Cinnamaldehyde alone or in a mixture with trimethoxybenzene and indole also were very attractive kairomones, and have been used experimentally in the field to capture beetles. These lures are especially good for detecting beetles when they are at low densities, and otherwise difficult to locate. Combinations of volatile attractants, cucurbitacins, and low rates of insecticides have been applied to corn cob grits to make lethal baits. The need for insecticides can be reduced if the timing of planting can be manipulated so that the beetles have already dispersed and deposited most of their eggs before planting.

Because there is such a wide range of suitable hosts and the insects are so mobile, crop rotation is usually not considered to be a practical management approach. There are some crops, however, such as cotton, that seem to be immune to injury. When corn is planted immediately after legumes, the larvae cause severe injury because the legumes are attractive to adults. Grass weeds growing in a field immediately before planting may also predispose a crop to injury, so clean cultivation is important. Broadleaf cover crops, especially hairy vetch, induces greater insect problems than grain crops such as wheat. Fallow, weed-free fields have a low incidence of problems.

Soil moisture conditions affect the insects and their damage. Crops grown in moist soil, due either to a high water table or abnormally heavy rainfall, are more likely to be damaged by larvae, probably due to enhanced larval survival. In contrast, water-stressed, wilted cucurbit plants are more attractive to beetles, and experience more foliar damage than turgid plants.

There are some varietal differences among cucurbits with respect to susceptibility to injury. Bitter cultivars, which have higher cucurbitacin content, are reported to be more attractive and injured; however, non-bitter cultivars have less bacterial wilt disease.

Springtails (Collembola)

Springtails are a primitive entognathous order of hexapods that sometimes (along with Protura and Diplura) are considered to be insects. They are among the most widespread and abundant terrestrial arthropods, and are found in Antarctica, where arthropods are scarce. Generally they are considered to be useful as they assist in the decomposition of organic materials, and few are pests.

Classification

There are over 6,000 species of springtails, and they are found throughout the world, including Antarctica. The order generally is subdivided into two suborders: Arthropleona, the elongate-shaped species, and Symphypleona, the globular species.

Class: Entognatha
- Order: Collembola
  - Suborder: Arthropleona
    - Family: Neanuridae
    - Family: Odontellidae
    - Family: Brachystomellidae
    - Family: Poduridae and water springtails
    - Family: Hypogasturidae and elongate and bodied springtails
    - Family: Onychiuridae and blind springtails
    - Family: Isotomidae and smooth springtails
    - Family: Entomobryidae and slender springtails
    - Family: Cyphoderidae
    - Family: Paronellidae
    - Family: Oncopoduridae
    - Family: Tomoceridae
    - Family: Coenaletidae
    - Family: Actoletidae
    - Family: Microfalculidae
    - Family: Protentomobryidae
  - Suborder Symphypleona
    - Family: Neelidae and short and horned springtails
    - Family: Sminthuridae and globular springtails
    - Family: Mackenziellidae and Mackenzie globular springtails
    - Family: Dicyrtomidae

Characteristics

These are small animals, measuring only 0.25–10 mm in length, and usually less than 5 mm long. They are either elongate or globular in body form. Their color varies greatly, and though often obscure, some are brightly colored. The antennae are short to medium in length, and consist of 4–6 segments. The compound eyes are small, with only a few facets per eye. The mouthparts are basically the biting (chewing) type, but sometime extensively modified, and somewhat enclosed by the head. The legs are small, and lack extensive modifications. Wings always are absent. The abdomen consists of 5 or 6 segments, though some may be obscure. Springtails often are equipped with a jumping apparatus that serves as the basis for the common name. This apparatus consists of a fork-like furcula originating near the tip of the abdomen that is flexed ventrally and held by a catch, the tenaculum. When the tenaculum releases, the furcula springs with a snap that propels the insect forward. In addition, springtails possess a small ventral tube-like structure on the first abdominal segment, called a collophore or ventral tube. The collophore has various functions, including water absorption and excretion, and possibly adhesion to smooth surfaces. They lack cerci. Metamorphosis may be lacking or incomplete. Collembolans often display 6–8 molts during their life, with sexual maturity attained after the fifth molt. Thus, unlike insects, they continue to molt as adults. The immatures usually resemble the adults in external morphology.

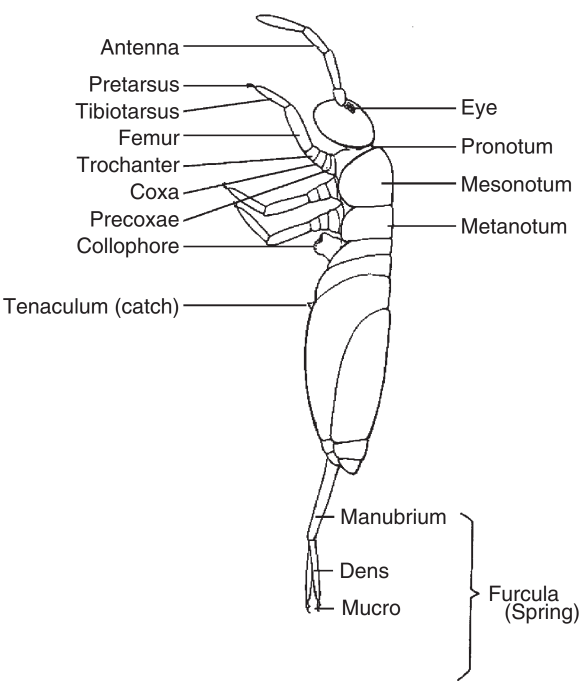
There are three major body types found among springtails: globular, elongate, and grub-like. In globular species, the abdominal segments are fused to form a globe-shaped abdomen. Such species typically inhabit open, grassy habitats. In elongate species, the first thoracic segment is reduced in size relative to the other thoracic segments, producing a "neck" -like structure. Also, the legs and antennae, and furcula are elongate, and the eyes well developed. Sometimes these insects are will marked with patterns or colors, and the body is covered with scales or hairs that help reduce the rate of drying when the springtails forage over the surface of the soil. This body form is called entomobryomorphoid. The grub-like springtails have short legs, antennae, and furcula, and poorly developed eyes.

The first thoracic segment is the same size as the other thoracic segments. Such springtails typically lived deep in the litter or soil, and the body form is called podomorphoid (Fig. 106).

Biology

Springtails occur in numerous habitats, including the water surface of fresh water, the tidal region of salt water, in soil, leaf debris, bird nests, beneath bark, and occasionally on foliage. They feed primarily on lichens, pollen, fungi, bacteria, and carrion, though a few feed on seedling plants or are carnivorous. In general, the above-ground species are in the suborder Arthropleona, are slender in shape, brightly colored, relatively large, and have long antennae and legs, and relatively well-developed eyes. The below-ground species are small, pale colored, with short antennae and legs, and with reduced eyes and the jumping apparatus. The species in the suborder Symphypleona, which are globular in shape, dwell in moist habitats or caves, and are active jumpers. Like the other above-ground species, their eyes are well developed, and their body pigmented. Springtails generally lack trachea, with gas exchange occurring through the integument. Springtails often aggregate in large groups, and this can be observed on the surface of water, snow, or on organic material. The purpose or cause of aggregations is unknown.

The reproductive behavior of springtails is consistent with other entognathous insects. Sperm transfer is indirect, with sperm deposited in stalked droplets on the ground. In most cases, sperm uptake by the female is a passive process, but in some of the more advance species, the male guides the female to his sperm.



Springtails (Collembola), Figure 106 **A diagram of a springtail showing a lateral view.**

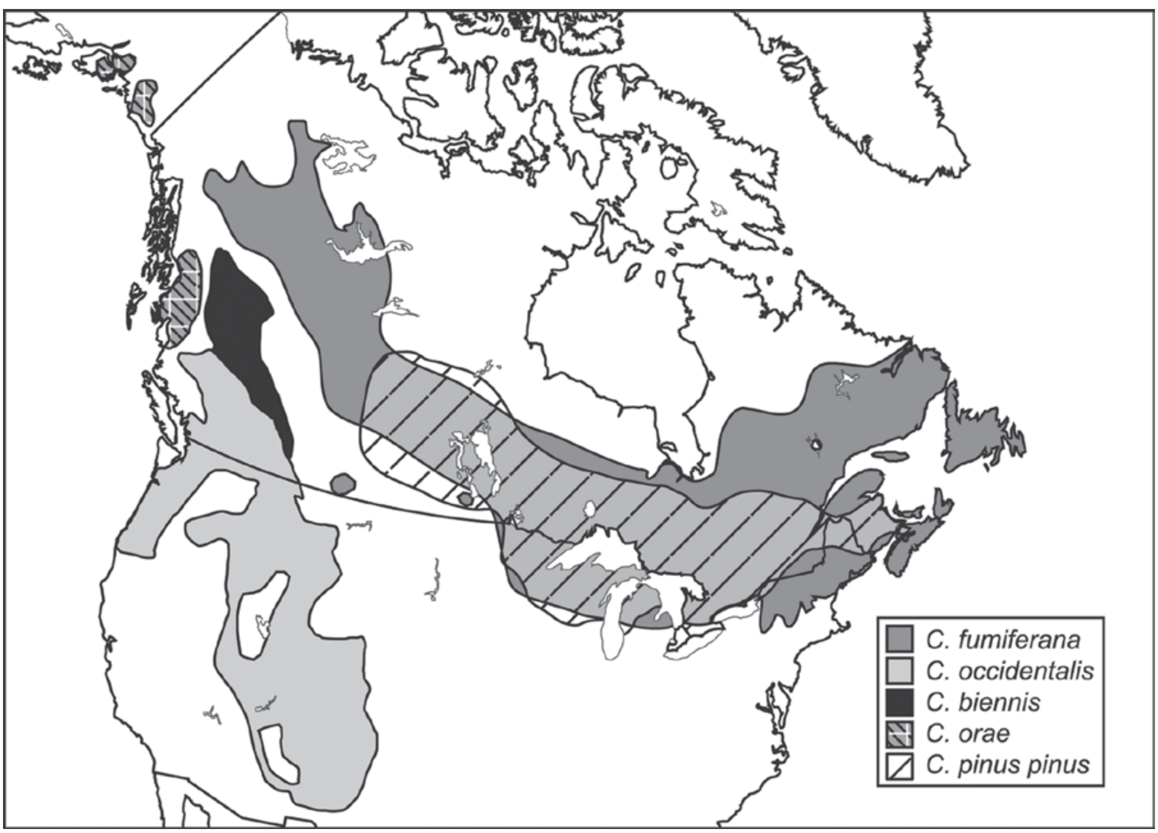
Spruce Budworms, *Choristoneura* Lederer (Lepidoptera: Tortricidae)

VINCENT G. NEALIS
Natural Resources Canada-Canadian Forest Service, Pacific Forestry Centre, Victoria, BC, Canada

Spruce budworms in the genus *Choristoneura* display cyclical dynamics in several major northern conifer forest ecozones in North America. Periodic outbreaks cause defoliation over extensive areas and are characteristic ecological disturbances in these forest ecosystems. Tree mortality may be extensive in severe outbreaks, especially in understory or suppressed trees, and growth rates are significantly affected even in moderate outbreaks.

At least 12 taxa of conifer-feeding *Choristoneura* are currently recognized in North America, with the greatest diversity west of the Rocky Mountains. Five closely related species, the (eastern) spruce budworm, *C. fumiferana* (Clem.), the jack pine budworm, *C. pinus pinus* Free., the western spruce budworm, *C. occidentalis* Free., the 2-year-cycle spruce budworm, *C. biennis* Free., and the coastal spruce budworm, *C. orae* Free., are notable for causing significant damage and consequently attracting the attention of forest entomologists (Fig. 107).

There are few consistent, conventional taxonomic characters to distinguish these budworm species. Polymorphisms are common and isozyme studies have been equivocal. Major pheromone components are similar especially among the geographically disjunct spruce-feeding species. All species tested to date hybridize freely in captivity and produce fertile offspring, suggesting a relatively recent phylogenetic divergence. The most reliable means of distinguishing these species is by their principal host trees and associated geographical distributions. The (eastern) spruce budworm feeds primarily on spruces (*Picea* spp.) and balsam fir [*Abies balsamea* (L.) Mill.] from the Atlantic coast to the continental divide and possibly into Alaska. The jack pine budworm has a similar, although more restricted, sub-boreal geographic range reflecting the distribution of its preferred host, jack pine (*Pinus banksiana* Lamb.). The western spruce budworm occurs west of the continental divide where it is most commonly associated



Spruce Budworms, *Choristoneura* Lederer (Lepidoptera: Tortricidae), Figure 107 Distribution of spruce budworm species in North America. (Map by Mark Lindal, Natural Resources Canada-Canadian Forest Service.)

with Douglas fir [*Pseudotsuga menziesii* (Mirb.) Fanco]. True firs (*Abies* spp.) are also important hosts, especially in the central portion of this budworm's extensive latitudinal range. The coastal spruce budworm occurs in coastal Alaska and British Columbia north of 52° and feeds on sitka spruce [*P. sitchensis* (Bong.) Carr.] and on amabilis fir [*A. amabilis* (Dougl.) Forbes]. The 2-year-cycle spruce budworm has an allopatric distribution to all of these other species, occurring in the submontane forest zones of north-central British Columbia, Canada, and in the Rocky Mountains, where it feeds on spruces (*Picea* spp.) and subalpine fir [*A. lasiocarpa* (Hook.) Nutt.]. Although other tree species such as larch (*Larix* spp.) and hemlock (*Tsuga* spp.) have been reported as occasional hosts for spruce budworms, the identities and distributions of the budworm species considered here are largely defined by the biogeography of their principal hosts.

Life History

All of these budworm species have nearly identical life histories. Eggs are laid in masses of 15 (*C. fumiferana*) to 60 (*C. pinus pinus*) overlapping eggs on host foliage in mid-summer and hatch within 2 weeks. Neonates do not feed but seek sheltered locations throughout the tree where they establish a hibernaculum, molt to a second instar and pass the winter in obligatory diapause. In this dormant phase, larvae are cold-hardy to at least −30°C. Diapause development requires approximately 4 months at cool to moderate temperatures (0° to about 10°C). Once diapause is complete, larvae are maintained in a quiescent state until temperatures exceed about 15°C.

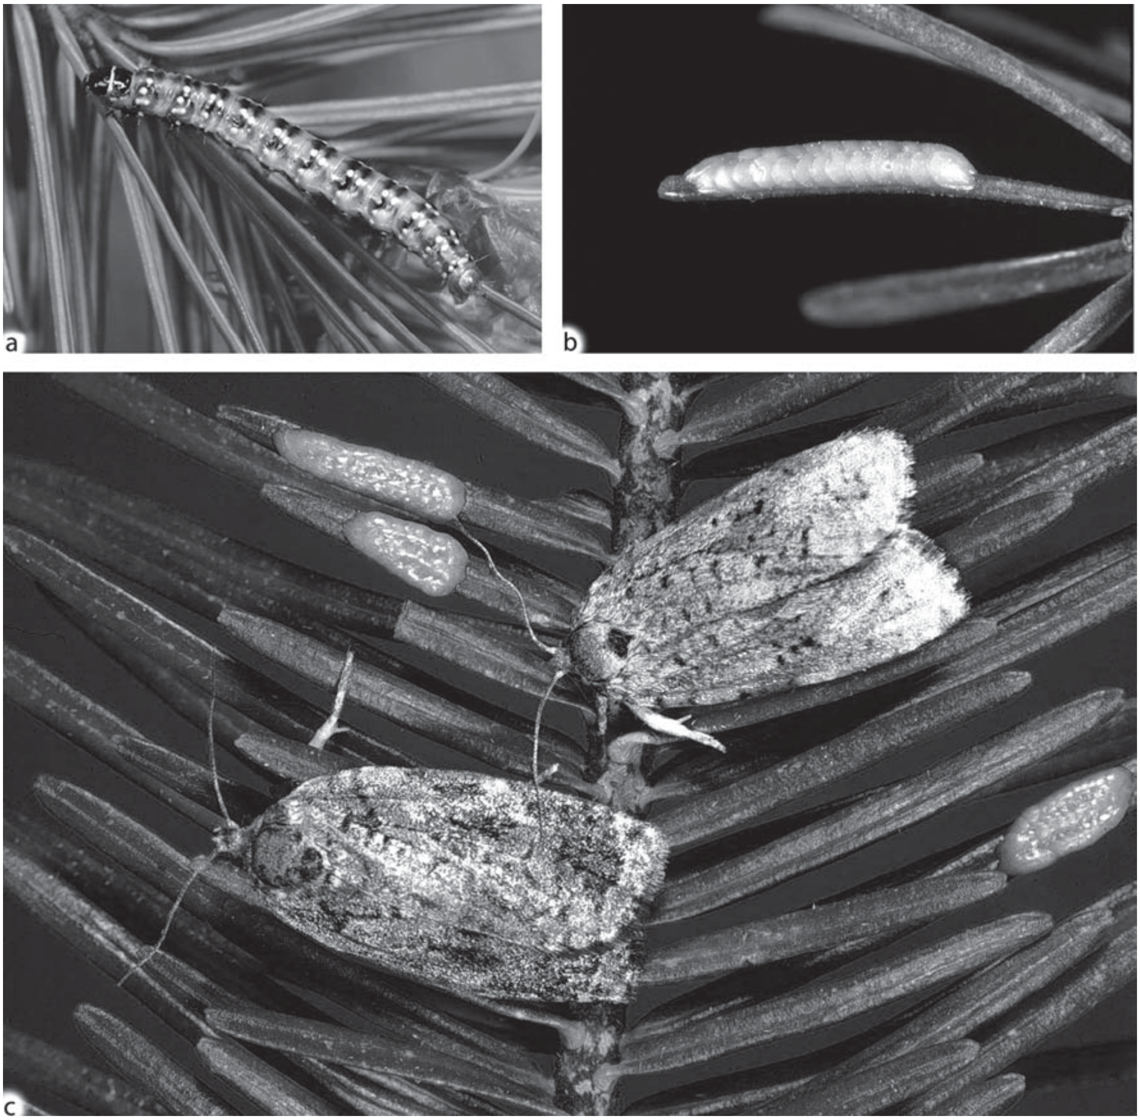
Larvae emerge on warm days in early spring and forage for feeding sites both within and between tree crowns by ballooning on silk threads. Spring emergence of these budworms is typically in advance of bud flush, so early-stage larvae often occupy pollen cones or mine needles of previous years' growth before finally constructing a feeding shelter in expanding, current-year shoots. A second diapause event in which budworms completing the first diapause feed for a brief period and enter a second diapause at the end of the third larval stage has been observed in all spruce budworm species. The frequency ranges from rare (<2%) in eastern spruce budworm and jack pine budworm to more than 50% in the coastal spruce budworm to nearly 100% in the aptly named 2-year-cycle spruce budworm. The frequency in western spruce budworm can be manipulated to a relatively high level (>40%) by rearing at short photoperiods but in nature is likely much lower. Diapause-free strains can also be obtained in this species using artificial conditions.

Spring foraging activities result in frequent movement and re-distribution of early-stage larvae whereas later feeding stages seldom move from their shelters unless disturbed. All budworms prefer current-year foliage and only feed on previous years' growth if forced by severe defoliation. The number of larval instars among this complex of species varies between five and eight and can be polymorphic within a species. Pupation occurs on the foliage near the ultimate feeding shelter. Moths emerge in mid-summer of the same year. Males are attracted to females by a sex pheromone and mating occurs within the tree crown. Fecundity varies with the size of the female and usually exceeds 150 eggs in a well-nourished adult. Moths are capable of long-distance flight and migrations of more than 200 km have been documented (Fig. 108).

Outbreaks and Damage

The population dynamics of all four budworm species is characterized by fluctuation of population densities over several orders of magnitude. The periodicity, duration and extent of these outbreaks vary in ways that are significant to understanding damage and other impacts.

The most damaging outbreaks are those of the eastern spruce budworm. Historical data reveal a somewhat regular periodicity of outbreaks



Spruce Budworms, *Choristoneura* Lederer (Lepidoptera: Tortricidae), Figure 108 Some life stages of spruce budworms: (a) mature larva of *Choristoneura occidentalis*, (b) egg mass of *C. occidentalis*, (c), adults and egg masses of *C. fumiferana*. (Photos by Bob Duncan, Natural Resources Canada-Canadian Forest Service.)

(35 years on average). These outbreaks are relatively long in duration; usually more than six and often more than 10 years in any one location, and may be synchronized over very large areas. During the mid-1970s, severe defoliation was mapped in over 50 million ha of forest. The intensity and duration of these outbreaks frequently results in severe, even catastrophic, mortality especially in stands dominated by mature balsam fir. Spruce species are more tolerant of defoliation and larger trees often survive prolonged outbreaks albeit with marked reductions in growth rates. Even severely affected stands appear to regenerate to a similar forest type. Thus, despite the significant economic impacts of spruce budworm outbreaks over large areas in the short-term, the spruce-fir forest appears resilient to this ecological disturbance.

In contrast to the spruce budworm, the periodicity of jack pine budworm outbreaks is highly variable and apparently associated with fire history and edaphic conditions. Nonetheless, periods of outbreak can coincide over large areas. In the late 1980s and early 1990s, defoliation of jack pine forests peaked at four million ha in the forests surrounding the Great Lakes. The return time of outbreaks can range from 10 years to several decades. Outbreaks rarely last more than 4 years in any one location and individual trees are usually damaged for only a few years in each outbreak event. The result is that widespread tree mortality is the exception; top-kill and reduction in growth rates are more typical. Most mortality occurs in suppressed, understory trees.

Outbreak characteristics of the western spruce budworm appear intermediate to those of spruce and jack pine budworms with evidence of regular periodicity exceeding 10 years within some regions and no large-scale spatial synchrony. These patterns may be a function of the complex topography that fragments the host forest throughout the range of the western spruce budworm. Recent increases in the local dominance of Douglas fir because of fire suppression may be changing these patterns. Defoliation has been chronic, for example, in the southern interior of British Columbia since the mid-1980s, and is extending further north than previously observed. The duration of damaging outbreaks varies greatly at the local level from a few to as many as 8 years. Effects are equally variable, with intermediate and understory trees most vulnerable to damage.

The outbreak behavior of the coastal and 2-year-cycle spruce budworms is the least known of this species complex. Available evidence indicates a periodicity of outbreaks of approximately 35 years for *C. biennis*. When outbreaks occur, they extend over most of this insect's relatively restricted range, including isolated alpine populations. Interestingly, populations of 2-year-cycle spruce budworm are not synchronized across their range with respect to their life cycle: populations. In the northern and western portions of the range, populations reach the adult stage in odd-numbered years (e.g., in 2005) while those in the southern and eastern portions do so in even-numbered years (e.g., 2006). The alternating years of severe, then light, defoliation associated with the 2-year life cycle gives trees a reprieve during outbreaks so damage is reduced.

Population Dynamics

Our understanding of population dynamics of spruce budworms is based largely on detailed studies of *C. fumiferana* populations in the 1950s and 1980s in eastern Canada. The expansion of the forest industry north and west into the boreal forest and from the Pacific coast eastward to interior forests, as well as the increased commercial value of species such as balsam fir and jack pine, have increased the need to understand the causes and potential management of budworm outbreaks. Given the variable nature of outbreak behavior among the five budworm species considered here, there is unlikely a single driver of population behavior. The following considers the role of major mechanisms of population change common to all of these budworm species.

Weather

Early investigators sought a direct connection between weather and outbreak behavior, and identified correlations between successive years of warm, dry weather during the larval feeding stage and the initiation of outbreaks. Although there is little doubt that extreme weather events and average climatic conditions can influence local mean population densities, it is more likely that the effect of weather on population rates of change is via biological processes rather than by directly causing multi-season trends.

For example, the association of outbreaks with successive years of warm, dry spring weather in both spruce and jack pine budworm may be because these same conditions promote the production of pollen cones in host species which, in turn, provide a critical food source to foraging larvae. Or, the differential, temperature-dependent developmental responses of the host tree and budworm result in both spatial and temporal variability in the degree of synchrony between the budworm and its food source, with significant effects on survival. Weather conditions during the adult period clearly influence reproductive success and long-distance dispersal of moths, with potential repercussions on local rates of change in population density and the large-scale synchrony of outbreaks.

Host Plants

The most damaging outbreaks are associated with contiguous stands of mature, preferred host species. Severe defoliation and catastrophic tree mortality in these same stands has been invoked as the major determinant of population collapse. However, populations rise and fall without widespread mortality of host trees. Exhaustive study of foliage quality over the course of outbreaks has returned little convincing evidence that variation in nutritional quality of the trees plays a major role in budworm survival. Quantitative changes in foliage, however, may well influence population levels. Moth fecundity is reduced significantly during periods of moderate to severe defoliation, and cumulative defoliation reduces needle density and may increase emigration of moths and reduce survival of foraging larvae, both of which can influence local population densities.

There is increasing evidence that host tree phenology and structural changes associated with defoliation affect budworm survival in important ways. For example, jack pine budworm depends on the production of pollen cones by its host to bridge the period between spring emergence of the larvae and the availability of fresh foliage. Defoliation, however, reduces the trees' propensity to produce these cones with commensurate negative effects on jack pine budworm survival. This host plant relationship is especially significant to population dynamics because the reduction in pollen cones, and thus host suitability, is the direct result of previous budworm densities. Such a lagged, density-dependent relationship has the capacity to drive cyclical population behavior.

Natural Enemies

Natural enemies include predators, parasitoids and diseases that attack directly any life stage of the budworm. Birds are the most prominent vertebrate predators of budworms. Several species of migratory warblers can specialize on budworm larvae, and larger birds such as grosbeaks have been observed flocking to high-density budworm populations. The importance of bird predation, however, is restricted to lower-density budworm populations due to the limited numerical response and territorial behavior that characterize bird populations. The importance of invertebrate predators is more enigmatic. Spiders are very common on spruce and ants have been observed commonly feeding on western spruce budworms, but the link between their effects and population rates of change has not been established.

Insect parasitoids have received the most attention in terms of their influence on populations of budworms. More than 75 species of insect parasitoids have been recorded attacking budworms and there is a rich and complex guild of hyper- and secondary parasitoids to complicate the system further. There appear to be few parasitoid species that are specialists of the *Choristoneura*. In fact, many of the same species of parasitoids attack all budworm species throughout their ranges. Moreover, the relative abundance of these species also appears consistent during outbreak declines.

The most common species found in outbreak populations include parasitoids of the eggs, *Trichogramma minutum* Riley (Hymenoptera: Trichogrammatidae), early-larval stages, *Apanteles fumiferanae*

Viereck (Hymenoptera: Braconidae) and *Glypta fumiferanae* (Viereck) (Hymenoptera: Ichneumonidae), late-larval stages, *Meteorus trachynotus* Viereck (Hymenoptera: Braconidae) and *Smidtia fumiferanae* (Tothill) (Diptera: Tachinidae) and pupae, *Itoplectis conquisitor* (Say) (Hymenoptera: Ichneumonidae) and *Phaeogenes hariolus* (Cresson) (Hymenoptera: Ichneumonidae). The generalist parasitoids attacking the late-larval and pupal stages of the budworm have received the most attention as it is mortality in these latter stages that is most strongly correlated to generation rates of change in budworm density and therefore trends in population change. Recent evidence suggests that as outbreaks collapse, the impact of these generalist parasitoids is reduced and a distinct suite of more specialized parasitoids becomes prominent.

More than 15 species of pathogenic microorganisms (viruses, bacteria, fungi and protozoans) have been isolated from populations of spruce budworms. As with parasitoids, these pathogens appear common to all budworm species considered here. Interestingly, epizootics are uncommon and localized in spruce budworm populations compared to other eruptive forest Lepidoptera such as tussock moths and tent caterpillars. Viruses appear to play a minor role in natural mortality. Most natural epizootics have been caused by mycopathogens such as *Entomophaga aulicae*. A chronic and ubiquitous microsporidian, *Nosema fumiferanae* Thomson, has clear debilitating effects on heavily infected budworms. It has been difficult, however, to link the varied and insidious impacts of infections by *Nosema* to clear trends in population behavior of the budworm.

Management

Control of budworm populations has occupied forest managers for the past 60 years, especially in eastern North America. The emphasis has been on suppression of populations to save trees and protect growth of infested stands until harvest. The outbreaks of eastern spruce budworm in the late 1940s coincided with development of aerial application of effective pesticides such as DDT. A succession of synthetic products combined with advances in spray technology characterized successful operations into the 1970s when pesticides fell into public disfavor. The on-going need to protect the highly vulnerable forests stimulated research into alternative controls including use of parasitoids, pathogens, and so-called bio-rationals such as pheromones and hormonal analogs which disrupt biological processes such as mating and moulting. From this suite of products, the bacterial insecticide, *Bacillus thuringiensis* Berliner (*Bt*), has emerged as the most widely used operational alternative to chemical pesticides.

The singular reliance on *Bt* for forest protection and the sheer potential magnitude of outbreaks has stimulated forest managers to seek new approaches to prevent or at least mitigate severe damage through either novel strategies using existing products or through application of silvicultural practices that reduce risk. Novel strategies include moving away from the conventional reactive approach to reduction of risk through purposeful management of forests toward stand types less vulnerable to budworms. For example, it is well known that spruces are better able to withstand budworm damage than firs so the move toward planting and favoring spruce over fir in eastern forests could reduce losses. Tolerating a hardwood component also tends to reduce impacts. Management of pollen-cone production in jack pine stands by removing large, open-crown trees would reduce susceptibility to jack pine budworm while commercial thinning of Douglas fir could reduce the vulnerability of multi-stage stands to damage by the western spruce budworm. Combining these silvicultural approaches with effective control products when needed probably offers the most pragmatic approach to stand-level management.

At the landscape level, forest managers may just have to concede that occasional disturbance to growth of native trees by native defoliators is not only inevitable but perhaps necessary to sustain northern forest ecosystems. Accommodating more mixed-species forests in timber management, maintaining flexible supply areas, and developing diverse forest product options could help mitigate the negative economic impacts of these outbreaks.

Squash Bug, *Anasa tristis* (Degeer) (Hemiptera: Coreidae)

The squash bug attacks cucurbits (squash and relatives) throughout Central America, the United States, and southern Canada. In some areas of North America it is the most serious pest of cucurbits.

Description and Life Cycle

The complete life cycle of squash bug commonly requires 6–8 weeks. Squash bugs have one generation per year in northern climates and 2–3 generations per year in warmer regions. In intermediate latitudes the early-emerging adults from the first generation produce a second generation whereas the late-emerging adults go into diapause. Both sexes overwinter as adults. The preferred overwintering site seems to be in cucurbit fields under crop debris, clods of soil, or stones but sometimes adults also are found in adjacent wood piles or buildings.

Eggs

Eggs usually are deposited on the lower surface of leaves. The elliptical egg is somewhat flattened and bronze in color. The average egg length is about 1.5 mm and the width about 1.1 mm. Females deposit about 20 eggs in each egg cluster. Eggs may be tightly clustered or spread a considerable distance apart, but an equidistant spacing arrangement is commonly observed. Duration of the egg stage is about 7–9 days.

Nymph

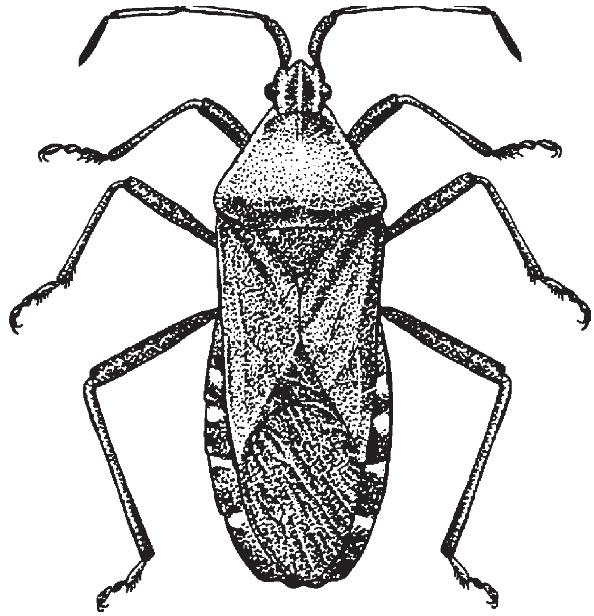
There are five nymphal instars, collectively requiring about 33 days for complete development. The nymph is about 2.5 mm in length when it hatches, and light green in color. The second instar is initially about 3 mm long, and its color is light gray. The third, fourth, and fifth instars initially are about 4, 6–7, and 9–10 mm in length, respectively, and darker gray. The youngest nymphs are rather hairy, but this decreases with each subsequent molt. In contrast, the thorax and wing pads are barely noticeable at hatch, but get more pronounced with each molt. Young nymphs are strongly gregarious, a behavior that dissipates slightly as the nymphs mature.

Adult

The adult measures 1.4–1.6 cm in length and is dark grayish brown in color. In many cases the edge of the abdomen is marked with alternating gold and brown spots (Fig. 109). Adults are long-lived, surviving an average of about 75–130 days, depending on availability and quality of food.

Host Plants

Squash bug has been reported to attack nearly all cucurbits, but squash and pumpkin are preferred for oviposition and support high rates of reproduction and survival. There is considerable variation among species and cultivars of squash with respect to susceptibility to damage and ability to support growth of squash bugs. New World varieties are preferred. Studies conducted in the United States



Squash Bug, *Anasa tristis* (Degeer) (Hemiptera: Coreidae), Figure 109 **Adult of squash bug, *Anasa tristis*.**

reported survival of squash bug to be 70, 49, 14, 0.3, and 0% when nymphs were reared to the adult stage on pumpkin, squash, watermelon, cucumber, and muskmelon (cantaloupe), respectively.

Damage

The squash bug causes severe damage to cucurbits because it secrets highly toxic saliva into the plant. The foliage is the primary site of feeding but the fruit is also fed upon. The foliage wilts, becomes blackened, and dies following feeding. Often an entire plant or section of plant perishes while nearby plants remain healthy. The amount of damage occurring on a plant is directly proportional to the density of squash bugs.

Natural Enemies

Several natural enemies of squash bug are known, principally wasp egg parasitoids (Hymenoptera: Encyrtidae and Scelionidae). Up to 30% parasitism among eggs collected in Florida, USA has been reported. The best known natural enemy is a common parasitoid of several hemipterans, *Trichopoda pennipes* (Fabricius) (Diptera: Tachinidae). The brightly colored adult fly is easy to recognize, having a gold and black thorax and an orange abdomen, with a prominent fringe of feather-like hairs on the outer side of the hind tibia. Flies develop principally in the adult bug, initially castrating the female, and then killing her when the fly emerges. In Connectcut, USA about 20% on the squash bugs have been found to be parasitized in late summer.

Management

Squash bug adults are unusually difficult to kill with insecticides. Although adult control can be accomplished if the correct material is selected, it is advisable to target the more susceptible nymphs. Squash bugs are not often considered a severe pest of large-scale cucurbit production, probably due to the absence of suitable overwintering sites in well managed crop fields and because the bug's effects are diluted by the vast acreage. However, small fields and home gardens are commonly damaged.

Pollinators, particularly honeybees, are very important in cucurbit production, and insecticide application can interfere with pollination by killing honeybees. If insecticides are to be applied when blossoms are present, it is advisable to use insecticides with little residual activity, and to apply insecticides late in the day, when honeybee activity is minimal.

Adult squash bugs preferentially colonize larger, more mature plants. Thus, early-planted crops may be especially prone to attack. Numbers are also highest on plants during bloom and fruit set. Use of early-planted crops as a trap crop has been proposed, but due to the high value of early season fruit most growers try to get their main crop to mature as early as possible. The use of squash or pumpkin as a trap crop to protect less preferred host plants such as melons and cucumbers is reported to be effective.

The tendency of squash bugs to aggregate in sheltered locations can be used to advantage by home gardeners. Placement of boards, large cabbage leaves, or other shelter for squash bugs induces the bugs to congregate there during the day where they are easily found and crushed. Row covers and netting delay colonization of squash, but bugs quickly invade protected plantings when covers are removed to allow pollination.

Removal of crop debris in a timely manner is very important. Squash bugs will often be found feeding on old fruit or in abandoned plantings, so clean cultivation is essential to reduce the overwintering population.

Squash Vine Borer, *Melittia cucurbitae* (Harris) (Lepidoptera: Sesiidaae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Squash vine borer, *M. cucurbitae*, is found in most of North and Central America, though infrequent in Canada. Though rarely a pest of commercial crops due to frequent application of insecticides, it is a severe pest in home gardens and elsewhere where insecticides are not used.

Life History

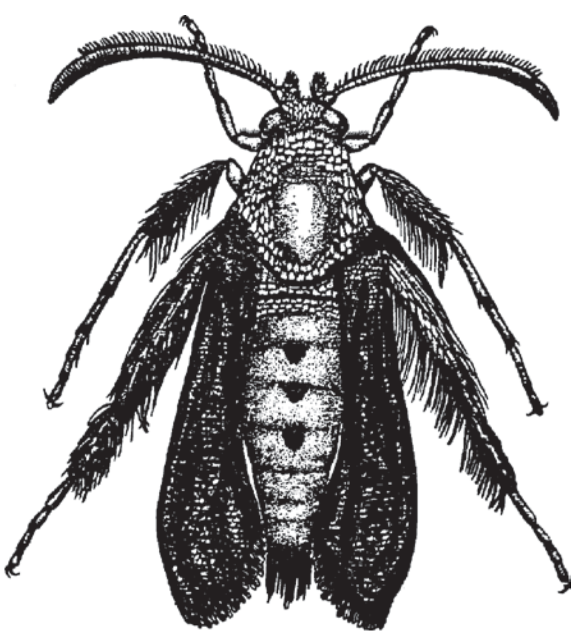
The squash vine borer completes its life cycle in about 60 days. In the southern areas of the USA it displays two generations annually, but in cooler climates only a single generation occurs regularly. In intermediate areas such as Ohio, USA, most borers diapause after the first generation, but some go on to complete a second generation. There has been considerable confusion concerning the number of generations, because in the field it is difficult to discern a single protracted generation from two overlapping generations. Each generation may remain active for 2 or 3 months.

Oval eggs, reddish brown in color, are glued to the plant tissue and are slightly flattened at the point of attachment. Eggs measure about 1.1 mm in length and 0.85 mm in width. Each female is capable of producing 150–200 eggs. Eggs are distributed singly on all portions of the plant except the upper surface of the leaves; most appear to be attached to the basal region of the vine, probably because this tissue is oldest and therefore exposed longer. The basal portion of leaf petioles receives a moderate number of eggs. Some eggs are deposited in cracks in the soil near the base of the plant. Eggs hatch in 10–15 days and larvae soon bore into the plant. Those that hatch on the vine usually remain in this location to feed, whereas those hatching on leaf petioles eventually work their way to the base and enter the vine.

Larvae are white in color with a dark brown or black head. Initially the larval body is markedly tapered posteriorly and equipped with numerous large hairs. As the larva matures it loses its tapered shape and hairy appearance and acquires a dark thoracic shield. There are four instars, with head capsule widths of about 0.4, 0.7, 1.3, and 2.0 mm, respectively. The larva requires 4–6 weeks to complete its development, and eventually attains a length of about 2.5 cm (Fig. 110). The mature larva exits the plant tissue and burrows into the soil to a depth of 4–5 cm where pupation and formation of a black cocoon occurs.

The pupa is mahogany brown in color and the anterior end is equipped with a short but sharply pointed cocoon breaker, a structure used to cut a hole in the cocoon when the moth is ready to emerge. There is some disagreement whether squash vine borer always pupates soon after producing the cocoon. In cooler areas it is reported that the fully grown larva overwinters in the cocoon, pupating in the spring prior to producing the single northern generation. However, in two-generation warmer areas the pupa is reported to overwinter. In any event, a distinctive, heavy-bodied moth eventually emerges from the cocoon.

The wingspan of the moth is about 3 cm. The front wings are blackish and tinged with olive-green while the hind wings are colorless. The abdomen is usually dull orange and marked with black dots dorsally (Fig. 110), although on some specimens the abdomen is entirely black. The hind



Squash Vine Borer, *Melittia cucurbitae* (Harris) (Lepidoptera: Sesiidaae), Figure 110 **Adult of squash vine borer, *Melittia cucurbitae* (Harris).**

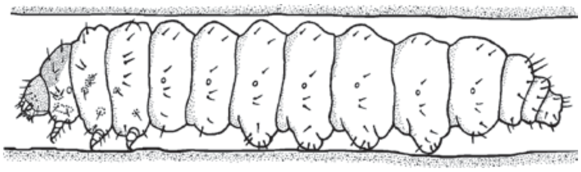
legs are prominently tufted and are colored orange and black. Adults are capable of oviposition about 3 days after emergence. Moths are active during the daylight hours (Fig. 111).

Squash vine borer feeds on wild and cultivated species of *Cucurbita*. Summer squash, *Cucurbita pepo*, and some winter squash, *C. maxima*, are most preferred for oviposition by adults, and most suitable for larval development. Some pumpkin, *C. mixta*, are intermediate in suitability. Winter squash derived from *C. moschata* does not support complete larval development. The weeds *C. texana* and *C. andreana* are very suitable hosts, while *C. okeechobeensis* is intermediate and several cucurbit weed species are unsuitable. Other cucurbit crops such as cucumber and melon may be attacked, but this occurs mostly when the more favored hosts are not present.

The natural enemies of squash vine borer are not well studied. General predators such as robber flies (Diptera: Asilidae) are reported to prey upon adults, and a wasp egg parasitoid, *Telenomus* sp. (Hymenoptera: Scelionidae) is known. Larvae seem to be relatively free of natural enemies.

Damage

The damage caused by these insects is accurately described by the common name: squash vine borer. The larva spends almost its entire life feeding within the plant stem. Because larvae feed within plant tissues they are hidden from view and easily overlooked. However, upon close examination frass can be found accumulating beneath small entrance holes. The presence of one, or even several, larvae is not always deadly to the plant. However, up to 142 larvae have been removed from a single plant, and obviously such large numbers of insects will disrupt the physiology of the plant beyond its ability to compensate successfully for the feeding injury. Often the first sign of infestation is wilting of the plant in the heat of the day while other plants remain turgid. If the vine is thin or heavily infested the portion beyond the feeding site of the larva(e) may be killed. Infestation of fruit is unusual. Commercial cucurbit production rarely suffers significant damage by squash vine borer. These borers seem to plague small plots especially severely; almost all home gardeners have had some unpleasant experience with this pest.



Squash Vine Borer, *Melittia cucurbitae* (Harris) (Lepidoptera: Sesiidae), Figure 111 Larva of squash vine borer, *Melittia cucurbitae* (Harris).

Management

A sex pheromone produced by females has been identified, and male moths of *M. cucurbitae* may be attracted to traps baited with the insect's sex pheromone, but thus far pheromone technology has not been demonstrated to improve management practices. In fact, one study reported increased injury of squash plantings when pheromone was released; the biological basis for this is uncertain.

Squash vine borer can be difficult to control with chemical insecticides because it is protected from contact with most insecticides by its burrowing activity. Therefore, it is imperative that insecticide residues be in place during oviposition so that when the larva hatches from the egg it has an opportunity to make contact with a lethal dose.

Pollinators, particularly honeybees, are very important in cucurbit production, and insecticide application can interfere with pollination by killing honeybees. If insecticides are to be applied when blossoms are present, it is advisable to apply insecticides late in the day, when honeybee activity is minimal.

It has long been known that early-planted crops experience minimal injury, so early planting is recommended. Also, the moths preferentially attack certain species such as summer squash; this can be used as a trap crop if the plants are then destroyed or sprayed, thereby protecting less preferred cucurbit species.

Cucurbit plants are very resilient, recovering well from injury. If accumulated frass can be located adjacent to vine tissue, indicating the presence of active feeding, larvae can be killed or removed with a knife without severely affecting growth of the remaining tissue. Vines also develop additional roots if covered with soil, which can compensate for damage by borers. Covering the vines near the base of the plant discourages oviposition near critically important tissue. Dying vines should be removed and destroyed.

Using a medicine dropper or similar device, the bacterium *Bacillus thuringiensis* and the entomopathogenic nematode *Steinernema carpocapsae* can be injected into squash vines to kill existing larvae or to prevent their establishment. The hollow, moist vines are especially conducive to the spread and survival of nematodes. Obviously this approach is not applicable to commercial crop production.

Stabilimentum

Some orb-weaving spiders created a zig-zag shaped band of silk at or near the center of the web; this structure is called a stabilimentum.

Stability

An expression of constancy. In population biology it refers to population densities and age structures that remain fairly constant over long periods of time (contrast with resilience).

Stable Fly, *Stomoxys calcitrans* (Diptera: Muscidae)

JAMES E. CILEK
Florida A&M University, Panama City, FL, USA

The stable fly (*Stomoxys calcitrans* L.), sometimes referred to as the dog fly or the biting house fly, is primarily a pest of cattle. This species closely resembles a house fly, but possesses piercing-sucking instead of sponging mouthparts (Fig. 113). Both sexes of the stable fly feed on blood 2–3 times per day from a variety of warm-blooded animals including humans. The act of feeding by several flies can produce quite an annoyance to cattle. Fly avoidance behavior often includes constant stomping of feet, tail switching, and "bunching," whereby the herd gathers or "bunches" together in a tight circle with heads facing inward to protect their front legs from feeding flies. When fly avoidance behavior takes up most of an animal's daily activity, it is not eating. Stable flies have been reported to reduce weight gain in beef cattle and lower milk production in dairy cattle. Research has estimated an economic threshold of less than 1–5 feeding flies per front leg depending on animal size, age, breed and production system. Because stable flies feed on blood, they are capable of transmitting pathogenic organisms that cause anthrax, brucellosis, swine erysipelas and equine infectious anemia to a variety of their animal hosts.

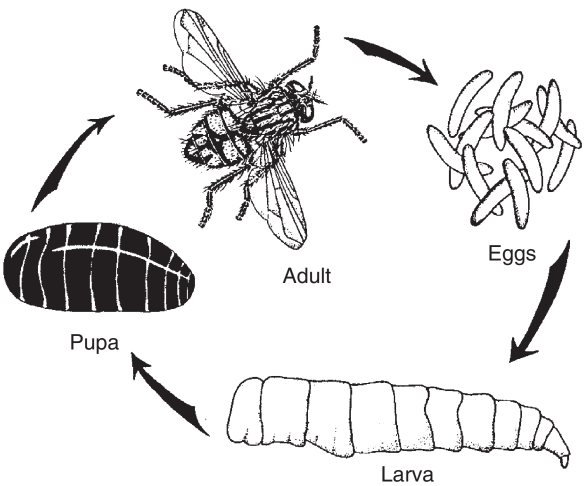
Stable Fly, *Stomoxys calcitrans* (Diptera: Muscidae), Figure 113 Comparison of nonbiting and biting mouthparts: left, sponging mouthparts of the adult house fly (source: Novartis Corporation); right, piercing-sucking mouthparts of the adult stable fly (source: Axtell, R. C. 1986. Fly control in confined livestock and poultry production. CIBA-GEIGY Agric. Div., Greensboro, NC).

Blood-seeking stable flies can also affect recreational areas. In some areas of the U.S. (e.g., Florida panhandle beaches, coastal areas of New Jersey, Great Lakes Region and Tennessee Valley Authority lakeshores) stable flies often disperse from cattle producing areas and congregate along the shorelines. Weather systems associated with the passage of cold fronts often move the flies to these areas. It is currently unknown how or why this happens.

Although most stable flies (Fig. 112) seldom disperse farther than needed to obtain a blood meal, studies have shown that this pest can routinely travel distances up to 8 km and as far as 225 km on storm fronts to Florida panhandle beaches. Suburban areas that have expanded into rural cattle production areas have experienced problems with stable flies. Oftentimes, this phenomenon occurs when stable fly populations are not adequately controlled on surrounding farms and they disperse into the surrounding environs. However, a study in Kansas indicated that a suburban stable fly problem was not the result of nearby rural livestock operations. Rather, local developmental areas for stable flies, such as numerous compost heaps located within the suburban landscape, contributed greatly to the problem. In any event, legal issues have arisen with many livestock operations going out of business.

Biology

Stable flies go through complete metamorphosis (Fig. 114). The eggs are laid on decayed vegetation, or vegetation mixed with cattle feces and/or urine. Improperly composted vegetative material, or decomposing grass clippings that remain wet can provide adequate developmental medium for stable flies in residential areas.



Stable Fly, *Stomoxys calcitrans* (Diptera: Muscidae), Figure 114 **Generalized fly life cycle (source: University of California Cooperative Extension).**

After oviposition, the eggs hatch in 1–5 h and the larvae go through three successive molts called instars. When the larva is mature (i.e., third instar), it ceases to feed and often migrates from the developmental area to pupate in drier conditions. Sometimes larvae will enter the ground to the depth of about 2–4 cm to pupate. At the time of pupation, the exoskeleton from the last larval instar will harden. This "shell" forms the puparium in which the pupa will reside. The pupa is the transitional stage from larva to adult fly. Depending upon temperature and other environmental parameters, the cycle from egg to adult can take as little as 10 days, but can be extended to 2 months or longer under unfavorable conditions. Several generations are produced annually and tremendous numbers of biting adults can develop if not held in check.

Adult flies can live about 20 days under favorable conditions. Adult stable fly seasonal peaks appear to change with climatic zone in the U.S. Populations in the more temperate areas (e.g., Minnesota, Michigan, and New York) primarily peak in mid-summer, whereas further south (e.g., Texas and Florida) the population peak is bimodal, occurring in late spring and again in late summer to early fall.

Control

The most effective method of reducing stable flies is to eliminate the habitat for fly development. The removal of accumulated feed, silage, manure, grass clippings, etc., in a timely manner (e.g., weekly) will help to reduce the fly population. If removal is not feasible, then it should be piled in rows and turned at least once a week to facilitate drying. In lieu of this, heavy black plastic can be placed over the piles (especially compost heaps). Oftentimes, the temperature produced by anaerobic decomposition of the pile will be high enough to kill any fly larvae present. Edges of the plastic should be covered with soil to create firm contact with the ground and prevent adult flies from ovipositing underneath the plastic.

Stable fly pupae have a variety of minute wasp parasitoids that parasitize them as a form of natural control. The most common parasitoids are referred to as microhymenoptera, and belong to the family Pteromalidae. These tiny wasps (about 2.0 mm in length) parasitize stable flies by ovipositing one or many eggs (depending on species) into a pupa. The egg(s) hatch and the larva(e) consume the developing fly, eventually killing it. The immature wasp then pupates and emerges from the stable fly puparium as an adult. As a result, wasps in this family are considered to be of potential use for the control of stable flies in animal facilities. Research has shown that native wasp parasitoids have the best potential for colonizing and impacting native stable fly populations. Currently, knowledge on how many parasitoids should be released, and the optimum number of releases to obtain control is poorly understood.

Application of insecticides to organic materials is not recommended because the quantity needed would be greater than the labeled rate to achieve any degree of control. Also, organic substrates often bind up insecticides making them ineffective against the targeted pest. Stable fly control on animals usually involves spraying labeled insecticides onto the animal's legs.

Because stable flies often rest on the sides of buildings, a residual insecticide applied to such surfaces may provide short-term control of adult flies. Currently, repellents do not give long-term relief for animals or humans against stable fly biting annoyance.

Stål, Carl

Carl Stål was born at the castle of Carlberg, in Sweden, on March 21, 1833. He was the greatest Swedish hemipterist and orthopterist, and one of the world's greatest authorities on Hemiptera. He began his education at Uppsala, Sweden, including medical studies, and obtained further education at Stockholm and Jena. Stål became an assistant to the Swedish coleopterist C.H. Boheman at the National Zoological Museum, and eventually supervised the entomological section of the Museum. Although he favored Hemiptera, Stål was an authority on Coleoptera, Orthoptera and Hymenoptera. Some of his noteworthy publications include "Hemiptera Fabriciana" (two volumes: 1868, 1869), "Enumeratio Hemipterorum" (five volumes: 1870–1876), "Revisio Pentatomidarum, Coreidarum, Lygaeidarum, Reduviidarum et Tingitidarum Europae," and "Recensio Orthopterorkum" (1873–1876). At his death, Stål was the world's authority on Hemiptera, and he left the Museum with the finest collection of Hemiptera in the world. He died at Trösundavik, Sweden, on June 13, 1878.

Steinhaus, Edward Arthur

Edward Steinhaus was born at Max, North Dakota, USA, on November 7, 1914. H graduated from North Dakota State University in 1936 with a degree in bacteriology, and then moved to Ohio State University where he received a Ph.D. in 1939. In 1940 he joined the staff of the U.S. Public Health Service Rocky Mountain Laboratory, and then moved to the University of California at Berkeley in 1944. He organized and chaired the Laboratory of insect pathology in 1945, which became the Department of insect pathology in 1960, and then the Division of invertebrate pathology in 1963. Later he moved to the University of California at Irvine as dean of Biological Science. Edward Steinhaus was the most distinguished insect pathologist of his era, and created the world's foremost program in insect pathology at Berekeley. He authored 200 publications on insect pathology and the first comprehensive publications on the subject: "Insect microbiology" (1946), "Principles of insect pathology" (1949), and "Laboratory exercises in insect microbiology and insect pathology" (1961). In addition, he edited a two-volume treatise "Insect pathology, an advanced treatise" (1963). Steinhaus founded and edited an important scientific journal, "Journal of invertebrate pathology," and founded the Society for Invertebrate Pathology. He was honored by the Entomological Society of America by being selected to present a Founders Memorial Lecture, and also served as president of the Society. He died at Newport Beach, California, on October 20, 1969.

Stem Cells

Stem cells are able to self-renew and generate cell populations that differentiate to maintain adult tissues. There are about two stem cells in the ovary of *Drosophila* that maintain oocyte production.

Stemmata

The small, simple eyes found on the side of the head of larvae in holometabolous insects. The number of stemmata varies from one to six in different taxa. They are similar to ommatidia of compound eyes in structure and function. A single simple eye of this type is called a stemma.

Stemmocryptidae

A family of bugs (order Hemiptera).

► Bugs

Stem Sawflies

Members of the family Cephidae (order Hymenoptera, suborder Symphyta).

► Wasps, Ants, Bees and Sawflies

Stenocephalidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Stenopelmatidae

A family of crickets (order Orthoptera). They commonly are known as Jerusalem crickets.

► Grasshoppers, Katydids and Crickets

Stenophagous

Feeding on a small number of hosts. Also called oligophagous.

Stenopsocidae

A family of psocids (order Psocoptera).

► Bark-Lice, Book-Lice or, Psocids

Stenostritidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Stenotrachelidae

A family of beetles (order Coleoptera). They commonly are known as false long-horned beetles.

► Beetles

Stephanidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Stephanocircidae

A family of fleas (order Siphonaptera).

► Fleas

Stereokinesis

Kinesis response with respect to contact with surfaces.

Sterile Insect Control

A pest control method using sterilized insects to interfere with normal mating behavior in a wild population, thereby disrupting reproduction of the wild (non-sterile) insects.

Sterile Insect Release Method (SIRM)

A technique used to control pest insects. Large numbers of mass produced males are given nonlethal but sterilizing doses of radiation or chemical mutagens and then released in nature. The natural populations are so overwhelmed by releases of large numbers of these males, that females are almost always fertilized by them. The resultant matings produce inviable progeny and a new generation is not produced. Used to eradicate the screwworm from the USA.

► Sterile Insect Technique

Sterile Insect Technique

WALDEMAR KLASSEN
University of Florida, Homestead, FL, USA

The sterile insect technique (SIT) is a form of birth control imposed on a population of an insect pest to reduce its numbers. Thus far, this has involved rearing large numbers of the target insect pest species, exposing them to gamma rays to induce sexual sterility and releasing them into the target population of the pest on an ecosystem-wide or area-wide basis. The concept of releasing insects of pest species to introduce sterility into wild populations, and thus to control them, was independently conceived by three scientists on three different continents. The first scientist to propose genetic control of insect species was A.S. Serebrovskii, a geneticist in the Institute of Zoology, Moscow State University, who proposed the use of chromosomal translocations for population suppression. The second was Dr. F. L. Vanderplank at a British Overseas Service tsetse research field station in rural Tanganyika (now Tanzania). He showed that the sterility of interspecific hybrids of two tsetse species could strongly suppress a field population of one of the species. The third was E.F. Knipling, a scientist with the U.S. Department of Agriculture. The sterile insect technique was conceived by Knipling in 1937 and first developed for use against the screwworm, *Cochliomyia hominivorax* (Coquerel), a deadly parasite of warm-blooded animals and man in the Americas. This article is limited to a discussion of the latter technique.

Sterile Insect Technique, Figure 115 **Edward F. Knipling in 1946.**

General Overview

The sterile insect technique harnesses the sex drive of insects. The idea of doing this first occurred in 1937 to Edward F. Knipling (Fig. 115), an entomologist with the U.S. Department of Agriculture at Menard, Texas. Knipling did not know of a method to induce sexual sterility. However, in 1926 Herman Müller at the University of Texas had found that X-rays cause numerous changes or mutations in the genes of the vinegar fly, *Drosophila melanogaster* Meigen, and that at high radiation doses, dominant lethal mutations are induced in the sperm or the eggs, which cause the embryos to die. After World War II, both the United States and the Soviet Union were testing hundreds of atomic weapons in the atmosphere. Müller was concerned that the radioactive fallout would induce numerous deleterious mutations in people, so in 1950 Müller publicized his findings that ionizing radiation induces mutations in the vinegar fly, and at high radiation doses, the insects are completely sterilized. Immediately thereafter, under Knipling's leadership, the sterile insect technique was developed and used against the screwworm fly, a major insect parasite of warm-blooded animals and man. Over a period of 43 years, this technique was used to eradicate the screwworm from the United States, Mexico, and Central America to Panama.

Considerable research has been conducted to develop the use of the sterile insect technique against a variety of major pests. For example, Dr. M.D. Proverbs initiated such research on the codling moth, *Cydia pomonella* (L.), in 1955 at Summerland, British Columbia, Canada, but more than two decades lapsed before a practical program was launched against this major pest of temperate tree fruits. Since radiation affects the chromosomes of moths quite differently than those of flies, and since the large scale rearing of moths also is more difficult, the work on moths has lagged behind similar work with flies.

The sterile insect technique has been used with great success against various species of tropical fruit flies. The Japanese used the sterile insect technique to eradicate the melon fly, *Bactrocera cucurbitae* Coquillett, from Okinawa and all of Japan's southern islands, and this has opened the main markets in Japan to fruits and vegetables produced on Okinawa and the islands.

Chile used the sterile insect technique to rid the entire country of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann). By 1980 the entire country of Chile had become a medfly-free zone, and since then Chilean fruits in huge volumes have entered the U.S. market without the need for any quarantine treatments. This has dramatically strengthened the economy of Chile. Now Argentina, Peru and other countries have sterile insect technique programs that they hope will enable them to become fly-free zones with free access to markets in southern Europe, Japan and the United States.

Also, Mexico has used the sterile insect technique to get rid of the Mediterranean fruit fly. Indeed Mexico is ridding large sections of its territory of all fruit fly species of economic importance. The Mexican states of Baja California, Chihuahua and Sonora have been freed of all economically important species of fruit flies, so that citrus, stone fruits, apples and vegetables are being exported from these states without any postharvest treatment. In other parts of Mexico, low prevalence fruit fly areas are being established by means of a systems approach.

To prevent the establishment of medflies that enter the United States with smuggled fruit, sterile medfly males are being released continuously over the Los Angeles Basin and over Tampa and Miami. This has obviated the need to spray these urban areas with the insecticide malathion to suppress outbreaks.

Tsetse flies, which transmit trypanosomes to people and to livestock, are regarded as the root cause of rural poverty in Sub-Saharan Africa because they prevent mixed farming. Food is produced with hoes and spades because African sleeping sickness kills draft animals. Milk cannot be produced and manure is not available to fertilize the worn-out soils. The conquest of sleeping sickness would allow the use of cattle for draft and for milk production, and this is key to facilitating rural development and well being in Sub-Saharan Africa. In 2001 the African Heads of State committed their countries to a campaign to rid Africa of sleeping sickness. This undertaking is known as the "Pan African Tsetse and Trypanosomosis Eradication Campaign." Eradication of the tsetse fly, *Glossina austeni* Newstead, and sleeping sickness from Zanzibar Island was completed in 1997 by means of the sterile insect technique. Previously tsetse populations had been eradicated by this means in small areas in Nigeria and Burkina Faso. Obviously the conquest of African sleeping sickness will require decades of concerted effort.

The sterile insect program against the codling moth is of great global significance, since it is pioneering the practical application of this technique against a species of moth. There are a number of very damaging moth species, and these include the gypsy moth, various cutworm moths, the corn earworm, the European corn borer, the diamondback moth which plagues vegetable production and is resistant to almost all chemical insecticides, rice stem borers, a number of species that destroy stored products, and many others. For a number of years, sterile pink bollworm moths, *Pectinophora gossypiella* Saunders, have been released over the cotton fields in the San Joaquin Valley of California to prevent the establishment of pink bollworms that migrate from southern California. However, the prevention of incipient infestations is not nearly as demanding as coping with a well-entrenched pest population, such as the codling moth in the Okanagan Valley of British Columbia, Canada. Success against the codling moth in the

Okanagan is likely to provide the confidence needed to initiate SIT programs against moth pests in other countries.

Clearly over the past four decades the SIT has come to play a progressively greater role in overcoming poverty, and in expanding free, fair and safe trade between countries, and this is being accomplished with minimal pollution and ecological disruption.

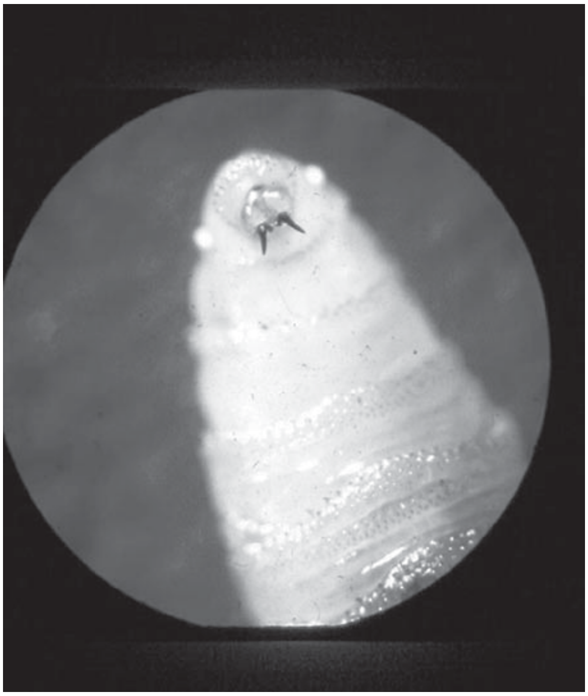
The Theoretical Basis of the SIT and Screwworm Eradication

The New World screwworm is adapted to range throughout the tropics and subtropics. Before it was eradicated from the USA, the parasite survived the winters in southern Arizona, California, Florida and Texas, and ranged far to the north during the summers. The conceptualization of the SIT arose out of the tremendous difficulty of coping with infestations of wounds of livestock by what was believed to be the carrion-feeding blow fly, then known as *Calitroga macellaria* (Fabricius). (The common name of this species was later changed to the secondary screwworm.) However, Emory Cushing, an employee of the Bureau of Entomology and Plant Quarantine, U.S. Department of Agriculture (USDA) at Menard, Texas, suspected that a complex of species was involved. Consequently, Cushing took specimens of the various life stages collected from wounds, carcasses and traps to the Liverpool School of Tropical Medicine for investigation under the guidance of Professor Walter S. Patton, an expert on the taxonomy of Diptera. Cushing and Patton discovered that in addition to *C. macellaria*, a second species was involved in wound infestations, which they named *Calitroga americana* Cushing and Patton. This second species, an obligate parasite, proved to be the major species involved in causing wound infestations, but its identity had been mistaken for *C. macellaria*, which feeds on necrotic tissue and not on living flesh. Thus, it was said that Cushing and Patton had "unmasked the great insect imposter." Clearly, efforts to suppress screwworm attack through the practices of burying carcasses and mass trapping *C. macellaria* adults had been utterly futile. The name of this New World screwworm was later changed to *Cochliomyia hominivorax* (Coquerel), since the screwworm (Figs. 116 and 117) had first been described by Coquerel, a French naval physician, who in 1854 described this parasite as the cause of the deaths of prisoners held on Devil's Island, French Guyana.

Of course, the biology and ecology of this new species needed to be elucidated, and this was facilitated by an unfortunate development. In 1933 a drought visited the Great Plains, and ranchers sought to rescue cattle by shipping them to Georgia and Florida where water and grass were plentiful. This program inadvertently introduced the screwworm to the southeastern USA, whereas previously it had not existed east of the Mississippi. The climate in Florida permitted the pest to reproduce year round, and its population grew explosively. The USDA sought to ameliorate the problem by establishing a small facility at Valdosta, Georgia, with the goal of educating cattle owners on ways of managing their herds in order to minimize the number of screwworm cases.

One of the scientists assigned to the Valdosta laboratory was Edward F. Knipling, who had grown up on a farm at Port Lavaca, Texas, where coping with screwworm-infested wounds

Sterile Insect Technique, Figure 116 **Female screwworm laying a mass of eggs on the edge of a wound.**



Sterile Insect Technique, Figure 117 **Anterior end of a screwworm larva showing the mouth hooks used to tear living flesh.**

in farm animals was an unrelenting chore. The USDA scientists at Valdosta taught cattle owners to control the insemination of cows so that they would calve only during the winter, and also to restrict any operations that result in wounds (branding, castration, dehorning) to the winter when the screwworm populations were depressed. Knipling found time to investigate the biology of the newly described screwworm. Unlike the common blowfly, which can complete its development on carcasses, the screwworm proved to be an obligate parasite of warm-blooded mammals. The female fed on the serum oozing from wounds and laid her eggs at the edges of wounds, and not on carcasses. In addition, the density of screwworms per square mile was quite low. These and later studies led Knipling to estimate the number of screwworms that survive the winter to be roughly 10–20 per square mile, and that peak densities rarely exceeded 1,000 screwworms per square mile.

Meanwhile, Raymond C. Bushland, a young scientist at Menard, Texas, had the duty of rearing the screwworm species on rabbits in order to provide screwworm larvae for evaluating candidate toxicants for inclusion in wound treatments. Bushland devised an economical method of rearing the screwworm on a mixture of hamburger meat, citrated blood and formalin. Bushland was readily able to rear about 5,000 screwworms on one pound of hamburger meat.

In 1937, Knipling was transferred to Menard, Texas, and for the first time he was able to observe the mating behavior of screwworms in the cages of adults maintained by Bushland. Knipling noted that the flies mated on the second and third day of adult life, and that the females mated only once, but that the males remained highly aggressive sexually. Thus, the great idea was born in Knipling's mind that if sexual sterility could be induced in the males, and if vast numbers could be reared, sterilized and released into nature, then the screwworm population could be suppressed strongly. Knipling reasoned that if a natural population could be over-flooded overwhelmingly with sexually sterile males for several successive generations, then most of the wild females would be mated with sterile males and the population would decline towards extinction. Knipling developed very simple mathematical models to simulate the dynamics of screwworm populations, and to assess the effects of the sterile male method and of insecticides on the dynamics of screwworm populations.

Knipling recognized that the level of suppression that is required to prevent further growth (stabilize) a population depends on its actual rate of increase (Table 19). This can be summarized as follows:

Knipling estimated that the overwintering screwworm population typically increases at roughly fivefold between generations, and that this same rate of increase is likely to occur for the next two or three generations. For example, in an area of 100,000 square miles, if 1,000,000 screwworms overwinter, this population will increase

Sterile Insect Technique, Table 19 Rates of mortality and survival required to prevent population growth and decline in relation to various intrinsic rates of increase

			To prevent population increase			
Intrinsic rate of increase	Progeny per female	Number that must survive to prevent population from declining (fraction)	Number that must die	Fraction that must die	Percent that must die	Percent that may survive
2-fold	4	2 (1/2)	2	2/4 = 1/2	50	50
3-fold	6	2 (1/3)	4	4/6 = 2/3	67	33
4-fold	8	2 (1/4)	6	6/8 = 3/4	75	25
5-fold	10	2 (1/5)	8	8/10 = 4/5	80	20
10-fold	20	2 (1/10)	18	18/20 = 9/10	90	10
20-fold	40	2 (1/20)	38	38/40 = 19/20	95	5

to 5,000,000, 25,000,000 and 125,000,000 in the F_1, F_2 and F_3 generations, respectively. In any subsequent generations, the rate of increase would be less than fivefold so that the population would not greatly exceed 1,000 per square mile. In order to calculate the consequences of releasing sterile screwworms into a population of fertile screwworms, Knipling listed the various types of matings, calculated the frequency of each type of mating and assigned ten progeny to each mating of a normal (fertile) female (NF) with a normal (fertile) male (NM). When both sterile males (SM) and sterile females (SF) are released, there are four types of matings. Thus, the above wild population has 500,000 normal males (NM) and 500,000 normal females (NF), and 4,500,000 sterile males (SM) and 4,500,000 sterile females (SF) are released. The frequencies of the various matings and the progeny produced are shown in the following table (Table 20).

Using this method, Knipling constructed a model showing the trend of this hypothetical screwworm population subjected to sterile insect releases when the normal increase rate is fivefold (Table 21).

Knipling's model indicated that if we assume a given insect has a net capacity to increase fivefold each generation, the ratio of fully competitive sterile to fertile insects will have to be 4:1 in order to keep the natural population stable. However, when the increase rate is fivefold, a sustained release rate sufficient to achieve an initial sterile to fertile ratio of 9:1 will have the effect shown in the table above. The first column of figures in that table shows the relative trend of an uncontrolled population increasing at a fivefold rate. Theoretically, an initial ratio as low as five sterile to one fertile will be adequate to start a downward trend in the natural population when the net increase rate is only fivefold. Actually, starting with this lower over-flooding ratio, theoretical elimination of the population will be achieved with fewer insects than will be required with a 9:1 ratio. However, in these models we are concerned with the overall population. In actual practice, the density of insects will vary in different parts of the environment. Moreover, the distribution of sterile insects will never be uniform. Therefore, in control operations, the initial ratio should be sufficiently high to be certain that an overall reduction in the population will occur in all parts of the environment from the start. In some instances, the sterility procedures might reduce the vigor and competitiveness of the organism. Allowance must be made for this factor.

The ratio of sterile to fertile insects increases asymptotically as the density of the wild population

Sterile Insect Technique, Table 20 Method of calculating frequencies of various types of matings and resultant progeny when sterile males (SM) and females (SF) are released in to a population of normal males (NM) and females (NF)

Type of mating	Number of matings	Progeny per mating	Number of progeny
NF×NM	$\frac{500{,}000 \times 500{,}000}{5{,}000{,}000} = 50{,}000$	10	500,000
NF×SM	$\frac{500{,}000 \times 4{,}500{,}000}{5{,}000{,}000} = 450{,}000$	0	0
SF×NM	$\frac{500{,}000 \times 4{,}500{,}000}{5{,}000{,}000} = 450{,}000$	0	0
SF×SM	$\frac{4{,}500{,}000 \times 4{,}500{,}000}{5{,}000{,}000} = 4{,}050{,}000$	0	0

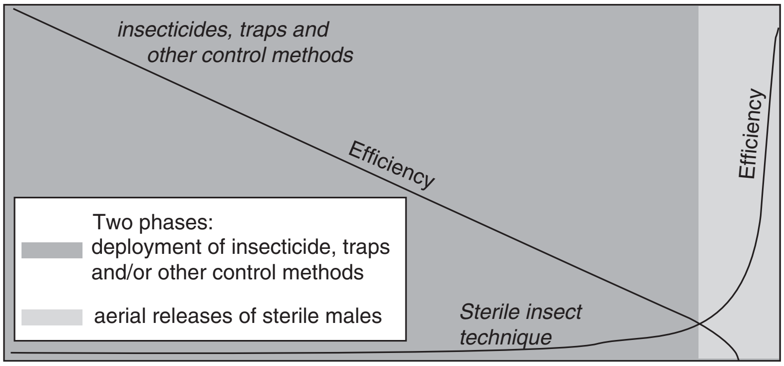
Sterile Insect Technique, Table 21 Trend of an insect population subjected to sterile insect releases when the normal increase rate is fivefold

Generation	Uncontrolled natural population (5X increase rate)	Controlled population		Ratio sterile to fertile
		Natural population	Sterile population	
1	1,000,000	1,000,000	9,000,000	9:1
2	5,000,000	5,00,000	9,000,000	18:1
3	25,000,000	1,31,625	9,000,000	68:1
4	125,000,000	9,535	9,000,000	942:1
5	625,000,000	50	9,000,000	180,000:1

declines to low levels. Thus, in order to take advantage of the tremendous power of the SIT against sparse populations of pests, Knipling advocated that releases of sterile insects should be initiated when the wild population was at a seasonal low, or immediately after adverse weather events, such as freezes and hurricanes, had decimated it. In addition, Knipling designed pest management systems in which insecticides, biocontrol agents, etc., were used to reduce the density of the target population to a level at which the SIT could manifest its great suppressive power (Fig. 118).

Over a period of several years, Knipling and Bushland continued to delve into screwworm behavior and to discuss Knipling's notion on finding a way to harness the sex drive of the screwworm to combat the parasite in a preventive manner rather than making rescue wound treatments after the livestock had become infested. However, neither Knipling nor Bushland knew of a method of inducing sexual sterility in insects. The quest to harness the screwworm's sex drive was interrupted in 1940 with Knipling's transfer to Portland, Oregon, to conduct investigations on mosquitoes and then by World War II when in 1942 both Knipling and Bushland were assigned to Orlando, Florida, to develop methods to combat insect vectors of diseases of concern to military personnel.

In 1946, Knipling was appointed Chief of the USDA's research on insects affecting livestock, man, households, and stored products. Knipling again turned his attention to the possibility of eliminating the deadly screwworm by means of the production and release of sterile flies. An absolutely essential technology was needed to induce sexual sterility in insects. However, such a method had



Sterile Insect Technique, Figure 118 Schematic representation of the sequential use of methods of suppression that efficiently decimate a dense population followed by use of the sterile insect technique, which becomes progressively more suppressive as the pest population declines. Source: FAO/IAEA.

already been discovered in 1926 at the University of Texas by Herman J. Müller, who used X-rays to induce mutations in the vinegar fly, *Drosophila melanogaster*. In 1950, Müller, now a Nobel laureate, published a popular article in the American Scientist with the intent of explaining to the scientific community that radioactive fallout from atmospheric testing of atomic bombs produced both lethal and non-lethal mutations in the sperm and eggs of living organisms. Müller had found that at elevated doses, X-rays caused complete sterility in both male and female flies. In correspondence between Müller and Knipling, Müller assured Knipling that X-rays and gamma rays would probably be effective in sexually sterilizing the screwworm. Accordingly, Knipling assigned Bushland to investigate the effects of X-rays on the screwworm. In brilliantly executed laboratory experiments, Bushland and Hopkins identified doses of X-rays that completely sterilized both sexes of the screwworm. They found that somatic damage did not occur when pupae were irradiated shortly before the adults emerged, because at this late stage all divisions of somatic cell required to form the adult had been completed. Also, Bushland showed that in laboratory cages, sexually sterile males, in competition with normal males, reduced the number of progeny of normal females, in accordance with Knipling's theoretical calculations.

Next, in 1953 Bushland's team evaluated the sterile male release concept on Sanibel Island, two miles off the coast of Florida. By over-flooding the native population with sexually sterile flies, the numbers of screwworm cases were, at times, reduced to zero. However, the continuous influx of flies from the Florida peninsula prevented the total elimination of the screwworm.

It was Knipling's incredibly good fortune that in 1953, B. A. Bitter, an animal health officer on the Dutch island of Curaçao, contacted him about screwworm control forty miles off the coast of Venezuela. Bitter requested the assistance of the USDA in dealing with a major screwworm infestation that was taking a major toll on goats and dairy cows. The USDA negotiated a cooperative agreement with the Government of The Netherlands to conduct a pilot eradication experiment on this island of 176 square miles. Bushland's team at Orlando produced sterile flies, and A. H. Baumhover and W. D. New were dispatched to conduct the operational program on Curaçao. In 1954, about 150,000 sterile screwworm flies per week were released over Curaçao, and within 3 months and the time needed for four generations to mature and the screwworm had been eradicated from the island. The Curaçao venture entailed considerable political risk, since failure surely would have resulted in severe criticism from the Congress for wasting money on such an unheard-of scheme.

The Florida livestock industry soon demanded that the USDA conduct an eradication program in the southeastern United States, and a plan to do so was developed. However, Knipling was hesitant to take this giant step, and he argued for an additional 2 years to develop more robust technologies, which could reduce program costs by $2 million. However, Florida Governor Thomas Leroy Collins asked Knipling, "Why wait 2 years to save $2 million when losses are $10 million per year?" Knipling often cited the Governor's astute reasoning in encouraging subordinates to take well thought out risks. The Florida Legislature appropriated $3 million for the program and the U.S. Congress matched this. The program started late in 1957 when a cold air mass invaded Florida and killed all screwworms southward to a line running from Tampa to Vero Beach, Florida. The program took advantage of this development by initially releasing sterile flies over the northern half of Florida to prevent reinfestation. An aircraft hangar in Sebring, Florida, was converted quickly into a giant "fly factory" and, by the fall of 1958, it produced 50 million sterile flies per week. A fleet of 20 aircraft dropped sterile flies over the infested area, while livestock owners treated all wounds with insecticide smears. The University of Florida Cooperative Extension Service trained cattle producers in management practices needed to minimize opportunities for screwworms to infest animals, to report all cases of infestations, to collect samples of larvae from infested wounds and submit them for identification at the program's headquarters in Sebring. No screwworms could be found in Florida after the end of June 1959.

Cattle producers in the states bordering on Mexico insisted on a program to eradicate the pest from the entire southwest. The Southwest Animal Health Research Foundation raised $3 million from producers to initiate the program. The Texas Legislature had appropriated $2.8 million to match the federal appropriation. A mass rearing facility was built by the Foundation at an air base in Mission, Texas. The plan was to let the cold weather destroy the screwworms to the north of the overwintering area, and to release sterile flies only on the overwintering area. As soon as screwworms had been eradicated from the overwintering area, the sterile flies would be deployed to create a barrier zone along the U.S.-Mexico border to protect against reproduction by invading flies. In this way, the parasite was eliminated from Texas, New Mexico, Arizona and California, but the parasite population in the adjacent area of northern Mexico was managed to minimize the number of flies that would enter the United States.

During 1966 no screwworms could be found in the United States for several months, and the state governors persuaded the U.S. Secretary of Agriculture to declare that the parasite had been eradicated from the United States. This declaration caused the screwworm to be considered a foreign pest, and thus the federal government became solely responsible for costs incurred when screwworms reappeared in the United States.

Eradication of the screwworm to the Isthmus of Tehuantepec was the long-range goal, but the program could not be moved into Mexico because the Governments of Mexico and the United States took 6 years and until 1972 and to negotiate an agreement. The strategy of eradication was replaced with area-wide population management as a static holding action along the entire border with Mexico. During this static decade many difficulties arose. The sterile fly barrier proved to be narrower than the flight range of the screwworm, so that infestations occurred north of the international boundary. The deer population in Texas exploded, and many ranchers reduced the number of cowboys needed to treat wounds. Screwworm cases began to arise as far as 300 miles north of the Mexican border. Serious difficulties were encountered in 1968 when almost 10,000 cases were recorded in the United States, and 1972 was a disaster with more than 95,000 cases. Prestigious scientists criticized the program and decried the strategy of eradication.

The Mexico-American Screwworm Eradication Agreement was signed in 1972 by the two Secretaries of Agriculture with the purpose of removing the parasite to the north of the Isthmus of Tehuantepec and then establish there a sterile fly barrier. For this purpose, a Joint Mexico-U.S. Screwworm Eradication Commission was created. Field operations began in 1974 and a newly constructed screwworm factory near Tuxtla Gutierrez came into full production in January 1977 with a capacity of 500 million flies per week. By 1982, the Commission employed 2,031 people.

The approaches and technologies employed were the latest versions of those that had been pioneered in the U.S. campaigns with the addition of SWASS (Screwworm Adult Suppression System), and a pelletized form of attractants and toxicant developed under the leadership of Wendell Snow for broadcast application. SWASS was effective in attacking high population densities, a necessity to obtain an overwhelming ratio of sterile to wild flies.

The initial deployment of sterile flies was in the Mexican states bordering the U.S., Baja California, and regions of Tamaulipas and Vera Cruz, which provide very favorable screwworm habitat and propitious routes for flies migrating toward Texas. Heavy emphasis was placed on examining and, if it was necessary, treating every animal. Some livestock inspectors traveled routes by horseback that required 15 days to traverse. About 11% of the larvae recovered from wounds were secondary species. By 1984, the Commission had achieved the goal of eradicating to the Isthmus of Tehuantepec.

Dr. Peneda-Vargas, who served as the Mexican Director of the Commission during this period, wrote, "I feel compelled to state that this accomplishment, eradication, was the result of hard work by thousands of people both in the Commission and outside of it, but it would be impossible to overstate the contribution of the Mexican rancher. It was the livestock owner who first saw the need for the program, who initiated and supported it for a period of almost 25 years, and who was in the final analysis most responsible for its success. It was his attention to his animals and his cooperation that made it possible to locate and eliminate every infestation from this large country with all its extremes of terrain and ecology."

In 1986, operations were extended to the Yucatan Peninsula and the countries bordering Mexico. Mexico was declared free of screwworm in February 1991. In order to further reduce the threat of the screwworm to the United States, the decision was made to move the sterile fly barrier to Panama. Thus, agreements were signed between the U.S. Department of Agriculture and the various Central American governments. By 2001, the screwworm had been cleared from Central America north of Panama and a barrier of sterile flies was established across Panama from the Atlantic to the Pacific Ocean (Fig. 119).

It is important to keep in mind that with modern travel and transportation, *C. hominivorax* could easily be re-introduced into areas that have been cleared of this plague. The defenses against this parasite would be improved if all of the Caribbean countries could be freed of the parasite, and eventually the problem in South America must be addressed. However, sufficient progress has been made to enable us to recognize the triumph of an original idea and the benefits nuclear science can add to our quest to assure a reliable and adequate food supply.

Physiological and Cytogenetic Bases of Sterility

Reproductive Physiology of Male Insects

To understand the physiological nature of sexual sterility in insects, familiarity with fertility and reproduction in insects is important. The insect male's mating drive is scarcely affected by castration, and spermatogenesis is under the control of the frontal ganglion and the prothoracic gland. The paired testes become visible in the early instars,

Sterile Insect Technique, Figure 119 **Progress in eradication of the screwworm.**

and in many species sperm are produced before adult emergence. Nevertheless, the development of the germ cells is not correlated closely enough with morphogenesis to estimate the degree of sex-cell maturation based on the individual's life stage. In many species, all types of germ cells are present in the late immature instars and in adults. However, in other species, most notably those belonging to the Lepidoptera, only one or two types of germ cells are present at a given life stage. The spermatozoa pass from the testis through the vasa deferentia into paired seminal vesicles for temporary storage. Typically, a pair of accessory glands flanks the seminal vesicles, and their secretions are transferred with sperm during copulation (Table 22).

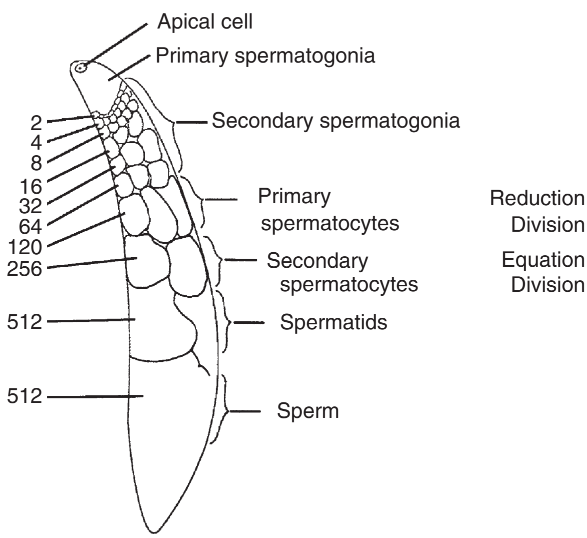
Each testis consists of tubules or follicles, and each tubule is divided into a number of zones. Most distal in the tubule lies the germarium comprised of the primary spermatogonia. Usually, each spermatogonium detaches from the germarium and becomes enveloped by cyst cells (Fig. 120). The spermatogonium then undergoes mitotic divisions to form 256 primary spermatocytes. Next, in the zone of maturation and reduction, each of these primary spermatocytes divides into two haploid secondary spermatocytes, and then each secondary spermatocyte divides to produce two spermatids. In the zone of transformation, the spermatids (still enclosed in the cyst) elongate to form sperm. Finally the sperm rupture the cyst and accumulate in the seminal vesicles as densely packed bundles. In Diptera, during mating the sperm are transferred in semen from the seminal vesicles to the female's spermatheca, while in Lepidoptera the male synthesizes a spermatophore, fills it with sperm bundles, and positions the opening of spermatophore to allow the sperm bundles to pass down the seminal duct to the spermatheca (Table 23).

The amount of time required for a spermatogonium to develop into a bundle of mature sperm varies from species to species, but in most species this time period probably ranges from 5 to 15 days. In *Drosophila melanogaster*, this period is roughly 5–6 days, and another 2 days of maturation are required before the sperm are transferred during mating. Newly formed sperm bundles continuously enter the elastic seminal vesicle to increase its volume and to mix with sperm that had matured previously (Table 24).

Male insects produce much less sperm than do male mammals. An inseminated *Drosophila* female stores 500–700 sperm in her spermatheca, and all of these sperm may be utilized, because a female may lay more than 500 eggs. When the

Sterile Insect Technique, Table 22 Types of germ cells present in the testes of many species of male insects at a given life stage

Life stage	Cell stage in testes
Hatching to penultimate level	Spermatogonia
Pupa	Spermatogonia, primary and secondary spermatocytes
Pupa and adult	Spermatogonia, primary and secondary spermatocytes, spermatids and mature sperm



Sterile Insect Technique, Figure 120 Schematic diagram of a testis tubule as found in Diptera and Coleoptera. The numbers on the left indicate the number of cells in a cyst or sperm bundle.

Drosophila female remates, the sperm of the second mating may displace the majority of the stored sperm. In contrast, when the female boll weevil remates, the sperm received from the second mating are used much more frequently than the sperm from the first mating.

The frequency of copulation by males, and their ability to transfer sperm in successive matings, varies between species. Habrobracon males can mate 14 times in rapid succession and transfer sperm in every mating. Boll weevil males mate 2.55 ± 1.50 times per day. Male *Aedes aegypti* have been observed to mate 30 times in 30 min, however, sperm is transferred only to the first 3 or 4 females. Also, in *Drosophila*, few sperm are transferred after the third closely spaced mating. In *Drosophila* this inability to transfer sperm is not caused by the lack of sperm, but by the exhaustion of the accessory gland secretion, without which sperm transfer is impossible. Regeneration and replenishment of accessory gland secretion in *Drosophila* requires more than 2 h, and 24 h in *Aedes aegypti*.

Reproductive Physiology of Female Insects

Each female possesses a pair of ovaries for egg production. Each ovary consists of ovarioles varying in number from one to several hundred depending on the species. Primitive orders such as Odonata and Orthoptera have panoistic ovarioles without special cells for yolk production. In such insects, nutrients absorbed from the hemolymph are converted into yolk by an enlarged oocytes nucleus or germinal vesicle.

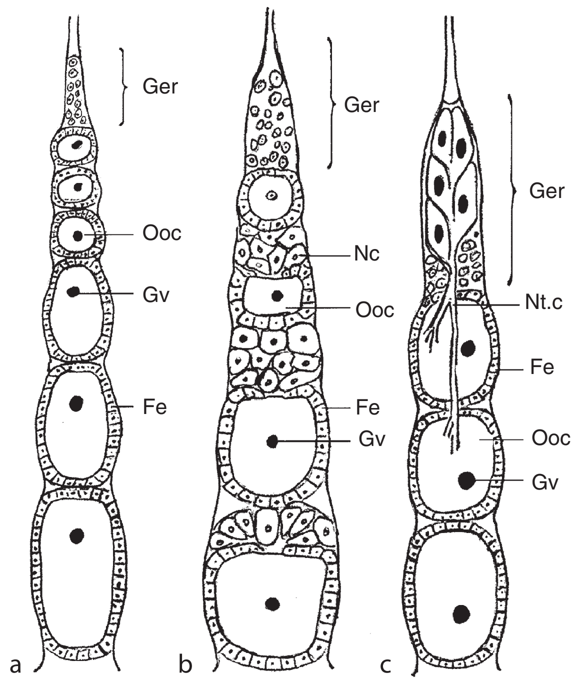
In other orders, special nutritive cells or trophocytes for yolk production are present in the meroistic ovarioles. Depending on the location of the nurse cells in relation to the oocytes, meroistic ovarioles are categorized as either telotrophic or polytrophic. In telotrophic ovarioles the trophocytes are distant from the oocytes, and they deliver yolk via cytoplasmic strands. In polytrophic ovarioles, the trophocytes lie adjacent to the oocytes and form part of the egg follicle. Telotrophic ovarioles are characteristic of Coleoptera, while polytrophic ovarioles are characteristic of Diptera and Hymenoptera.

Sterile Insect Technique, Table 23 **Types of germ cells present at given life stages of the silkworm (Sado, 1961)**

Life stage	Cell stage in testis
Hatching to first instar	Primary spermatogonia
Second to third instar	Secondary spermatogonia
Third to fourth instar	Spermatocytes in early meiotic prophase
Fourth to fifth instar	Spermatocytes in early and late meiotic prophase
Fifth instar to spinning	Same as fourth instar plus a few early spermatids
Pupa	Spermatids and fully formed spermatozoa
Emerged adult	Only fully formed spermatozoa

Sterile Insect Technique, Table 24 **Schedule of spermatogenesis in *Drosophila melanogaster* (Martin, 1965)**

Late spermatogonia	Primary spermatocytes	Secondary spermatocytes	Spermatids		Sperm
0 h	24 h	48 h	72 h	96 h	120 hs



Sterile Insect Technique, Figure 121 **Diagrams of the principal types of ovarioles based on R.E. Snodgrass (1935): (a) panoistic (Odonata and Orthoptera); (b) meroistic and polytrophic (Diptera and Hymenoptera); and (c) meroistic and telotrophic (Coleoptera). fe = folicular epithelium, ger = germarium, gv = germinal vesicle, nc = nurse cell, nt.c = nutritive chord, ooc = oocyte.**

The following description pertains to species with polytrophic ovarioles (Fig. 121).

Egg production depends on mitotic division of oogonial cells. These oogonial divisions produce a cyst of interconnected cells. Depending on the species, each oogonium gives rise to one oocyte and 1, 7, 15, 31 or more trophocytes. For egg maturation to commence, important changes first must occur in the nuclei of the trophocytes. These cells must nurse the growing oocytes. In preparation for this, the nurse-cell chromosomes undergo endomitosis, which entails the repeated replication of trophocyte chromosomes without cell division.

During oogenesis, the volume of a trophocyte cell nucleus increases an estimated 2,000-fold. Thereafter, the oocyte proceeds to grow rapidly. In *Drosophila*, the volume of the oocytes increases by over 100,000-fold in 3 days. After the oocytes have matured, the trophocytes degenerate and disappear. After vitellogenesis has been completed, the follicle cells secrete the chorion, but leave an opening, the micropyle, to facilitate entry of sperm. Finally, the egg ruptures through the follicle, passes down the vagina, receives sperm from the spermatheca, and is deposited. The presence of the sperm in the egg stimulates its nucleus to divide into four haploid nuclei. One nucleus becomes the female pronucleus and unites with the sperm (syngamy) to form the zygote.

Causes of Sterility

Sterility is defined as the inability to produce offspring. Conversely, fertility is the ability to reproduce. Fecundity is the number of progeny produced per female. Thus, only females can be infecund. Sterility may be caused by (i) inability of females to lay eggs (infecundity), (ii) inability of males to produce sperm (aspermia), or inability of sperm to function (sperm inactivation), (iii) inability to mate or (iv) dominant lethal mutations in the reproductive cells of either the male or the female. All of these mechanisms may be induced by exposure of insects to gamma rays or X-rays or to certain chemicals. In addition, sterility may be induced by insect growth regulators, which can be transferred from a treated male to an untreated female during mating, and subsequently disrupt the development of the embryo by interfering with endocrine mechanisms.

Dominant lethal mutations are of foremost importance in the effective use of sterility by means of the sterile insect technique (SIT). In many instances, the successful use of the SIT also requires that infecundity has been induced. For example, in the use of the SIT against the New World screwworm, both males and females are irradiated in the late pupal stage with a dose of gamma rays that induces dominant lethal mutations in all of the sperm of the male and that induces infecundity in all females. In addition, this dose must destroy the spermatogonia of the male so that the male cannot recover fertility.

Infecundity

A reduction in fecundity is expressed as a depression of egg production. Depressed egg production is almost always observed following the treatment of female insects with certain chemicals (antimetabolites and alkylating chemicals), various forms of ionizing radiation (X-rays, gamma rays, and neutrons), ingestion of radioisotopes and intense ultraviolet radiation.

Egg production is dependent on the differentiation and development of oocytes from oogonia and their supply of nutrients from properly functioning nurse cells (trophocytes). Both the oogonia and the trophocytes are readily impaired by the above treatments. Severe damage to these two cell types results in permanent infecundity. In Diptera, the trophocytes attain a high degree of polyploidy during development. Before the trophocytes have fully differentiated (during endomitosis), they are extremely sensitive to the effects of ionizing radiation and to antimetabolites and alkylating agents. On the other hand, after the trophocytes have differentiated they are extremely resistant to impairment by these agents. For example, when the yellow fever mosquito, *Aedes aegypti*, females are irradiated 4 h after ingesting a blood meal, only 10 krad are required to induce infecundity, yet 100 krad are required to induce the same effect when the irradiation occurs 42 h after the blood meal.

Inability or Failure to Mate

Irradiation of either male of female insects with very high doses of ionizing radiation or of chemosterilant, or the application of these mutagenic agents when many somatic cells are dividing, can prevent the treated insects from mating, or at least from mating readily. For example, weevils are debilitated at substerilizing doses of ionizing radiation or by most alkylating chemosterilants. This phenomenon was studied in detail in the boll weevil, *Anthonomus grandis* Boheman. In the midgut of the adult boll weevil, the secretory cells are sloughed to release the digestive enzymes into the lumen of the gut, and these secretory cells are continuously replaced by dividing cells. The latter are destroyed with doses of ionizing radiation or alkylating agents that are only a fraction of the doses required to induce dominant lethal mutations in the sperm. The damage to the midgut prevents the boll weevil from digesting food, and also makes the gut vulnerable to penetration by microorganisms. The capacity of male weevils to mate falls off sharply several days after exposure to ionizing radiation or most alkylating agents.

In the Lepidoptera, the large doses required to induce sterility in the males may impair the transfer of sperm from the male to the spermatheca of the female. During coitus, lepidopteran males enclose their sperm in a spermatophore and position the opening of the spermatophore against the opening of the seminal duct so that the sperm can traverse from the spermatophore down the seminal duct to the spermatheca. Irradiated males in some species experience difficulty in placing the spermatophore opening against the seminal duct opening. Consequently the females from such pairings do not lay eggs, and they call for another mate.

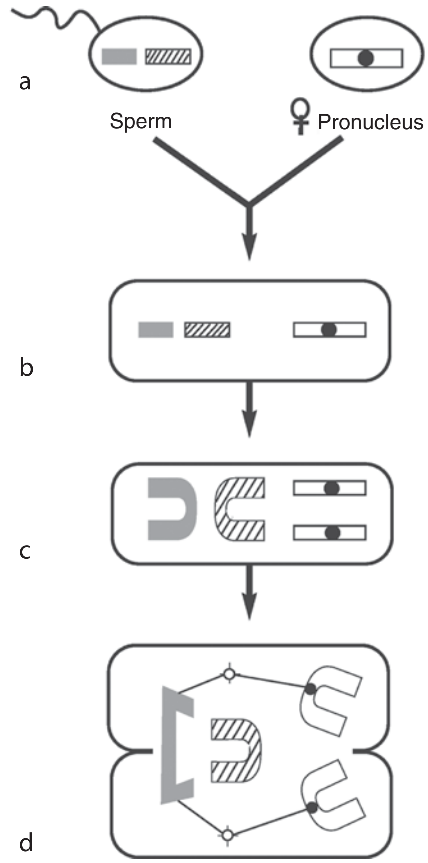
Sperm Inactivation

In most insects of economic importance, the frequency of sperm inactivation is not easily ascertained because lack of egg hatch can be the result of dominant lethal mutations, aspermia or sperm inactivation. However, sperm inactivation by mutagenic agents is studied most readily in the Hymenoptera in which fertilized eggs develop into females, and nonfertilized eggs develop into males. Any egg fertilized with a sperm in which a dominant lethal mutation has been induced will not hatch because the mutation will cause the embryo to die. Generally, inactivation of a significant portion of the sperm requires higher doses than are needed to induce dominant lethal mutations. Careful studies have shown that in some species, some sperm are inactivated at fairly low doses of radiation. However, sperm inactivation has not been found to be an important factor affecting applications of the sterile insect technique.

Dominant Lethal Mutations

Ionizing radiation induces dominant lethal mutations. A dominant lethal mutation is a change in the nucleus of the sperm or the egg that usually causes the death of the zygote, even when such mutation is introduced by only one of the two germ cells that unite at fertilization. (Of course there are also dominant lethal mutations that are expressed at later stages of development and they prevent reproduction of the bearer of the mutation.) A dominant lethal mutation does not impede the maturation of the treated germ cell into a gamete or the subsequent participation of the gamete in fertilization to form the zygote. However, the dominant lethal mutation prevents the zygote from developing into a reproducing adult. Lethal mutations are not lethal to the treated cell. Rather, lethal mutations are lethal to a descendant of the treated cell. Because only one dose of a dominant allele is needed for expression, dominant lethal mutations are expressed in the first generation of the treated cell. However, recessive lethal mutations may be passed on to many generations before they appear in homozygous form required for expression.

Numerous studies that involved insect species in diverse orders and families have shown that dominant lethal mutations are characterized by the presence of chromosome fragments and bridges between dividing nuclei in the zygote or young embryo. The vast majority of dominant lethal mutations induced by ionizing radiation are the result of chromosome breaks (Fig. 123). A broken chromosome, in which the two segments do not rejoin and heal prior to cell division, is the simplest kind of dominant lethal mutation. The chromosome fragment, which lacks a centromere, may not be included in the daughter nucleus, and this would be a lethal deficiency. Moreover, the broken end of a chromosome is sticky and readily joins with any other broken end of a chromosome. Chromosome breaks that rejoin, but not in the original fashion, invariably have a lethal effect. Such asymmetrical exchanges result in acentric fragments (fragments without a centromere) and dicentric chromosomes. Dicentric chromosomes form bridges between the two daughter nuclei formed during cell division. Such a bridge may block cell division or the bridge may break to form genetically unbalanced chromosome fragments that are lethal. In the eggs of the screwworm formed in matings of irradiated males and untreated females, numerous chromosome aberrations occur in the first two cleavage divisions, and that embryonic development seldom progressed beyond the second cleavage division. However, when an irradiated female was mated to an untreated male, numerous chromosome aberrations were found during the first two meiotic divisions. These meiotic divisions occur after the egg is laid and before the cleavage divisions can occur. Again, numerous chromosome aberrations occurred during the cleavage divisions and the embryos invariably died before blastoderm formation (Fig. 122).



Sterile Insect Technique, Figure 122 Schematic representation of the effects of a broken chromosome in a sperm on cell division in the zygote or early cleavage stage. (a) Irradiated sperm with broken chromosome unites with normal oocyte pronucleus; (b) and (c) after syngamy, each chromosome produces sister chromatids. Broken ends of chromatids stick together and heal to form acentric and dicentric isochromosomes. (d) At the cleavage division, a chromosome bridge is formed and the acentric fragment is lost. The bridge may terminate cell division or it may break. In any case the daughter cells will be genetically unbalanced.

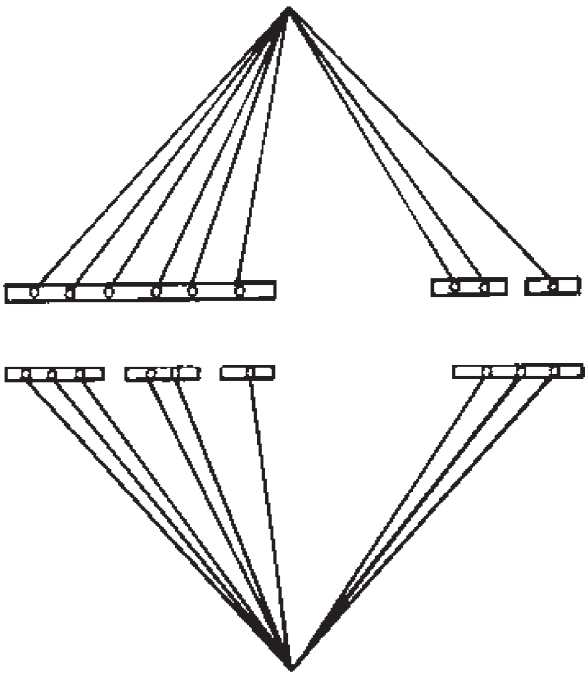
Aspermia

Aspermia is the lack of a supply of sperm. Either mature sperm are not produced or their supply becomes exhausted and their replenishment is prevented. Aspermia can be induced by exposure of immature insects to a dose of a mutagenic agent sufficiently high to inhibit the spermatogenic cycle (kill the spermatogonia). Irradiation of an immature whose testes contains only spermatogonia may destroy them, so the resulting adult is devoid of sperm. Irradiation of the adult male also can result in aspermia because the spermatogonia are killed at substerilizing doses. Thus, such an adult male may exhaust his supply of sperm after several matings.

In order to achieve permanent sterility by means of irradiation, it is necessary to kill all of the spermatogonia. Any spermatogonia that survive irradiation will continue to divide and to repopulate the germarium. Sperm derived from such surviving spermatogonia lack chromosome breaks, and hence they largely lack dominant lethal mutations.

Transfer of a Chemosterilant During Mating

A compound with hormonal effects can be transferred to females by treated males in the process of mating in sufficient amounts to prevent the



Sterile Insect Technique, Figure 123
Diagrammatic representation of a one holokinetic chromosome at late metaphase in a dividing nucleus. The breaks have been induced with ionizing radiation. In the F_1, broken ends of chromosomes join to form a variety of translocations between chromosomes. These translocations cause lethal genetic imbalances in the gametes, and are the primary cause of sterility in the F_1 generation.

development of progeny. This was first shown by Massner et al. with *Pyrrocoris apterus* (L.). As pointed out by Knipling, such a chemical sterilant, when applied to individuals in the wild populations has the following two effects: (i) it prevents the treated insect from reproducing and (ii) it converts the treated insect into a biological agent that can nullify the biological potential of untreated individuals with which it mates. For example, if 90% of a population of 1,000,000 were simply killed, the 100,000 survivors would reproduce normally. However, if 90% of the population was effectively treated with the sterilant, then the 900,000 treated insects would compete for mates with the 100,000 untreated insects. Thus only 10,000 insects would succeed in reproducing. Clearly, if this level of treatment were continued for several more generations, the population would become extinct. Pheromone-baited traps fitted with contaminating devices were developed to dispense the mutagenic chemosterilant bisazir to flies. Subsequently, an insect growth regulator was used as the sterilant, and it provided encouraging results in a field trial. The latter compound arrests development during the pupal stage. More recently, this approach was used against tsetse on the Buvuma Islands, Uganda. Unfortunately, only 25–30% of wild tsetse populations are attracted into the contaminating devices, though models indicate that the effect of this level of sterilization of untreated individuals by mating with chemosterilant-contaminated individuals is considerable. This autosterilization approach is entirely compatible with the release of sterile insects, and is especially applicable as a component of barriers to reinvasion of zones from which the pest has been completely eliminated.

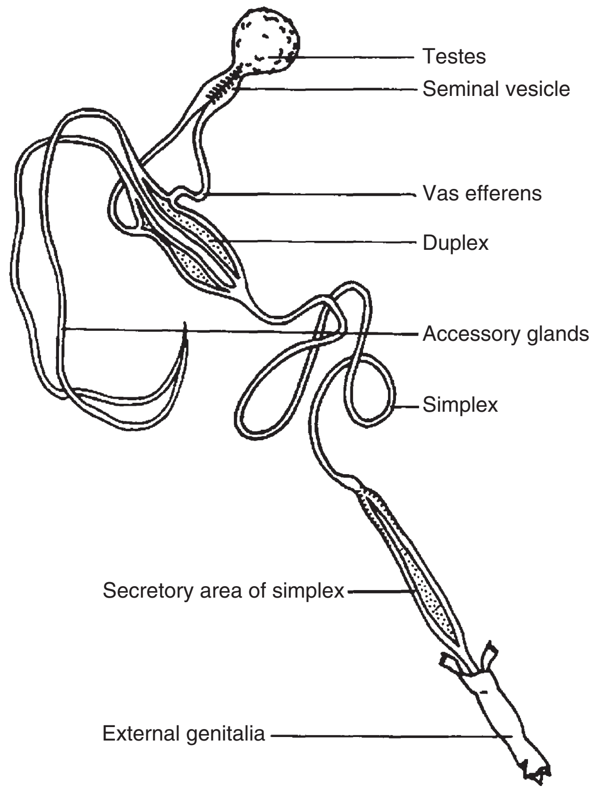
Inherited Sterility in Lepidoptera

Because the very high doses of gamma rays (40,000 krads) required to induce complete sterility in codling moth males is quite debilitating in most species, the effects of partially sterilizing doses of radiation on the competitiveness of the codling moth were investigated. When the treated males were crossed to untreated females, most of the progeny were males. Further, F_1 males crossed to untreated females produced F_1 males with a higher level of sterility than their irradiated fathers. Also, the F_1 females had a high level of sterility. Simulation models showed that released males with inherited sterility would suppress the wild population to a greater extent than the release of equal numbers of fully sterile males.

The phenomenon of inherited sterility was found to occur in species whose chromosomes have a "diffuse centromere" with multiple spindle fiber attachments that are characteristic of the Lepidoptera, Hemiptera and Acari. Such chromosomes have a diffuse centromere and have been referred to as holokinetic or holocentric. Some have argued that these terms are not appropriate, since the kinetochore plates do not extend the full length of the chromosome, but only about 70% of the length, as in the milkweed bug, *Oncopeltus fasciatus* (Dallas). In any case, these multiple spindle fiber attachments insure that most radiation-induced chromosome breaks will not lead to the immediate loss of chromosome fragments. Indeed, these fragments persist and are transmitted through the germ cells to the next generations. The chromosome fragments may unite and form various types of chromosomal translocations, which result in genetically unbalanced gametes in the F_1, and serve as the primary cause of the enhanced level of sterility.

In spite of the existence of inherited sterility, its application for suppressing lepidopteran pests has been slow to develop because ionizing radiation harshly affects (i) the formation and functioning of the two types of sperm, eupyrene and apyrene, and (ii) the ability of the male to properly position the spermatophore opening adjacent to the opening of the seminal duct and thus facilitate the transfer sperm to the spermatheca (Fig. 124).

Eupyrene sperm occur in bundles and possess nuclei and large mitochrondrial derivatives. These nucleate sperm are needed to fertilize the egg. Apyrene sperm do not occur in bundles after they leave the testis, and they lack nuclei. Apyrene sperm appear to be necessary for the transport of the eupyrene sperm from the spermatophore down the seminal duct into the spermatheca, and to prevent the inseminated female from calling for another mate. Eupyrene sperm are susceptible to damage by irradiation, and damage to the flagellum and apex of the sperm cell are frequent. Moreover, in the F_1 male progeny, the number of eupyrene sperm per sperm bundle appears to be reduced, and the many sperm exhibit ultrastructural abnormalities. However, only normal appearing sperm are found in the spermathecae of females that mated with an F_1 male (Fig. 125).

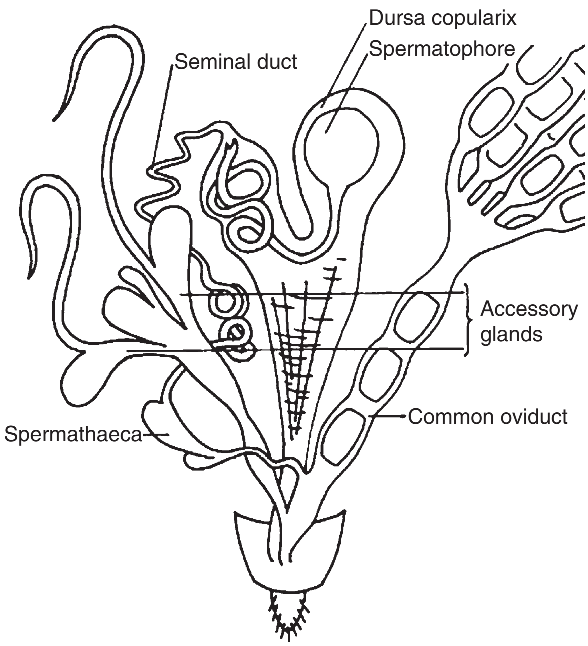


Sterile Insect Technique, Figure 124 Diagram of the male reproductive system of the tobacco budworm, *Heliothis virescens* (Fabricius). Courtesy of H. M. Flint.

Even though F_1 males have not been irradiated, they often fail to transfer sperm to the spermathecae of females. For example, when P_1 adult *Anagasta kuehniella* (Zeller) males received 15–20 krads of gamma rays, roughly 50% of F_1 males failed to transfer eupyrene sperm. Nevertheless, season-long releases of partially sterile males, which resulted in production of F_1 progeny on the field, strongly suppressed wild populations of *Heliothis virescens* in North Carolina and of *Cydia pomonella* in Washington.

Appropriate Applications and Some Limitations of the SIT

The sterile insect technique is a tactic almost always used in association with other control tactics as part



Sterile Insect Technique, Figure 125 Diagram of the female reproductive system of the tobacco budworm, *Heliothis virescens* (Fabricius). Note the position of the open end of the spermatophore at the entrance of the seminal duct. Courtesy of H. M. Flint.

of a pest management system designed to accomplish a certain strategy of pest management. Thus, a "tactic" is a method for detecting, monitoring or controlling a pest. A "system" is an assemblage of tactics that are applied simultaneously or sequentially so that the effects on the pest population of individual tactics are either additive or mutually potentiating, and so that counter-productive (negative) interactions are avoided or minimized. A pest management "strategy" is a broad overall plan for employing pest control tactics to minimize negative ecological, economic, sociological and/or political impacts of a pest problem, both in the short term and in the longer term. Successful strategies should strongly protect agriculture on a sustained basis.

Pest management strategies include (i) prevention or containment, (ii) temporary alleviation, (iii) management of local populations, (iv) management of total populations in an ecosystem or area-wide pest management, and (v) eradication of a pest, i.e., the destruction of every individual of a species in an area surrounded by natural or man-made barriers sufficiently effective to prevent re-invasion except through the intervention of man.

Each control tactic has characteristics that need to be considered in the design of a system to implement a strategy effectively and efficiently. Ecological selectivity is important to avoid the destruction of natural enemies needed to prevent the resurgence of the pest population following a control operation. Most conventional insecticides are relatively nonselective. Highly selective tactics include the SIT and other genetic techniques, resistant crop varieties, certain insect pathogens, parasitoids and predators and certain artificial and naturally occurring attractants. Light traps, some attractant baits, "general" predators, parasitoids and pathogens, and certain insecticides are only moderately selective. These characteristics are displayed in Table 25.

Ideally pest management systems are based on an appreciation of the selectivity and efficiency of the available tactic. Whenever possible, highly selective measures should be chosen. When suppression of populations to very low levels is required, methods that are effective against high populations, and methods that are effective against low populations, should be integrated in such a way that the former potentiate the latter. When the economic threshold of the pest is moderately high, several tactics that are effective against dense populations often may be combined to give much more reliable suppression than a single method.

Because the SIT is not efficient in combating dense pest populations, it is almost always used in concert with a method that is effective against dense populations. Conversely, since the SIT is extremely efficient in suppressing or eradicating low density pest populations, it is used to eradicate incipient infestations of major pests. By analogy, the SIT is useless against the "roaring blaze" but extremely effective in extinguishing the sparks. Thus, the SIT is used effectively as a preventive measure to prevent the establishment of immigrant

Sterile Insect Technique, Table 25 Characteristics of control tactics and their efficiencies

	Constant efficiency at all pest densities	Efficient at high pest densities	Efficient at low pest densities
Highly selective ecologically	Resistant varieties; sex pheromones used to confuse; synthetic attractants	Selective insect pathogens, parasitoids and predators	SIT and other genetic techniques; sex pheromone baited traps
Moderately selective ecologically	Light traps; food baits; systemic insecticides	General predators, parasitoids and pathogens	
Nonselective ecologically	Most chemical insecticides; cultural measures; harsh weather events		

populations of the Mediterranean fruit fly in the vicinities of Los Angeles, Tampa and Miami, and of the pink bollworm in cotton growing areas of California. Similarly, the SIT was used to prevent the spread of the screwworm throughout Africa and to eradicate it from its foothold along the Mediterranean coast of Libya.

The SIT is extremely useful for combating the leading edge of a pest population invading uninfested territory. To be effective, the width of the sterile insect barrier must be greater than the range of dispersal of the wild females. Thus, the MOSCAMED Program has used the SIT as an important component of the barrier to contain the Mediterranean fruit fly in Guatemala and prevent its movement into Mexico. Since 1957 the SIT has been used in barriers to contain populations of the screwworm.

Pest-free zones and pest-free fields of production are area-wide approaches to facilitating exports of agricultural commodities without the need for postharvest or quarantine treatments. Both the International Plant Protection Convention and the Sanitary and Phytosanitary Agreement are structured to accept and encourage area-wide pest management as a tool for promoting safe trade and contributing as much as possible to the complementary goals of food security and economic security for all countries. In Florida, sterile Caribbean fruit flies, *Anastrepha suspensa* Loew, are part of a system used each year to create fly-free fields of citrus production as required to permit the export of fresh citrus to Japan.

The effectiveness of the SIT is affected by many variables. For pest species, which have contagious or clustered distributions, it is the overflooding ratio in the clusters that determines the effectiveness of the SIT. Seasonal patterns of abundance must be taken into account, since a high overflooding ratio can be established most easily when the wild population is low, and since the SIT has tremendous impact when imposed on a wild population with a low or negative intrinsic rate of increase. The longevity of gravid females is important, because they tend not to mate. Thus, it is often cost effective to make one blanket treatment with an insecticide to kill gravid females. The overlapping of generations prolongs the period during which sterile insects must be released. Advantage should be taken of climatic events that synchronize insect development. For example, in the program to eradicate the screwworm from Libya, releases of the sterile flies were begun on December 18, 1990, when the cold rainy weather had halted all reproduction and the wild population consisted entirely of pupae in the soil. Thus, early in February 1991, when wild flies emerged synchronously from beneath the soil, they encountered numerous sterile males. Consequently, the wild population was decimated, and no wild flies could be found after the end of April 1991. The induction of close to 100% sterility is critically important in combating pest species with high intrinsic rates of increase. Also, rearing, sterilization, and release procedures may diminish the quality of the released flies. Clearly no other method of pest suppression is influenced by as many factors as is the SIT.

The SIT is an underutilized and widely misunderstood technology. There is a need for additional data to correlate the frequencies of matings of sterile males with wild females with the dynamics of the pest population.

Economic Analysis of SIT Programs

Apart from clearly objective measures such as technical effectiveness or cost efficiency, there are several subjective measures that come into the evaluation of SIT and other area-wide programs. These include risk of failure of containment or eradication, the boundaries of externalities (for example, variable probabilities of pesticide drift under different conditions, or concerns of people who feel they have no economic stake in a program, as is usually the case when an agricultural pest must be combated in an urban setting), and time preferences for returns on capital investments (such as insect rearing facilities). Such subjective issues may cause great difficulties in reaching agreed decisions, even with a consensus on the data used. It is useful to analyze three general classes of economic problems: (i) annual comparisons of costs and benefits, (ii) initial capital costs with delayed projected benefits, and (iii) initial costs with delayed and uncertain future benefits.

The two basic principles governing the selection of area-wide management over individual local pest management are effectiveness and efficiency. Containment and eradication can be achieved only on an area-wide basis, and total effectiveness is required. Questions of efficiency subsequently arise in deciding which area-wide techniques to employ, not in comparing them to uncoordinated local control. Nevertheless, economic efficiency must be considered at an early stage to decide whether containment and eradication are affordable goals, and if so, whether the resources can be assembled.

The SIT also may be applied on an area-wide basis for population suppression and not for eradication, and this is certainly the case when the SIT is used to create pest-free fields of production. Suppression may or may not be more effective by area-wide management than by management on a local basis, but the main issue is one of cost efficiency. Is area-wide pest suppression more cost efficient than the sum of local pest management? This is a challenge, because local pest management often yields private returns of 4:1.

Size, Coordination and Economies of Scale

Legal authority to conduct a coordinated SIT program may be based on existing laws, or it may require a referendum of all affected parties. Usually, in the USA such referenda must pass with a majority of two thirds.

The optimal size of an area or a sub area for a SIT program depends on the mobility of the pests, the uniformity of their densities and the costs of coordination, and whether pre-existing decision-making and administrative institutions exist. Total detection plus suppression costs per hectare of crop usually will decline as the size of the area increases. However, suppression costs usually decline with increasing size, but they may increase in very large programs if expensive items as helicopters or airplanes must be purchased. Per hectare organizational costs (management, meetings, solving financial problems, etc.) tend to rise sharply with project size.

Approaches to dealing with problems of coordination and economies of scales include: centralized handling of area-wide surveillance with suppression left to individual producers, and division of the area into zones and sub-zones. For example, a zone may correspond to a political subdivision, and sub-zones may be established for areas of uniform pest density. In some eradication programs, growers in areas where the pest is only a minor problem are unwilling to pay as much per hectare as growers in areas were the pest is devastating.

Benefit-Cost Assessment and Discounting Net Returns

Investment in large-scale SIT programs usually is made with the expectation that program benefits will accrue over a multi-year time horizon. Therefore, we must discount future benefits to balance them against present or near term expenditures. The stream of discounted annual benefits and costs for many years of an undertaking can be summed up and expressed as a single value, known as the present value net benefits (PVNB). The formula for calculating the PVNB for a 15-year project is as follows:

$$\text{PNVB} = \text{NB}_1 + w_2\,\text{NB}_2 + w_3\,\text{NB}_3 + w_4\,\text{NB}_4 + \ldots\, w_t\text{NB}_t \ldots\, w_{15}\text{NB}_{15},$$

where NB_t represents the net benefits in year t, and w_t represents the weighting factor for year t. The weighting factors are a function of a discount rate (r):

$$w_t = \frac{1}{(1+r)^t}$$

The discount rate is the "opportunity cost" of the money, or the interest value that money could earn if allocated to the best alternative use. This rate may be established by subtracting the national inflation rate from the bank interest rate for savings. In normal times, this procedure generally will produce a figure around 4 or 5% in developed countries. This represents the "reasonable" person's discount on the future, since people put their money in the bank to gain this premium, and otherwise they would spend it now. So, the benefit of eradication next year is worth 5% less if it is brought back to the present. Benefits in 20 years are only worth 37% of their face value when brought back to the present. In riskier economic environments, discount rates will be much greater, so the calculated net present value of future benefits may be insignificant. However, for SIT programs involving vectors of human diseases, the futures of groups of people are at stake, and it does not seem appropriate to discount benefits in the manner appropriate for private investments. The health of the human population 30 years in the future seems just as important as the health of the population at present. Nevertheless, investments in vector control programs must be subjected to critical analysis in the interest of efficient and sound management. However, if high discount rates (e.g., 25%) are selected commensurate with economic risk in many developing countries, then it seems unlikely that vector control programs in these countries would ever be launched.

With respect to the screwworm eradication in Jamaica, discount of the benefits and costs at 11% and produce the following data (Table 26).

The benefit-cost ratio for screwworm eradication in Mexico was in the order of 10:1.

Who Should Pay for SIT Programs? Or How Much Does Each Group of Beneficiaries Gain?

In developing a concept of how the cost of an area-wide project should be partitioned between producers and consumers, it is helpful to consider the market effects on the market price of the commodity produced. An effective area-wide program will have the immediate effect of increasing supply of the commodity. The relative benefit to producers and consumers can be determined easily by analyzing the relationship of unit price to quantity of production.

If producers profit significantly from the SIT program (increased yield and lowered costs), they may be expected to expand the area under production. If the price of the commodity is elastic (because extra production is easily stored and exported), then an increase in supply will not

Sterile Insect Technique, Table 26 **Benefits and costs of screwworm eradication**

Discounted value	After year 3		After year 10	
	Scenario 1 (US$ million)	Scenario 2 (US$ million)	Scenario 1 (US$ million)	Scenario 2 (US$ million)
Benefits	18.3	18.3	48.0	48.0
Program costs	4.5	8.2	4.5	8.2
Net savings	13.8	10.1	43.5	39.8
Benefit-cost ratio	4.1:1	2.2:1	10.7:1	5.9:1

greatly reduce the market price. In this case, consumers are likely to benefit more than producers, and they should shoulder part of the program cost. On the other hand, for a commodity with an inelastic demand any program that greatly stimulates production will cause the unit price to fall, and this could be damaging to producers.

SIT programs have good potential for capturing returns through commercial sales or privatized management. Privatization is likely to become common for SIT where it is used for suppression rather than eradication. In eradication programs, the period in which sterile insects are used may be too short to recover the cost of private investment in a rearing facility. However, in suppression programs, profits realized over a much longer period can repay private investment in facilities and avoid the need for publicly initiated or coordinated control programs. In particular, the easy and efficient intercontinental transport of sterile insects by air can be expected to allow commercial competition based on price and quality and opportunities for specialization and economies of scale in production facilities.

Stern, Vernon M

Vern Stern was born in 1923 and died in 2006 after a long and illustrious career with the University of California, Riverside. He is remembered principally for his promotion of aspects fundamental to the integrated pest management (IPM) concept. Important aspects included restricting the use of insecticides to only when natural mortality agents were not functioning adequately, the economic threshold concept (treating with insecticides only when treatment was economically justified), and the recognition of the deleterious aspects of pesticide use. Vern Stern (along with Ray Smith, Robert van den Bosch and Ken Hagen) published a landmark paper on the concept of integrated control in Hilgardia in 1959 that laid out many of the key elements of IPM, and became a citation classic. This was followed by numerous papers on economic thresholds, strip cropping, and natural control, and he was also recognized as a leader in the field of biological control. A "colorful" individual who gave interesting and unpredictable talks, Stern was an effective mentor for numerous graduate students who spread around the globe and greatly enhanced the reputation of the University of California, where he served on the faculty from 1956 to 1991.

► Stick and Leaf Insects

Stick and Leaf Insects (Phasmida)

ERICH TILGNER
University of Georgia, Athens, GA, USA

Phasmida are terrestrial, nocturnal, phytophagous insects found in nearly all temperate and tropical ecosystems. Scientists have described over 3,000 species, yet this figure is uncertain since some taxon names are synonyms, and many new species have not been formally described.

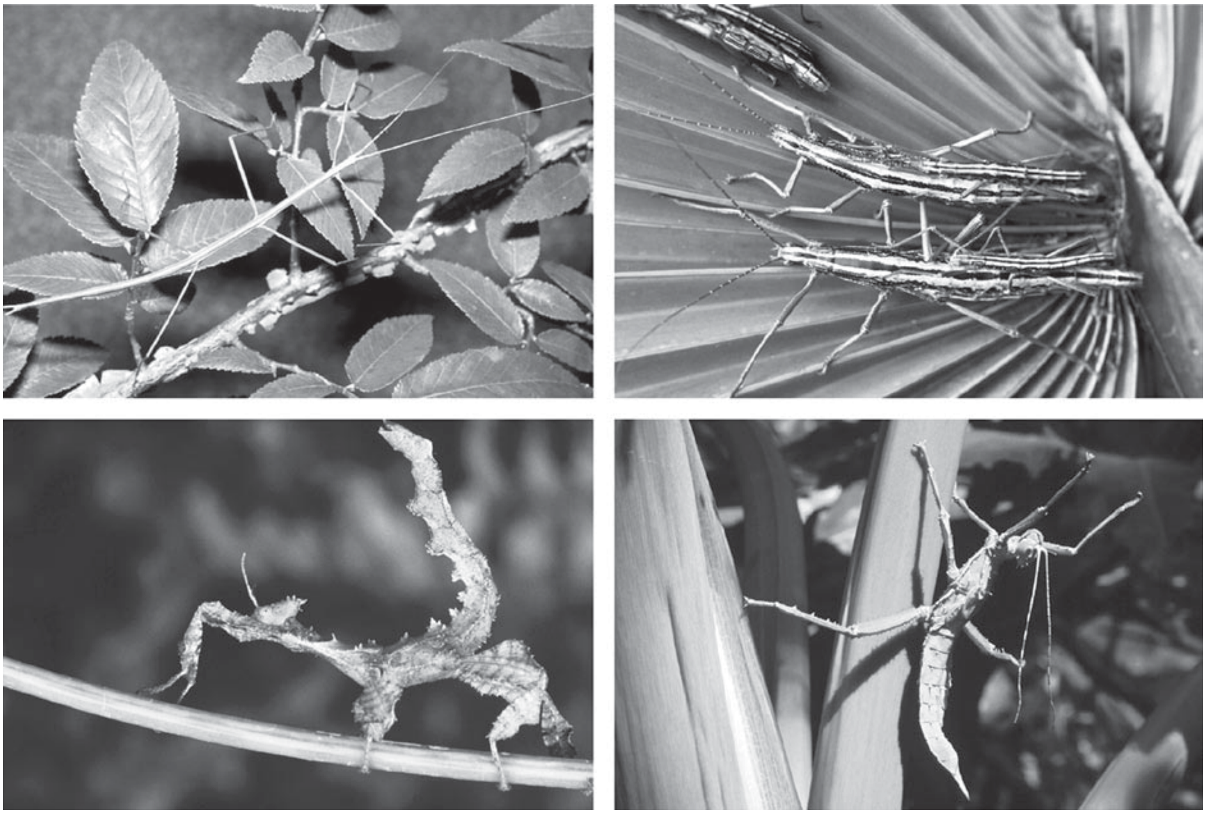
They are variable in appearance, ranging from relatively plain forms, to some that are wonderful mimics of sticks and/or leaves (Fig. 126). They display varying degrees of brachyptery, and can be winged or wingless. The tarsi have three articles in *Timema* Scudder and five in other Phasmida. Cerci are composed of one article, except for adult males of *Timema* which have a lobe on the right cercus.

Sexual dimorphism is usually extreme: the males are smaller and more gracile than the females. Reproduction is typically sexual, but parthenogenesis occurs frequently. The egg capsule is distinctively shaped, possessing a lid called the operculum and a micropylar plate. Eggs are large and oftentimes highly sculptured resembling plant seeds. They are laid singly, and are either dropped, flicked, buried, glued to a surface, or riveted to a leaf. Some species that drop the eggs rely on ants to disperse them in a process analogous to myrmecocory. The entire life cycle from egg to adult can take from several months to several years, depending on the species.

The order consists of two extant monophyletic groups: the genus *Timema* and the remaining species of Phasmida termed the Euphasmida. These two clades diverged at least 50 million years ago and are phenotypically distinct.

Timema are small, wingless Phasmida that lack elongation of the body segments. They have three tarsal articles, unlike other Phasmida which have five. Using her large paddle-shaped cerci, the female coats each egg with defecated soil before oviposition. This forms a coating that may protect the egg from fire.

Timema are found only in the mountains of the western United States and are primarily associated with the Chaparral biome. They live on their host plants and are highly cryptic due to their coloration and habits while resting. When disturbed they release a spray from the prothoracic exocrine glands, but it has not been demonstrated to have a defensive function. They are unusual in that they feed on a variety of plants, including both Gymnosperms and Angiosperms.



Stick and Leaf Insects (Phasmida), Figure 126 **Some stick insects: *top left*, *Diapheroma femorata*; *top right*, *Anisomorpha buprestoides* (Stoll); *lower left*, *Exactosoma tiaratum*; lower left, *Heteropteryx dilatata* (top photos by Lyle Buss, lower photos by Mike Turco).**

Euphasmida are commonly referred to as stick and leaf insects. Exquisitely camouflaged, many species look like twigs and may have the appearance of being covered by lichens, mold, bird feces, or moss. The leaf-like forms usually bear a striking resemblance to foliage, exhibiting leaf veins, mildew spots and even apparent insect feeding damage.

Their primary means of avoiding predators is crypsis. If discovered, they either play dead (catalepsy), or they try to scare the predator with a startle display which can include wing flashing, leg kicking, or spastic motion. Some species also release an irritating "tear gas-like" spray when disturbed. In addition, many Euphasmida can purposely lose some of their legs to help free them from a predator's grasp, or free them from the exuvia while molting. If this occurs during the immature stages, they can regenerate the lost limbs during successive molts.

Compared to other insects, Euphasmida are large, and a few are gigantic. Several species measure over 200 mm in length and the world's largest extant insect is the Euphasmida *Phobaeticus serratipes*, with one documented female measuring 555 mm.

Since Euphasmida are wonderful looking insects, and are relatively easy to rear in captivity, they are popular as pets and for displays at zoological gardens.

Stick Katydids

A subfamily of katydids (Saginae) in the order Orthoptera: Tettigoniidae.

► Grasshoppers, Katydids and Crickets

Sticky Trap

A method of insect sampling that uses an adhesive material to capture insects. Sticky traps normally use visual attraction based on color, or chemical attraction based on sex pheromone, to attract the insect to the trap. Some sticky traps depend instead on interception of flying insects with transparent material such as glass to obtain an unbiased assessment of population density because they do not concentrate the insects, as do lures.

► Traps for Capturing Insects

Stictococcidae

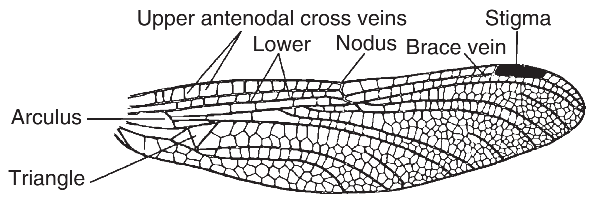
A family of insects in the superfamily Coccoidae (order Hemiptera). They are sometimes called false soft scales.

► Scales and Mealybugs
► Bugs

Stigma

The dense, often discolored portion of the costal margin of a wing, usually at the end of the radius. This is also known as the pterostigma (Fig. 127).

► Wings of Insects



Stigma, Figure 127 Front wing of a dragonfly (Odonata).

Stiletto Flies

Members of the family Therevidae (order Diptera).

► Flies

Stilt Bugs (Hemiptera: Berytidae)

MIGUEL COSTAS, ÁNGELES VÁZQUEZ
Universidad Complutense Madrid, Madrid, Spain

Berytids are characterized by a slender and elongate body, with long four-segmented antennae and very elongated and slender legs. The first antennal segments as well as the femora are thicker apically. They have a pair of ocelli in the head, three-segmented tarsi and a limited number of veins in the hemelytra. Some have long spines on the pronotum and scutellum. The suture between the clavus and corium is very conspicuous.

The family Berytidae was established by Fieber in 1851, in order to cluster seven genera. Traditionally, authors have divided this family in two subfamilies Berytinae and Metacanthinae, and this classification was maintained until 1995. Following cladistical analysis by Henry in 1997, which included all the genera in the world, this family was divided into three subfamilies, each with two tribes. The subfamily Berytinae with Berytini and Berytinini, Gampsocorinae with Gampsocorini and Hoplinini, and Metacanthinae with Metacanthini and Metatropini. Henry's phylogenetic analysis clarifies the monophyletic character of this family, as well as the relationships between this taxon and the rest of families that are part of the superfamily Lygaeoidea.

There are 170 species known worldwide, segregated in 35 genera. In the Paleartic Region there are 54 species in 35 genera, but only five tribes, because the tribe Hoplinini is not represented in the Paleartic fauna.

In general, the berytids present univoltine biological cycles with hibernating adults that seek refuge in leaf litter and mosses. Almost all species are polyphagous and there are some reports of facultative predaceous species, such as *Berytinus minor* attacking aphids. In general, the berytids of temperate regions do not represent a threat to crops. However, in Peru, *Jalysus wickhami* Van Duzee and *Parajalysus spinosus* Distant are pests in tomato and cacao crops respectively.

Stink Bugs (Hemiptera: Pentatomidae), Emphasizing Economic Importance

ANTÔNIO R. PANIZZI
Embrapa, Londrina, Brazil

This is one of the largest groups within the suborder Heteroptera, the so-called true bugs. This family is the third largest of the suborder; it is surpassed by the Reduviidae, the predatory assassin bugs, and the Miridae, the plant bugs or capsids, which is by far the largest family of Heteroptera. Of over 36,000 described species of true bugs, more than 4,000 species belong to the family Pentatomidae. The classification of the family is as follows:

Order: Hemiptera
  Suborder: Heteroptera
    Superfamily: Pentatomorpha
      Family: Pentatomidae

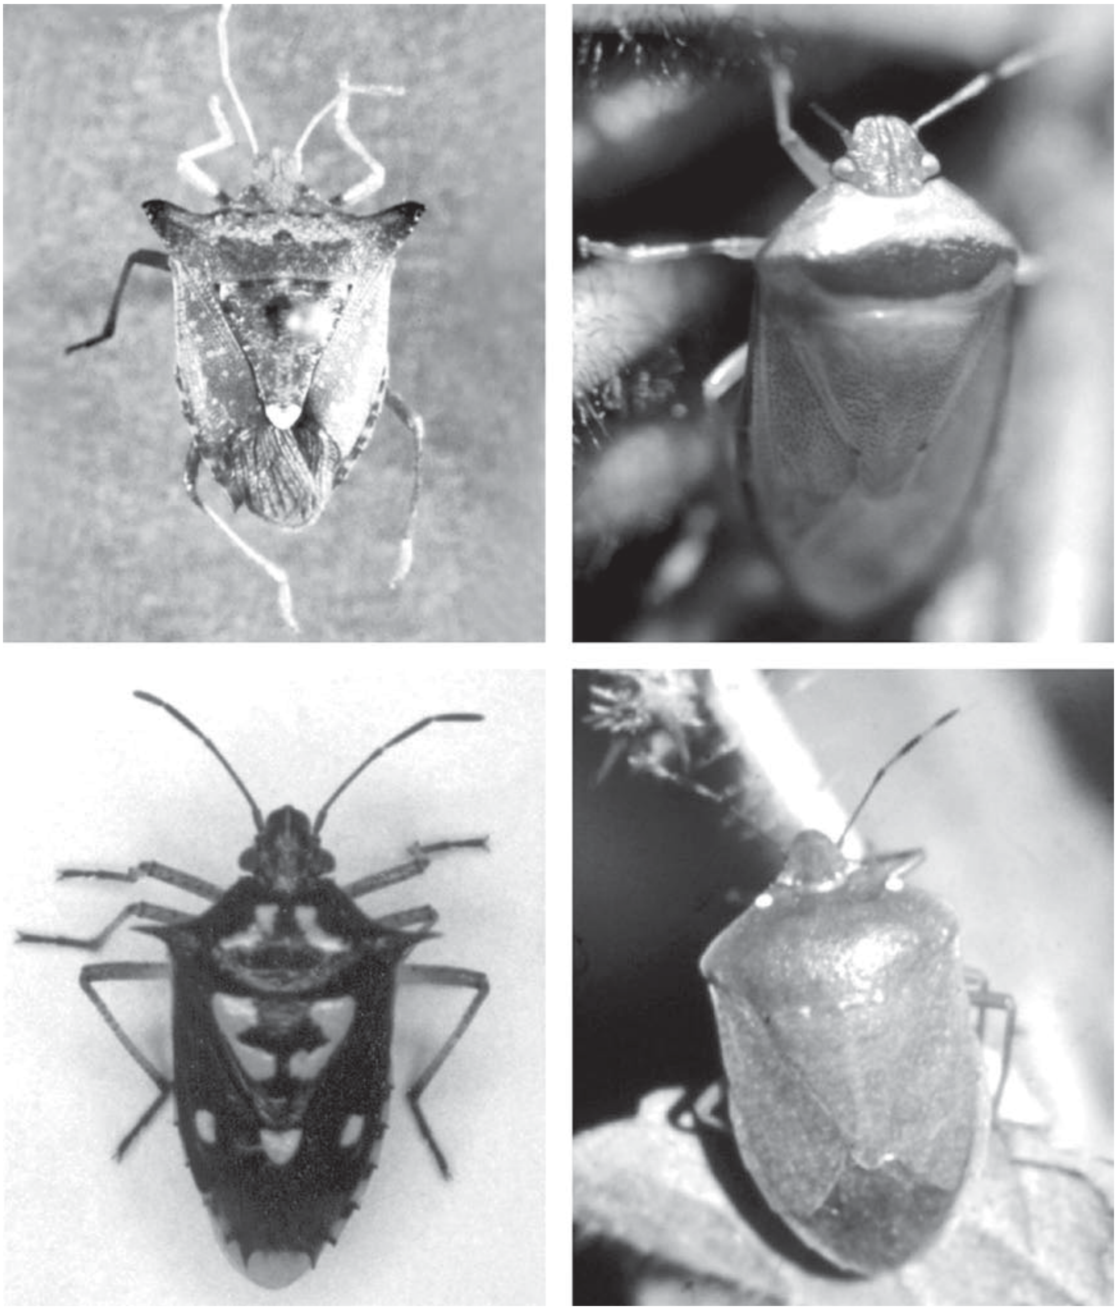
Within the family pentatomidae there are eight subfamilies: Asopinae, Cyrtocorynae, Discocephalinae, Edessinae, Pentatominae, Phyllocephalinae, Podopinae, and Serbaninae. Members of the subfamily Asopinae are distributed worldwide, and are predatory. Because of their feeding habits they are important biological control agents, particularly those of the genera *Podisus* and *Perillus*. Members of the subfamily Cyrtocorinae are found only in the Neotropical Region, and are cryptically colored, resembling tree bark. They are of minor economic importance, feeding on branches of weeds, shrubs or trees. Eventually they may be found feeding on soybean. The Discocephalinae are flat and colored dark, typical from the Neotropics and of no economic importance. The Edessinae are large stink bugs, being abundant in the Neotropics. They are pests of several crops, including Leguminosae and Solanaceae. The Pentatominae contains most of the species in the family and are plant feeders. They are cosmopolitan. These phytophagous pentatomids are characterized by being round or ovoid, with five-segmented antennae, three-segmented tarsi, and a scutellum that is short, usually narrowed posteriorly, and more or less triangular. Several species are pests of major crops, feeding mostly on legumes and brassicas, but by being extremely polyphagous, also damage fruit trees, nut trees, palms, etc. Members of the subfamilies Phyllocephalinae, Podopinae, and Serbaninae are, in general, flat, feeding on bark of trees. They are mostly present in the Neotropics. With very few exceptions, they are of no economic importance (Fig. 128).

Pentatomids are called stink bugs because they produce a disagreeable odor by means of scent glands which open in the region of the metacoxae. Some nymphs have scent glands located on the dorsum of the abdomen.

Stink bugs feed by inserting their stylets into the food source to suck up the nutrients. By doing this, they cause injury to plant tissues, resulting in plant wilt and, in many cases, abortion of fruits and seeds. During the feeding process, they also may transmit plant pathogens, which increase their damage potential. Because they feed on several plant species of economic importance, they are regarded as major pests.

The economic importance of these insects varies greatly from species to species and within a species depending on the plant attacked. From the subfamily Edessinae, the species *Edessa meditabunda* (F.) is a pest of many vegetable crops, particularly Solanaceae such as tomato and potato, and Leguminosae, such as peas, soybean, and alfalfa. It also feeds on cotton, eggplant, tobacco, sunflower, papaya, and grapes. Of the many host plants, soybean is perhaps the most important. Among the Pentatominae, the pest species injure a wide range of plants, from vegetables to trees. The generalist southern green stink bug, *Nezara viridula* (L.), is a pest of grain, legumes and vegetables worldwide; *Piezodorus* spp. feed mostly on legumes, being a severe pest of soybean in South America, in Africa, and in the Orient. Members of the genus *Euschistus* are major pests of several crops, mostly damaging legumes such as soybean in the New World; *Eurydema* spp. in the Orient also attack grain legumes and vegetables. Members of the genera *Oebalus*, *Mormidea*, and *Aelia* are major pests of Gramineae, particularly on rice and wheat. Pests of trees include the spined citrus bug, *Biprorulus bibax* Breddin, on *Citrus* spp. in Australia; *Lincus* spp. on coconut in South America; *Bathycoelia thalassina* (Herrich-Schaeffer) on cocoa in Africa; and *Plautia* spp. on orchard plants in the Orient. The wide ranges of bug species and the host plants fed upon, with frequently detrimental effects to plant production, make this perhaps the most economically important group of insects among the Heteroptera. As an example of this, total losses from Hemiptera during 1985, including stink bugs, were estimated at 3.5 million dollars for the pecan industry in Georgia. In addition, pentatomids may disturb human beings by invading houses in large numbers for overwintering. Finally, because they are polyphagous, pentatomids feed on an array of wild plants.

After copulating, which may last for several hours in an end-to-end position, stink bugs lay eggs in clusters. First instars remain on the top of egg shells, apparently acquiring symbionts, and do not feed. During the second and third stadia, they are gregarious and feed, in general, on immature seeds of their host plants. As nymphs develop through the fourth and fifth stadia, the gregarious behavior decreases, and



Stink Bugs (Hemiptera: Pentatomidae), Emphasizing Economic Importance, Figure 128 **Some stink bugs (Pentatomidae) of economic importance: *top left*, Neotropical brown stink bug, *Euschistus heros*; *top right*, small green stink bug, *Piezodorus guildinii*; *lower left*, small rice stink bug, *Oebalus poecilus*; *lower right*, southern green stink bug, *Nezara viridula*.**

nymphs disperse. Fifth instars molt into adults, which usually disperse further to colonize other host plants. Several generations (1–7) are produced per year, depending on the favorability of abiotic (e.g., temperature, photoperiod, humidity) and biotic (e.g., food availability) factors.

Stink bugs have several natural enemies, the most common being the egg parasitoids

(Hymenoptera) and tachinid flies (Diptera: Tachinidae), which are parasites of adults. Birds also prey on stink bugs.

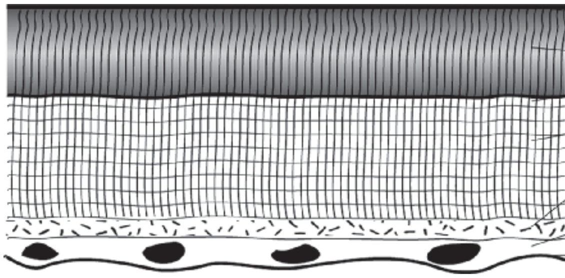
St. Louis Encephalitis

JORGE R. REY
University of Florida, Vero Beach, FL, USA

St. Louis encephalitis is the most important mosquito-transmitted disease in the United States. It was first detected in the city after which it is named in 1939 where it claimed 220 lives. It is distributed throughout most of the continental United States although epidemics have only occurred in the Midwest and Southeast. The Centers for Disease Control (CDC) report more than 4,000 confirmed cases in the United States since 1964. The disease is also found in parts of Central and South America and the Caribbean. The pathogen that can cause the disease is an arbovirus (arthropod-borne virus). These viruses are maintained in nature



Schmidt's Layer, Figure 130 **Cross section of the insect cuticle and epidermis (adapted from Chapman, The insects: structure and function).**

through transmission between vertebrate hosts and blood-feeding arthropods (mosquitoes, flies, ticks, etc.). The St. Louis encephalitis virus belongs to the family Flaviviridae and is related to the Japanese encephalitis virus.

The Virus Transmission Cycle

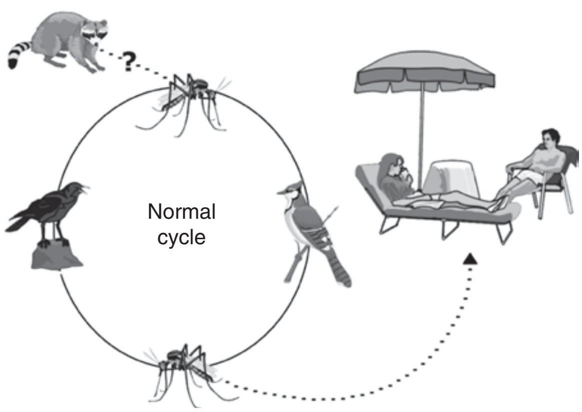
The transmission cycle of St. Louis encephalitis is not completely known, but we know that wild bird populations are of paramount importance in the cycle. When a wild bird is infected by the bite of a carrier mosquito, it produces large amounts of the virus in its bloodstream that can then infect other mosquitoes that subsequently bite the bird. This process is known as "amplification" and is essential for virus transmission. The hosts, in this case wild birds, are known as "amplification hosts." Birds do not show any symptoms of the disease and become immune after infection. In an infected mosquito, the virus replicates and invades other parts of the body, including the salivary glands. From there, the virus can be transferred to other hosts because when mosquitoes bite they inject a small amount of saliva to act as an anti-coagulant.

Mosquitoes remain infective for life, but the virus disappears from the amplification host in a few days. As more and more birds become immune after recovering from the infection, transmission to uninfected mosquitoes diminishes. Therefore, as infected mosquitoes die off (they usually live a week or two) the epidemic subsides. It is unclear what roles other vertebrates such as raccoons and squirrels play in the transmission cycle of St. Louis encephalitis. Mosquitoes known to play a role in transmission of the St. Louis encephalitis virus include *Culex nigripalpus* in Florida, *Culex pipiens* and *Culex quinquefasciatus* in the Midwest and Gulf Coast, and *Culex tarsalis* in western states.

Although humans are not part of the natural transmission cycle, they can become infected by the bite of a vector mosquito. However, humans are "dead-end hosts," meaning that sufficient amplification of the virus does not occur in humans and therefore, uninfected mosquitoes cannot acquire the virus from a human. Also, St. Louis encephalitis is not transmitted directly from human to human (Fig. 131).

Symptomology and Treatment

There have been more than 4,000 human cases of St. Louis encephalitis reported in the United States since 1964. However, less than 1% of St. Louis encephalitis infections are clinically apparent and the vast majority of cases go unreported. Symptoms of infection range from mild headaches and low fever to full meningoencephalitis symptoms including severe headaches and high fever, impaired motor skills, drowsiness, seizures, and central nervous system malfunction. Neurological symptoms may persist for some time after the disease has subsided. Symptoms are usually milder in children than in adults and are most severe in the elderly. Mortality rates for the disease range from 5 to 15%.



St. Louis Encephalitis, Figure 131 Transmission cycle of St. Louis encephalitis.

All resident of areas where active cases of the disease have been confirmed are considered at risk of contracting the disease. Disease risk increases in those persons that are frequently exposed to mosquito bites. The elderly are particularly prone to exhibit severe symptoms and death. Diagnosis of the disease is confirmed by a fourfold rise in antibody titer, or detectable immunoglobular M antibody in sera or cerebrospinal fluid, or by isolation of the viral agent from the patient. Other techniques such as enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction techniques can increase the speed and accuracy of diagnosis, and are increasingly being used in clinical settings. There is no specific treatment for the disease and no vaccines are available for humans. Affected persons are given supportive treatment for the symptoms and after-effects.

Preventing Infection

As in most arthropod-transmitted diseases, prevention involves personal protection and control of the vector populations to break the transmission cycle in nature. Personal protection includes the use of clothes that protect against mosquito bites (long-sleeved shirts and long pants), the use of repellents containing DEET, and avoidance of areas where mosquitoes are present, particularly after dark, when the *Culex* mosquitoes are most active. Vector population control includes the use of approved pesticides to kill adult and/or immature mosquitoes, and reduction or elimination of sites known to breed mosquitoes.

Surveillance programs are important parts of disease prevention. An effective surveillance program can provide an early warning of when the risk of disease transmission to humans is high. During those times, local health departments may alert the public that personal protection measures against mosquito bites are advisable. It can also trigger increased mosquito control efforts in the affected area. Surveillance programs monitor virus activity in nature, usually by monitoring virus activity in captive chicken flocks ("sentinel chickens"). Weather, particularly rainfall, is an important factor in prediction of vector abundance and is thus an integral part of successful surveillance programs. Direct monitoring of mosquito abundance, behavior, and movement is obviously of paramount importance in predicting risk for human populations, and a variety of techniques are routinely used by mosquito control and health agencies to monitor these vector-related variables. Finally, if disease transmission to humans does occur, it is important to monitor the distribution of cases in time and space, to determine the demographic characteristics of infected persons, and to try to determine the likely place of exposure for each case.

Stonebrood

Aspergillus spp. fungi cause a disease in honeybees called stonebrood. Several species may be involved, although *A. flavus* and *A. fumigatus* are most commonly implicated. Larvae and pupae are transformed into stone-like mummies, which is the basis for the name of this disease. The disease is known from Europe, North and South America.

These fungi are ubiquitous, and found widely in the soil. They affect other insects, not just honey bees, and also other organisms. Both larval and adult bees are susceptible to infection. Infection occurs by ingestion of spores. Eventually the fungus sporulates on the surface of the insect, imparting a greenish color. These fungi are not highly infectious, and normally only a small part of the colony is affected. Some have suggested that the disease only appears when colonies are stressed. There is no good treatment, but colonies are commonly burned if the beekeeper is concerned about spread of the disease.

Stoneflies (Plecoptera)

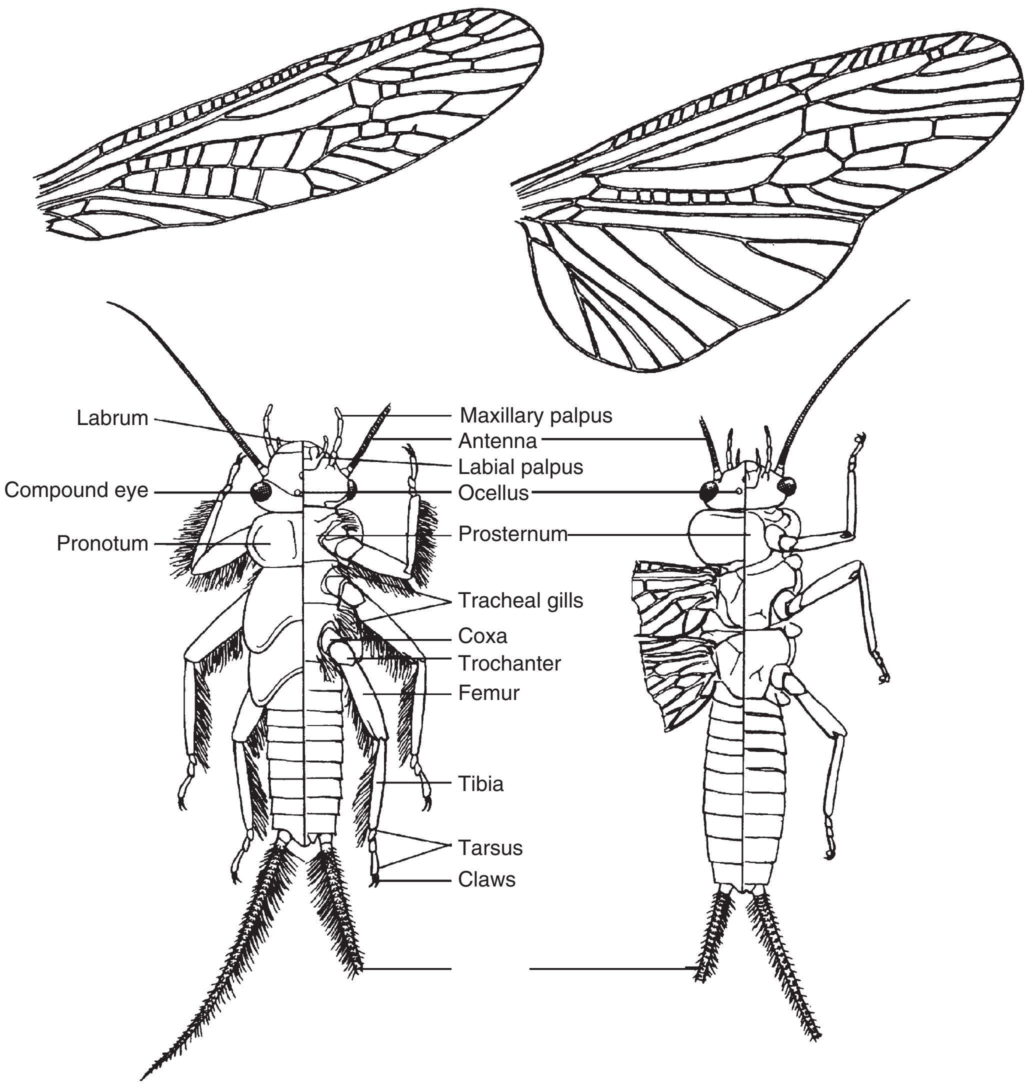
BORIS C. KONDRATIEFF
Colorado State University, Fort Collins, CO, USA

The order name Plecoptera is derived from the Greek "pleco" or folded and "ptera" or wings. More than any other order of insects, stoneflies are typical inhabitants of running waters. Nearly all species occur exclusively in streams, and many are restricted to running water habitats of mountainous regions of the world. Usually water temperatures of these streams are below 25°C and have high dissolved oxygen levels. These requirements make them excellent indicators of water quality.

Stoneflies display incomplete metamorphosis (hemimetabolous development), though it is sometimes called gradual metamorphosis (paurometabolous development). Adult stoneflies can be distinguished from other insects that undergo hemimetabolous development by the long, thin antennae; membranous wings, when not used, lying flat over the abdomen; and the front wings straight and about the same length as the body. The front wings usually have a "fish skeleton-like" venation pattern. The hind wings usually have an expanded posterior area that folds like a fan. Some adult stoneflies have reduced wings or even lack wings. All stonefly adults have two tails or cerci that project from the end of the abdomen; however, in some species these are reduced to a single segment. In addition, all stoneflies have three tarsal segments and two tarsal claws on each leg (Fig. 132).

The nymphs have either cylindrical or flattened bodies; the head has long, thin antennae and wings pads are usually present on the thorax in more mature individuals. Three pairs of segmented legs are present bearing three-segmented tarsi with two terminal claws, and two long, thin tails or cerci occur at the end of the abdomen. Some species have single or branched gills on the thorax or abdomen.

Most stonefly nymphs are herbivores, feeding principally on plant detritus. Even the young nymphs of many carnivorous species feed on fine detritus before switching to animal prey. The Perlodidae, Perlidae, and Chloroperlidae are predominantly predators as older instars. Mature nymphs range in length from a few millimeters (some



Stoneflies (Plecoptera), Figure 132 **Diagram of stonefly wings (*above*); adult female stonefly (*lower right*); immature (*lower left*). Note that the adult and immature are divided into a dorsal perspective (*left portion* of each diagram) and ventral perspective (*right portion*).**

capniids) to over 5 cm (Pteronarcyidae). Although some species emerge in autumn, most stoneflies transform to adults in spring or early summer. Mature nymphs often congregate at emergence sites such as piles of rocks, bridge abutments, and woody debris. The cast skins or exuviae of the nymphs are often abundant at these sites.

Stonefly nymphs occur most commonly in lotic habitats with rocky bottoms and with high dissolved oxygen concentrations, but some species are restricted to seeps and springs, and others to high gradient coldwater streams. One species is known only in both nymphal and adult stages from the depths of Lake Tahoe. Many stonefly nymphs, when subjected to low dissolved oxygen concentrations, will exhibit a "push up" behavior that apparently increases the rate of water movement over the body and gills.

A remarkable behavior of adult stoneflies is the two-way communication between sexes called drumming. Males tap, rub or scrap their elongated abdomens upon various substrates such as branches and leaves. The female adult detects this vibration and she will answer, allowing for an eventual location of each other. The drumming pattern in amplitude, frequency, or duration is species specific.

Numerous "winter stoneflies" occur in North America. These species typically emerge as soon as openings appear in the ice (late winter, early spring); the dark-colored adults are seen on snow-covered stream banks, bridges, fence posts or tree trunks. The remarkable aspect of these stoneflies is the reversal of the typical development pattern of aquatic insects, in that growth and maturity occur during the coldest part of the year. Eggs laid by adult females during the winter or early spring hatch quickly, and the nymphs migrate into the interstitial spaces of the loose, rocky streambed (known as the hyporheic zone) and begin a state of inactivity or diapause throughout the warmer months. As water temperatures begin to cool in the fall and early winter, nymphs move back to the substrate surface and complete development.

The classification of the order is relatively well established, with over 2,000 species in the world placed in 16 families. Nine of these families occur in North America, including about 626 species. The following web site, maintained by R.E. DeWalt, provides a listing of all North American species by province or state: http://plsa.inhs.uiuc.edu/plecoptera/.

- Order: Plecoptera
  - Suborder: Arctoperlaria
    - "group" Euholognatha
      - Family: Capniidae
      - Family: Leuctridae
      - Family: Nemouridae
      - Family: Notonemouridae
      - Family: Taeniopterygidae
      - Family: Scopuridae
    - "group" Systellognatha
      - Family: Chloroperlidae
      - Family: Peltoperlidae
      - Family: Perlidae
      - Family: Perlodidae
      - Family: Pteronarcyidae
      - Family: Styloperlidae
  - Suborder: Antarctoperlaria
      - Family: Austroperlidae
      - Family: Diamphipnoidae
      - Family: Eustheniidae
      - Family: Gripopterygidae

A short synopsis of the families found in North America follows:

Family Capniidae (Small Winter Stoneflies)

This family is composed primarily of small species. It contains many "winter stoneflies," with adults typically emerging from January to April. The numerous species are most common in small streams, including seeps and springs. Nymphs are usually found in leaf packs, accumulations of woody debris, and develop during the coldest water temperatures of winter. The early instars diapause in the hyporheic zone of the stream. Most species of capniids are detritivore shredders. Common genera include the eastern *Allocapnia* and the western *Capnia*.

Family Leuctridae (Rolledwinged Stoneflies)

Nymphs occur in lotic habitats from intermittent streams, springs to small rivers, and are associated primarily with leaf packs, woody debris or mineral substrates. Nymphs are considered shredder-detritivores. Adults of some species emerge during late winter to early spring (*Paraleuctra*), some during the entire summer (*Leuctra*), and others in the fall (*Despaxia*). Some species are very tolerant of low pH.

Family Nemouridae (Nemourid Stoneflies)

Nymphs occur in a wide range of aquatic habitats, from seeps and springs to lakes. Some species also are found in large rivers. Nymphs typically occur in leaf packs, woody debris, but also rocky areas. Most species are restricted to higher elevations. Most adults are recognized by one-segmented cerci and the X-pattern of veins of the front wing. The life cycles vary from 1 to 2 years for completion. Emergence of adults occurs typically in the spring, but some species emerge in the winter, and others in the fall. Several genera are common, *Amphinemura* in eastern North America and *Malenka* in western North America.

Family Taeniopterygidae (Winter Stoneflies)

This family is another well-known group of "winter stoneflies." Adults in warm-weather regions emerge during the winter, and in cool climates and at high elevations they emerge through the spring and early summer. The nymphs, characterized by their stout, robust habitus with divergent wing pads, can be found in almost all sizes of permanent streams. Nymphs usually are associated with leaf packs, wood debris, but also coarse mineral substrates. They are primarily detritivore shredders. The common genera in the east are *Strophopteryx* and *Taeniopteryx*, and *Taenionema* in the west.

Family Chloroperlidae (Green Stoneflies)

Chloroperlid nymphs are small, elongate, gill-less inhabitants of the hyporheic zone, the interstitial spaces between substrate particles in the streambed. Some species reside at considerable depths in the substrate and laterally under the banks. Most species are found only in clean, cool streams of mountainous areas. Adults are recognized by slender bodies and yellow or green coloration. The western genus *Paraperla* is a collector-gatherer and scraper. Other genera are predaceous on other aquatic insects (often chironomid midges), but also act as collector-gatherers. The genus *Sweltsa* is one of the most common genera.

Family Perlidae (Common Stoneflies)

The distinctively patterned yellow and brown nymphs can be found in all types of streams from intermittent to large rivers, and some species occur along wave-swept shores of lakes. Members of this family inhabit warmer waters than most other stoneflies. Nymphs are usually associated with large loose rocks, but also leaf packs, woody debris, and submerged logs.

Several genera, *Hesperoperla* and *Claassenia* in the western USA and *Acroneuria* and *Paragnetina* in the eastern USA, are relatively large and conspicuous stoneflies. The nymphs are predatory, feeding largely on other aquatic insects. The life history varies from 1 to 3 years, with most adults emerging from May to August. Adults often can be found attracted to lights near streams.

Family Perlodidae (Perlodid Stoneflies)

Perlodid nymphs are medium to moderately large-sized and predatory. If gills are present, they are simple (unbranched) and are restricted to the thorax or neck region, except in the rare California genus *Oroperla*, which has lateral gills on abdominal segments. Nymphs of most species are restricted to cool, swift, mountain streams with rocky bottoms. Some species are found only at splash zones of seeps. Others are restricted to large silty western rivers. All species apparently have a single generation per year. Emergence is generally in the spring, but some species are active as adults in the fall. Several species have egg diapause as long as 5–7 months. *Isoperla* is the most common and widespread genus in North America.

Peltoperlidae (Roach-Like Stoneflies)

The "roach-like" appearance of the nymphs makes them one of the most recognizable of all North American stoneflies. Nymphs can be abundant in leaf packs of small woodland streams of the southern Appalachians. Some species are restricted to splash zones of seeps, springs, and even intermittent streams. All species are shredders-detritivores and are important in the breakdown of leaves. Adults generally emerge in the spring and early summer.

Family Pteronarcyidae (Giant Stoneflies)

Nymphs of this family are usually found in cool steams and rivers of small to medium size. Nymphs can be especially abundant in accumulations of woody debris, or among large rocks in the swifter reaches. They are shredders that typically feed on submerged leaf material, but sometimes take in animal material. The life cycle requires 1–4 years to complete, depending on geographic location. Adult emergence typically occurs in May or June for most species. The adults are the largest stoneflies found in North America, reaching 5–6 cm.

Members of the genus *Pteronarcys* are known as salmonfly to anglers, and are widespread over most of North America, whereas the other genus, *Pteronarcella*, is restricted to the west. Adults and nymphs use reflex bleeding to repel potential predators.

Stop Codon

One of the three mRNA codons (UAG, UAA, and UGA) that prevents further polypeptide synthesis.

Storage Protein Receptors

NORBERT H. HAUNERLAND
Simon Fraser University, Burnaby, BC, Canada

During metamorphosis of holometabolous insects, most larval structures are broken down, while adult tissues are formed. Many new proteins need to be synthesized, requiring vast mounts of amino acid precursors. These amino acid resources, however, must be present prior to pupation, because pupae are not able to feed and take up nutrients from external sources. Specific larval serum proteins, often called "storage proteins," provide these amino acid resources. These proteins accumulate in the hemolymph of last instar larvae, and move shortly before pupation into the fat body, where most new proteins are synthesized. Storage proteins enter the fat body in small vesicles, which fuse with one another to form larger, often crystalline protein granules. As development progresses, these granules are hydrolyzed to provide the needed amino acids.

Most storage proteins are members of the hexamerin family; these proteins are composed of six subunits of 80 kDa each, and are evolutionarily related to hemocyanin. The most common storage protein is arylphorin, a protein rich in aromatic amino acids, but most species contain other storage proteins as well. In one lepidopteran family (Noctuidae), an additional, structurally unrelated storage protein has been found: a very high density lipoprotein (VHDL) composed of four 150 kDa subunits. VHDL is colored brightly blue, due to biliverdin that is bound non-covalently to the protein.

The uptake of storage proteins into fat body cells is selective. Storage proteins are present at very high concentrations in the hemolymph of last instar larvae in both lepidopteran and dipteran species, but prior to pupation they are efficiently removed from the hemolymph, and sequestered by the fat body. Other hemolymph proteins, such as lipophorin, remain in the hemolymph. Storage proteins enter the fat body via endocytosis; to be selective, the uptake is mediated by specific endocytotic receptors, proteins that are associated with the fat body membrane. Such receptors have been found in Diptera and Lepidoptera.

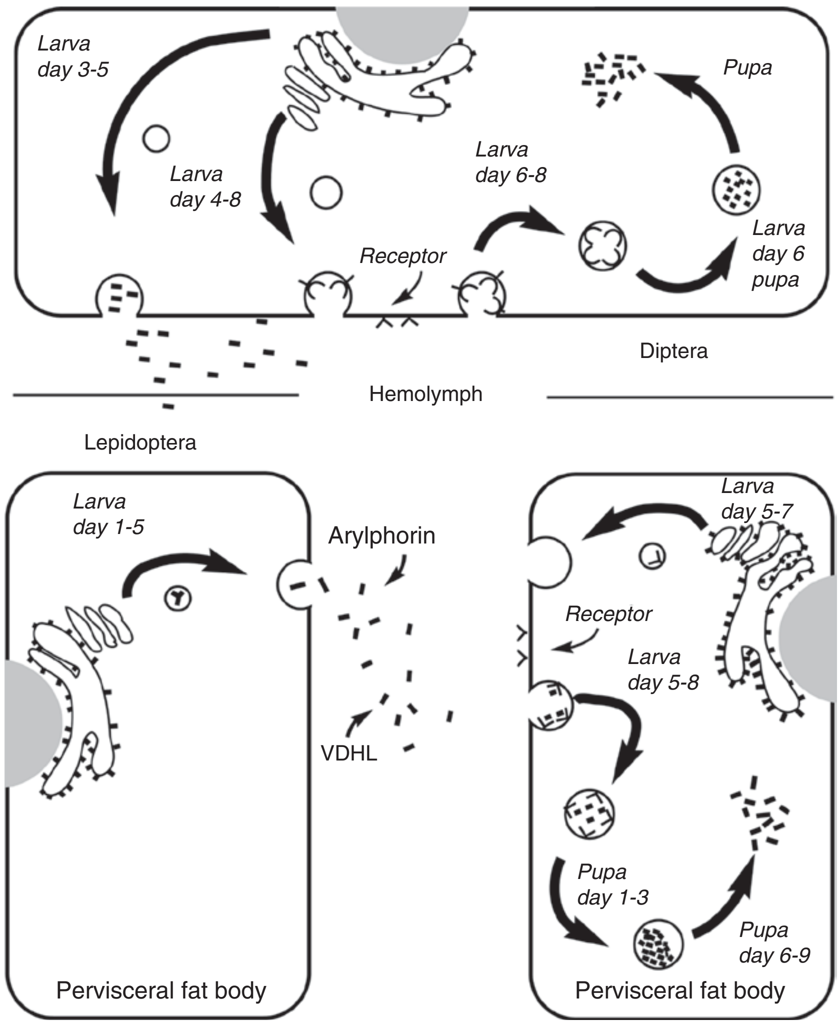
Dipteran Storage Protein Receptors

Storage proteins receptors have been identified in two dipteran species, namely the fleshfly *Sarcophaga peregrina* and the blue bottle fly *Calliphora vicina*. These proteins bind arylphorin in a saturable manner, with dissociation constants between 2 and 800 nM. Binding generally requires Ca^{2+} ions and is pH dependent, with optimal binding at the slightly acidic pH of the hemolymph (pH 6.5). While the reported molecular weights for the arylphorin receptor vary between 50 and 140 kDa, it is now clear that the observed variability is the result of the cleavage of an initial protein of around 140 kDa. The protein is encoded by a gene that is evolutionary related to its own ligand, arylphorin, and other members of the hexamerin superfamily. The genes of the arylphorin (or storage protein) receptors of *Calliphora vicina* (Genbank ID 630903) and *Sarcophaga bullata* (Genbank ID 984655) show high sequence homology with the previously identified fat body P1 protein from *Drosophila melanogaster* (Genbank ID 544281) which appears to be the storage protein receptor in that insect species. The transcription of the latter gene is under the control of the hormone 20-hydroxy ecdysone. While the exact mechanism of action of the receptor remains unclear, proteolytic cleavage of the initial gene product is necessary for the formation of the active receptor. Following the removal of the signal peptide, a protease removes a C-terminal fragment of approximately 50 kDa. The remaining receptor protein is then moved to the outside of the cell, where it can bind to its ligand. The uptake of the bound arylphorin, however, cannot occur until the receptor is further processed by another protease, which appears to be under the control of the hormone 20-hydroxy ecdysone, however at the post-translational level.

Interestingly, the active receptor does not contain a typical membrane spanning domain, and is likely a peripheral membrane protein that is attached to the membrane through another transmembrane protein (Fig. 133).

Lepidopteran Storage Protein Receptors

In contrast to the activation of the dipteran storage proteins receptor, the receptor identified in Lepidoptera does not seem to be regulated by



Storage Protein Receptors, Figure 133 **Model of storage protein uptake and use. The times of the various events are indicated as days after hatching for the dipteran species, and as days after the preceding molt for Lepidoptera.**

proteolytic cleavage. The apparent receptor is a basic 80 kDa protein that is glycosylated. In *Helicoverpa zea*, the protein binds arylphorin as well as VHDL, with similar binding constants (Kd approximately 100 nM). Binding of its ligands occurs between pH 6.5 and 7.5, and requires at least 4 mM Ca^{2+}. The receptor protein can be found only during the second half of the last larval instar, and only in those regions of the fat body that take up storage proteins, located centrally surrounding the gut (perivisceral fat body). In contrast, the storage proteins themselves are synthesized in different regions of the fat body (peripheral fat body). Electron microscopy revealed that the uptake process occurs through classical receptor mediated endocytosis, via coated pits that are internalized as coated vesicles into the perivisceral fat body, where they fuse to form endosomes. Fusion with primary lysosomes leads to the digestion of membrane components and of the receptor protein, so that the electron dense protein granules containing arylphorin and VHDL can be formed.

The receptor protein is generally associated with the cell membrane fraction, and cannot be found in the hemolymph. It does not bind to antibodies against arylphorin or VHDL, and antibodies raised against the receptor do not cross-react with these or other cytosolic proteins. Its sequence was recently reported; the receptor appears to be also related to members of the hexamerin superfamily, namely to the basic juvenile hormone suppressible proteins identified in another noctuid species. It is not entirely clear how it is associated with the fat body cell membrane. Although it contains one potential transmembrane region, it lacks other motifs typically found in endocytotic receptors, like adaptin binding sites that link the receptor to the coat protein clathrin. Hence, another integral membrane protein may be required to serve as an intermediary of the uptake process, as it has been suggested for dipteran species.

Storage Proteins

DANIEL A. HAHN
University of Florida, Gainesville, FL, USA

Insect life cycles are characterized by periods of feast and famine, wherein times of high nutrient demand are not always associated with high nutrient intake. This is evident in molting and metamorphosis, a time when insects require substantial nutrients for fueling metabolism and body building but are not feeding. Therefore, raw materials for molting and metamorphosis must come from nutrient reserves accumulated during prior larval feeding. Nutrient storage is a critical trait for insect physiology and life cycles because it decouples times of nutrient need from times of availability, and numerous insect life history traits such as holometabolous development, long-distance migration, diapause, and reduced adult feeding would not be possible without extensive nutrient reserves. In addition to storing fat and carbohydrates, insects are capable of storing large quantities of amino acids in specialized storage proteins. Storage proteins are functionally defined as proteins that are synthesized during feeding, when amino acid availability is in excess of demand, and depleted to provide substrates during periods of high demand, such as molting. The best characterized and most common storage proteins are the hexamerins, which have been found in all insects that have been investigated. However, non-hexamerin proteins that appear to function as storage proteins have been identified in Lepidoptera, Hymenoptera, and Coleoptera, suggesting that proteins with amino acid storage functions have evolved multiple times within the insects.

Hexamerins: Structures and Evolutionary Relationships

The hexamerins are a family of proteins consisting of six identical or similar subunits with molecular weights between 70 and 90 kD each. These proteins are synthesized by the fat body during feeding and secreted into the hemolymph where they can accumulate to very high concentrations. An amazing diversity of protein storage strategies exists among insect species, wherein any single species can synthesize between one and five different hexamerins. Furthermore, patterns of hexamerin synthesis, accumulation, and utilization throughout the lifecycle can differ both among the various proteins within a species and among homologous proteins between species. For example, the hexamerins in three grasshopper species have been well studied and all three species show a different pattern of storage protein accumulation and utilization: (i) the American locust *Schistocerca americana* contains a single abundant storage hexamerin during both nymphal development and in adulthood; (ii) the migratory locust *Locusta migratoria* contains two storage hexamerins, including one that accumulates to high levels in nymphs but is not present in adults, and one that occurs in only low levels in nymphs but is present in high levels in adults; (iii) the lubber grasshopper *Romalea microptera* contains three different hexamerins that are synthesized and utilized in both the larval and adult stages.

Much of the early efforts to characterize hexamerins were based on biochemical properties of the proteins. Across all organisms most proteins differ little in total amino acid composition. Therefore, elevated contents of particular amino acids within a protein suggest a specific function. Two groups of insect hexamerins immediately stood out based on their amino acid composition. Hexamerins in many insect species were termed arylphorins because they contained high quantities of the aromatic amino acids phenylalanine and tyrosine, up to twice as much as in the average protein. Similarly, some hexamerins identified in Lepidoptera contained almost twice as much methionine than the average protein and were termed methionine-rich hexamerins. Other hexamerins were initially characterized by functional observations, such as the riboflavin-binding hexamerins and the juvenile hormone-suppressible hexamerins of Lepidoptera. Some hexamerins were also named by their occurrence during the insect life cycle. For example, the larval storage hexamerin of the migratory locust, *Locusta migratoria*, is found only in larvae whereas the persistent storage hexamerin occurs in larvae and persists into adulthood. Antibody cross-reactivity was also frequently used to assess homology between hexamerins within and between species. Due to their hexameric shape and similar-sized subunits, it was hypothesized that hexamerins were derived from the hemocyanins, respiratory proteins found in other arthropods that form hexamerins or multi-hexamer aggregations and utilize two copper ions in each subunit to bind and transport oxygen in the blood.

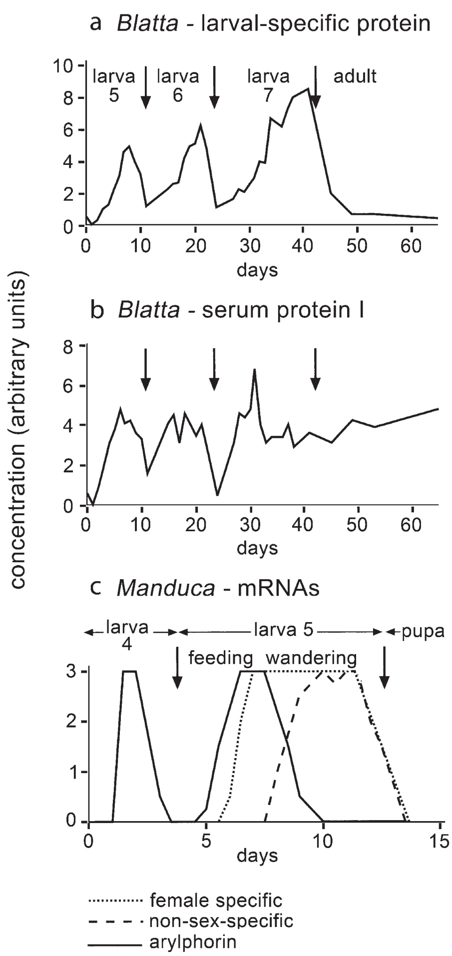
Accumulation of nucleotide sequence data followed by phylogenetic analysis has established that the hexamerins are part of the larger arthropod phenyloxidase-hemocyanin-hexamerin protein family (Fig. 137). While the majority of insects exchange gases directly with the environment via the tracheal system, some basal groups also contain hemocyanins that facilitate oxygen transport and storage in the blood like those observed in crustaceans. Insect hemocyanins have been best studied in the stonefly *Perla marginata* (Plecoptera) which has retained a functional hemocyanin composed of two different subunits containing copper-binding sites. Interestingly, phylogenetic analysis of the two subunits suggests that one is more basal and the other is sister to the insect hexamerins. Therefore, it is thought that the insect hexamerins evolved early during the hexapod radiation, likely due to the duplication of basal insect hemocyanin genes that secondarily lost their copper-based oxygen binding sites. The high efficiency of tracheal gas exchange may have later facilitated the loss of hemocyanin-based oxygen transport in the blood of higher insects. In support of this hypothesis, putative hemocyanins have been identified in many hemimetabolous orders, but appear to be absent from the holometabola. This scenario for the evolution of storage hexamerins from functional hemocyanins after the insects diverged from crustaceans is bolstered by a convergent evolutionary event in crustaceans wherein the Dungeness crab, *Cancer magister*, contains both hemocyanin for oxygen transport and a hexameric protein called cryptocyanin, which has lost its copper-oxygen binding sites. Like insect hexamerins, cyrptocyanin is accumulated during the intermolt feeding period and utilized during molting. Similarly, the American lobster, *Homarus americanus*, contains both a functional hemocyanin and a cryprocyanin-like molecule that has lost its copper-oxygen binding sites and may play a role in molting.

Within hexapods, divergence of the hexamerins largely follows that of the insects themselves (Fig. 136). All hemimetabolous groups appear to contain a single lineage of hexamerins, while the Diptera and Lepidoptera each contain more than one distinct clade of hexamerins. In Diptera the two hexamerin clades, the LSP-1 and LSP-2 protein groups, are sister to each other. In contrast, among the three clades of Lepidopteran hexamerins the arylphorins and methionine-rich hexamerins are sister to each other, but the riboflavin-binding hexamerins appear to have evolved earlier and are basal to the rest of the hexamerins in holometabola. Both the Dipteran LSP-1 group and the lepidopteran arylphorins have very high contents of the aromatic amino acids phenylalanine and tyrosine (>15%) that play a key role in cuticular growth and sclerotization. Prior to phylogenetic analysis of hexamerin nucleotide sequences these two groups were thought to be homologous. However, it is now clear that one lineage in each group has converged on the disproportionate accumulation of aromatic amino acids. Interestingly, hexamerins of some basal clades such as grasshoppers and cockroaches are also higher in aromatic amino acids than the typical protein suggesting that the functional demand for aromatic amino acids for producing cuticle proteins and sclerotization during molting may have affected amino acid composition independently several times within the hexamerins.

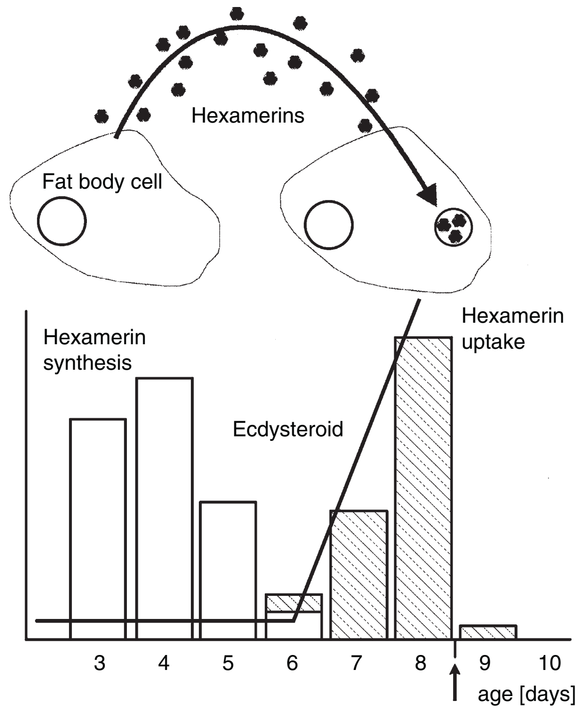
Hexamerins in Nymphs and Larvae

Hexamerins are synthesized during juvenile feeding and can accumulate in large quantities in the hemolymph during the intermolt period. Hexamerin transcripts have been found expressed in a variety of tissues including the epidermis, gut, brain, and ovaries, but the majority of hexamerin expression and protein synthesis occurs in the fat body. Hexamerins synthesized in the fat body are secreted into the hemolymph where they accumulate. The timing and extent of hexamerin synthesis can differ dramatically among species and between different hexamerins within a species (Fig. 134). For example, larvae of the tobacco hornworm, *Manduca sexta*, synthesize three different hexamerins. The *Manduca* arylphorin is expressed in the penultimate larval instar and again at the beginning of the final larval instar prior to wandering, whereas the *Manduca* female-specific hexamerin and methionine-rich hexamerin are not produced until after wandering in the last instar. Because insects do not feed during molting, hexamerins provide a critical pool of amino acids for the large pulse of protein synthesis that occurs during the molt. In hemimetabolous insects such as the cockroach *Blatella orientalis*, hexamerins accumulated in the hemolymph during inter-molt feeding are largely depleted at the time of molting, although some can also be carried into adulthood. During the molting event, storage hexamerins are taken up from the hemolymph and hydrolyzed and their constituent amino acids are incorporated into a vast array of tissues, such as cuticle and muscle. Although hexamerins are largely broken down, some evidence exists for the incorporation of intact hexamerins or large peptide fragments directly into structures such as cuticle.

Holometabolous larvae tend to accumulate even greater quantities of hexamerins in their blood during larval feeding than hemimetabolous nymphs. These hexamerins are transiently stored in the hemolymph, as in hemimetabola, but are largely taken up out of the hemolymph into the fat body prior to metamorphosis (Fig. 135). Hexamerin uptake is mediated by a specific receptor-mediated endocytotic process induced by ecdysteroids during the larval wandering period just prior to pupation, after which hexamerins are concentrated in distinctive protein granules in the fat body cells. Amino acids can be subsequently mobilized from protein granules to support both energy metabolism and catabolic building reactions during metamorphosis.



Storage Proteins, Figure 134 **The timing of expression and accumulation of particular storage proteins can differ within a species lifecycle. For example, the larval specific storage protein of *Blatta orientalis* is only accumulated by larvae and is utilized prior to adulthood (a), whereas the persistent storage protein accumulates in both larvae and adults (b) (modified from Duhamel and Kunkel, 1978). The three storage proteins expressed by larvae of *Manduca sexta* differ slightly in the timing of their transcription during the last instar (c) (modified from Riddiford and Hice, 1985).**

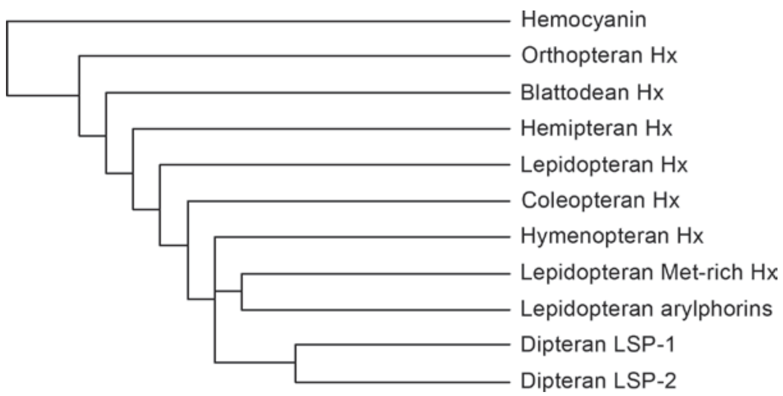


Storage Proteins, Figure 135 **Hexameric storage proteins are synthesized by the fat body and secreted into the blood during the feeding period in the last instar larvae of the blowfly, *Calliphora vicina*, age days 3–5 after laying on the x-axis. Once the larvae wander from the food, synthesis ceases and storage proteins are taken back up by the fat body cells via specific receptor-mediated endocytosis (days 6–8), clearing storage proteins from the blood (taken from Burmester and Scheller, 1999).**

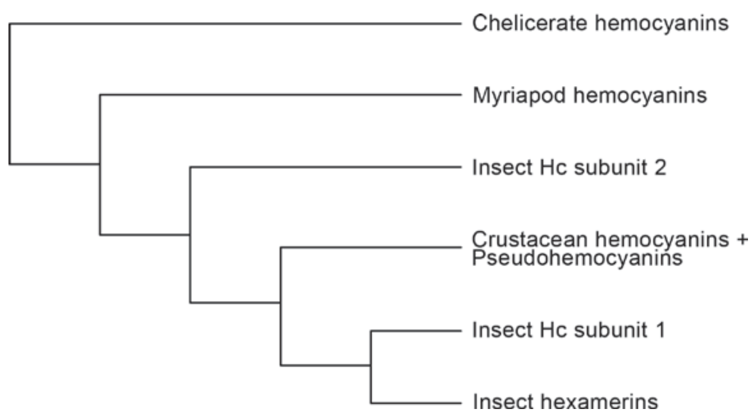
Among species that express multiple types of hexamerins, their distinct amino acid profiles, patterns of uptake from the hemolymph, localization within the fat body, and incorporation into different tissues or substrates is evidence for specialization of hexamerins for distinct roles in metamorphosis and post-metamorphic development. For example, larvae of the monarch butterfly, *Danaus plexippus*, produce an arylphorin that is used to support metamorphosis and adult development and two methionine-rich hexamerins that are used to support egg development later during adulthood.

Hexamerins in Adults

While hexamerins were initially characterized as larval-specific proteins, it is clear that they also



Storage Proteins, Figure 136 **This phylogenetic tree showing the relationships among the insect hexamerins, supports the hypothesis that the hexamerins were present in the most basal insects and diversified along with the insects (modified from Burmester, 2002).**



Storage Proteins, Figure 137 **This Bayesian phylogenetic tree shows the relative relationships of the two subunits of the insect hemocyanin to the crustacean hemocyanins and the insect storage hexamerins and crustacean pseudohemocyanin storage proteins, supporting the hypothesis that the storage hexamerins are derived from hemocyanins (modified from Burmester and Hankelen, 2007).**

play important roles in adult insects. Although hexamerins are used during molting and metamorphosis, some species carry significant quantities of hexamerins over from larval life into adulthood. This is particularly apparent in the Lepidoptera wherein most species do not feed on significant quantities of protein as adults and therefore rely on larva-derived protein reserves to support egg production. Females of many Lepidoptera species will store greater quantities of hexamerins or will contain a different complement of hexamerins than males, and amino acids from these hexamerins have been shown to be utilized for vitellogenesis. Similarly, larvae of autogenous mosquitoes that can reproduce without taking a blood meal have been shown to accumulate greater quantities of hexamerins than their anautogenous counterparts, which must feed on blood to obtain the amino acids necessary to reproduce. The importance of larva-derived amino acid reserves is readily apparent in species with adults that do not protein feed, however, larva-derived protein reserves may also play important roles in insects that continue to feed on protein as adults. For example, lines of *Drosophila melanogaster* that were genetically manipulated to eliminate or drastically reduce the production of the larva-expressed LSP-1 hexamerin did not show any significant developmental or metamorphic defects, but had significant reproductive deficiencies in both males and females.

Many insect species have also been shown to synthesize and accumulate hexamerins during adult feeding. Accumulation of hexamerins in adults is often greater in females with hexamerin depletion occurring to support vitellogenesis. An extreme example of adult hexamerin accumulation occurs in claustral-founding ant queens that accumulate substantial hexamerin stores in their natal colonies prior to mating flights. After the mating flight, these queens seclude themselves in a nest chamber and use stored fat and hexamerins to rear their first brood without foraging; semi-claustral queens that will forage during founding and queens of parasitic species do not accumulate substantial hexamerin stores prior to the mating flight.

Other Hexamerin Functions

Many species of diapausing insects accumulate greater nutritional reserves than their non-diapausing counterparts, including the accumulation of hexamerins which lead to their initial characterization as "diapause proteins." For example, diapause-destined adults of the Colorado potato beetle, *Leptinotarsa decemlineata*, accumulate more than twice the quantity of DP-1 hexamerin prior to burrowing into the soil and entering diapause than equivalently-aged, non-diapausing individuals. This hexamerin pool is utilized to support metabolism during the non-feeding diapause period and to support post-diapause functions, such as rebuilding the thoracic flight muscles. Interestingly, the wax moth, *Galleria mellonella*, continues to actively synthesize hexamerins during the non-feeding larval diapause period. In addition to serving as amino acid reservoirs, it has been suggested that hexamerins play other roles during diapause, such as altering blood osmolarity to prevent cold-induced damage or acting as part of the humoral immune defense.

Hexamerins may also have other important physiological functions aside from nutrient storage in non-diapausing insects. Hexamerins from many species have been shown to bind organic molecules in the hemolymph including juvenile hormone, ecdysone, pesticides, and vitamins such as riboflavin. The low binding coefficients of hexamerins for many of these organic molecules has prompted some authors to suggest that this binding role is accidental due to the presence of hydrophobic residues in the hexamerins. However, hexamerins can occur in great abundance, as much as 60% of hemolymph protein, so despite low binding coefficients the sheer numbers of hexamerins available for binding molecules hexamerins may still have a physiologically important role in organic molecule binding. One of the most intriguing current topics is whether hexamerins can act as signaling molecules during juvenile and adult development. For example, the peak of hexamerin accumulation in adult females of the lubber grasshopper, *Romalea microptera*, is directly associated with the timing of juvenile hormone release that initiates vitellogenesis. This has prompted the suggestion that hexamerin accumulation may serve as an internal signal that the animal has reached an appropriate nutritional condition to successfully reproduce, triggering the endocrine cascade leading to egg production. In addition to diapause and reproduction, differences in hexamerin titers have been associated with developmental polyphenisms, such as the solitary and migratory phases of locusts or the castes of bees, ants, and termites. A recent study on the development of the soldier caste in the termite, *Reticulitermes flavipes*, has shown that manipulating the titer of storage hexamerins affects whether nymphs differentiate into soldiers or remain as nymphal workers. Whether this dramatic effect of decreased hexamerin titer on development was due to a shift in the nutritional milieu of the nymphs or was due to alteration some other function of the hexamerins, such as binding juvenile hormone or other organic molecules, is currently unknown.

Other Storage Proteins

In addition to the hexamerins, unrelated proteins that appear to perform a similar storage function have been identified in several species. A very high density lipophorin (VHDL) has been shown to play a storage role in several species of noctuid moths. In the corn earworm, *Helicoverpa zea*, VHDL occurs as a dimeric protein that contains approximately 10% lipid, far less than typical lipid-transport proteins but much more than the hexamerins. VHDL is synthesized by the fat body of feeding larvae, secreted into the blood, and taken back up into the fat body at pupation, after which it is broken down and used to support metamorphosis. Dimeric VHDL-like proteins have also been identified in honeybees, wasps, and ants where they have been associated with seasonal cycles and colony founding. Lepidopteran and Hymenopteran species that contain VHDL also contain hexamerins and the patterns of accumulation and utilization appear to be similar in the two groups of proteins, begging the question of whether there are functional differences between VHDL and hexamerins. In addition, a group of tyrosine-rich storage proteins has been identified in several beetle species. Two major characteristics differentiate these tyrosine-rich storage proteins from the hexamerins and VHDL: (i) they are composed of much smaller subunits ranging in size from 20 to 50 kDa, and (ii) while they are synthesized in the fat body and utilized during metamorphosis, these tyrosine-rich storage proteins are never released into the hemolymph. However, like other known storage proteins they accumulate during feeding and are depleted at metamorphosis. Considering the diversity of form, function, and phenology of the known storage proteins, there may also be other groups of proteins that serve storage functions during juvenile or adult reproductive development that remain to be identified.

Stored Grain and Flour Insects and Their Management

JEFFREY C. LORD
U.S. Department of Agriculture, Grain Marketing and Production Research Center, Manhattan, KS, USA

Hundreds of insects are found in stores of grain and milled cereal, but only a few species cause direct damage to products that are in sound condition. Most pest species can feed only on processed or damaged grain and mold, and their presence results in food contamination with their waste, caste skins, webbing, and body parts. Insects may also contribute to the conditions that cause grain to heat and mold. Approximately fifty species are deemed pests of economic concern. Nearly all of them are beetles or moths.

Environmental Factors

Insect infestation in stored grain is fostered by moisture, moderate heat, and damaged kernels. Not only does high moisture content in grain and processed food provide a favorable physical environment for development of many pest species, it also fosters the development of the molds on which some insects feed. The most favorable grain moisture range for stored grain insects is from 12 to 18%. In many instances, insect infestation amplifies mold problems in grain by exposing otherwise hidden endosperm surfaces to molds, transporting mold spores to new areas and encouraging mold germination in microhabitats made moist by insect metabolic activity. Indeed, insect and mold metabolic activity can raise grain temperatures.

At grain temperatures below 60°F (15°C) insect development and activity are minimal and pest populations can be expected to remain static. Temperatures a few degrees above 35°F (90°C) are detrimental or lethal to stored-product insects, and brief treatments of 122°F (50°C) are used for stored-product pest control.

Grain insects move within the grain mass at a rate that is determined by the season and grain temperature. During the summer and fall, insect infestations are usually on the surface of the grain. In cold weather, insects congregate at the center and lower portions of the grain and may escape detection until high population numbers are reached.

The presence of damaged grain, dust, and chaff, collectively known as dockage, is quite beneficial to the survival and reproduction of insects that feed externally. For example, flour beetles are reportedly unable to maintain populations in dockage-free wheat. Accordingly, grain stored without cleaning is subject to more severe insect infestation than is cleaned grain.

Damage

Some insects, designated primary pests, damage grain by developing inside kernels (egg, larvae, pupae), feeding on the inner endosperm, and chewing holes in the kernels through which the adult insects exit. The five primary pests of stored grain in the U.S.A. are the lesser grain borer, *Rhyzopertha dominica* (Fabricius), the rice weevil, *Sitophilus oryzae* (L.), the granary weevil, *Sitophilus granarius* (L.), the maize weevil, *Sitophilus zeamais* Motschulsky, and the Angoumois grain moth, *Sitotroga cerealella* (Olivier) (Gelechiidae), all of which deposit eggs in undamaged kernels. Other insect species, designated secondary pests, do not develop within the kernels, although they may hide inside cracked grain, making detection very difficult. Some secondary pests, including most of those designated as grain beetles, feed primarily on mold. Other species such as the sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.), the flour beetles, and moth larvae feed on damaged grain or fines.

Insect damage can reduce grain quality through loss of weight or nutritional quality, spreading and encouraging mold germination, adding to the fatty acid content of the grain, and leaving quantities of uric acid that cause grain rancidity. Insects also create fines and broken kernels when feeding that reduce air flow through grain and prevent proper aeration. In addition, the presence of insects in a grain sample can cause price discounts and shipping restrictions.

In the U.S.A., the presence of two insects of any kind in 1 kg of wheat, rye, or triticale causes the grain to be graded the lowest quality category, sample grade. Insect tolerances in finished commodities such as flour or cornmeal are stricter.

Perhaps the most difficult problems associated with insect infestation of grain are quarantine and export restrictions. Many nations require the fumigation or return of grain shipments that harbor the Khapra beetle, *Trogoderma granarium* Everts. Under the most restrictive export laws, detection of a single insect in grain precludes its shipment.

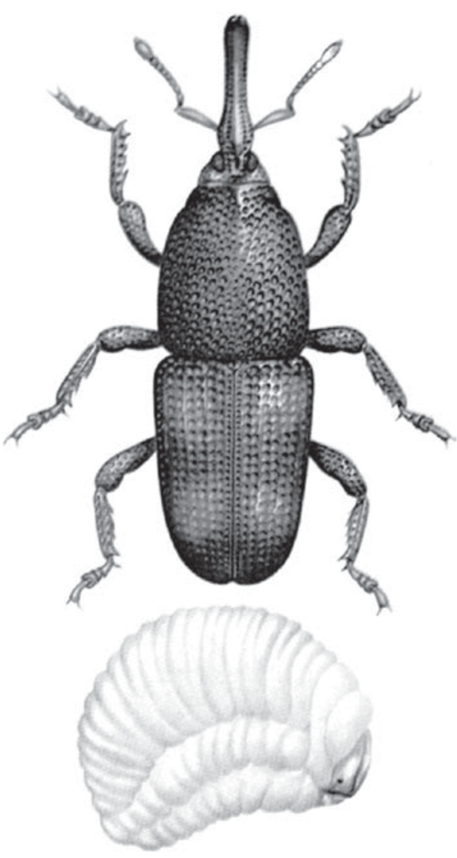
Monitoring and Control

Grain processing facilities are monitored by light or pheromone traps and by visual inspections. In stored grain, plastic pitfall traps are the dominant method, but sticky traps are useful for headspaces. Also, grain can be inspected by screening or sieving and searching in the screenings for insects, examining kernels for damage, checking grain for webbing, and investigating off-odors. Monitoring is especially important in summer and early fall when temperatures are optimum for rapid development. Grain temperature should be monitored as an indicator of grain condition and to locate areas of bulk grain in which conditions are favorable for insects. The number of insects found in traps is recorded and charts constructed so that changes in population size can be easily noticed and management tactics can be implemented as needed. Traps are used following control interventions to determine whether the treatments are effective.

The first defense against stored-grain insects is exclusion by means of pest-resistant construction, protective packaging, and sanitation. Empty storage and processing facilities can be treated with chemical insecticide sprays. Residual grain protectants are sometimes added directly to grain at the beginning of storage. These are usually organophosphates, but synergized pyrethrum or diatomaceous earth may be used. The dominant method for control of insects in stored grain is fumigation with phosphine. Non-chemical controls include temperature modification, either by heat treatment or lowering temperature through aeration. Atmosphere modifications to reduce oxygen are used primarily outside the U.S.A.

Grain Weevils

The three economically important species of the weevil family Curculionidae that infest cereal grains in storage are the rice weevil, *S. oryzae* (Fig. 138), the maize weevil, *S. zeamais*, and the granary weevil, *S. granarius* (L.). Adult weevils can be distinguished from other grain-infesting insects by their long snouts with chewing mouth parts at the tip and elbowed antennae. Both the rice and maize weevils have two light areas on each elytron and dense small, nearly round pits on the pronotum, giving a rough appearance. The granary



Stored Grain and Flour Insects and Their Management, Figure 138 **Rice weevil, *Sitophilus oryzae* (L.): adult above, larva below.**

weevil is uniformly colored and has less dense elliptical pits on the pronotum, giving the prothorax a glossier appearance than that of the other two species. Adults of all three species are dark brown, with the rice and maize weevils being slightly darker than granary weevils. Adult maize and granary weevils are 3–4.5 mm long, and the slightly smaller rice weevils are about 3 mm long. Egg, larval, and pupal stages are spent within the grain kernel. The larvae of all three species are nearly identical, being legless and crescent shaped. As with the adults, larvae of maize and granary weevils are slightly larger than larvae of rice weevils.

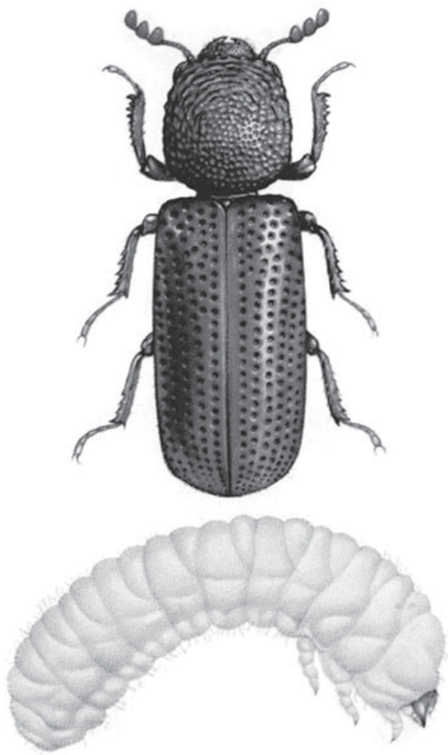
After mating, a female weevil uses her long snout to chew a small cavity in a grain kernel into which she places an egg. She then seals the hole with a gelatinous egg plug. From this time until the new adult chews its way out of the kernel, the infestation is inapparent. Each female can lay as many as 300–400 eggs in her lifetime. Under similar conditions, rice weevils generally lay more eggs than maize or granary weevils. Two rice weevils may develop in a wheat kernel, one on either side of the crease, but usually only one maize or granary weevil develops in a kernel. The four larval instars feed on the endosperm of the grain kernel. Pupation and adult emergence take place within the kernel. The adult chews its way out of the kernel, leaving visible damage behind. About one third of a wheat kernel is consumed by rice weevils and over half by maize or granary weevils. Under favorable conditions, granary weevils require about 40 days to complete their development and maize and rice weevils about 35 days. Almost immediately after emerging as adults, the females are mated and the developmental cycle is repeated. The adult weevils live as long as 5–8 months.

The rice weevil is the most destructive pest of stored grain. It is found in all parts of the world where grain is used and is particularly abundant in warm climates where it breeds continuously. Although wings are present some question the ability of the rice weevil to fly. Infestations of grain field origin lend credibility to the presumption of flight ability. The rice weevil's habitat is almost identical to that of the granary weevil. The granary weevil is one of the oldest known insect pests. It has been carried to all parts of the world by commerce. It prefers temperate climates and, in the US is more frequently found in the northern states than the southern states. The granary weevil cannot fly and must reside in accumulations of grain or be carried from place to place in infested lots of grain. Maize weevils are capable of flight, and in warm areas, they commonly fly to fields and infest corn before it is harvested. They can easily move from one lot of stored grain to another.

Grain Borers

The family Bostrichidae, which comprises mainly wood-boring beetles, has two species that are important primary pests of grain. The lesser grain borer, *R. dominica* (Fig. 139), is one of the most damaging insects found in grain, especially in wheat. The larger grain borer *Prostephanus truncatus* (Horn) is a more serious pest of maize in warm tropical areas, especially where maize is stored on the cob.

Adults of the lesser grain borer are cylindrical and about 3 mm long. The prothorax forms a hood over the head, which is directed downward. The hood has distinct, sharp tubercles on the top and near the front margin of the prothorax. The wing covers have rows of indentations, but they are glossy. Each antenna has a distinctive loose, three-segmented club at the end. Individual segments of the club are frequently found in flour milled from wheat that has been infested with the lesser grain borer. The adult has functional flight wings and is a strong flyer. Most larvae develop inside whole grain kernels and thus are rarely visible. The larvae have three pairs of small legs located on the segments immediately behind the head. The head is a partially withdrawn into the thorax. The body of the larva is grub-like with the thorax and last segments of the abdomen enlarged.



Stored Grain and Flour Insects and Their Management, Figure 139 **Lesser grain borer, *Rhyzopertha dominica* (F.): adult above, larva below.**

The female lays as many as 300–400 eggs, placing them among, but not inside the grain kernels, sometimes in clusters of up to 45. Larvae chew into kernels or penetrate through cracks in the pericarp. Inside the kernel, the borers pass through three to five larval instars and a pupal stage and emerge as adults. In some instances, where broken kernels and much dust are present, larvae may feed and develop externally. Adult insects live an average of 7–8 months and often return to kernels from which insects have emerged to feed and more extensively damage the grain.

Lesser grain borer infestations are characterized by the presence of grain dust and a characteristic sweetish, musty odor. The dust is mostly fecal matter. In localized heavy infestations, the dust and heavily damaged kernels form compacted areas that can cause uneven aeration or fumigant penetration.

The lesser grain borer is better able to survive in drier grain than the weevils, which probably accounts for its being a more serious pest of farm-stored wheat in the central and southern plains areas of the United States.

Larger grain borers are similar to lesser grain borer in development, habits, and appearance. The adults also have the typical cylindrical borer shape, but they are somewhat larger than the lesser grain borer, measuring 3–4 mm in length. In contrast to those of the lesser grain borer, the posterior portions of the elytra are steeply flattened with many small tubercles on the surface. The head is turned under and covered by the prothorax. The antennae terminate in flattened, three-segmented clubs similar in appearance to those of the lesser grain borer. The larvae are similar in appearance to the lesser grain borer larvae, but larger.

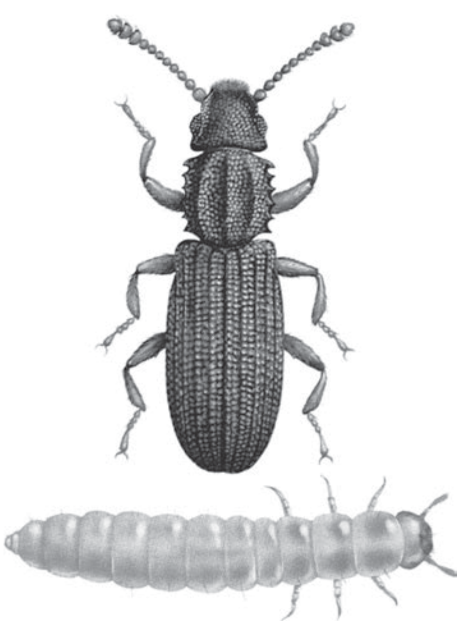
The larger grain borer is a serious pest of corn, as well as dried cassava. It is seldom found in the United States but is common in Central and South America. It was introduced into Kenya in the 1970s and has rapidly spread across sub-Saharan Africa, where it has become an extremely serious pest. The climate and the prevalence of farm storage corn on the cob in parts of Africa are particularly favorable for larger grain borer infestations. Adult borers infest corn shortly before and after storage. Shelled corn is a marginal medium for development, but unhusked corn is particularly vulnerable to infestation. Females bore into the attached kernels and lay eggs in side tunnels. Larvae feed mainly on dust, much of which is created by adult feeding. The developmental cycle can be completed in about 27 days under optimum conditions and about a week longer in dry grain.

Grain Beetles

Often the most abundant insects in stored grain are those belonging to a guild of dorso-ventrally-flattened beetles that feed on damaged grain, dust and mold. None of these grain beetles attack undamaged grain. The larvae of grain beetles do not stay within a single grain, but crawl about actively to feed. The development times are typically about a month under favorable conditions, and populations often build up rapidly.

The family Laemophloeidae includes eight species in the genus *Cryptolestes* that are secondary pests of cereals and cereal products. Two are prominent, particularly in moist environments. The rusty grain beetle, *Cryptolestes ferrugineus* (Stephens), is a cold-tolerant species and is often the most abundant insect in stored grain in temperate climates. The flat grain beetle *Cryptolestes pusillus* (Schönherr) is a minute beetle of about 1.5 mm in adult length. It is cosmopolitan, but less tolerant of low temperature and humidity than the rusty grain beetle and is more common in warm moist climates such as Southeast Asia.

The members of the family Silvanidae are generally larger (2–4 mm adults) and more active than *Cryptolestes* species, but they lack the flying ability of *Cryptolestes*. The sawtoothed grain beetle, *O. surinamensis* (Fig. 140), derives its common name from the tooth-like projections on the sides of its thorax. It is among the best-known cosmopolitan pests in stored grain and grain products and is considered the most serious stored grain pest in the United Kingdom. The merchant grain beetle, *Oryzaephilus mercator* (Fauvel), is often confused with the sawtoothed grain beetle, but it prefers oilseed products, including nuts. Several other Silvanidae can infest cereals but are of minor importance.



Stored Grain and Flour Insects and Their Management, Figure 140 **Sawtoothed grain beetle, *Oryzaephilus surinamensis* (L.): adult above, larva below.**

Flour Beetles

In the family Tenebrionidae, *Tribolium castaneum* (Herbst), the red flour beetle, and *Tribolium confusum* Jacquelin du Val, the confused flour beetle, are the most intractable insect pests of grain and flour processing areas. They are notoriously difficult to control with chemical insecticides. The adults are 3–4 mm long, reddish brown to brown and rather glossy. The light, honey-colored larvae have darkened heads and darkened forked processes at the tips of their abdomens that distinguish them from other grain-infesting larvae. Like other grain insects that feed externally, the larvae develop best in the presence of grain dust and broken kernels. Where such material is abundant, flour beetles can develop in grain with as little as 8% moisture content. The larvae will pass through 5–11 larval instars depending on growing conditions, and pass from egg to adult in less than a month under ideal conditions. The adults are known to live for up to 5 years.

Stressed or agitated flour beetles secrete quinones that have a pungent odor and can give a pink hue to heavily infested flour. There is concern that the quinones may be carcinogenic.

Mealworms

The mealworms comprise several large members of the family Tenebrionidae that are nocturnal and frequent dark, damp places. Three species are common, the yellow mealworm *Tenebrio molitor* L., the dark mealworm *Tenebrio obscurus* Fabricius, and the lesser mealworm, *Aphitobius diaperinus* Panzer. The yellow and dark mealworms are the largest insects found in grain and grain products. The larvae are 26–30 mm long and resemble wireworms. Under natural conditions, the yellow and dark mealworms complete only one generation per year and, consequently, are not serious pests. The lesser mealworm is similar to the yellow and dark mealworms, but reaches only 5.5–7 mm in length. All three species prefer damp, out of condition grains and grain products, but they also feed on various deteriorating food materials. Lesser mealworms are especially common in poultry feed.

Dermestid Beetles

Dermestidae is a small but important family whose members scavenge and feed on animal matter. It includes some 55 species that have been reported as stored-product pests. The black carpet beetle, *Attagenus megatoma* (Fabricius), is a cosmopolitan species that is often found in cracks in warehouses, but most of the dermestid pests are *Trogoderma* species. *Trogoderma* adults are reddish-brown to black, ovoid and convex, mainly 2–4 mm in length, and covered with scales. The larvae are very hairy, with setae of various characteristic shapes. *Trogoderma inclusum* LeConte, *T. glabrum* (Herbst), and *T. variable* Ballion are common pests of grain, seed, and other stored products. The adults of these beetles live only 1–3 weeks, but development from egg to adult can take from 1 month to as long as a few years. The ability of the larvae to remain in a quiescent state for several months in the absence of food makes *Trogoderma* species especially dangerous pests.

The Khapra beetle is the only truly phytophagous dermestid beetle. It feeds on many stored foodstuffs in addition to grain. Worldwide, it is the most destructive member of this group. The Khapra beetle is believed to have been eradicated from the U.S. in 1961 and has been a quarantine target since that time.

Other Beetles

The cadelle, *Tenebroides mauritanicus* (L.), is a member of the family Trogositidae that infests flour, meal, and grain worldwide. Larvae and adults have the destructive habit of moving from kernel to kernel, devouring the germs. Both stages are omnivorous and will eat other insects.

The cigarette beetle, *Lasioderma serricorne* (Fabricius) and the drugstore beetle, *Stegobium paniceum* (L.) are in the family Anobiidae. Both are found in all temperate and subtropical regions. As its common name indicates, the cigarette beetle infests tobacco, but it also attacks various food products, including grain. Its ability to penetrate packaging materials makes it a threat to high value stored products. The drugstore beetle has an extremely diverse diet, and takes its name from its ability to feed on pharmaceutical drugs.

Lepidoptera

Among the Lepidoptera, there is only one important primary feeder in grain, the Angoumois grain moth. It is a pest of stored grain throughout the tropics and subtropics, primarily in on-farm stores. Each larva eats out the inside of a single grain and remains in the grain through pupation, leaving no visible signs of infestation. The complete life cycle requires approximately 1 month at 30°C. Adults are 5–7 mm long, pale brown moths with fringed wings and long up-turned labial palpi. The female adult lives only 5–12 days, during which time she lays about 200 eggs. Angoumois grain moths are thought to compete with *Sitophilus* spp. for larval habitat and may dominate in drier habitats that are stressful for the weevils.

In the family Pyralidae, the subfamily Phycitinae or knot-horn moths, comprises the most important secondary lepidopterous pests of stored grains. Among them, the Indianmeal moth *Plodia interpunctella* (Hübner) (Fig. 141) is the most important pest of stored foodstuffs worldwide. It is especially common on corn, hence its common name.

In grains the larvae feed primarily on embryos. During the development of the 5–7 instars, Indianmeal moth larvae spin webs that are often dense enough to attract attention. The last instar spins a silken cocoon. Adults are 5–10 mm in length and about 16 mm in wingspan. They are easily recognized by the distinctive appearance of the forewing, which is light gray basally and bright copper red distally. The females lay up to 400 eggs that can develop into adults in as few as 28 days under optimal conditions. In the tropics, there may be 6–8 generations; in temperate zones 1–2 generations are usual.

In addition to the Indianmeal moth, several other pyralids are pests in stored grain. The Mediterranean flour moth, *Ephestia kuhniella* Zeller, a native of Europe, is a general feeder that was once the most troublesome pest in US flour mills. Its pest status was primarily due to the particle matting created by the larva-produced silken thread. Other occasional pyralid pests include the meal moth, *Pyralis farinalis* (L.), the tobacco moth *Ephestia elutella* (Hübner), the raisin moth, *Cadra figulilella* (Gregson), and the almond moth, *Cadra cautella* (Walker). Among these the almond moth is the most serious pest especially in rice and sorghum grain in tropical and subtropical climates.

Straight-Snouted Weevils

Members of the family Brentidae (order Coleoptera)

► Beetles

► Weevils, Billbugs, Bark Beetles and Others

Stratified Sampling

A method of allocating sampling units in which the sample universe is subdivided into two or more sections and sample units are randomly collected from each subdivision in proportion to their size or relative variability. Examples include the subdivision of a crop field into border and interior sections, the subdivision of a plant along vertical strata, or different rooms within a structure.

► Sampling Arthropods

Stratiomyidae

A family of flies (order Diptera). They commonly are known as soldier flies.

► Flies

Strawberry Bud Weevil, *Anthonomus signatus* (Say) (Coleoptera: Curculionidae)

In some areas, this is an important pest, affecting the fruit of strawberries.

► Small Fruit Pests and Their Management

Strawberry Sap Beetle, *Stelidnota geminata* (Say) (Coleoptera: Nitidulidae)

This can be an important fruit pest, damaging ripe strawberry fruits.

► Small Fruit Pests and Their Management

Streblidae

Formerly a family of flies (order Diptera). They (and Nycteribiidae) were commonly known as bat flies, but are now included in the family Hippoboscidae.

► Flies

Strepsiptera

JEYARANEY KATHIRITHAMBY
Oxford University, Oxford, United Kingdom

The order name is derived from the Greek *Strepsi-* (twisted) and *pteron* (wing). The term "twisted wing" refers to the free-living male, which, when in flight, gives the impression that its hind wings have a "twisted" motion.

Strepsiptera are unique, bizarre, obligate entomophagous parasites of cosmopolitan distribution and exhibit extreme sexual dimorphism. There are only two free-living stages: the adult male, and the first instar host-seeking larva, except in the family Mengenillidae, where both male and female emerge to pupate externally from the host. The neotenic adult female in all the other families remains endoparasitic, except for the anterior region, the cephalothorax, which is extruded through the host cuticle. The number of species described worldwide so far is about 600, but recent studies suggest that many of these are cryptic species. If so, the true estimate might be nearer double that number.

Strepsipteran genomes are among one of the smallest insect genomes reported and are associated with their unique morphology and life history.

Several fossil Strepsiptera have been discovered and described, of which the families Protoxenidae and Mengeidae from the Baltic amber, and the genus *Cretostylops* from the Cretaceous Burmese amber, are extinct. Until further fossils are described, and on-going studies on DNA sequence data are analyzed, the two extinct families and genus are placed under the suborder Mengenillidia and the rest of the seven extant families in the suborder Stylopidia.

- Suborder Mengenillidia
  - Family Protoxenidae (extinct)
  - Family Incerta Sedis
    - Genus *Cretostylops* (extinct)
  - Family Mengeidae (extinct)
  - Family Mengenillidae
- Suborder Stylopidia
  - Family Corioxenidae
  - Family Myrmecolacidae
  - Family Xenidae
  - Family Stylopidae
  - Family Elenchidae
  - Family Halictophagidae
  - Family Bohartillidae

Strepsiptera parasitize Aptery-, Exo- and Endopterygota insects belonging to seven orders and 28 families. The hosts are Thysanura: Lepismatidae; Blattodea: Blattidae; Mantodea: Mantidae; Orthoptera: Gryllidae, Tettigoniidae, Tridactylidae; Hemiptera (Homoptera): Cercopidae, Cicadellidae, Delphacidae, Dictyopharidae, Eurybrachyidae, Flatidae, Fulgoridae, Issidae, Membracidae, Ricaniidae, Tettigometridae; Hemiptera (Heteroptera): Coreidae, Cydnidae, Lygaeidae, Pentatomidae; Diptera: Tephritidae and Hymenoptera: Formicidae

[Dolichoderinae, Ecitoninae, Formicinae, Myrmicinae, Ponerinae, Pseudomyrmecinae], Vespidae [Eumininae, Masarinae, Polistinae, Stenogastrinae, Vespinane], Sphecidae [Bembicinae, Larrinae, Sphecinae], Colletidae [Hylaeinae, Panurginae], Halictidae [Rophitinae], Andrenidae [Andreninae]).

In one family, the Myrmecolacidae, the males and females parasitize different hosts: males parasitize ants, whereas females parasitize grasshoppers, crickets and mantids. The dual host nature of this family is unusual not only in Strepsiptera but also among parasites.

Some of these hosts are pests of economic crops, or are nuisance pests. *Nilaparvata lugens* Stål and *Sogatella furcifera* Hováth (Hemiptera: Delphacidae) spread viruses in rice, causing "hopper burn" in South and Southeast Asia, and *Javesella pellucida* (F.) (Delphacidae), which is a vector of oats in the Palaearctic region, is parasitized by *Elenchus* sp. (Elenchidae); *Nephotettix* sp. (Hemiptera: Cicadellidae) is a vector on rice in Southeast Asia and is parasitized by *Halictophagus* sp. (Halictophagidae); the corn leafhopper *Dalbulus maidis* (Delong & Wolcott) (Cicadellidae) is a vector of three pathogens on corn and is parasitized by *Halictophagus naulti* Kathirithamby & Moya-Raygoza (Halictophagidae) in Mexico; *Proutista moesta* (Westwood) (Hemiptera: Derbidae), a pest of coconuts, and araca nuts and oil palm in southern India, is parasitized by *Halictophagus palmi* Kathirithamby & Ponnamma; fruit flies *Dacus* sp., that damage fruits in Australia, the South Pacific, and Southeast Asia, are parasitized by *Dipterophagus daci* Drew & Allwood (Halictophagidae); *Segestes decoratus* Redtenbacher, *Sexava nubila* (Stål), *Segestidea defoliaria defoliaria* Uravov and *Segestidea novaeguineae* Brancsik (all Orthoptera: Tettigoniidae), which feed on palm fronds and cause severe defoliation of oil palm, coconut and *Pandanus*, are parasitized by *Stichotrema dallatorreanum* Hofeneder in Papua New Guinea; *Solenopsis invicta* Buren (Hymenoptera: Formicidae), a nuisance pest in the southern Nearctic region, is parasitized by *Caenocholax fenyesi texensis* Kathirithamby & Johnston.

Morphology

Male

The adult free-living male is most conspicuous because of its flabellate antennae, raspberry-like eyes, and large hind wings. The antennae have 4–7 segments with sensorium (Fig. 143). The eyes have 15–150 ommatidia, which are separated by strips of cuticle or setae. Except in the family Corioxenidae, all males have mandibles. Maxillae vary in size, with a shorter basal segment and longer palpi. In the Bohartillidae, however, the basal segment is six times longer than the palpi.

The pro- and mesothorax are reduced; the latter has a pair of reduced wings which are analogous to the halteres of Diptera. The metathorax is large, and bears the flight muscles that power the large hind wings, which have reduced veins.

The legs have 2–5 segmented tarsi, with absence of trochanter in the fore- and midlegs. Claws may either be present or absent.

There are ten abdominal segments. The ninth abdominal segment has a simple aedeagus, except in *Caenocholax fenyesi sensu lato*, which has a large shield-shaped plate dorsally. There are no parameres. The tenth abdominal segment varies in size, and overhangs the ninth segment.

Female

Only the females of the family Mengenillidae are free-living as pupae and adults. They emerge to pupate externally from the host and, as both pupae and neotenic adults, have a head which bears eyes and antennae, and legs. The neotenic adult also has a genital orifice, but is wingless. The females of the suborder Stylopidia remain endoparasitic in the host, except for their cephalothorax, which is extruded at the neotenic adult stage. They do not possess any adult insect characters, and are viviparous. The brood canal opening in the cephalothorax is used both for the insemination of the female by the male and for

Strepsiptera, Figure 143 A diagram of a male Strepsiptera (above) showing a dorsal view with the left wing removed. The lower diagrams show a close-up of the male antenna and mouthparts (left) and a ventral view of a neotenic endoparasitic female (right) (scale bar = 0.8 mm).

the emergence of the first instar larvae. The brood canal opening leads into the brood canal, which in turn leads to the genital ducts which open into the body cavity of the female. The entire body is filled with developing oocytes/first instar larvae.

Immature Stages

The first instar larva is free-living and is about 0.08–0.30 mm in length. The head has stemma, antennae, mandibles, and labium. The ventral region of the head is made up of microtrichia with serrated edges containing fringes. The thoracic and abdominal sternites and tergites and intercoxal sternites are serrated. The abdomen bears long caudal setae (Fig. 142). Entry of the first instar larva into the host occurs when the host is at the nymph or larva stage, and parasitization at the egg stage has also been reported. The point of entry of the first instar larva is usually via the abdomen and thorax (in nymphal hosts), or the head, thorax and abdomen (in larval hosts). In *Stichotrema dallatorreanum* Hofeneder in Papua New Guinea, which parasitizes tettigoniids, the first instars have been observed to enter the host via the tarsi.

On entry into the host, the first instar moults to an apodous second instar, and there are three endoparasitic stages which undergo apolysis without ecdysis, whereby the larva sheds the cuticle but does not emerge from it. Instead, it retains the cuticles as layers. At the late fourth instar, the male and female of the suborder Stylopidia extrude their cephalotheca and cephalothorax, respectively. In the Mengenillidae, the male and female at the end of the fourth instar emerge to pupate externally.

The male pupates within the puparium which is formed by the last instar cuticle. During the pupation of the male Stylopidia, the host remains mobile, and the strepsipteran male emerges as a free-living adult by breaking the cap of the cephalotheca. On extrusion of the cephalothorax, the fourth instar female Stylopidia becomes a neotenic adult, and awaits fertilization by the male. The females are viviparous, and after fertilization the larvae begin development. The first instars emerge via the brood canal opening of the female Stylopidia or the genital orifice of Mengenillidae, and seek new host nymphs or larvae to parasitize.

Host Associations

Species of Strepsiptera have been found not to be host specific, and may parasitize several genera (up to 23) and several species (up to 42). Recent studies show that this superficial polyphagous nature may by due to cryptic speciation.

Parasitization by Strepsiptera (stylopization) may affect morphology and behavior of the host. The reduction in the secondary sexual characters is marked in Delphacidae (Hemiptera), where the male and female genitalia are extremely reduced when stylopized (Fig. 142f). Abnormal facial coloration and foveae, proportions of the antennal segments, reduction in the pollen-basket on the leg, anal fimbria, ovipositor and male genitalia, have been reported in stylopized Hymenoptera.

Stylopization also affects hymenopteran host behavior such as loss in the power of flight, less savage when stinging, unbalanced flight and a lack of pollen-collecting instinct. Studies on the paper wasp, *Polistes dominulus* (Christ), showed that stylopized wasps desert the nest before the extrusion of the male cephalotheca and female cephalothorax, and form summer aggregations consisting of castrated wasps, in order to facilitate mating of the strepsipteran.

The behavior of stylopized ants is different from the behavior of stylopized wasps described above. It has been suggested that, when ants are stylopized, they abandon the nest, ramble about, and climb high on grass and bushes. However, when whole nests were dissected, a large proportion of ants with extruded cephalotheca containing fully developed male myrmecolacids that were ready to emerge were found. The pupal instar of the male strepsipteran is long, and it is most likely that the stylopized ants only leave the nest when the male strepsipteran is ready to emerge from the host. When the stylopized ant leaves the nest, it climbs onto grass stems or a bush in order to release the male myrmecolacid. Stylopized ants, unlike stylopized wasps, only leave the nests when the male strepsipteran is ready to emerge, because the worker ant is safer from predators in the nest than outside, and this could be adaptive for the strepsipteran.

Strepsiptera

An order of insects. They commonly are known as twisted-wing parasites or stylopids.

► Stylopids

Stress-Induced Host Plant Free Amino Acids and Insects

ALLAN T. SHOWLER
USDA-ARS SARC, Weslaco, TX, USA

Various researchers have demonstrated that individual amino acids differ in their effects on insect growth and development. Subsets of amino acids are the mechanistic bases of relationships between total plant nitrogen and insect vitality. For example, artificial diets with the amino acid distribution found in anthers were found to be successful for rearing tobacco budworms, *Heliothis virescens* F. At least to some extent, nutritional strength has been linked with insect preference for host plants and higher levels of readily available (unbound) amino acids presumably improve insect development. Similarly, plants with accumulations of certain free amino acids (FAAs) are, in some cases, preferred by some herbivorous insects.

Abiotic Plant Stress Factors and FAAs

Higher levels of some FAAs, especially free proline, in association with water deficit stress occur in many plants, including cotton, *Gossypium hirsutum* L.; soybeans, *Glycine max* (L.) Merr.; wheat, *Triticum aestivum* L. Pers.; cowpea, *Vigna unguiculata* L.; tomato, *Lycopersicon esculentum* Mill.; and jack pine, *Pinus banksiana* Lamb. In corn, *Zea mays* L., seedlings, drought treatment caused an increase in total FAA content and a consistent rearrangement of the amino acid pool with increased accumulation of free alanine, arginine, valine, aspartate, serine, threonine, and tyrosine. Lower amounts of free glutamic acid, glycine, and methionine likely resulted from a strong decrease in glutamate. In cotton, increasing degrees of water deficit stress increased foliar free alanine, arginine, glycine, histidine, isoleucine, phenylalanine, proline, and valine, but associations between the weekly volume of water provided and the quantity of individual FAAs were not always linear.

Researchers have most often focussed on the relationship between water deficit stress to plants and free proline accumulations. Suspension culture cells of water deficit adapted tomatoes to polyethylene glycol had a 300-fold bigger free proline pool than untreated cells, the result of a tenfold rise in proline synthesis via the glutamate pathway. Use of N-15 labels in tomato plants determined that ornithine was an unlikely precursor to proline, and it has been suggested that the rate of proline synthesis in unstressed cells only slightly exceeds the rate required to sustain both protein synthesis and free proline pool maintenance. Mechanisms restricting free proline oxidation, and oxidation of other FAAs, can operate at different rates governed by the degree to which water deficit stress is imposed. Some researchers have interpreted the accumulation of large pools of free proline and other FAAs in water deficit stressed rice as being an indication of protein synthesis pathway disruption, or an increase in protein degradation. Others concluded that the higher free proline levels in *Arabidopsis thaliana* (L.) Heynh tissues with low water content resulted from increased biosynthesis. Osmotic stress in *A. thaliana* induced a rapid accumulation of free proline through *de novo* synthesis from glutamate, and during recovery from osmotic stress, accumulated free proline is oxidized to glutamate and the first step of this process is catalyzed by proline oxidase. A study using water deficit stressed bermudagrass, *Cynodon dactylon* (L.) Pers., showed that 10–100 times more free proline accumulated than in controls and it was suggested that, because proline turns over more slowly than other FAAs during water deficit stress, free proline might function primarily as a nitrogen storage compound.

Alternatively, in hydroponic potatoes, *Solanum tuberosum* L., subjected to water deficit stress induced by polyethylene glycol, plants were able to grow in "dry" conditions by accumulating organic solutes for use in osmoregulation. Osmoregulation in the tubers occurred in two phases: (i) during the first 2 days hexoses were accumulated, and (ii) after 7 days osmotic adjustment was mostly due to the accumulation of FAAs, especially proline (150 times the amount found in unstressed controls). Free proline might act as a compatible solute, a readily utilizable source of energy, and a sink for soluble nitrogen. Plants originating in dry climates were found to have higher levels of free proline than plants in wetter climates, and it has been postulated that the high free proline levels accompany survival and growth rather than being a result of damage. One study demonstrated that free proline sprayed on cotton plants counteracted the effects of water deficit stress. Leaf relative water content, dry matter content, and chlorophyll content and stability to heat increased. FAA accumulations associated with disease and nematode infections of plants might result from osmotic disruption, but also from other reasons, including xylem injury repair, syncytial wall formation in nematode-induced root galls, cell wall formation, and blockage of protein synthesis. Other abiotic stresses that have been associated with significantly increased foliar free amino acids accumulation include high soil salinity and soil nitrogen levels (each results in increased free proline in particular), and shade (particularly free arginine).

Biotic Plant Stress Factors and FAAs

Weed Competition

Competition with weeds has been associated with increased free arginine accumulations, but not proline, in sugarcane and cotton. In cotton, shade from weeds was attributed to be the cause of the stress. Sugarcane canopy closure shaded out weed growth after weeds had already caused a significant sugarcane stand reduction, and the higher free arginine levels in weed-free sugarcane habitats were attributed to shade caused by denser stands of the crop itself.

Fungi and Bacteria

Plants infected with various pathogens have been found in association with increased accumulations of FAAs. *Fusarium solani* (Mart.) altered host plant metabolic activity in citrus, and it was suggested that the higher levels of free arginine, asparagine, glutamic acid, glycine, and proline were caused by a fungal toxin that enhanced xylem membrane permeability. Pecan trees, *Carya illinoinensis* (Wangenh.) K. Koch, are more susceptible to fungal leaf scorch, *Phomopsis* sp. and *Glomerella cingulata* (Ston.), when under water deficit stress, and FAAs were more abundant in scorch-infected tree leaves. It was suggested that foliage with higher FAA levels might favor the growth and development of leaf scorch. Tobacco, *Nicotinia tabacum* L., infected with crown gall, caused by the bacteria *Agrobacterium tumefasciens*, had 70-fold higher accumulations of free proline than healthy controls. Similarly, crown gall infected tomatoes, *Lycopersicon esculentum* Mill., had 22 times more free proline as compared to healthy controls. Non-pathogenic fungi can also influence FAA accumulations in plants. For example, the vesicular-arbuscular mycorrhizal fungus, *Glomus faciculatum* (Thax. Sensu Gerd.) caused ammonia-fed corn to accumulate more FAAs than control plants. Major components of the FAA pool were glycine, glutamine, alanine, serine, asparagine, and GABA. These FAAs were between two and threefold more concentrated in *Glomus*-colonized roots.

Viruses

Tomato plants infected with tomato leaf curl virus had higher concentrations of soluble amino acids than controls, and it was suggested that virus infection stimulates nitrogen metabolism and mobilization of proteins. The rate of turn-over of FAAs into bound amino acids is enhanced by virus infection. FAAs are not directly converted to amino acids in viral protein, but they are incorporated into viral protein by way of bound amino acids. Aspartic acid, glutamic acid, serine, alanine, phenylalanine, and other amino acids are actively turned over and used for the synthesis of viral protein (these amino acids comprise much of the viral protein). FAAs have also been shown to increase in association with a variety of viruses infecting different plants, including barley yellow dwarf virus infection of barley, *Hordeum vulgare* L., and wheat, *Triticum aestivum* L.; cassava mosaic virus infection of cassava, *Manihot esculenta* Crantz; pigweed mosaic virus infection of pigweed, *Amaranthus* sp.; southern bean mosaic virus infection of cowpea, *Vigna* sp.; common bean mosaic virus infection of mung bean, *Vigna radiata* (L.) Wilczek; and soybean mosaic virus and bean pod mottle virus infection of soybean, *Glycine max* (L.) E. Merill.

Plant Stress, FAAs, and Phytophagous Nematodes

Some phytophagous nematodes have been shown to be associated with higher host plant FAA levels than healthy controls, including *Radopholus similis* (Cobb) Thorne infected grapefruit, *Citrus* x *paradisi* Mcfad., seedlings; reniform nematode, *Rotylenchulus reniformis* Linford & Oliveira, in cotton, *Gossypium barbadense* L.; green gram, *Phaseolus aureus* Roxb.; black gram, *P. mungo* (L.); and cowpea; and stem nematode, *Ditylenchus dipsaci* (Kuhn) Filipjev, infecting alfalfa, *Medicago sativa* L. Augmentation of root knot nematodes, *Meloidogyne* spp., was associated with lower levels of free cysteine, histidine, proline, and serine concentrations in sugarcane, *Saccharum officinarum* L. Shading in dense stands of sugarcane elevated levels of some FAAs compared to less dense stands of sugarcane, and the increases were correlated to populations of stunt nematodes, *Tylencorhynchus annulatus* Cobb. Concentrations of FAAs were unchanged when roots of *Beta patellaris* (Moq.), a resistant species of beet, were infected with cyst nematodes, *Heterodera schactii* (Schmidt). However, in the susceptible sugar beet, *B. vulgaris* L., concentrations of aspartic acid, glutamic acid, and glutamine, and total FAAs were significantly higher when infected with cyst nematodes. Another study determined that infection of tomato plants by *Meloidogyne javanica* (Treub) Chitwood resulted in accumulation of free proline in galls. The concentration of free proline increased with increasing density of nematodes, but the highest concentration occurred at the time of egg production, and the concentration of free proline was highest in *M. javanica* eggs and egg sacs compared to portions of the plant. Proline is reported as being a major constituent of the egg shells of phytophagous nematodes, including *M. javanica* and *Heterodera rostochiensis* Wellenweber. Other researchers have suggested that proline might stimulate xylem production following injury induced by phytophagous nematodes.

Although the previous examples of research have indicated an association between nematode feeding and elevated accumulations of FAAs in the host plant, other studies have shown that host plant resistance to nematodes is conferred through high levels of FAAs. For example, quantities of FAAs in segments of cotton roots resistant and susceptible to *Meloidogyne incognita* (Kofoid and White) were compared. Following infection, the susceptible cultivar had greater percentage increases in certain FAAs than a resistant cultivar, but the sum total of FAAs was greatest in the resistant cultivar. Another study, using ring nematode, *Criconemella xenoplax* (Raski) Luc & Raski, showed that nematode resistant cultivar peach, *Prunus persica* (L.) Batsch, seedlings accumulated significantly more FAAs in the root tissue in association with phytophagous nematode populations.

Virus infected host plants, presumably with greater accumulations of FAAs, have been shown to be associated with higher numbers of certain phytophagous nematodes than healthy control plants. *Meloidogyne javanica* juveniles entered bean, *Phaseolus* sp., plant roots, infected with tobacco ring spot virus more than uninfected plants, though the growth of the nematodes was unaffected. The root knot nematode grew more rapidly on tobacco mosaic virus-infected beans than on controls, but the virus did not affect the number of nematodes entering the root. Root exudates can attract nematodes, and it is possible that the exudates are attractive at least in part because they contain FAAs or other constituents of the exudate signal high FAA levels in the host plant.

Plant Stress, FAAs, and Phytophagous Insects

One study demonstrated that mildly water deficit stressed soybean plants were preferred by Mexican bean beetle, *Epilachna varivestris* Mulsant, larvae, possibly as a result of higher levels of FAAs in the foliage. Beet armyworm, *Spodoptera exigua* (Hübner), eggs have been reported as being most concentrated on water deficit stressed cotton in fields and this observation might be because water deficit stressed cotton plant foliage has greater accumulations of FAAs. However, water deficit stress has been shown to decrease aphid populations because the insects are more dependent on water pressure in the plant than other insects.

Insects that depend on host plant water pressure for efficient ingestion of nutrients have been shown, in some cases, to prefer virus infected host plants over non-infected plants, presumably because the nutritional value of the plant is enhanced by higher accumulations of FAAs. Pigeon pea, *Cajanus cajan* (L.) Millsp., plants infected with a mosaic virus were infested with more potato leafhoppers, *Empoasca kerri* Pruthi, than healthy plants. The virus-infected leaves had higher accumulations of total nitrogen, peptides, and FAAs than the controls. Sweetpotato whitefly, *Bemisia tabaci* (Gennadius), populations were higher on pumpkin, *Cucurbita pepo* L., infected with squash leaf curl virus than healthy pumpkin plants. Sugar beet, *Beta vulgaris* L., leaves with a mosaic virus were more suitable food for aphids than uninfected leaves. Grasshopper, *Melanoplus* sp., preferred to feed on leaves of sunflower, *Helianthus* sp., infected with rust, *Puccinia* sp. Cotton aphids, *Aphis gossypii* Glover, lived longer and produced more offspring on pumpkin plants infected with zucchini yellow mosaic virus than non-infected plants. Aphids, *Rhopalosiphum padi* (L.) and *Sitobion avenae* (F.), reared on oats, *Avena byzantina* (Koch), infected by various isolates of barley yellow dwarf virus were much more likely to mature as winged adults than were aphids reared on healthy oats. However, sweetpotato whitefly populations were lower on squash, *Cucurbita* sp.; tomato; and cotton plants infected with squash leaf curl virus, chino del tomate virus, and cotton leaf crumple virus, respectively, than non-infected controls. In some studies, no significant differences were observed between herbivorous insect populations and virus-infected host plants.

Insects absorb nitrogen through the gut primarily in the form of FAAs or small peptides. Thus, the initial cost of proteolysis is saved if amino acids are ingested in this form. The distinction between FAAs and those bound in proteins may be important for insects such as aphids that cannot ingest large molecules or are not exposed to large molecules because of the composition of the plant's phloem sap on which insects like aphids feed, but this is separate from the costs of proteolysis. In terms of optimizing insect development, it is probable that the balance between different amino acids is particularly important. For example, pink bollworm, *Gossypiella pectinophora* (Saunders), larvae raised on a diet in which one of the essential amino acids was omitted grew slowly and failed to survive beyond the second instar. Increased glutamic acid caused growth stimulation. In some cases, amino acids such as glycine have been shown to be essential. Beet armyworms prefer to oviposit on pigweed, *Amaranthus hybridus* L., over cotton, *G. hirsutum*, and third instars prefer to feed on pigweed foliage over cotton foliage. Beet armyworm larvae also grow and develop better on pigweed than on cotton, and it has been suggested that the lack of gossypol and other deterrent or toxic compounds found in cotton leaves, and the higher accumulations and greater diversity of FAAs in pigweed leaves make pigweed the superior host. However, in some insect-plant relationships, preferences for the plant host that most favors phytophagous insect growth and development is not always evident.

At least in some cases, the increased availability of readily available nitrogen appears to not only improve the chances of some disease organisms becoming established, but might also increase the likelihood of survival of insects feeding on the infected plants. Environmental stresses, whether biotic or abiotic, seem to affect the survival, fecundity, morphology, and vitality of some phytophagous insects through physiochemical processes mediated by corresponding changes of FAA accumulations in the host plant.

Stria

Grooves or indented lines.

Striate

The occurrence of fine, parallel grooves or impressions of the surface of the integument.

Stridulate

To produce a noise by rubbing together two surfaces.

Stridulating Slantfaced Grasshoppers

A subfamily (Gomphocerinae) of grasshoppers in the order Orthoptera: Acrididae.

► Grasshoppers, Katydids and Crickets

Strigilation

The oral removal of secretions by one insect from another.

Strip Cropping

Cultivation or harvesting crops in strips rather than in large expansive fields, with the strips sometimes following the natural contours of the land.

► Cover, Border and Trap Crops for Pest and Disease Management

Stripe

A line that runs horizontally or lengthwise on an insect. This term often is confused with a “band” or transverse line.

Striped Earwigs

Members of the earwig family Labiduridae (order Dermaptera).

► Earwigs

Striped Walkingsticks

A family of walkingsticks (Pseudophasmatidae) in the order Phasmatodea.

► Walkingsticks and Leaf Insects

Structural Gene

A gene that codes for an RNA molecule or protein other than a regulatory gene.

Structural Genomics

The study of protein structure based on DNA sequences.

Structural Fumigation

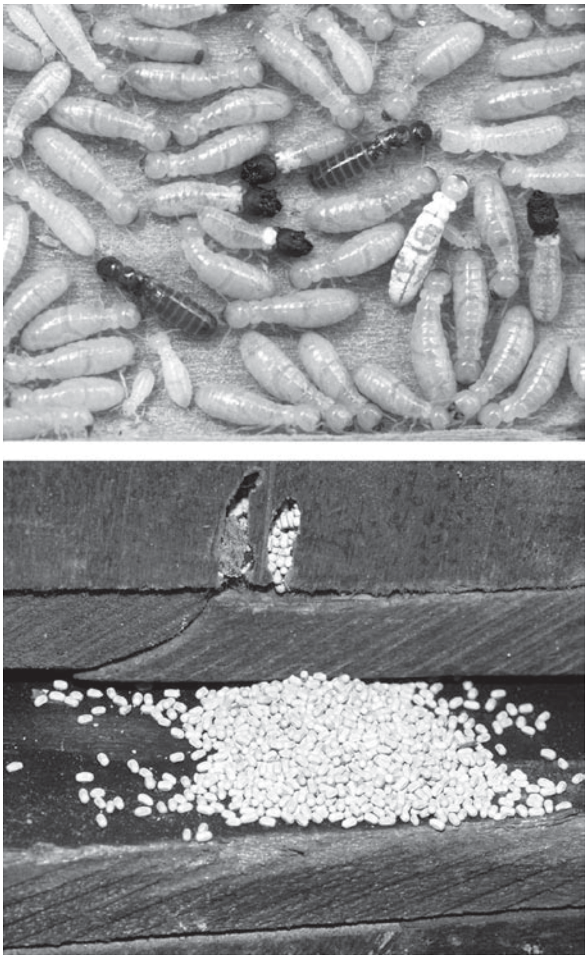
RUFOLF H. SCHEFFRAHN
University of Florida, Fort Lauderdale, FL, USA

Fumigation is a category of pest control in which a gaseous pesticide (fumigant) is applied within a measured volume of space that is enclosed by tarpaulins or otherwise sealed. The fumigant must be confined in this space for a time and at a concentration sufficient to kill the target organism. A fumigant is a chemical that, at a required temperature and pressure, can exist in the gaseous state in sufficient concentration to be lethal to a given organism. Fumigation should not be confused with the Spanish word "fumigación" which has a broader definition that includes spraying of liquid pesticides. Structural, soil, and commodity fumigation are named for the material type which harbors the target pest(s). Quarantine fumigation is usually ordered by governmental regulators to prevent the transportation of exotic pests, usually infesting a commodity, into a jurisdiction which is free of that pest. Structures most commonly fumigated include residential and commercial buildings, however, boats, railcars, and truck trailers may also require fumigation.

Structural fumigation is unlike any other category of modern pest control. It demands that a sequence of procedures be conducted in varying, and often difficult, physical environments using toxic gases and an assortment of heavy, costly, and specialized equipment. Fumigation is the only method of pest control that allows for complete and rapid eradication of a target organism within a defined space. The great advantage of structural fumigation over other methods of pest control is that all target pests are killed within the fumigated space, regardless of their location. Fumigants follow all the physical laws of gases; therefore, their molecules diffuse freely through air and infiltrate the minutest of spaces. The disadvantage of fumigation is the lack of residual activity to protect the fumigated space from subsequent reinfestation.

Target Pests

Drywood termites (Family Kalotermitidae) are by far the most important target pests of structural fumigations (Fig. 144) while wood-boring beetles (families Lyctidae, Bostrichidae, Anobiidae, and Cerambycidae) and aerial infestations (including boats) of subterranean termites (families Rhinotermitidae and Termitidae) account for the other wood-destroying insects controlled by fumigation. Although most structural fumigations in the United States are for wood-destroying insects, infestations of other pests may arise



Structural Fumigation, Figure 144 **Termites are the most common target pests of structural fumigation: (*top*) the West Indian drywood termite, *Cryptotermes brevis*, a widespread target of structural fumigation, (*bottom*) drywood termite pellets are a common sign of infestation.**

that require fumigation. Among such insect pests are cockroaches, carpet beetles, stored-product beetles and moths, clothes moths, bedbugs, and spiders. Rodents such as rats and mice are common vertebrate pests for which fumigation might be prescribed. Large or severe infestations, infestations in difficult to treat or sensitive locations, or when standard methods of non-fumigant control are not working are potential candidates for structural fumigation.

Fumigants

Numerous volatile solvents and gases have been used in the past as structural fumigants. Over the last 15 years, methyl bromide, once a widely used structural fumigant, has been phased out for this use because of its reactivity with atmospheric ozone. The only viable structural fumigant for the foreseeable future is sulfuryl fluoride which is sold under the trade names Vikane® and Zythor®. Chloropicrin (nitrochloromethane) must be released simultaneously with sulfuryl fluoride because the latter is relatively odorless. Chloropicrin is a potent teargas that prevents unauthorized entry into the fumigated airspace.

It remains unlikely that any new fumigant will be discovered but the mixture of fumigants with carbon dioxide or other synergistic gases may be developed to increase the efficacy of currently available fumigants. The relatively small pool of candidate chemicals does not include a single gas with some, or even a few, of the many desirable properties needed for a structural fumigant. In late 2001, chlorine dioxide was the first new structural fumigant to be used since sulfuryl fluoride was introduced over 40 years ago. Chlorine dioxide gas was implemented under a strict USEPA emergency exemption to decontaminate anthrax spores from several federal government buildings at the cost of hundreds of millions of dollars. Although chlorine dioxide has antibacterial properties, it is very short-lived, unstable, and explosive. In addition, this gas cannot be containerized, is highly corrosive, and is effective only in a narrow temperature and humidity range.

Transport Equipment

Equipment and chemicals must be transported to the fumigation site using vehicles specially designed for this purpose. Vehicles carrying hazardous materials (sulfuryl fluoride or chloropicrin) must also have warning signage and a secure chemical storage area separate from that of the driver and passengers. Some companies choose to carry all needed material on a single truck (Fig. 145). Other companies use one vehicle for transporting chemicals and another for sealing materials.

Inspection and Measurement

The target pest, volume of the structure, building design, and sealing conditions must be determined in order to deliver the proper equipment to the site. A graph of the structure, in aerial view and marked with linear dimensions, is required to calculate the volume under seal. A measuring wheel, tape measure, and graduated pole can be used to determine dimensions. Several photographs are also useful for considering any special procedures or equipment for the job.

Exterior and Interior Preparation and Sealing

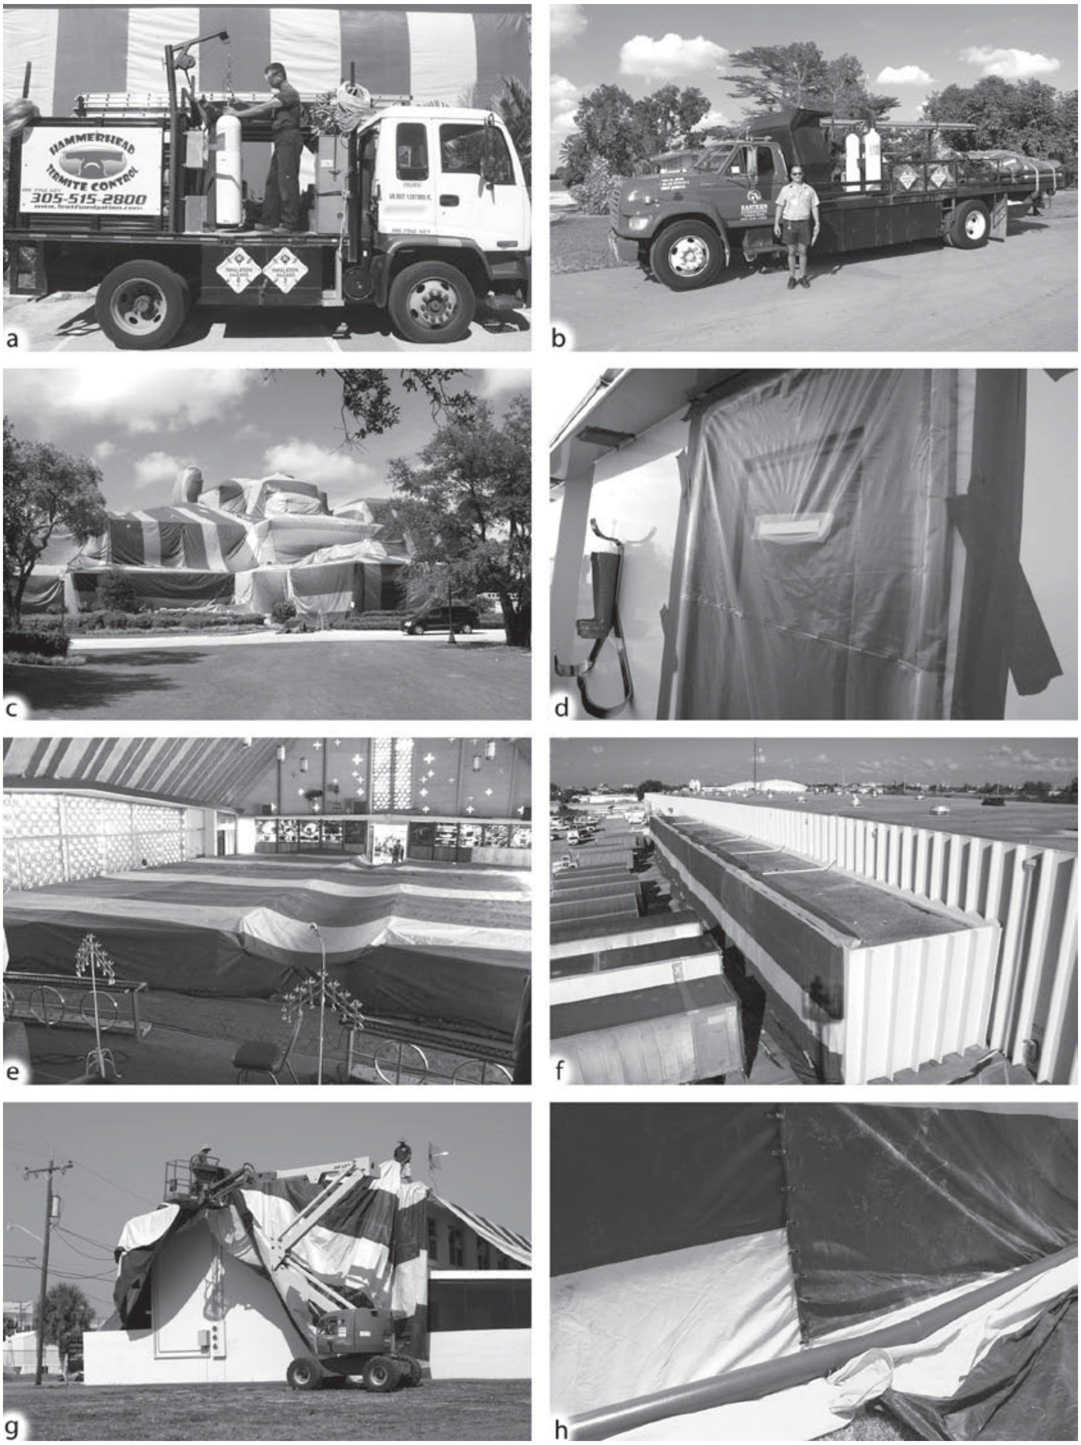
There are three basic categories of sealing a structure for fumigation: (i) tarpaulin sealing of the entire structure, (ii) "tape and seal" using polyethylene sheeting and tape to seal windows and doorways of a structure with an otherwise impermeable exterior structure (e.g., concrete, steel, fiberglass), and (iii) compartmental fumigation in which only the infested portion of a larger structure is sealed.

In a typical fumigation, exterior and interior preparations are done simultaneously. Exterior preparation in tarpaulin fumigations involves the removal or repositioning of fragile components such as antennas, awnings, and patio screening. The ground around the structure must be freed of porous substrata, curbs, and roots by removing, raking, or placing a layer of sand over the area. The tarpaulin apron can then be secured at ground level using sand or water "snakes" to weigh down and seal the tarpaulin to the smooth substrate. The tarpaulins are then positioned on the roof of the structure, dropped to the ground, and adjoining seams are sealed with hand clamps. Warning signs must be placed on all sides of the structure and must have contact information to reach the fumigator in case of an emergency.

Interior preparation includes the sealing of food and medicinal items inside special nylon bags, removal of all plants and animals, opening all possible indoor enclosures (e.g., windows, cabinets, closets, attic access doors, etc.), placement of high output fans to facilitate fumigant diffusion, securing the sulfuryl fluoride introduction hose location(s), and the chloropicrin evaporation pan site(s). All flames and exposed hot elements must be turned off. All operable doors must be locked using secondary locking devices that only the fumigator can open.

Introduction of Chloropicrin and Sulfuryl Fluoride

The target pest, volume, exposure time, seal quality, and weather conditions will determine the total quantity (and concentration) of fumigant and warning agent to be applied. Seal quality includes the condition of tarps, the quality of the ground seal (tarp apron on ground), and underseal (concrete slab or soil type). Special handheld calculators or programs supplied by the manufacturers are used to calculate fumigant dosage based on quantitative or qualitative value for each of the variables listed above. Colder temperature, strong wind, and small total volume contribute to higher calculated dosages. Efficacious rates for sulfuryl fluoride against drywood termites are up to 10 times lower than rates for some solitary insects like wood boring beetles because egg kill is not needed to eradicate termite colonies. Rodents and other vertebrate



Structural Fumigation, Figure 145 **Fumigation of structures: (a) a compact truck for narrow streets, (b) a full size truck provisioned to transport equipment, chemicals, and crew members to a fumigation site, (c) tarpaulin fumigation of a mansion, (d) "tape and seal" fumigation of a boat (exterior door shown), (e) compartmental fumigation of church pews, (f) a combination tarpaulin and "tape and seal" fumigation of a warehouse (g) mechanical lift to raise tarpaulins onto building, (h) water "snake" for proper ground seal.**

vermin are killed at half the rate required for drywood termites at 80°F (25°C).

After the structure has been sealed, the interior preparation completed (Fig. 146), and a final walk-through inspection is made to insure that no people or pets are in the structure, fumigation can proceed. The fumigator enters an open seam (tarpaulin fumigation) or doorway (tape and seal fumigation) with a measured quantity of chloropicrin which is poured into one or more evaporation pans (1 pan and up to 3 fluid ounces per 45,000 cubic feet). After pouring the chloropicrin into the pan, the fumigator exits the structure and the entrance opening is sealed. After allowing at least 5 min for the chloropicrin to begin evaporating, the sulfuryl fluoride can be introduced. Cylinders containing 125 lbs. of fumigant when full are hoisted onto a balance, a release hose is connected, and the cylinder valve is opened. When the appropriate quantity of fumigant has been released (typically 4–8 ounces per 1,000 cubic feet (= 4–8 g/m3) for drywood termites), the cylinder valve is closed. Typical fumigation exposure periods range from 18 to 48 h. Depending on urgency to reoccupy building, exposure periods can be shortened by the addition of a higher initial fumigant concentration.

Monitoring, Aeration and Clearance

During a fumigation, the concentration of sulfuryl fluoride can be measured using a Fumiscope® thermal conductivity detector. Monitoring is not typically required but may be an important procedure if seal conditions are uncertain or a very large structure is fumigated. By monitoring the concentration, the fumigator can add additional fumigant if needed and will thus insure that the fumigation is successful. If the fumigator is only concerned with detecting overt leaks in the seal, he/she can use a halogen leak detector to locate leaks and correct them.

Upon completion of the predetermined exposure period, the aeration process begins. The seal is first broken and the fumigator enters the structure wearing a self contained breathing apparatus. The fumigator opens all operable doors (and windows in a tape and seal fumigation). At this time the structure must be aerated with doors open for a minimum of one hour. During this period, the crew removes all sealing materials from the structure and after 1 h, the doors can be relocked. Six to eight hours after the beginning of initial aeration, the fumigator returns to the structure to test the concentration of residual sulfuryl fluoride before reoccupancy can take place. Using an Interscan® pyrolytic fluoride detector or an ExplorIR® infrared analyzer, the fumigator walks throughout all rooms of the structure. If all readings are equal to or less than one part per million, the structure is deemed safe for reentry and clearance notices are affixed to all doors allowing for people to reenter and restore the structure to its original state.

Hazards and Limitations of Structural Fumigation

Structural fumigation produces sufficient concentration of sulfuryl fluoride to be toxic to humans upon relatively short exposure. With the proper building inspection procedures, secondary locks, warning signs, and chloropicrin release, accidents involving human exposure have been greatly minimized in recent years. Because sulfuryl fluoride diffuses readily between structural walls, the entire building must be evacuated, typically for two nights, even if only part of the building needs fumigation treatment. Occasionally, vegetation is planted so close to a building that it must be covered by the fumigation tarpaulin. Dowsing soil around roots with water reduces sulfuryl fluoride exposure but temporary leaf-drop will often occur in many plant species.

Structural Fumigation, Figure 146 **Fumigation, continued: (a) warning signs should be placed on all sides of the structure, (b) liquid chloropicrin is poured into an evaporation pan placed next to a fan and the outlet of the sulfuryl fluoride release hose, (c) sulfuryl fluoride is released as a liquid. Upon exiting the end of the release hose, the liquid boils and spontaneously turns into a gas at atmospheric temperature and pressure, (d) Fumiscope® used to measure working concentrations of fumigant, (e) halogen leak detector is useful for finding leaks in the seal of a fumigated structure, (f) initial aeration requires that the fumigator enters the building to open doors wearing a self-contained breathing apparatus, (g) gn Explorer IR clearance detector can measure down to 1 ppm sulfuryl fluoride.**

Structural Pest

A pest that affects the structural wood in buildings.
► Urban Entomology

Stylet

The elongated needle-like portions of the piercing-sucking type of insect mouthparts in Hemiptera.
► Mouthparts of Hexapods

Stylet-Borne Virus

A virus that does not persist in the vector, but which is a mechanical contaminant of the insect's mouthparts (stylets). Also known as nonpersistent virus.

Stylopidae

A family of insects in the order Strepsiptera.
► Stylopids

Stylopization

The occurrence of parasitism by stylopids (Strepsiptera).

Stylus

A finger-like process; a simple, primitive ovipositor.

Subalare

A small, upper portion of the pleuron, posterior to the wing, to which wing muscles are inserted.

Subcosta

The longitudinal vein running parallel to the costa. It usually turns and connects to the anterior margin of the wing before reaching the wing apex, and usually is unbranched.
► Wings of Insects

Subcosta Fold

The depression between the costa and the radius.

Subcuticular Space

The space created between the epidermal cells and the endocuticle during molting.

Subdorsal

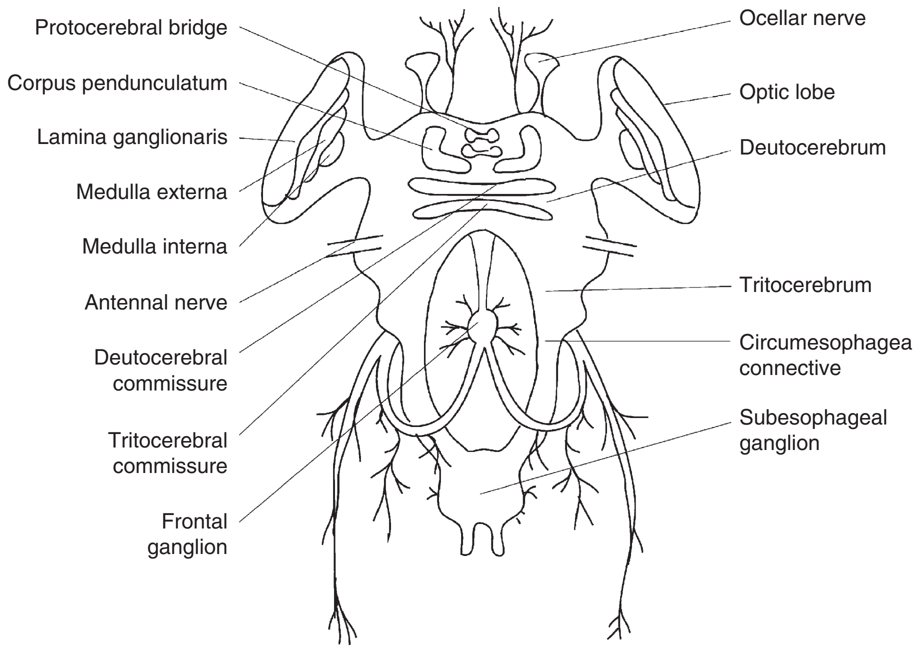
A region between the dorsal and lateral areas.

Subesophageal Ganglion

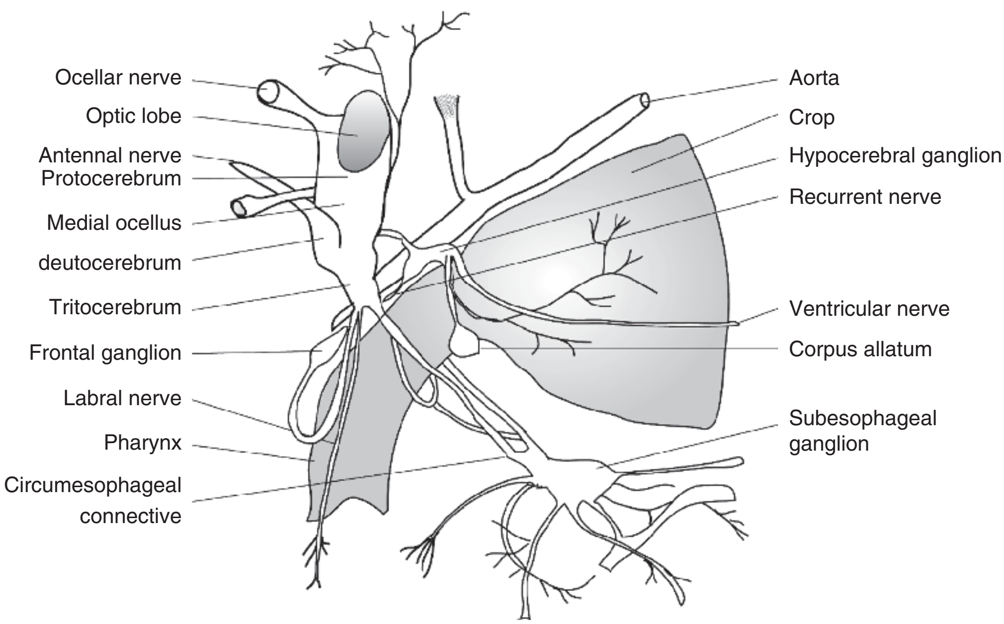
A ganglion located in the head that is found beneath the digestive tract (Figs. 147 and 148), and which innervates the mouthparts.
► Endocrine Regulation of Insect Reproduction
► Nervous System

Subfamily

In classification, a major division of the family unit consisting of related tribes or genera. Subfamily names end in -inae. Although not one of the major taxonomic units, subfamilies sometimes are quite useful in describing clusters of like taxa.



Subesophageal Ganglion, Figure 147 **Cross section showing the relationships of the principal endocrine glands with the brain (adapted from Chapman, The insects: structure and function).**



Subesophageal Ganglion, Figure 148 **Lateral view of the insect brain (adapted from Snodgrass, Insect morphology).**

Subgalea

A maxillary segment associated with the stipes.

Subgenital Plate

A plate covering the gonopore from below.

Subimago

The first of two winged instars of mayflies (Ephermeroptera) after they emerge from the water.

Submedial Arc

Pigmentation in the form of an arc occurring on the face or top of the head in caterpillars.

Submentum

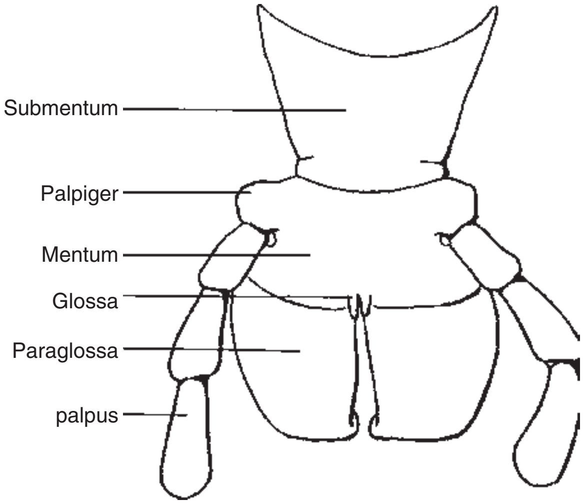
The basal portion of the insect labium (Fig. 149), by means of which it attaches to the head.

► Mouthparts of Hexapods

Subsocial Behavior

A level of sociality less than eusocial behavior. A type of presocial behavior. It involves cooperation within a family, usually expressed as a mother caring for her offspring. However, the cooperation does not extend to include to cooperation between sisters.

► Presocial
► Solitary



Submentum, Figure 149 External aspect of the labium in an adult grasshopper, showing some major elements.

► Communal
► Quasisocial
► Semisocial
► Eusocial Behavior
► Sociality in Insects

Subspecies

A subdivision of species, usually a geographic race and differing slightly or greatly in appearance but capable of interbreeding. Subspecies generally carry little importance, but may be indicative of speciation in progress. In some taxa, particularly with butterflies (Lepidoptera, in part) subspecies are widely recognized.

Subspiracular

The area immediately below the spiracles.

Subterranean Termites

A group of termites in the family Rhinotermitidae that maintain contact with the soil as they attack wood.

► Termites
► Termites in South America

Succession

A progressive series of changes in the vegetation of a site, starting with colonization and ending with establishment of a climax community. Also called ecological succession.

Sucking Lice

This suborder of wingless ectoparasitic insects is also called Anoplura, and usually is grouped together with the chewing lice (Mallophaga) into a single order, Phthiraptera, though sometimes they are treated as separate orders. The name is based on the Greek word *sipho* (tube) and the Latin *cula* (little).

Sugarcane Rootstock Borer Weevil, *Diaprepes abbreviatus* (Linnaeus) (Coleoptera: Curculionidae)

This insect, also known as *Diaprepes* weevil, attacks numerous crops in tropical regions of the Americas.

► Citrus Pests and Their Management

Sugarcane Pests and Their Management

Robert L. Meagher[1], Maria Gallo[2]
[1]USDA, Agricultural Research Service, Gainesville, FL, USA
[2]University of Florida, Gainesville, FL, USA

Sugarcane is a tropical, perennial grass that evolved in Asia, most likely the South Pacific, probably the island of New Guinea. It is composed of six species in the genus *Saccharum* L. Two species are wild, *S. spontaneum* and *S. robustum*, and four species are cultivated, *S. officinarum*, *S. barberi*, *S. sinese*, and *S. edule*. All commercial sugarcane cultivars grown today are interspecific hybrids of *Saccharum*.

History of Sugarcane

Humans have cultivated sugarcane for at least the last two millennia. Traders and migrating populations hybridized and moved sugarcane from southeastern Asia through India and China, through the Middle East and northern Africa, and into the Mediterranean. Europeans introduced sugarcane into the islands off the west coast of Africa, and Columbus transported sugarcane from the Canary Islands to the Dominican Republic on his second voyage in 1493. Sugarcane plantings and production spread during the next century into the other Caribbean islands and into Mexico, Central America, and South America.

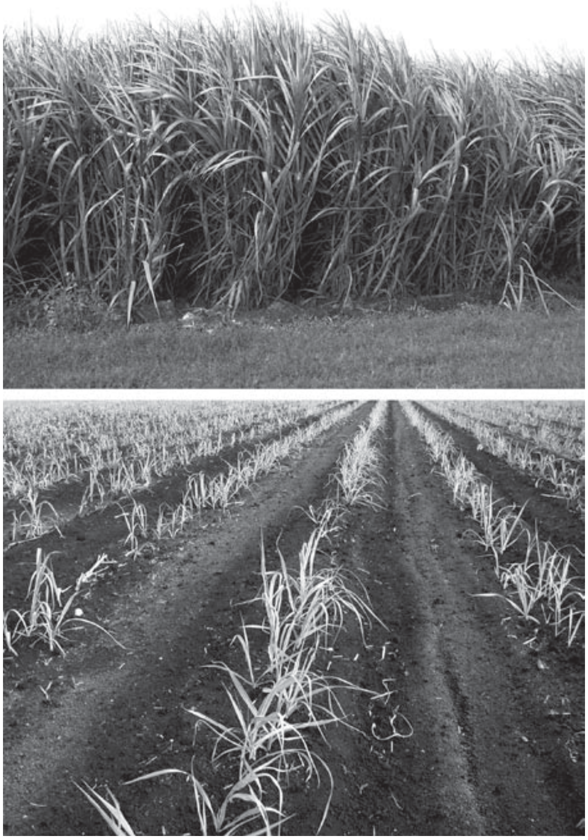
Sugarcane Production in the USA

Sugarcane is grown commercially in four states in the USA, with over 900,000 acres harvested and a value of $754 million. Jesuit priests brought sugarcane into New Orleans, Louisiana, in 1751. Commercial-scale production in New Orleans began in 1795. Sugarcane is now grown on 435,000 acres in 24 parishes in southern Louisiana. The value of sugarcane production in Louisiana in 2005 was over $282 million.

Sugarcane has been grown in many locations in Florida since the arrival of the French and Spanish. Commercial production today is centered south, east, and west of Lake Okeechobee in the southern part of the state (Fig. 150). The sugarcane industry expanded in Florida during the 1960s and harvested acres in 2006 reached 405,000. The value of sugarcane production in Florida in 2005 was almost $357 million.

Sugarcane has been grown in several locations in Texas, from the Houston area south to the Rio Grande Valley. Sugarcane was introduced into the Rio Grande Valley in the early 1800s and by 1913 there were five sugar mills. However, due to economic hardships, the last mill closed in 1921. Research was conducted in the 1960s to determine the economic feasibility of growing the crop again and in 1973 a new sugar mill was completed in south Texas. In 2006 the harvest was 46,500 acres. The value of sugarcane production in Texas in 2005 was over $54 million.

Commercial sugarcane production started in Hawaii in 1837. However, because of increasing land values and poor economic returns, production



Sugarcane Pests and Their Management, Figure 150 **Sugarcane: a mature field of sugarcane (*above*), and recently planted (*below*).**

has declined steeply since the mid-1980s. Final sugarcane harvests occurred in 1996 on the islands of Oahu and Hawaii, and in 2006, there were 22,300 acres harvested on Kauai and Maui. The value of sugarcane production in Hawaii in 2005 was over $61 million.

Sugarcane Botany

Commercial sugarcane is vegetatively propagated by planting seed pieces. Seed pieces are sections of stalks that contain two or more nodes and internodes. A node is where the leaf attaches to the stalk but is also where the buds and root primordia are located. After planting, a primary shoot and two different types of roots emerge from the bud. Secondary shoots (tillering) emerge after the primary shoot and each shoot develops their own root system. Above ground, the sugarcane leaf is composed of a leaf sheath which surrounds the stalk and a leaf blade. Sugarcane stores sucrose in the stalks with decreasing concentrations as you move up the stalk. Commercial production involves the use of plant cane fields and ratoon or stubble fields. Stubble fields have been harvested and the plants are allowed to regrow. The number of stubble crops depends on various factors such as sugarcane variety, plant diseases, soil type, and soil insect pressure.

Pest Descriptions

This section includes the important mite and insect species that attack sugarcane in the USA (Florida, Hawaii, Louisiana and Texas). Sugarcane insect pests are generally local insects that have adopted this plant as a host after its cultivation; however the movement of sugarcane has provided new geographical areas for these adopted pests. Many other insects inhabit sugarcane fields and act as predators or parasitoids. These insects are not mentioned here. Pest management considerations are discussed at the end of this section.

Acari

Although sugarcane may be infested by many different mite species, few are economic pests. Species within the genus *Oligonychus* (Tetranychidae) are occasional pests. *Oligonychus stickneyi* (McGregor) occurs in Hawaii and Florida and *O. pratensis* (Banks) is known to attack Florida sugarcane. A new mite, *O. grypus* Baker & Pritchard, was found infesting sugarcane in Florida greenhouses in 2002. This species, originally from Africa, was previously found in Cuba and

Brazil. The mite *Steneotarsonemus bancrofti* (Michael) (Tarsonemidae) is rarely found in Hawaii and Florida.

Collembola

During the 1950s in Louisiana, control measures were taken against "small soil arthropods" although there was little evidence that they caused damage. *Lepidocyrtus cyaneus* Tullberg, *Onychiurus armatus* (Tullberg), *Proisotoma minuta* (Tullberg) and *Pseudosinella violentus* (Folsom) are soil-dwelling, whereas *Salina beta* Christiansen & Bellinger have been found on the underside of leaves in Florida.

Orthoptera

In other regions of the world where sugarcane is grown, grasshoppers can be serious pests. In the USA, several species of grasshoppers and field crickets may inhabit but usually don't economically damage sugarcane. These include the grasshopper *Schistocerca obscura* (F.) and the field crickets *Gryllus assimilis* (F.) and *G. firmus* Scudder. Two species of mole crickets, *Scapteriscus borellii* Giglio-Tos and *S. vicinus* Scudder, sometimes attack young sugarcane plants.

Isoptera

Termites can be major pests of sugarcane, especially in parts of Australia, China, and India. In the USA, *Coptotermes formosanus* Shiraki in Hawaii and *Reticulitermes flavipes* (Kollar) in Florida are considered minor pests.

Psocoptera

Few species of Psocoptera have been identified in sugarcane. *Ectopsocopsis cryptomeriae* (Enderlein) was found in Florida and perhaps consumes sugarcane rust fungus (*Puccinia melanocephala* H. & P. Syd).

Hemiptera

At least 11 families have been documented to cause plant injury to sugarcane. Injury is caused by feeding from xylem or phloem tissues or by vectoring a plant pathogen which causes disease. Results of these types of injury can cause economic damage through a reduction in sugar production or plant death. Management tactics for hemipteran species include varietal resistance and the use of natural enemies.

Acleridae

This very small family of scale insects has two representatives from Louisiana, *Aclerda holci* Teague and *A. sacchari* Teague. Neither species is important economically.

Aphididae

Several aphid species are considered serious pests of sugarcane, while several other species are probably incidental inhabitants. Aphids cause injury by direct feeding and by vectoring plant diseases.

The sugarcane aphid, *Melanaphis sacchari* (Zehntner) is a widely distributed species. It was reported in Hawaii in 1896, Florida in 1977, and Louisiana in 1989. It was not found in Texas in a survey conducted in 1990. Large populations can sometimes be present and it is known to vector sugarcane yellow leaf virus (SCYLV). Although large numbers of aphids can be present, natural enemies can keep the aphids under economic control.

The yellow sugarcane aphid, *Sipha flava* (Forbes), occurs in Florida, Louisiana, and Texas. In 1989, it was found to be established in Hawaii. It is a serious pest of sugarcane and can cause premature yellowing and death of sugarcane leaves. Young plants are sometimes killed by large populations, and if the plant survives, there is a reduction in sugar yield. Natural enemies, such as predators, and varietal resistance are the two strategies used for control, although in Florida chemical control is common in some years.

Five aphid species are known vectors of the potyvirus mosaic virus: *Acyrthosiphon pisum* (Harris), *Hyperomyzus* (= *Nasonovia*) *lactucae* (L.), *Hysteroneura setariae* (Thomas), *Rhopalosiphum maidis* (Fitch), and *Uroleucon* (= *Dactynotus*) *ambrosiae* (Thomas). *Rhopalosiphum maidis* also transmits SCYLV and the phytoplasma causal organism of grassy shoot disease, which is not currently in the Western Hemisphere.

Cercopidae

Froghoppers or spittlebugs are serious pests of sugarcane in many areas of Mexico, Central and South America. These insects can attack sugarcane roots and also feed from leaf or stem tissues. Important genera include *Aeneolamia*, *Mahanarva*, *Sphenoclypeana*, *Sphenorhina*, and *Tomaspis*. Only one species, *Prosapia bicincta* (Say), is present in Louisiana and Florida. Surveys taken in Texas failed to find this species.

Cicadellidae

Many species of leafhopper can be found in sugarcane but it is doubtful that they cause economic damage. *Draeculacephala portola* Ball is a common species found in sugarcane and was once thought to be a vector of the sugarcane disease chlorotic streak. Other species collected in USA sugarcane include *D. mollipes* (Say) (Hawaii, Louisiana), *Balclutha caldwelli* Blocker (Florida), *B. rosea* (Scott) (Texas), *Graminella nigrifrons* (Forbes) (Florida, Texas), *G. plana* (DeLong) (Texas), *G. sonora* (Ball), *Homalodisca insolita* (Walker) (Florida, Texas), and *Oncometopia lateralis* F. (Louisiana).

Cixiidae

Two cixiid planthopper species have been found in USA sugarcane and have been reported in other sugarcane-producing areas of the New World. *Myndus crudus* Van Duzee, the American palm cixiid, is a serious pest of palms and is known to vector the palm disease lethal yellowing. Nymphs develop on the roots of grasses and adults feed on the foliage of palms. *Oliarus texanus* Metcalf is a species found in Texas and is not considered to be an economic pest.

Coccidae

One species of soft scale, *Pulvinaria elongata* Newstead, has been found in Florida, Hawaii, Louisiana, and Texas. It is a serious pest of sugarcane through its feeding, but also has been shown to vector a disease called sugarcane yellow leaf luteovirus. Natural enemies, including parasitoids and predators, can be effective in controlling populations.

Cydnidae

Burrower bugs attacking sugarcane are found in several areas in South America (Brazil and Venezuela) and southeastern Asia (Indonesia, Myanmar, Philippines, and Taiwan). In Florida, *Cyrtomenus ciliatus* (Palisot de Beauvois) and *Pangaeus bilineatus* (Say) are sometimes found at low populations levels, and in Louisiana, *P. bilineatus* and *Sehirus cinctus* (Palisot) can be abundant during spring and early summer.

Delphacidae

Two species of delphacid planthopper are potentially important pests to sugarcane in the USA. *Perkinsiella saccharicida* Kirkaldy, the sugarcane delphacid, was found in Florida in 1985, Texas in

1991, Louisiana in 1994, and Hawaii in the early 1900s. This pest can cause severe economic damage and is a vector of *Fijivirus* sp., causal agent of Fiji disease of sugarcane. Currently the disease is restricted to southeastern Asia, Madagascar, and the southern Pacific. *Saccharosydne saccharivora* (Westwood) is found in Florida, Louisiana, and Texas. This species has the potential to build up large populations on some varieties, but it usually doesn't cause economic damage in the USA. However, reports from Cuba have recently (2005) identified this species as a vector of sugarcane yellow leaf phytoplasma, a plant pathogen that inhabits the phloem sieve tubes of infected plants. Surveys in Florida and Texas have documented several other delphacid species on sugarcane, but it is not believed that they are breeding on the host plant.

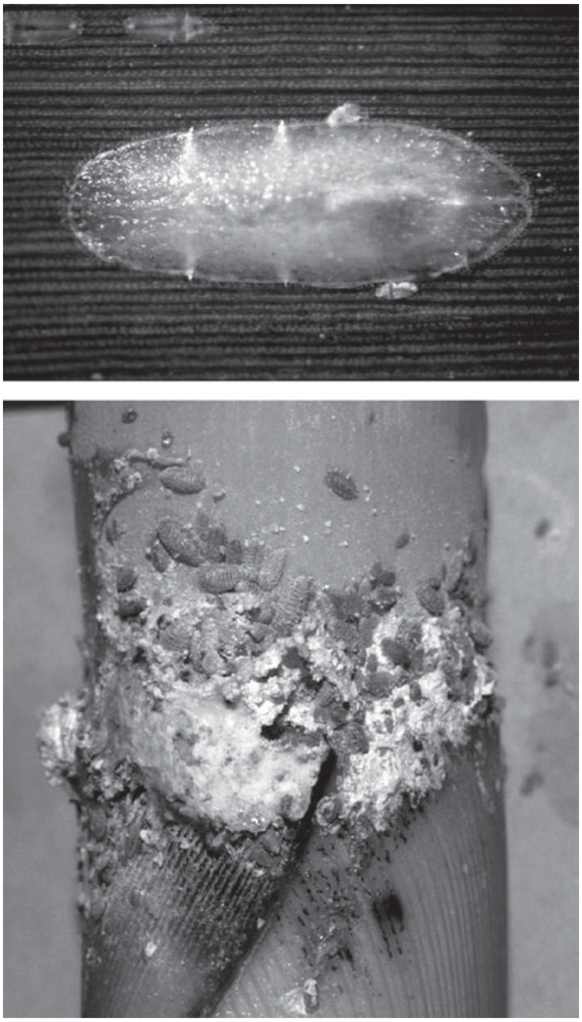
Diaspididae

Several species of armored scales are important pests of sugarcane. They congregate on the stalks under the leaf sheaths and can produce several generations during a season. Large populations can reduce sugar production. Two species, *Aulacaspis tegalensis* (Zehntner) and *Melanaspis glomerata* (Green), are not present in the USA, but are serious pests in other sugarcane areas.

Several species do occur in the USA but are not considered serious pests. *Aspidiella sacchari* (Cockerell) and *Odonaspis saccharicaulis* (Zehntner) are found in Florida, Hawaii, and Texas. *Aspidiotus destructor* Signoret is a serious pest of coconuts but is only casually found in sugarcane. *Duplachionaspis divergens* (Green) was discovered on *Miscanthus* sp. in Florida in 2000 and on sugarcane in a greenhouse in 2003. It has been reported as a minor sugarcane pest but as of yet has not been found infesting Florida sugarcane in the field. Sugarcane is noted as being a host plant for three other species, *Diaspis bromeliae* (Kerner), *Hemiberlesia cyanophylli* (Signoret), and *Selenaspidus articulatus* (Morgan).

Pseudococcidae

Mealybugs infest sugarcane in all production areas of the world. In the USA, several common species are found, although none are considered economic pests. *Dysmicoccus boninsis* (Kuwana), the gray sugarcane mealybug, is a common species found in all sugarcane-producing states. *Saccharicoccus sacchari* (Cockerell), the pink sugarcane mealybug (Fig. 151), is present in Florida, Hawaii, and Texas. It was found in Florida in



Sugarcane Pests and Their Management, Figure 151 **A sugarcane-feeding soft scale, *Pulvinaria elongata* Newstead (*above*), and pink sugarcane mealybug, *Saccharicoccus sacchari* (Cockerell) (*below*).**

1944 but was not found in sugarcane until 1995. Both species attack sugarcane by feeding on the stalks behind leaf sheaths. *Dysmicoccus brevipes* (Cockerell), the pineapple mealybug, is found in Florida and Hawaii and attacks roots and stalks near the ground. The Rhodesgrass mealybug, *Antonina graminis* (Maskell), is a pest of rangeland grasses along the USA Gulf Coast and is seldom found in sugarcane. *Birendracoccus* (= *Pseudococcus*) *saccharifolii* (Green) was noted to be in Florida and is a disease vector. It has not been found in surveys. Two other species, *Chorizococcus rostellum* (Lobdell) and *Pseudococcus longispinus* (Targioni-Tozzetti), have been noted as attacking sugarcane in Hawaii. Natural enemies and healthy seedcane programs (using uninfested cane for planting) appear to keep populations managed.

Tingidae

The sugarcane lacebug, *Leptodictya tabida* (Herrich-Schaeffer) was documented in Texas sugarcane as early as 1910, being known as a common species in Mexico, Venezuela, and the Caribbean. When the sugarcane mills shut down in the 1920s, sugarcane lacebug disappeared until its rediscovery in 1989. This species was discovered on Maui in 1985 and in Florida in 1990. Although having the potential to produce large populations, it has not yet created economic damage.

Thysanoptera

Several thrips species have been documented in Hawaiian sugarcane but few have been noted in sugarcane in the continental USA. However, many of the species listed from Hawaii are cosmopolitan in distribution and have been reported from other plants in Florida, Louisiana, and Texas. Therefore, the species listed below is where there is a historical reference to being found in sugarcane. Thrips appear not to cause economic damage to sugarcane.

One species from the family Phlaeothripidae, *Haplothrips halophilus* Hood, has been documented in Louisiana sugarcane. Eight species from the family Thripidae have been documented either from Florida, Hawaii, or Louisiana. Most of these species are cosmopolitan in distribution and probably occur in Texas. The grass thrips, *Anaphothrips obscurus* (Müller), and the Hawaiian grass thrips, *A. swezeyi* Moulton, are pests in turf grasses but also can be found in sugarcane. Four species, *Arorathrips* (= *Chirothrips*) *mexicanus* (Crawford), *A.* (= *Chirothrips*) *spiniceps* (Hood), *Chirothrips sacchari* Moulton, and *Thrips saccharoni* Moulton, have only been documented in sugarcane in Hawaii. *Hercinothrips femoralis* (Reuter), the banded greenhouse thrips, has a world-wide distribution both in greenhouses and in the field in subtropical and tropical areas. It is probably present in all USA sugarcane areas, but has only been documented in Hawaii and Florida. *Bregmatothrips venustus* Hood has been found in Louisiana sugarcane.

Coleoptera

Beetle pests of sugarcane either tunnel within the stalks or infest the roots and seed pieces. There are a couple of families where only a few species are found in association with sugarcane in the USA. These include Alleculidae (*Lobopoda* sp.), Cerambycidae [*Prionus* sp. and *Prosoplus bankii* (F.)], Nitidulidae [*Carpophilus humeralis* (F.)], and Tenebrionidae (*Eutochia lateralis* Boheman). Most of these species are only casually associated with sugarcane and may not feed on any plant tissue.

Buprestidae

One species, *Aphanisticus cochinchinae seminulum* Obenberger, was found in Florida sugarcane in 2000. This species is a leafmining insect, as larvae tunnel between the upper and lower leaf epidermal layers. This feeding injury results in dead tissue. Adults are small and elongated in shape and feed on leaf tissue. This beetle is native to Malaysia and southeastern Asia and was reported in Hawaii in 1984 and Texas in 1994. It is not considered an economic pest.

Chrysomelidae

Two flea beetle species, the desert corn flea beetle *Chaetocnema ectypa* Horn and *C. pulicaria* Melsheimer, can be found feeding on sugarcane leaves. The desert corn flea beetle was found injuring sugarcane leaves in Florida in 2000 and is a common species being recorded from a variety of grass hosts. It is probably not an economic pest in sugarcane. *Diabrotica* spp. (rootworms) have been reported in Florida sugarcane and are probably present in Louisiana and Texas.

Curculionidae

The Diaprepes root weevil, *Diaprepes abbreviatus* (L.), is native to the Caribbean and is an important pest of sugarcane on some of the islands. It was found in central Florida near Apopka in a nursery in 1964. Populations have moved south and adults were found in sugarcane in 2002. These weevils were associated with alternate host plants such as hemp sesbania [*Sesbania exaltata* (Raf.) Rydb. Ex A.W. Hill] and sicklepod (*Cassia obtusifolia* L.). Thus far it has not been a problem in sugarcane but is a major concern to the citrus industry.

The silky cane weevil, *Metamasius hemipterous sericeus* (Olivier), is a subspecies of the West Indian cane weevil, *Metamasius hemipterous* (L.). It was first reported in southern Florida in 1984 but not reported infesting sugarcane until the mid-1990s. It is distributed throughout the Caribbean, Central, and South America. Females are attracted to sugarcane stalks that are cracked or have other types of injury. Larvae tunnel in the stalks and cause damage so severe that stalks may lodge or break. Pheromone trapping technology is available for monitoring, and varietal resistance (especially varieties that don't produce growth cracks) appears to be the best management approach. This insect is also an important pest of nursery palms and banana plantings.

Southern blue-green citrus root weevil adults, *Pachnaeus litus* (Germar), have been found in sugarcane fields but there has been no observed injury to sugarcane leaves or roots. It is not known if they can complete development on sugarcane host plants.

The New Guinea sugarcane weevil or sugarcane weevil borer, *Rhabdoscelus obscurus* (Boisduval), is currently one of the three most important pests to sugarcane in Hawaii. This species has a wide distribution throughout the western Pacific, including Australia, and was documented in Hawaii in the 1880s. Females lay eggs either into bored holes or into stalks previously injured by insects or rodents. Larvae tunnel extensively in the stalks. A tachinid fly, [*Lixophaga sphenophori* (Villeneuve)], was imported from New Guinea into Hawaii in the early 1910s and again in the early 1970s. This parasitoid appears to be an important mortality agent.

Xyleborus kraatzi Eichhoff is only casually associated with sugarcane and is not thought to cause damage.

A complex of billbug species are occasionally found associated with sugarcane. These include *Sphenophorus cariosus* (Olivier), *S. coesifrons* Gyllenhal, *S. maidis* Chittenden, and *S. venatus vestitus* Chittenden. These insects are pests of forage and turf grasses and are not generally considered to be economic pests of sugarcane.

Elateridae

Wireworms, the larval stage of click beetles, are considered one of the most important pest groups attacking sugarcane. Many species are found in the sugarcane growing regions of the USA, but *Melanotus communis* (Gyllenhal) and various species of *Conoderus* are the most serious pests.

Wireworms feed on the buds and root primordia of newly planted seed pieces and on the young shoots and roots after germination. Wireworms are seldom pests of stubble sugarcane. The death of buds or young shoots leads to stand reductions. Chemical control is the most common management technique, although cultural controls such as change in planting date (Louisiana) or flooding (Florida) have had some success. Sampling for larvae is tedious and difficult; therefore, researchers in Florida have developed baits composed of rolled oats as a monitoring tool.

Scarabaeidae

This is a large family of beetles that are serious pests of sugarcane in many parts of the world, especially India and Australia. Scarabaeidae is separated into several subfamilies which in the literature may be given family status, including Cetoniinae (flower beetles), Dynastinae, Melolonthinae (May or June beetles), and Rutelinae (shining leaf chafers). Most scarab species damage sugarcane by feeding on roots and underground stems of stubble crops, especially around field edges. Some species will attack buds and root primordia of newly planted sugarcane and the apical meristem of growing plants [sugarcane beetle, *Euetheola humilis rugiceps* (LeConte)]. In Louisiana the white grub *Phyllophaga latifrons* (LeConte) is a pest, while in Florida *Tomarus* (= *Ligyrus*) *subtropicus* (Blatchley) is the most serious (Fig. 152) grub pest. Studies in Florida have shown that high infestations of *T. subtropicus* caused yield reductions in tonnage of 39%. Chemical control tactics are not always effective against white grubs in the USA, but are successful in other sugarcane areas. Biological controls (parasitoids, milky disease *Bacillus popilliae*, and the fungal disease *Metarhizium anisopliae*) occur naturally and may have positive benefits to lowering populations. Cultural practices such as disking, reducing the number of stubble crops, and flooding are also used against these pests, and have reduced the impact of *T. subtropicus* in Florida.

Sugarcane Pests and Their Management, Figure 152 **An important sugarcane-feeding white grub species, *Tomarus* (= *Ligyrus*) *subtropicus* (Blatchley): larva (above) and adults (below).**

Diptera

Few fly species are noted as pests in sugarcane. In Florida adults of the otitid *Euxesta stigmatias* Loew (cornsilk fly) are found in sugarcane fields but no injury has been recorded.

Lepidoptera

Moth species attack both above- and belowground portions of the sugarcane plant. Many of the families we have listed (Elachistidae, Noctuidae, and Oecophoridae) contain species that are only casual occupants in sugarcane. One exception is fall armyworm (FAW) [*Spodoptera frugiperda* (J.E. Smith)], a sporadic pest that can, under certain conditions, defoliate a field of newly planted sugarcane.

Crambidae and Pyralidae

The most important group of moth pests is the crambid and pyralid stalkborers. Species in these groups are found everywhere that sugarcane is grown, and in many locations, a stalkborer species is the most important insect pest in that region. In the USA, sugarcane borer (SCB) [*Diatraea saccharalis* (F.)] is the species of concern in Florida and Louisiana. In Texas, the Mexican rice borer (MRB) [*Eoreuma loftini* (Dyar)] surpassed SCB as primary pest (Fig. 153). In Hawaii few stalkboring species are present but the lesser cornstalk borer [*Elasmopalpus lignosellus* (Zeller)] has invaded and is a serious pest.

Stalkborers lay eggs on sugarcane leaves (SCB) or in dried leaf material at the base of plants (MRB). The first few instar larvae feed or mine in the leaves, midribs, and leaf sheaths. The resulting injury appears as "pinholes" or "window-panes." In young plants, feeding within the inner whorl of leaves can cause "deadhearts," where the central growing shoot is killed. Older instar larvae enter and tunnel within stalks, creating injury defined as a "bored internode." Tunnels constructed by SCB larvae are cleaner and more linear than tunnels created by MRB larvae. Sugarcane borer larvae may tunnel in stalk sections between internodes, whereas MRB larvae generally meander within one internode. Pupation is completed within the stalk and adults emerge through their tunnels. Stalkborer feeding weakens the stalks so that they break or lodge more easily. Also, feeding allows entry for saprophytic red rot fungi [*Glomerella tucumanensis* (Speq.) Arx & E. Müller (= *Colletotrichum falcatum* Went.) and various secondary insect pests (Nitidulidae).

Chemical, biological, and plant resistance techniques are used to manage stalkborer populations. Insecticides applied that are targeted to the adult and young larval stages can be effective, but once larvae enter the stalks control is difficult. *Cotesia flavipes* Cameron, a parasitoid of *Chilo* spp. in India and Pakistan, was initially brought to the Caribbean for SCB control. It is now the main natural enemy of SCB in Florida and Texas. In Florida, augmentative releases of this parasitoid are made in some areas. In Louisiana, predation by the red imported fire ant, *Solenopsis invicta* Buren, provides good biological control. The search for effective natural enemies of MRB continues in several states of western Mexico. Certain varieties of sugarcane have natural tolerance (ability to produce high sugar yields under stalkborer pressure) or confer resistant characters (tough leaves or rind hardness) that reduce populations. New techniques such as the production of plants with insecticidal proteins are showing positive results.

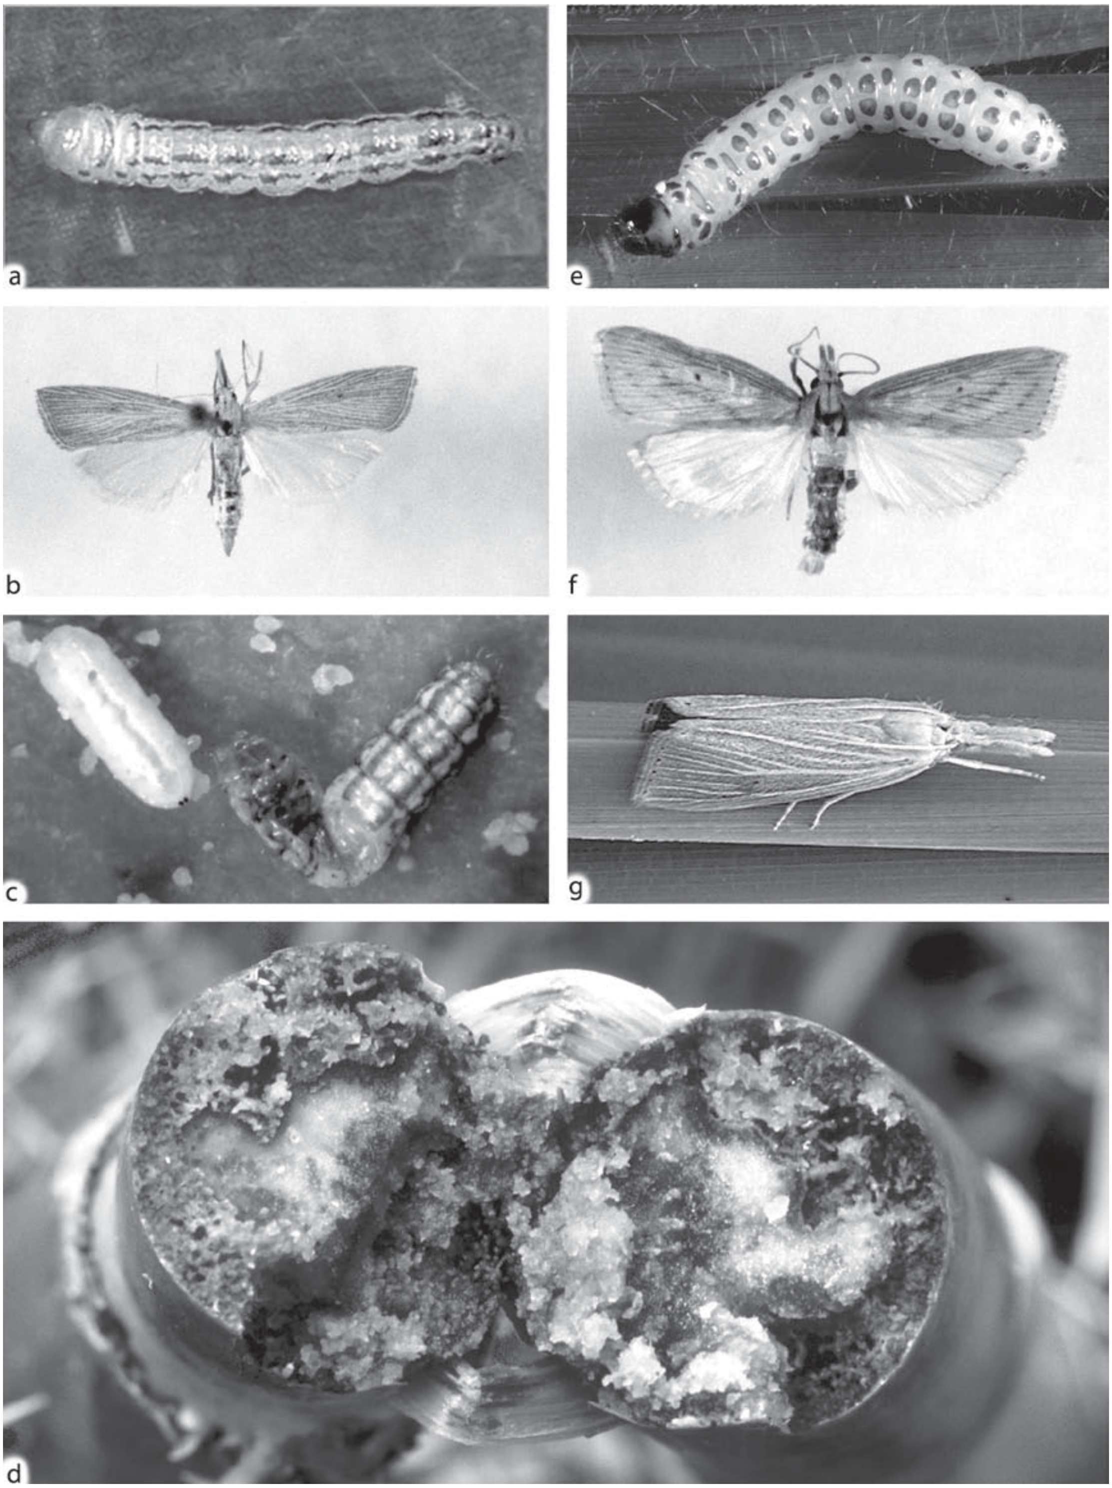
The lesser cornstalk borer (LCB) is native to the southeastern USA and is a pest of sugarcane on sandy soils. It is a relatively new pest in Hawaii, being first recorded in 1986. Lesser cornstalk borer is a more serious pest to young sugarcane plants under dry conditions. Eggs are laid just below the soil surface and larvae feed from silken tunnels at or below the soil level. Larvae kill the primary shoots causing deadhearts. Cultural controls, such as regulating irrigation, insecticides, introduction and conservation of parasitoids, and varietal resistance are some of the management techniques that are used for control.

Sugarcane Pest Management

Management Strategies

Growers use a variety of approaches to control insect and mite pests of sugarcane. Cultural control is defined as using agronomic techniques to reduce the likelihood of pest problems. These techniques include planting clean seed pieces (i.e., planting uninfested cane pieces), the use of irrigation or flooding, disking or tillage of fields, reduction of the number of ratoon crops, and sanitation of infested plant material.

Biological control is another management strategy that has been very successful with some sugarcane pests. The introduction of insect pathogens (for beetle and stalkborer pests) and predators (for aphid, scale insect, and mealybug pests) has



Sugarcane Pests and Their Management, Figure 153 **Some important Lepidoptera affecting sugarcane: Mexican rice borer, *Eoreuma loftini* (Dyar) larva (a), adult (b), larva from which a tachinid parasitoid has emerged (d), and tunneling damage in cane stalks; and sugarcane borer, *Diatraea saccharalis* (F.) larva (e) and adults (f, g).**

had varying degrees of success. However the introduction and conservation of parasitoids has had the most success in controlling insect pests. Insect species within families of Diptera (Tachinidae) and Hymenoptera (Bethylidae, Braconidae, Eulophidae, Ichneumonidae, Scelionidae, and Trichogrammatidae) have been released in large numbers to control various hemipteran and lepidopteran pests. For example, 17 species in six parasitoid families have been introduced into Texas sugarcane for biological control of the crambid pest MRB. Continued research into the requirements of these parasitoids and the conditions which promote their establishment and population growth will guarantee success of biological control.

Chemical control, especially against soil pests, is used in USA sugarcane production. In Florida and Louisiana, two materials are registered for wireworm and other soil insect control. Insecticides are also labeled for SCB, LCB, and aphid control in Florida and Louisiana. To maintain the presence of biological control agents, insecticide applications are made to <1% of the sugarcane acreage in Hawaii and Texas.

Varietal resistance through classical breeding has been an important management strategy against stalkborers. There is variability in the number of bored internodes among the commercial and non-commercial sugarcane clones when tested against SCB and MRB. Resistance can be separated into leaf and stalk components. Young larvae must be able to become established within the leaves, midribs, and leaf sheaths and obtain sufficient nutrients before entering stalks. Leaf sheath appression and leaf midrib hardness have been shown to be resistant characters. Stalk resistance involves the ability of larvae to enter and tunnel. Rind hardness (an interior section of the stalk), stem

diameter, and physical attributes of the interior part of the stalk are mentioned as possible resistant characters.

However, classical breeding for sugarcane improvement is labor intensive as well as time consuming, and is often limited by genetic complexity and low fertility. Unlike many other grasses, sugarcane tissue culture and transformation is, for the most part, genotype independent. Consequently, elite sugarcane cultivars can be genetically engineered for improved traits like insect resistance.

Sugarcane plants have been genetically engineered through the biolistic method of transformation (using a "gene gun" to insert genes into the tissue) using embryogenic callus as the target tissue derived from young plant tissue. Additionally, *Agrobacterium*-mediated transformation has been successful using meristematic sections and axillary buds of the sugarcane plant. A lectin-encoding gene (*Galanthus nivalis* agglutinin) from the snowdrop lily was used to transform sugarcane, and experimental results showed less feeding by larvae and fewer eggs placed on these plants by MRB and SCB. Partial resistance to SCB was also observed in transgenic sugarcane plants expressing genes encoding soybean proteinase inhibitors. However, the most common genes used for insect resistance in sugarcane have been modified *Bacillus thuringiensis* (Bt) endotoxin protein genes. Transgenic sugarcane plants expressing these Bt genes have displayed resistance to the LCB, SCB, and FAW.

Sugar-Feeding in Blood-Feeding Flies

FIONA F. HUNTER
Brock University, St. Catharines, ON, Canada

In the order Diptera, there are several groups of haematophagous (blood-feeding) flies that also feed on carbohydrates. Many a hiker can attest to the fact that when you get swarmed by black flies and accidentally crush a few between your teeth, the black flies taste quite sweet. This is due to the presence of sugars within the crop, the sugar-storage organ.

In contrast to some blood-sucking flies (e.g., stable fly, family Muscidae; tsetse fly, family Glossinidae), in which both sexes feed on blood, it is only the females that blood-feed in the following dipteran families: Simuliidae (black flies); Culicidae (mosquitoes); Tabanidae (deer flies, horse flies); and Ceratopogonidae (biting midges). Depending on the species, sugars are required by both sexes for increased longevity and/or flight. Females benefit from the blood meal because they use the extra protein for egg development; however, in certain species fecundity is increased following sugar feeding.

Sugar Meal Sources

The major sources of sugar meals are floral nectar, extrafloral nectaries, and hemipteran honeydew; minor sources include tree sap, rotting or damaged fruit, and leaf wounds. Floral nectar contains three major sugars, namely fructose, glucose and sucrose. A few floral nectars also contain maltose, melebiose and/or raffinose. Most studies on the sugar-feeding biology of biting flies have used the cold-anthrone test to detect fructose and fructose-containing sugars, under the assumption that most biting flies use floral nectar as their main source of sugar. Recently, several studies have employed other techniques such as gas chromatography, high performance liquid chromatography and thin layer chromatography in which the trisaccharide melezitose (and in some instances, the trisaccharide erlose or the tetrasaccharide stachyose) is used as an indicator sugar to show when flies have fed on honeydew. Using these techniques, the incidence of honeydew feeding in biting Diptera has been reported to be from approximately 5–55% in mosquitoes (with most species <15%), 0–5% in biting midges, 20–50% in black flies (with an average of 35%), 45–85% in deer flies (with an average of 65%) and 50% in horse flies.

Black Flies and Sugar Sources

A long-held view has been that black flies preferentially take nectar from plants with small white, yellow or green flowers. There have been several records of black flies feeding on ivy and willow. Folklore has it that on the Canadian Shield black flies are a major pollinator of lowbush blueberries (*Vaccinium angustifolium* and *V. myrtilloides*), but it has been shown experimentally that although they will enter the flowers and feed avidly on blueberry nectar, black flies do not assist in pollination. The exact plants on which black flies nectar-feed can sometimes be determined by examining the crop contents for pollen grains and identifying the pollen microscopically. They have been observed feeding directly on the honeydew produced by adelgids found on tamarack.

Mosquitoes and Sugar Sources

Depending on the species, early spring *Aedes* mosquitoes have been recorded nectar-feeding on Canada plum, pin cherry and a variety of woodland plants. Even in the high Arctic, mosquitoes have been observed feeding on floral nectar from the flower *Dryas integrifolia*. A relatively high incidence of crops tested positive for honeydew sugars in *Anopheles* mosquitoes (about 55%) but other genera seem less inclined to feed on hemipteran honeydew (Fig. 154).

Sugar-Feeding in Blood-Feeding Flies, Figure 154 Mosquito feeding on nectar from plant nectary. (Photo by Doug Burkett, University of Florida.)

Tabanids and Sugar Sources

There have been only a few observations of tabanids feeding on floral nectar, whereas several researchers have observed tabanid flies feeding on aphid honeydew (e.g., on the leaves of marsh elder, *Iva frutescens*). For salt marsh horse flies it has even been suggested that honeydew represents a more important source of sugar than floral nectar.

Role and Timing of Sugar-Feeding

The role of the sugars in the biology of biting flies varies according to the species. For example, it is known that a mosquito species that feeds almost exclusively on human blood, *Aedes aegypti*, does not feed often on sugars in the wild although it will nectar-feed when flowering plants are abundant. In fact, in *Aedes aegypti*, feeding on sugars results in a decrease in longevity and fecundity.

Most other biting Diptera (including most mosquitoes) are thought to sugar-feed soon after emergence for it is from sugar-meals that energy from general maintenance and for flight is acquired. Most haematophagous Diptera will also sugar-feed before mating, host-seeking and oviposition. As a result, it is generally thought that sugar-feeding occurs more often than blood-feeding.

Almost all mosquitoes, black flies, biting midges and tabanids survive significantly longer in captivity when provided with sugar-meals (such as 10% sucrose) as opposed to water alone.

The composition of the sugar-meal can affect fly longevity as well as other traits such as flight distance and duration, parasite transmission and/or egg development. The optimal sugar-feeding regime (i.e., source and frequency of sugar-feeding) for a given species and gender will depend on a number of factors including the amount of larval fat body reserves carried forward into the adult stage, the amount of flying to be done, the parasite load, and the parous state (for females).

Following sugar-feeding and digestion, circulating monosaccharides are removed from the hemolymph, assembled into large macromolecules of glycogen and stored in the fat bodies. When sugars are required, there is hydrolysis of individual glucose molecules from the glycogen reserves. The non-reducing disaccharide, trehalose, is then synthesized and released into the hemolymph. Subsequently, when flight energy is required, the trehalose is transported to the flight muscles (where it is broken back down into monosaccharides which fuel the actual flight).

In the females of some *Culex* mosquitoes lipids accumulate in the fat body after sugar-feeding. This is correlated indirectly with a behavioral switch to host-seeking (i.e., becoming attracted to blood-host odors over floral odors). Furthermore, it has been shown that the switch to host-seeking mode following a sugar-meal is mediated by juvenile hormone (JH) activity (caused by follicular development that, itself, can be triggered by a sugar-meal). Diapausing females in the genus *Culex* sugar-feed more frequently and for longer periods than do non-diapausing mosquitoes in order to build up adequate fat reserves. Nocturnal sugar-feeding behavior is also greater in diapausing vs. non-diapausing mosquitoes.

Historical Considerations

Hemiptera appear in the fossil record in the Permian, Diptera in the Triassic and flowering plants (angiosperms) in the Cretaceous. There are three ancestral traits among Diptera that facilitate honeydew usage. First, the presence of a pseudotracheate labellum allows flies to secrete saliva onto dried sugars and then suck up the liquefied sugars. This type of labellum seals off the dissolved sugars from the air, thereby reducing evaporative water loss. Second, the presence of tarsal sensilla sensitive to sugars allows the flies to "taste" sugars with their feet. This is convenient for testing the surface of leaves for honeydew (but less convenient for tasting sugars within floral nectaries). Third, flies tend to be attracted to glossy spots on leaf surfaces; this helps foraging flies flying over vegetation to locate honeydew droplets.

It is not surprising, therefore, that black flies (which appeared in the Jurassic) are capable of using honeydew sugars; effectively, nectar-feeding was a more recent development in this family. Interestingly, tabanids appeared in the fossil record at about the same time as the flowering plants and apparently maintained an ancestral preference for honeydew over floral nectar. Mosquitoes, in contrast, did not appear in the fossil record until the late Cretaceous (Senonian) or the Paleocene of the Tertiary, long after the angiosperm radiation had begun; this probably explains why mosquitoes seem to preferentially exploit nectar sources. In addition, mosquitoes have olfactory chemosensilla on their palps which respond to nectar odors and their long mouthparts are well adapted for probing flowers for nectar.

Sulcate

Used to describe a surface that is furrowed or grooved.

Sulcus (pl., sulci)

A groove or furrow formed by the infolding of the body wall.

Sulfurs

Some members of the family Pieridae (order Lepidoptera).

► Yellow-White Butterflies
► Butterflies and Moths

Summit Disease

A disease of grasshoppers caused by the fungus *Entomphaga grylli*. Not all grasshoppers are equally susceptible, and different pathotypes of the fungus are known. Those that are infected typically die at the top of plants (the basis for the name), and are found clinging to the substrate as if alive. In arid environments, the disease is associated with the margins of water bodies such as the vegetation surrounding ponds, presumably because the humidity is higher, favoring the sporulation of this fungus.

Sun Moths (Lepidoptera: Heliodinidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Sun moths, family Heliodinidae, are a small family of 56 species, mostly Neotropical (31 sp.); actual fauna probably exceeds 100 species. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (7–15 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi porrect; maxillary palpi minute, 1-segmented. Wings elongated (Fig. 155), with lanceolate hindwings with long fringes. Maculation usually brilliantly colored, with metallic-iridescent markings and sometimes raised scale tufts. Adults are diurnal. Larvae are mostly leaf skeletonizers, but some are borers in fruit racemes. Several plant families are used as hosts, particularly Chenopodiaceae, Nyctaginaceae, Portulacaceae, and Scrophulariaceae, among others.

Sun Moths (Lepidoptera: Heliodinidae), Figure 155 Example of sun moths (Heliodinidae), *Heliodines galapogoensis* Heppner & Landry from Galapagos Islands.

Sunn Pest

This term applies to several scutellerid pests of wheat (Hemiptera: Scutelleridae). The species *Eurygaster integriceps* is most important.

► Wheat Pests and Their Management

Supergene

Mutually advantageous genes clustered together on the same chromosome by selection for this beneficial association. Separation of the genes is so infrequent that they function as if they were a single gene.

Supernumerary

From a developmental perspective, this is the occurrence of extra instars (more than the "normal") in immature stages of insects. The presence of additional juvenile hormone apparently stimulates this effect, although it is correlated with environmental stress. From a morphological perspective, this refers to the occurrence of extra or added structures on an insect.

Superorder

Closely related orders, sharing common traits and thought to have evolved from one another or from a common ancestor. This level of classification is not often used, but is useful in understanding phylogeny.

► Classification

Superorganism Concept

In ecology, the concept that communities consist of some species that are tightly linked together now and in their evolutionary history. In social insects, the concept that the different castes perform functions equivalent to the physiological properties of a single organism.

Superparasitism

When more parasites (parasitoids) are developing on or in a host insect than can survive to maturity.

Supersedure

The replacement of an old or sickly queen by a new one reared by the workers.

Supplementary Reproductive

A queen or male termite that takes over the reproductive functions of the colony after removal of the primary reproductive.

Supraspiracular

The area immediately above the spiracles.

Surfactant

A pesticide adjuvant that affects surface tension of the pesticide, and enhances penetration and retention. An abbreviated form of "surface active agent."

► Insecticides

► Insecticide Formulations

Survivorship

The probability of a newly born individual surviving to a particular age, usually to maturity or reproduction.

Survivorship Curve

A plot of the declining numbers of a cohort or population as the individuals die over time.

Survivorship is usually expressed as a percentage of the initial population.

Suture

A seam or impressed line that indicates the juncture of two body plates.

Swallowtail Butterflies (Lepidoptera: Papilionidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Swallowtail butterflies, family Papilionidae (including birdwings, parnassians, and kites), total about 589 species worldwide, with about 250 species being Indo-Australian. Three subfamilies are recognized: Baroniinae (a single relict species in Mexico), Parnassiinae, and Papilioninae. The family is in the superfamily Papilionoidea (series Papilioniformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Hundreds of local races have been given subspecies names, and form names without validity, for European *Parnassius* (Parnassiinae). Adults large (35–285 mm wingspan); head sometimes roughened (Parnassiinae); antennae mostly with elongated clubs (more compact in Baroniinae and Parnassiinae). Wings triangular (Fig. 156) and mostly with relatively acute apexes (rounded in Baroniinae and most Parnassiinae; hindwings usually with tails (some species tailless, including Baroniinae and most Parnassiinae); body mostly robust. Maculation very varied, with many color combinations and sometimes with iridescence, but Parnassiinae mostly pale (even hyaline) with various spotting on both fore- and hindwings. Adults diurnal; usually slow and gliding fliers. Larvae leaf feeders; with an osmeterium defensive gland behind head. Host plants include many plant groups, especially Crassulaceae, Lauraceae, Leguminosae, Rutaceae,

Swallowtail Butterflies (Lepidoptera: Papilionidae), Figure 156 Example of swallowtail butterflies (Papilionidae), *Byasa polyeuctes* (Doubleday) from India.

and Saxifragaceae, among others. Birdwings use various Aristolochiaceae vines. Some economic species are known, mainly citrus feeders.

Swallowtail Moths (Lepidoptera: Uraniidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Swallowtail moths, family Uraniidae, comprise about 120 species from all tropical regions, mostly Indo-Australian (85 sp.); one species strays into the United States-Mexican border region (mainly in Texas). Two subfamilies are known: Microniinae, for the smaller mostly white species with very short tails (all Old World), and Uraniinae for the more well known larger and long-tailed species. The family is in the superfamily Uranioidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults medium to large (31–160 mm), with head somewhat roughened; haustellum naked; labial palpi often long with short apical segment; maxillary palpi small, 1-segmented; antennae often serrate and thickened. Wings triangular, with acute forewings (Fig. 157) and mostly tailed hindwings (margins of hindwings usually with some emarginations). Maculation usually dark browns to black, with green or pale striae, but some smaller species mostly white with very short tails on hindwings; one colorful African species (*Chrysiridia*) has three tails on each hindwing. Adults nocturnal or diurnal, with some of the larger diurnal species known to migrate (*Urania*). Larvae are leaf feeders. Host plants are known in Asclepiadaceae and Myrtaceae for the larvae in Microniinae, and Euphorbiaceae for the larvae in Uraniinae.

Swallowtail Moths (Lepidoptera: Uraniidae), Figure 157 Example of swallowtail moths (Uraniidae), *Urania leilus* (Linnaeus) from South America.

Swammerdam, Jan

This Dutch naturalist played an important role in the development of biology during the 1660s and 1670s. This was an important period in the development of science because it marked the re-ascendency (dormant since the Greek scholars) of scientific observation and experimentation, and the consequent diminution of divine interpretation. Swammerdam was born in Amsterdam on February 12, 1637; his father was an affluent apothecary who, though frustrated by Jan's lack of a "proper" vocation (medicine), apparently provided support to Jan throughout his life. Indeed, the elder Swammerdam is likely responsible for the younger Swammerdam's interest in insects, as he had a notable insect collection. Jan enrolled in the medical program at the University of Leiden at the age of 24 and received his M.D. in 1667, though there is no evidence that he ever practiced medicine. Jan Swammerdam made several important anatomical discoveries, including the presence of valves in lymph ducts, respiration and nerve-muscle function; the presence of human ovarian follicles; and the mechanism of penile erection. In 1669 he published a book: "Historia Generalis Insectorum," in which he put forth a revolutionary classification of insects based on their mode of development. His work supported that of Francesco Redi, who maintained (contrary to popular belief) that insects were not the product of spontaneous generation, but originated from eggs deposited by females. Stimulated by the work of the physiologist Marcello Malpighi, in 1670 Swammerdam began to study insects under a microscope. In this effort, he greatly advanced our knowledge of insect anatomy, particularly that of the honey bee. Unfortunately, Swammerdam fell under the influence of the religious mystic Antoinette Bourignon, and abandoned his scientific activities for several years, only to become disillusioned with Bourignon and return to science in 1676. The result of his latter work, particularly his magnificent drawings, were published much later by the Dutch physician Herman Boerhaave in 1737–1738 as "Bibliae Naturae," revealing a wealth of detail about insects and insect anatomy. Swammerdam died prematurely at the age of 43 in Amsterdam on February 17, 1680.

Swarming

The exodus of the reproductive (or reproductives) from the original nest, with the intent to form a new colony. In bees, this is normally accomplished by a single female accompanied by a large number of workers, whereas in ants and termites, usually large numbers of reproductives disperse but new colonies are founded by only a pair of individuals.

Sweetpotato and Silverleaf Whiteflies (Hemiptera: Aleyrodidae)

DAN GERLING

Tel Aviv University, Ramat Aviv, Israel

The whitefly (Hemiptera: Aleyrodidae) species *Bemisia tabaci* (sweetpotato whitefly or cotton whitefly) was described by Gennadius infesting tobacco in Greece in 1889. In the mid 1980s, following outbreaks of a similar, but not identical, insect (initially called *B. tabaci* biotype B) was recognized and in 1994, Bellows and Perring described it as *B. argentifolii* (silverleaf whitefly). To date, the validity of the "B" biotype as a separate species is still disputed. In addition, about ten biotypes have since been recognized using molecular and biochemical methods. They differ in host plant relationships and their capacities to transmit plant disorders and/or viral diseases. In the present discussion, the whole *B. tabaci* complex will be treated under the name *B. tabaci*.

Following its description in 1889, *B. tabaci* was recorded from the United States in 1894, and shortly thereafter in several African and Asian countries. It was considered to have originated in India or Pakistan until recently, when molecular studies pointed to an African origin. Moreover, some of the different biotypes probably arose locally; e.g., the "B" and the "Q" biotypes originated in the Mediterranean basin, E is from Benin, H from India and K from Pakistan. *Bemisia tabaci* was first reported as a pest from India, The Sudan, and several mideastern countries. In the United States, damage was first noted when cotton leaf crumple virus was found to be transmitted by *B. tabaci* in 1954. During the last 20 years, with the spread of the B biotype, *B. tabaci* became a cosmopolitan pest. It attacks vegetable, ornamental and field crops in tropical and subtropical regions, and greenhouse crops in colder climates.

Plant Injury

Bemisia tabaci damages plants through direct removal of plant assimilates, honeydew contamination, virus transmission and the induction of physiological plant disorders. Direct damage may range from slight plant injury to plant death. The honeydew of both nymphs and adults, and the sooty mold fungi that develop on the honeydew, contaminate plant leaf surfaces, thereby reducing their photosynthetic efficiency. The insects also contaminate the produce, reducing its market value. The most severe contamination-related economic damage is caused to cotton, where stickiness may sharply reduce lint value. The transmission of more than 70 different kinds of viral plant diseases by *B. tabaci* is a major agricultural problem. Most viruses belong to the Begomoviruses (Geminiviridae), but recently Carlaviruses, Closteroviruses, Criniviruses, Luteoviruses, Nepoviruses and Potyviruses also were recorded. Some Begomoviruses, such as the Tomato Yellow Leaf Curl Virus (TYLCV) and the East African Cassava Mosaic Virus (EACMV), drastically curtail crop production and raise great difficulty in devising an integrated or biological control program for the pest. Physiological plant disorders have mainly been associated with type B of the pest The best known disorder is leaf silvering of squash, in which the plant cuticle separates from the underlying cells giving the leaf a silvery appearance, and providing a basis for its new name (silverleaf whitefly or *B. argentifolii*). Another disorder, "uneven tomato ripening" appears when heavy whitefly populations are present during tomato ripening season.

Biology

Like all whiteflies, the *B. tabaci* female inserts its eggs into the leaf tissue by means of a pedicel. On most plants, development occurs on the underside of the leaves. They hatch into crawlers that settle close to the point of hatching, insert their mouth parts into the phloem, molt into the second instar, and loose their ability to walk on the leaf. The second to fourth instars are spent in the same location, with the developing nymphs growing from ca. 0.2–0.8 mm in length depending upon growing conditions and plant species. The nymphs may have a glabrous or spiny dorsum, in direct correspondence to the degree of pubescence of the leaf upon which they develop. The nymphs feed by inserting their 100–300 μm long mouthparts (stylets) into medium to small phloem tubes and imbibing the exuded fluid. The fourth instar includes a developing stage during which it continues to grow, and a later sessile stage that can be distinguished through appearance of larger, red eye spots. This sessile stage corresponds to the pupal stage of the Holometabola when larvae undergo metamorphosis to adults. Therefore, the red-eyed stage of the fourth instar is often referred to as a "pupa." The adults emerge through the dorsum of the "pupal" case, leaving a T-shaped split behind. The body of the emerging adults is covered with wax and is completely white. Both sexes are winged, and their body is about 12 mm long, with males somewhat shorter than the females.

Bemisia tabaci is arrhenotokous, having haploid males and diploid females. Their longevity, fecundity and developmental duration may vary greatly depending the temperature, the host plant and the whitefly biotype. Typically, females live 20–30 days in outdoor conditions during which they often lay 50–150 eggs per female. However, the number of eggs may vary, and as many as 500 eggs per female have been recorded. Developmental duration from egg to adult ranges between 2 weeks in the summer and over 2 months in the winter, in subtropical and temperate regions.

Emerging adults may stay on the leaf of emergence, mate there and lay their eggs near the point of emergence. Often, however, they migrate to the top of the canopy where they settle on younger leaves of the same or of neighboring plants. In addition to trivial, short-distance flight, long distance migration (up to 7 km) has been recorded. Individuals that migrate have somewhat different body proportions, a smaller egg load and less investment in vitellogenins than the trivial flyers.

Host Range

The full host plant range of *B. tabaci* is probably not known. Recent reports record over 500 different plant species with some reports reaching as many as 900 hosts. Given the ease at which this pest adopts new host plants, it is useful to consider any plant, especially of the dicotyledons, as a potential host, rather than to adhere to a fixed host plant list. Host plant finding is a random process until the plant itself is reached and selection takes place following a short probing. *B. tabaci* interacts with plant physiology, and plant nutrition, including nitrogen levels, influences the insect's developmental success. Feeding by *B. tabaci* can change the source-sink relationships in young melon plants, redirecting the flow of amino acids and thus enriching its feeding sites. Induced plant resistance, in which previously infected plants are relatively less suitable for insect growth than unifested plants, does not seem to affect *B. tabaci*, thus differing from other phytophagous insects such as the leaf miner *Liriomyza trifolii* or from several noctuid larvae.

Bemisia tabaci adults produce several compounds that apparently render them better adapted to the high summer temperatures in which they live and to the variation in osmotic pressures they may experience while feeding on a wide variety of plants. In addition to the presence of heat-shock proteins, which are produced in response to short-term heat stress, diurnal increases in environmental temperature induce *B. tabaci* adults to accumulate a high level of sorbitol (15–27-fold increase to ca. 0.5 M) in their body fluids which apparently protect the insect's proteins from heat damage. The presence of the recently discovered \ isobemisiose in the adult's body fluids, and its absence from the excreted honeydew, have led to the conclusion that the creation of this trisaccharide and/or it decomposition into smaller moieties facilitates adjustment of the osmotic pressure in the hemolymph, enabling the insect to withstand the relatively wide fluctuations in sugar concentration of the imbibed phloem.

Management

Because it is a very serious pest of both greenhouse and outdoor field crops, this whitefly is often treated with insecticides. This brought about widespread insecticide resistance that ranges from five to tenfold, to over 1000-fold, to both conventional materials such as organophosphates and pyrethroids, and to the newer insect growth regulators (IGRs) such as buprofezin and pyriproxyfen. IPM programs, including the insecticide resistance management (IRM) strategies recently established in Israel and the southwestern USA, depend on alternating key insecticides and limiting the numbers of yearly applications of IGRs, thus reducing the buildup of resistance. The use of insect pollinators such as bumblebees in tomatoes and in peppers, and the high incidence of resistance, brought about a widespread search for other control solutions. These include plant varieties that are resistant to the transmitted viruses or to the whitefly, the use of cultural methods such as enclosing the crop in 50-mesh screenhouses, the use of UV absorbent sheets plastic (that apparently affect the insect's orientation) and screens in greenhouses and the utilization of natural enemies: parasitoids, predators and fungal diseases. Many of the natural enemies appear spontaneously in the field crops, but may not do so early enough or in large enough numbers to control the pest by themselves. Therefore, their augmentation through timely releases in concert with utilization of other control measures, are often recommended.

Natural Enemies

The principal species of *B. tabaci* parasitoids belong to the genera *Eretmocerus* and *Encarsia*, whereas the predators may belong to numerous families and vary greatly according to the geographic location. In recent years, predators that invaded Spanish greenhouses in the spring, mainly Miridae and Anthocoridae, were found to be effective and are artificially reared and sold as control in agents in addition to the parasitoids. The use of fungal diseases to control *B. tabaci* is not widespread, mainly due to their cost and their lack of efficacy under low humidity conditions.

Organizations, Literature and Web Sites

A *Bemisia* website is available: http://rsru2.tamu.edu/BIRU/sweetpot.html. It directs readers to the various United States-based agencies that work and publish on this insect. In addition several international organizations are devoted to the study and application of *Bemisia* control. The main ones are:

European Whitefly Studies Network (EWSN) at http://www.jic.bbsrc.ac.uk/hosting/eu/ewsn/What.html

Sustainable Integrated Management of Whiteflies as Pests and Vectors of Plant Viruses in the Tropics, an SP-IPM Task Force led by CIAT at http://www.cigar.org/spipm/tf/wgv.html

Action Network for Whitefly and Geminivirus Management in Ibero America and the Caribbean, at http://www.catie.ac.cr/moscablanca

The quarterly newsletter *Mosca Blanca al Dïa* (*Whitefly Update*), which has been published since 1993, is included in this site.

In addition, over 300 publications about *B. tabaci* appear each year, listed by Dr. S. Naranjo, T. Henneberry and colleagues (Western Cotton Research Laboratory of the USDA, Phoenix, AZ) at http://www.wcrl.ars.usda.gov

Until the end of 2000 a *Bemisia Newsletter* was published and can be obtained at http://207.43.217.12/biru/BEMISIA13.htm

From 2001 on, it has been united with the EWSN newsletter that appears about every 3 months since 1998 and can be seen at http://www.jic.bbsrc.ac.uk/hosting/eu/ewsn/EWSN_ News04.htm

Sweetpotato Flea Beetle, *Chaetocnema confinis* (Coleoptera: Chrysomelidae: Alticinae)

PIERRE JOLIVET
Paris, France

Chaetocnema (*Tlanoma*) *confinis* Crotch, 1873 is a very small (1.4–1.8 mm) and light species.

Although thought to have originated in North America (USA), it has become ubiquitous in the tropics of the Old and New World. It is becoming the most widely spread species of leaf-beetle. It has two known synonyms: *C. flavicornis* J. LeConte and *C. etiennei* Jolivet. *Chaetocnema perplexa* Blake from Central America is probably also a junior synonym.

Morphology

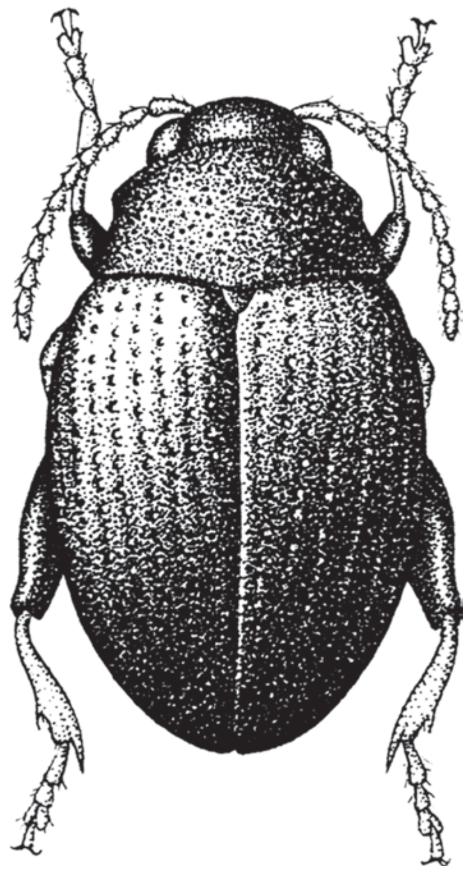
Chaetocnema confinis is a very small species; even the female is <2 mm. The adult is black to dark bronze, moderately glossy, with the antennae pale brown, the ventral surface black to dark brown, the femora brown to dark brown, the tibiae brown to pale brown, the tarsi pale brown. The striae on the elytra are parallel and the punctures moderate. The punctures are deep on the pronotum (Fig. 158).

The male has the fore and middle tarsus with the first segment somewhat enlarged. The aedeagus relatively small and sinuate. *Chaetocnema perplexa* Blake seems to differ by only a small variation of the shape of the aedeagus. The eggs are deposited in small groups and do not differ from those of related species (0.8 × 0.2 mm). The larvae are eruciform, straight, cylindrical, legged and measure 6 mm at the final stage. They live on plant roots.

Biology

Normally, *C. confinis* larvae feed inside Convolvulaceae roots, but they also attack the collar at the limit between stem and root. Long narrow grooves are eaten in the leaves, especially on the upper surface along the veins, during May and early June in North America, and throughout the year in the tropics. When these channels are numerous, the leaf may wilt. In the tropics there are many generations per year and no winter diapause. Otherwise in the US the species is univoltine.

In the US, *C. confinis* overwinters as adult under trash and various sheltered places. When they come out of hibernation, adults attack the plants when they are set out from seedbeds. By the end of June, they leave the sweet potatoes, migrating to bindweed where they lay their eggs and die. The larvae hatch after 3 weeks incubation. The new generation of beetles will feed and enter diapause in the fall. In the US and Canada, both sexes are present. In the Old World tropics only thelytokous parthenogenetic females are present, and so far as is known this is the condition in Central and South America.



Sweetpotato Flea Beetle, *Chaetocnema confinis* (Coleoptera: Chrysomelidae: Alticinae), Figure 158 ***Chaetocnema confinis*** **Crotch.**

Distribution

Chaetocnoma confinis originated in the US and Canada where both sexes are present. The beetle walks, flies and jump easily. Its recent dispersal in Africa and Asia-Pacific is probably due to typhoons and hurricanes because the beetle is light, small and winged. The first specimen was discovered on *Ipomoea aquatica*, a vegetable grown in Reunion, in 1976. It was then described under the name of *C. etiennei* Jolivet and 10 years later M. L. Cox synonymized it with *C. confinis*. Having only females in the tropics makes identification rather difficult.

Then the beetle invaded Madagascar, Mauritius and spread over most of tropical and southern Africa. *C. confinis* is also known from Brazil and Galapagos, Central America, Oceania (Palau), New Caledonia, Asia (India, Vietnam, Thailand, Ryukyu islands, etc.). At the speed that it spreads, New Guinea, Indonesia and Australia are the next targets. It is very probable that the species is already in New Guinea and several Indonesian islands. Probably it will soon cover all the tropical lands of Indian Ocean and Pacific.

Food Plants

The beetle feeds on Convolvulaceae. It feeds on *Convolvulus arvensis* (bindweed) in the US and Canada, but it has adapted to many other Convolvulaceae: sweet potato, *Ipomoea aquatica*, *I. pandurata*, *Calystegia sepium*, *Pharbitis purpurea*, *P. cathartica*, etc.

The beetle has become secondarily polyphagous, and adapted mostly in North America to corn (*Zea mays*), sugarbeet, tomato, and many other crops and weeds. In the tropics, so far it remains a major pest of sweet potato and related plants.

Conclusion

Few parasites have been recorded on this beetle and related species: fungi (Laboulbeniales, *Beauveria*), nematodes (*Howardula*), bacteria (*Xanthomonas*) and one parasitoid (Ichneumonidae).

Except in the US, where the beetle can become a serious pest on various crops, sweet potato seems to be the only host in the tropics. Several other *Chaetocnema* species and other alticines are also parthenogenetic and that seems to help in the expansion of the species. *Chaetocnoma confinis* is invading the whole of the tropics, mainland and islands together, and is becoming the most ubiquitous chrysomelid. Exchanges between Europe and the US have been common in the past (Colorado Potato Beetle, *Plagiodera* and many others) but only due to passive importations. This time the beetle seems to have dispersed by wind. Strict quarantine measures are certainly necessary in places like Australia when importing sweet potatoes, but aerial dispersion is very probable in the near future.

Sweetpotato Weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Brentidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Sweetpotato weevil presently is found in tropical regions of Africa, Asia, and North and South

America. Its origin is believed to be Africa or India despite the fact that the sweet potato plant likely evolved in northwestern South America. Thus, the association between this crop and its principal pest is relatively recent.

Life History

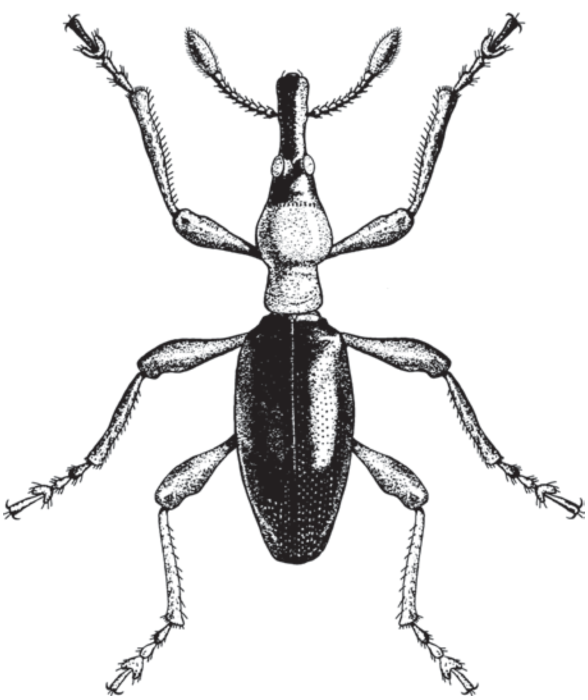
A complete life cycle requires 1–2 months, with 35–40 days common during the summer months. The generations are indistinct. In the USA, the number of generations occurring annually is estimated to be five in Texas, and about eight in Louisiana. Adults do not undergo a period of diapause in the winter, but seek shelter and remain inactive until the weather is favorable. All stages can be found throughout the year if suitable host material is available.

Eggs are deposited in small cavities created by the female with her mouthparts in the sweet potato root or stem. The female deposits a single egg, and seals the egg within the oviposition cavity with a plug of fecal material, making it difficult to observe. Most eggs tend to be deposited near the juncture of the stem and root (tuber). Sometimes the adult will crawl down cracks in the soil to access tubers for oviposition, in preference to depositing eggs in stem tissue. The egg is oval and creamy white. Its size is reported to average 0.65–0.79 mm in length and 0.41–0.50 mm in width. There is little distinct sculpturing on the surface of the egg. Duration of the egg stage varies from about 5–6 days during the summer to about 11–12 days during colder weather. Females apparently produce 2–4 eggs per day, or 75–90 eggs during their life span of about 30 days. Under laboratory conditions, however, mean fecundity has been reported to be 50–250 eggs per female.

When the egg hatches, the larva usually burrows directly into the tuber or stem of the plant. Those hatching in the stem usually burrow down into the tuber. The larva is legless, white in color, and displays three instars. The mean head capsule widths of the instars are 0.29–0.32 mm, 0.43–0.49 mm, and 0.75–0.78 mm for instars 1–3, respectively. Duration of each instar is 8–16, 12–21, and 35–56 days, respectively. Temperature is the principal factor affecting larval development rate, with larval development (not including the prepupal period) occurring in about 10 and 35 days at 30 and 24°C, respectively. The larva creates winding tunnels packed with fecal material as it feeds and grows.

The mature larva (Fig. 160) creates a small pupal chamber in the tuber or stem. The pupa is similar to the adult in appearance although the head and elytra are bent ventrally. The pupa measures about 6.5 mm in length. Initially the pupa is white, but with time this stage becomes grayish in color with darker eyes and legs. Duration of the pupal stage averages 7–10 days, but in cool weather it may be extended to up to 28 days.

Normally the adult (Fig. 159) emerges from the pupation site by chewing a hole through the exterior of the plant tissue, but sometimes it remains for a considerable period and feeds within the tuber. The adult is striking in form and color. The body, legs, and head are long and thin,



Sweetpotato Weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Brentidae), Figure 159 Adult of sweetpotato weevil, *Cylas formicarius* (Fabricius).

Sweetpotato Weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Brentidae), Figure 160 **Mature larva of sweetpotato weevil, *Cylas formicarius* (Fabricius).**

giving it an ant-like appearance. The head is black, the antennae, thorax and legs orange to reddish brown, and the abdomen and elytra are metallic blue. The snout is slightly curved and about as long as the thorax; the antennae are attached at about the mid-point on the snout. The beetle appears smooth and shiny, but close examination shows a layer of short hairs. The adult measures 5.5–8.0 mm in length. Under laboratory conditions at 15°C, adults can live over 200 days if provided with food and about 30 days if starved. In contrast, their longevity decreases to about 3 months if held at 30°C with food, and 8 days without food. Adults are secretive, often feeding on the lower surface of leaves, and are not readily noticed. The adult is quick to feign death if disturbed. Adults can fly, but seem to do so rarely and in short, low flights. However, because they are active mostly at night, their dispersive abilities are probably underestimated. Females feed for a day or more before becoming sexually active, but commence oviposition shortly after mating; the average preoviposition period is 7 days. A sex pheromone produced by females has been identified and synthesized.

This weevil feeds only on plants in the plant family Convolvulaceae. Although it has been found associated with several genera, its primary hosts are in the genus *Ipomoea*. Among vegetable crops only sweet potato, *I. batatas*, is a suitable host. Some cultivars of sweet potato are called yams, and these are susceptible to sweetpotato weevil. True yam, *Dioscorea* spp., belongs to the plant family Dioscoreaceae. Wild plants can be important hosts of sweetpotato weevil. Railroad vine, *Ipomoea pes-caprae*, and morningglory, *I. panduratea*, are among the suitable wild hosts.

Several natural enemies are known. Wasps such as *Bracon mellitor* Say, *B. punctatus* (Muesebeck), *Metapelma spectabile* Westwood (all Hymenoptera: Braconidae) and *Euderus purpureas* Yoshimoto (Hymenoptera: Eulophidae) have been reared from sweetpotato weevil larvae in the southeastern United States. There have been no studies of parasitoid effectiveness, but these species seem to be infrequent. Among predators, ants (Hymenoptera: Formicidae) seem to be most important. Diseases, especially the fungus *Beauveria bassiana*, have been observed to inflict high levels of mortality under conditions of high humidity and high insect density, but field conditions are rarely conducive for disease epizootics.

Damage

Sweetpotato weevil is often considered to be the most serious pest of sweet potato, with reports of losses ranging from 5–97% in areas where the weevil occurs. There is a positive relationship between vine damage or weevil density, and tuber damage. However, the plants exhibit some compensatory ability, with the relationship between vine damage and yield nonlinear.

A symptom of infestation by sweetpotato weevil is yellowing of the vines, but a heavy infestation is usually necessary before this is apparent. Thus, incipient problems are easily overlooked, and damage not apparent until tubers are harvested. The principal form of damage to sweet potato is mining of the tubers by larvae. The infested tuber is often riddled with cavities, spongy in appearance, and dark in color. In addition to damage caused directly by tunneling, larvae cause damage indirectly by facilitating entry of soil-borne pathogens. Even low levels of feeding induce a chemical reaction that imparts a bitter taste and terpene odor to the tubers. Larvae also mine the vine of the plant, causing it to darken, crack, or collapse. The adult may feed on the tubers, creating numerous small holes that measure about the length of its head. The adult generally has limited access to the tubers, however, so damage by this stage is less severe than by larvae. Adult feeding on the foliage seldom is of consequence.

Management

Planting time applications of insecticides are commonly made to the soil to prevent injury to the slips or cuttings. Either granular or liquid formulations are used, and systemic insecticides are preferred. Postplant applications are sometimes made to the foliage for adult control, especially if fields are likely to be invaded from adjacent areas, but if systemic insecticide is applied some suppression of larvae developing in the vine may also occur. Due to the long duration of the plant growth period, it is not uncommon for preplant or planting time applications to be followed by one or more insecticide applications to the plant or soil at mid season. Insecticides are also applied to tubers being placed into storage to prevent reinfestation and inoculation of nearby fields.

Cultural practices are sometimes recommended to alleviate weevil problem. Isolation is frequently recommended, and it is advisable to locate new fields away from previous crops and distant from sweet potato storage facilities, because both can be a source of new infestations. However, despite the infrequency of flight by adults, dispersal can occur over considerable distances. Dispersal rates of 150 m per day have been documented, with dispersal more rapid in the absence of suitable hosts.

Sanitation is particularly important for weevil population management. Discarded tubers and unharvested tubers can support large populations, and every effort should be made to remove such host material. Related to this, of course, is the destruction of alternate hosts; control of *Ipomoea* weeds is recommended.

Soil conditions affect weevil damage potential. Because adults crawl into cracks in the soil to gain access to tubers, efforts are made to reduce soil cracking. Irrigation, mulching, and hilling are common approaches, and planting in sandy soil is preferable to soil with high clay content because cracking is less likely.

Considerable research has been conducted on host plant resistance in sweet potato, and several commercially available varieties exhibit low levels of resistance. Unfortunately, resistance is not adequate when plants are exposed to high weevil population densities, and severe damage results.

Entomopathogenic nematodes seem to be the organisms with the greatest potential for practical biological suppression of sweetpotato weevil. Several strains of *Steinernema carpocapsae* (Nematoda: Steinernematidae) and *Heterorhabditis bacteriophora* (Nematoda: Heterorhabditidae) penetrate the soil and tubers, killing weevil larvae. In some soils, the infective nematodes are persistent, remaining active for up to 4 months. In some cases nematodes are more effective than insecticides at reducing damage.

Other methods of suppression are sometimes used, especially for postharvest treatment of tubers. Postharvest treatment not only prevents damage in storage, but allows shipment of tubers to areas where sweetpotato weevil is not found but might survive. Traditionally, postharvest treatment has been accomplished with chemical fumigants, but they have fallen from favor. Irradiation is potentially effective, although older stages of insects are less susceptible to destruction. Storage in controlled atmospheres, principally low oxygen and high carbon dioxide, is very effective for destruction of weevils, but requires good storage conditions.

Sweetpotato Weevils and their Eradication Programs in Japan

SEIICHI MORIYA
National Agricultural Research Center,
Tsukuba, Japan

The sweetpotato weevil, *Cylas formicarius* (Fabricius) (Coleoptera: Brentidae), is the most destructive pest of the sweet potato, *Ipomoea batatus* (Linnaeus). The insect occurs circumglobally in tropical and sub-tropical regions of Asia, the Pacific, Africa, the Caribbean and the United States. *Cylas* spp. are believed to have originated in Africa and/or Madagascar; only *C. formicarius* (Fig. 161) occurs world-wide as a pest species. Larvae and adults damage fleshy roots and stems of sweet potatoes. Larvae cause serious damage because they tunnel through the roots. Furthermore, the roots respond to weevil larvae feeding by producing ipomeamarone, a toxic furanoterpenoid with an unpleasant odor. The entire roots are rendered inedible, even though they are damaged in part, and because of their bitter taste, they cannot be eaten by livestock such as pigs, either. Because most of the larvae are cryptic in the roots below the soil surface, it is difficult to control the weevil populations effectively by the application of chemical insecticides. In 1986, the sex pheromone of *C. formicarius* was isolated, identified and synthesized in the United States. The synthesized pheromone strongly attracts the male adults of the weevil. Pheromone-trap monitoring systems have been developed in the field, and the monitoring trap is also used as a regulatory tool to detect an invasive organism in quarantined areas.

The West Indian sweetpotato weevil, *Euscepes postfasciatus* (Fairmaire) (Coleoptera: Curculionidae), is another major pest of sweet potato (Fig. 162) in the tropical and sub-tropical islands of the Pacific and the Caribbean and a part of Central and South America. The range of its distribution is narrower than that of *C. formicarius*

as a whole, but the two species coexist in some places such as the Pacific and the Caribbean regions. The adults of both species are quite different in shape; that is, *Cylas* is a snout beetle of ant-like appearance, while *Euscepes* is inconspicuous and looks like a soil particle, especially when it feigns death. However, their immature stages are indistinguishable by the naked eye, as is the damage they do to sweet potato roots. Unlike *C. formicarius*, no sex pheromone has been found in *E. postfasciatus* up to now, and no evidence has been obtained either in the laboratory or the field that this weevil can actually fly, even though the adults possess well-developed hind wings. These facts may limit available information on the management of *E. postfasciatus*.

In Japan, these two weevil pests are exotic and distributed only in the Ryukyu Islands and Bonin Islands, the southernmost part of Japan. Because the weevils are not found on the main islands of Japan, transporting host plants from infested areas to uninfested areas is prohibited by quarantine regulations, as with quarantine programs for *C. formicarius* in the United States and *E. postfasciatus* in the islands of the South Pacific. To solve the problems caused by this restriction, eradication programs were initiated by the Kagoshima and Okinawa Prefectural Governments in 1988 and 1990, respectively, under the supervision of the National Government of Japan.

A combination of two unique methods was adopted on *C. formicarius* to eradicate it from the target areas. One is to use sex pheromone traps to annihilate males; the other is to release into the field masses of laboratory-reared males sterilized by gamma irradiation, thereby depriving wild females of their chance to mate with wild males. Because of the absence of effective attractants for *E. postfasciatus*, only the sterile insect technique (SIT) could be applied to their case.

There are three steps in the course of the eradication programs, as there were with the melon fly, *Bactrocera cucurbitae* (Coquillett), which was successfully eradicated from the same area of the Ryukyu Islands in 1993. The first step was essentially a research phase to develop basic techniques required for the procedures, including mass rearing, a sterilization and marking method, and pilot eradication experiments started on two small islands (21–35 ha) in 1988 and 1990. The second step was to confirm the feasibility of the programs; thus, in 1994, experimental eradication projects were initiated on two "medium sized" islands of about 57 and 63 km^2. The sweetpotato weevil populations were almost eradicated in the target areas of both islands. The final step of the programs was put into practice in 2001 to eradicate the two weevil pests from all the distribution areas (ca. 3,500 km^2) in the Ryukyu Islands. Since this program constitutes the first attempt at area-wide eradication of sweetpotato weevils in the world, it might take longer for it to reach its goals than the melon fly eradication project, which took 22 years.

Swezey, Otto Herman

Otto Swezey (Fig. 163) was born near Rockford, Illinois, USA, on June 7, 1869. He attended Lake Forest College (B.A. 1896) and then obtained an M.A. from Northwestern University in 1897. He taught biology at Northwestern until 1903. He

Swezey, Otto Herman, Figure 163 Otto Swezey.

gained employment with the Hawaiian Sugarcane Planters Association in 1904, apparently the first American entomologist to be employed by a private company. In Hawaii, Swezey was instrumental in establishing biological control for sugarcane pests. He was a founder of the entomological section of the Bishop Museum in Honolulu, and pursued his interest in Lepidoptera, though he was more interested in describing life histories than in describing insects. Nevertheless, he described over 100 Lepidoptera. Swezey was editor of the Proceedings of the Hawaiian Entomological Society for 39 years, and also served as president of that society. A major publication was "Forest insects in Hawaii" (1954). Swezey died at San Jose, California, on November 3, 1959.

Swifts

Members of the family Hepialidae (order Lepidoptera). They also are known as ghost moths.

► Ghost Moths
►Butterflies and Moths

Swimmeret

Paired gill-like or plate-like abdominal or thoracic appendages on the aquatic larvae of some Neuroptera. They can serve as oar-like appendages to facilitate locomotion.

Sword-Tail Crickets

A subfamily of crickets (Trigonidiinae) in the order Orthoptera: Gryllidae.

► Grasshoppers, Katydids and Crickets

Sylvatic

A disease that is found in, or acquired in, a wooded or other undeveloped natural habitat.

Sylveira Caldeira, João Da

João da Sylveira Caldeira was born at Rio de Janeiro, Brazil, on June 28, 1800. After studying medicine at the University of Edinburgh, Scotland he worked for a time as a preparator at the "Jardin des Plantes" in Paris. Returning to Rio de Janeiro, he and others were commissioned to revise and publish the "Flora Brasiliensis." He also served as professor of chemistry and director of the National Museum. Following the proclamation of Brazilian independence in 1822, the holdings of the National Museum were greatly increased. He also established exchanges with European museums. Sylveira contributed materially to the collections of Macquart, and many species described by the latter are attributed to Sylveira, and several species were named after him. He died in Rio de Janeiro on July 4, 1854.

Symbiont

An organism living symbiotically with another organism.

Symbionts of Insects

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Symbiosis has been defined as mutualism (a beneficial interdependence of different species), and as parasitism (a form of interaction that is beneficial only to one partner and detrimental to the other). Today, symbiosis is sometimes equated with the concept of mutualism, in which one partner is considered the host and the other the symbiont. A difficulty with this definition is that it can be difficult to resolve relationships because the boundary between symbiosis and parasitism may be fluid. Symbionts may be intracellular or extracellular.

Mitochondria are Intracellular Symbionts

All arthropods have a nuclear genome with chromosomes consisting of DNA and proteins. In addition, insect cells also contain multiple copies of mitochondria, which are involved in basic functions of the cell. Mitochondria are generally accepted to be microbial symbionts that were modified after a long process of evolution within eukaryotic cells. Mitochondria retain a distinctive genome that is replicated and expressed, but all mitochondria are incapable of independent existence. Most of the genes in mitochondrial DNA were transferred from the mitochondrion to the nuclear genome of its eukaryotic host over the course of evolution. Only a few genes are left in the mitochondria which are located in the cytoplasm.

Multiple Symbionts May be Present

In addition to mitochondria, insects have intimate relationships with a diverse array of other symbionts, including viruses, bacteria, yeasts, and rickettsia. The details of the relationship between the host and the microorganism usually are unknown. There are intracellular symbionts (such as viruses and bacteria) as well as the extracellular symbionts.

The rice weevil *Sitophilus oryzae* (Rhynchophoridae), for example, has four genomes important to the weevil's biology. These are: nuclear, mitochondrial, principal gut endosymbiont, and *Wolbachia*. The principal gut endosymbiont is found (3×10^3 bacteria/cell) in specialized cells called bacteriocytes. A total of 3×10^6 of these bacteria are found in each weevil. The principal symbionts induce the specific differentiation of the bacteriocytes and increase mitochondrial oxidative phosphorylation. Their elimination impairs many physiological traits.

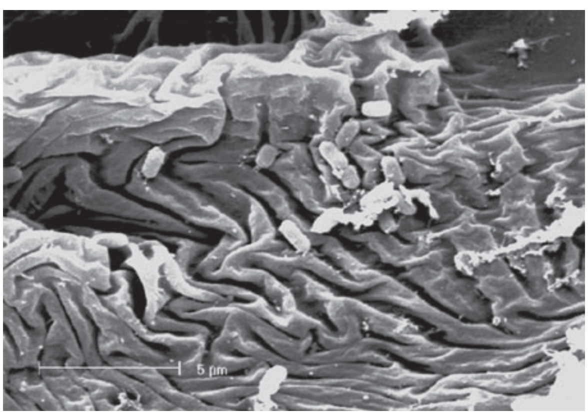
The multiple genomes found in this weevil support the serial endosymbiotic theory, which states that endosymbiosis did not occur just once in eukaryotic evolution with the origin of a nucleus, or even twice, when an anaerobic single-celled organism acquired a respiring bacterium which ultimately became the mitochondrion. Molecular data suggest the gut symbiont of *Sitophilis* was established prior to acquisition of *Wolbachia*. One scenario suggests that the colonization of cereal plants by *Sitophilus* was facilitated by the acquisition of the gut symbiont, a vitamin supplier.

Symbiont Function(s)

In many cases, symbionts possess metabolic capabilities that the insect host lacks and the insects use these capabilities to survive on poor or unbalanced diets. The insect and its microbes often require their mutual association. Many insects freed of symbionts grow slowly and produce few progeny; many symbionts cannot grow outside their insect host. The amazing diversity of relationships and organisms involved in symbiotic relationships with insects has raised many questions, but provided few clear cut answers because many symbionts cannot be cultured outside their hosts. Many symbionts are contained in special structures and transmitted by a highly-specific method, including transovarial transmission (transmission through the egg), to progeny. Transmission also can occur when larvae feed on contaminated egg shells or feces.

Some insect species contain several different types of symbionts in different tissues, including the gut, malpighian tubules, salivary gland, fat body, or gonads (Figs. 164 and 165). Usually these symbionts are neutral or beneficial to their hosts. For example, symbionts of some aphids (Hemiptera) synthesize essential amino acids, sterols, and vitamins and may function as genetic elements distinct from the host nuclear genome. Symbionts found in scale insects (Hemiptera) are particularly diverse, with almost twenty different types of associations described so far.

Antlions (Myrmeleontidae) prey on other insects by sucking out the body fluid after first paralyzing their prey with a toxin produced by salivary gland secretions produced by salivary bacteria. The paralyzing toxin produced by the bacterial endosymbionts is a homologue of GroEL, a protective heat-shock protein that functions as a molecular chaperone in the common bacterium *Escherichia coli*. In the antlion, the GroEL protein may act on receptors in insects to induce paralysis, perhaps having evolved this non-chaperone function to establish a mutually



Symbionts of Insects, Figure 164 Gut symbionts: scanning electron micrograph (magnification 6000X) of bacteria attached to the convolutions of the peritropic membrane in a *Ceratitis capitata* intestine (photo provided by Carol Lauzon, University of California, Hayward).

beneficial antlion-bacterium relationship. It is unknown if such insecticidal proteins are produced by endosymbionts to help other fluid-feeding predatory insects.

Insects lacking some symbionts are apparently completely normal. For example, in the beetle family Cerambycidae, all of which live in wood, some species have symbionts while others lack them. Thus, the hypothesis that symbionts always supply a deficiency in the insect's diet appears to be simplistic.

Gut Symbionts

The primary habitat for the majority of microorganisms associated with insects is the digestive tract, especially the hind gut. The termite gut is one of the better studied examples of symbiosis, and molecular tools are improving our ability to resolve the taxonomy of these complex relationships.

The hindguts of termites can be compared to small bioreactors where wood and litter is degraded, with the help of symbiotic microorganisms, to provide nutrients. The hindgut of termites is a structured environment with distinct microhabitats. The dense gut microbiota includes such organisms as Bacteria, Archaea, Eukaryotes, and yeasts. These organisms do not occur randomly within the gut, but may be suspended in the gut contents, located within or on the surface of flagellates, or attached to the gut wall. The identity, exact number, and location of most is inadequately known because these organisms are difficult to culture outside their hosts.

Molecular tools will provide significant new information. For example, the microbiota of termites includes spirochaetes, which account for as many as 50% of the organisms present in some termite species. Spirochaetes are a distinct phylum within the bacterial domain, but relatively little is known about them. One molecular analysis of spirochaetes in the termite *Reticulitermes flavipes* suggested there are at least 21 previously unknown species of *Treponema*, suggesting that the long-recognized and striking morphological diversity of termite gut spirochaetes is paralleled by their genetic diversity, which may reflect substantial physiological diversity.

Omnivorous cockroaches also have microbial communities within their guts, but the associations are less interdependent than those of termites. The gut microbial communities in cockroaches anaerobically degrade plant polymers and include hydrogen-consuming bacteria, especially methanogens (bacteria that produce methane gas). The densities of these microorganisms can be enormous; for example 5×10^{12} bacteria per ml were found in the hindgut of the cockroach *Periplaneta americana*.

Tsetse flies (Glossinidae) are vectors of African sleeping sickness disease in humans and animals. Microorganisms associated with these flies, that are blood feeders, are responsible for nutrients that the flies are unable to synthesize. Different microorganisms have been found in midgut, hemolymph, fat body and ovaries. Until molecular techniques were used, their taxonomic status was unresolved. Now we know that at least three different microorganisms are present: the primary (P) symbiont *Wigglesworthia glossinidia* is an intracellular symbiont residing in specialized epithelial cells that form a U-shaped organ (bacteriome) in the anterior gut. The secondary gut symbiont *Sodalis glossinidius* is present in midgut cells. The third, *Wolbachia*, is found in reproductive tissues.

Tsetse flies are viviparous, with females retaining each egg within her uterus, where it hatches. One young larva matures at a time and is born as a fully developed third instar larva. During its intrauterine life, the larva receives nutrients and both of the gut symbionts from its mother via milk-gland secretions. The *Wolbachia* are transmitted transovarially. Efforts to eliminate tsetse symbionts with antibiotics result in retarded growth and a decrease in egg production; because it is impossible to eliminate only one gut symbiont at a time, it is difficult to decipher the role each plays. However, they play a role in metabolism, supplying B-complex vitamins. *Sodalis* also produces a chitinase, which appears responsible for increasing the susceptibility of its host to the sleeping sickness trypanosome. An analysis of the *Wigglesworthia* and *Sodalis* genomes indicate that they each form a distinct lineage in the Proteobacteria. The phylogenetic data suggest that a tsetse ancestor was infected with a *Wigglesworthia* and from this ancestral pair tsetse species evolved along with the different *Wigglesworthia* strains existing today. No evidence exists that horizontal transfer of *Wigglesworthia* symbionts occurred between tsetse species. However, the *Sodalis* symbiont might have been acquired recently by each tsetse species or there may have been multiple horizontal transfers between tsetse species.

Perhaps the best studied gut endosymbiont of insects is *Buchnera aphidicola*, an associate of aphids. The complete genome of this symbiont has been sequenced. Buchnera is found in huge cells (bacteriocytes) in most of the 4,400 aphid species, supplying its host with essential amino acids. In return, *Buchnera* is given a stable and nutrient-rich environment. Aphids become sterile or die if their symbionts are eliminated. This relationship has been stable for 200–250 million years and *Buchnera* and aphids have co-evolved over a long period. About 9% of the *Buchnera* genome is devoted to producing essential amino acids for use by the aphid. Genes for nonessential amino acids are absent in *Buchnera* and thus this symbiont depends on its host for these, making Buchnera and the aphid co-dependent.

Analyses of different aphid species and their *Buchnera* symbionts indicate that vertical transmission of the symbionts has occurred from the time of the common ancestor of aphids, approximately 150–250 million years ago. Thus, the aphids and their symbionts appear to have co-speciated and there is no evidence of horizontal transfer, even within a single aphid species. In many *Buchnera* lineages, genes involved in tryptophan and leucine biosynthesis are present on plasmids rather than in the *Buchnera* genome. The location of these genes on plasmids would allow increased expression and, thus, increased benefit to their hosts. The number of copies of the plasmids appear to vary across *Buchnera* in different aphid lineages, perhaps reflecting coordinated, adaptive adjustment to the nutritional needs of the different aphid hosts. The genome of *Buchnera* is unusual when compared to the free-living bacterium *E. coli*. First the sequences are very AT-biased (about 28% GC) and second, DNA sequences evolve faster in *Buchnera* than in free-living relatives. Finally the genome of *Buchnera* from *A. pisum* is reduced, consisting of only about 650 kb (about one-seventh of the genome size of *E. coli*). It appears to contain only a subset of about 600 of the 4,500 genes present in an *E. coli*-like ancestor.

Remarkably, it appears that each *Buchnera* contains 50–200 chromosomal copies, with the number of copies varying with the life cycle stage of the host, suggesting chromosome amplification is used to vary the contribution of the symbiont to its host's nutrition. The amplification of genome copy number to 200 copies/cell is very unusual in the microbial world; *E. coli* typically has one or two chromosomes per cell. The dramatic reduction in genome size of *Buchnera* and the extraordinary increase in genome copy number make this intracellular symbiont resemble eukaryotic cell organelles such as mitochondria and chloroplasts—which are considered to be evolutionary descendants of symbiotic bacteria. *Buchnera* resemble these organelles also in that they are transmitted maternally between host generations.

A less intimate relationship between gut microbes and insects is that between *Enterobacter agglomerans*, found in the gut of the apple maggot *Rhagoletis pomonella*. Enterobacteriaceae are the most common microorganisms associated with the apple maggot in the gut and female reproductive organs, and there are suggestions the flies use the bacteria for some vital function(s). In addition to *E. agglomerans*, *Klebsiella oxytoca* is found in the gut of *R. pomonella* and both are most abundant in the esophageal bulb, crop and midgut.

These bacteria are found on host plants and other substrates in the environment. It appears that the bacteria provide usable nitrogen for *R. pomonella* and other tephritids by degrading purines and purine derivatives, making them facultative symbionts. The relationship between the *Enterobacter* and *Klebsiella* species is probably complex. *Rhagoletis* gut symbionts exist as a biofilm in the gut. A biofilm is a complex, structured community of microbes attached to surfaces. Biofilms function as a cooperative consortium in a complex and coordinated manner.

A full understanding of the genetic and evolutionary roles played by symbionts remains to be determined. In the few cases that have been well studied, a genetic interplay between insect host and symbiont occurs, factors are supplied to each from the other, and the microorganism has specific means of movement and relocation within the insect. Insects commonly control movement and multiplication of the symbiont, and the symbiont often influences growth and reproduction of the insect. A symbiont must not be subject to suppression or elimination by the insect immune system. Our understanding of how microorganisms were incorporated into insect tissues and cells and have evolved remains fragmentary, but advancing with the use of molecular tools.

Bugs Within Bugs Within Mealybugs

Perhaps most amazing is the recent discovery that there are bugs within bugs within mealybugs. Mealybugs (Pseudococcidae) have endosymbionts that live within the cytoplasm of large, polyploid host cells of a specialized bacteriome. The symbionts provide nutrients to their hosts and the relationship between hemipteran insects and these primary endosymbionts is ancient, perhaps dating to the origins of the families or superfamilies 100–250 million years ago.

The mealybug *Planococcus citri* packages its intracellular endosymbionts into mucus-filled spheres which surround the host cell nucleus and occupy most of the cytoplasm. These spheres are structurally unlike eukaryotic cell vesicles, and it was recently demonstrated that the mealybug cells actually harbor two types of Proteobacteria. The bacteria are not co-inhabitants of the spheres. Rather, the spheres themselves are β-proteobacteria with γ-proteobacteria living inside. This is the first report of an intracellular symbiosis involving two species of bacteria and the authors hypothesized that the internalization of the γ-proteobacterium by the β-proteobacterium may facilitate the exchange of genes and gene products to slow or reverse the genetic degradation that is common to long-term intracellular symbionts over evolutionary time.

Wolbachia

The genus *Wolbachia* is found in the α-proteobacteria. These bacteria are one of the most commonly found intracellular microorganisms found in arthropods. *Wolbachia* are gram-negative rods that cannot be cultured easily outside their hosts and are widespread, with estimates of infection frequency ranging to as many as 76% of all arthropod species.

Wolbachia have been implicated as both the cause of alterations in sex ratio (resulting in thelytoky and male killing), and cytoplasmic incompatibility in arthropods. Some *Wolbachia* improve fertility or vigor in their hosts, while other strains of *Wolbachia* appear to decrease these traits in their hosts.

The molecular mechanism(s) by which reproductive incompatibility are induced by *Wolbachia* are hypothesized to be due to *Wolbachia*'s ability to modify sperm. This hypothesis suggests that paternal chromosomes are modified during spermatogenesis by *Wolbachia* and this modification is "rescued" in eggs of females infected with the same strain of *Wolbachia* during fertilization. If, however, the female is not infected with *Wolbachia* and mates with an uninfected male or male infected with a different strain of *Wolbachia*, then the embryos die. Some *Wolbachia* strains have been identified that fail to modify sperm but can rescue the modification in eggs of other *Wolbachia* strains.

Species in which *Wolbachia*-induced cytoplasmic incompatibility has been documented include mosquitoes (*Culex pipiens*, *Aedes scutellaris*, *A. albopictus*), flies (*Drosophila similans*, *D. melanogaster*), the moth *Ephestia cautella*; beetles (*Tribolium confusum* and *Hypera postica*), the parasitoid *Nasonia*; and the hemipteran *Laodelphax striatellus*. Mites in the families Tetranychidae and Phytoseiidae also exhibit cytoplasmic incompatibility due to infection with *Wolbachia*.

Cytoplasmic incompatibility caused by *Wolbachia* may be partial or complete. Sometimes incompatibility is found in both reciprocal crosses (A × B and B × A, bidirectional incompatibility), perhaps due to the presence of different strains of *Wolbachia* in each population. Incompatibility more often is found in one reciprocal cross (A × B or B × A, unidirectional incompatibility). Cytoplasmic incompatibility typically is incomplete (<100%), perhaps due to inefficient transfer of *Wolbachia* to all progeny or to differences in the titer of *Wolbachia*. Such differences in titer could occur naturally if the infected insects encounter antibiotics in their environment or if they experience high temperatures (typically >30°C).

Some insects appear to have *Wolbachia* only in their germ line tissues (ovaries and testes) while others have *Wolbachia* in somatic tissues. Large numbers of *Wolbachia* have been found in ovaries and testes of populations with cytoplasmic incompatibilities. Incompatible strains have been converted to compatible by treating the colonies with heat or antibiotics to eliminate (or reduce the titer of) the *Wolbachia*.

Wolbachia can be transferred to new populations experimentally by microinjecting infected egg cytoplasm into uninfected eggs. Transinfected strains of *D. simulans* and *D. melanogaster* with high titers of *Wolbachia* exhibited cytoplasmic incompatibilities at high levels, but those with low titers exhibited low levels of incompatibility, suggesting that a threshold level of infection is required and that host factors may determine the density of the *Wolbachia* in the host.

Wolbachia have been identified in at least 70 species of parasitic Hymenoptera, including species in the Aphelinidae, Encyrtidae, Eulophidae, Pteromalidae, Torymidae, Trichogrammatidae, Cynipidae, Eucoilidae, Braconidae, Ichneumonidae, Proctotrupoidae and in three dipteran parasitoids (Tachinidae). Both cytoplasmic incompatibility and induction of parthenogenesis occur in these parasitoids. Many hymenopteran parasitoids have both bisexual (arrhenotokous) and unisexual strains consisting only of females (thelytoky), probably due to the presence of *Wolbachia*.

Phylogenetic analysis suggests that the *Wolbachia* common ancestor evolved between 80 and 100 million years ago, whereas the arthropod common ancestor occurred at least 200 million years earlier. Thus, *Wolbachia* probably invaded arthropods through horizontal transmission. In fact, the molecular phylogenies of *Wolbachia* and arthropods do not match, supporting the hypothesis that horizontal transmission is important in the distribution of different strains of *Wolbachia* among arthropods.

Several methods have been proposed as mechanisms for horizontal transfer, including the movement of *Wolbachia* from host arthropods to their parasitoids and vice versa. Experimental microinjection (artificial horizontal transfer) of *Wolbachia* from the parasitoid *Muscidifurax uniraptor* into its host *D. simulans* resulted in a temporary infection, but no specific phenotypic effects were observed. These results suggest that host-symbiont interactions are important for successful establishment of a *Wolbachia* infection in a new host. The reasons for failure to experimentally transfer *Wolbachia* remain unknown, but it is clear that *Wolbachia* has successfully bridged large phylogenetic distances in its horizontal movements over evolutionary time. Some arthropods have been found to have double or even triple infections of

Wolbachia. The effects of these multiple infections are diverse, but usually are unknown.

The availability of genetic information about *Wolbachia* has fostered increased knowledge of *Wolbachia*. The molecular technique called the polymerase chain reaction (PCR) allows scientists to study *Wolbachia* even though *Wolbachia* cannot be cultured outside their arthropod hosts. The availability of PCR primers for *Wolbachia* genes revolutionized the study of the distribution and evolution of *Wolbachia*. The *Wolbachia* genome project will further revolutionize such studies. Based on a phylogeny developed using DNA sequences from the *fts*Z gene, *Wolbachia* infecting arthropods have been divided into Groups A and B, which are estimated to have diverged from each other 58–67 million years ago. Phylogenies based on the *wsp* gene sequences have yielded more groups, indicating considerable genetic variation exists among different *Wolbachia* strains.

Wolbachia may have a role in the speciation of arthropods by generating reproductive isolation, although some argue that the role of *Wolbachia*'s in this important process remains unproved. Typically, *Wolbachia* cause unidirectional cytoplasmic incompatibility when a *Wolbachia*-infected male mates with an uninfected female. The eggs or embryos of such matings die, resulting in a fitness cost to uninfected females, which over time results in the infected cytotype becoming fixed in the population. A problem with this speciation hypothesis is that *Wolbachia* females transmit <100% of the time to progeny, so some progeny will be produced that are compatible. Secondly, incompatibility is not completely expressed (incomplete penetrance of the trait) when infected males and uninfected females mate in natural populations, perhaps due to differences in the titer of the *Wolbachia* within the different individuals. Furthermore, selection on both the host and *Wolbachia* may favor reduced penetrance of the incompatibility phenotype or loss of *Wolbachia*. This could lead to a situation in which there is no gene flow to some gene flow, reducing reproductive isolation. Thus, unidirectional incompatibility caused by *Wolbachia* may be insufficient to cause the reproductive barriers that could lead to speciation, although such reproductive isolation could assist in the process of speciation. Additional factors, such as hybrid sterility (sterility of the hybrid when crossed with either of the parental species) and hybrid breakdown (the inviability or sterility of progeny resulting from a backcross of hybrid progeny with either of the parental species) may also be involved in the speciation process.

A second speciation mechanism possibly associated with *Wolbachia* may be by the induction of thelytoky (reproduction by females only), as has been found in the hymenopteran *Encarsia formosa*. Some populations of *Encarsia* no longer have males, so that they essentially become clonal and over time could differentiate genetically. A third potential *Wolbachia* speciation mechanism is by bidirectional incompatibility; if a population is infected with two different strains of *Wolbachia* that are incompatible with each other, then the incompatibility could act as a post-zygotic reproductive barrier.

How *Wolbachia* are maintained in populations has considerable theoretical and practical importance. *Wolbachia* have been proposed as vectors for genetically transforming their host arthropod, as well as mechanisms for driving genes into arthropod populations in genetic manipulation projects for improved pest control.

The interest in the biology and evolution of *Wolbachia*, with its fascinating effects on reproductive isolation (thus potentially having effects on speciation), sex ratio, feminization, and male killing, has led to the development of a *Wolbachia* genome project, with four different groups of *Wolbachia* as targets.

Despite the wealth of information obtained about *Wolbachia* within the past few years, our understanding of the role of *Wolbachia* in arthropod biology and evolution probably remains fragmentary. For example, some *Wolbachia* in arthropods were recently shown to contain bacteriophages named WO. A phylogenetic analysis of different WOs from several *Wolbachia* strains yielded a tree that was not congruent with the phylogeny of the *Wolbachia*, suggesting that the phages were active and horizontally transmitted among the various *Wolbachia*. Because all *Wolbachia* strains examined had WO, the phage might have been associated with Wolbachia for a very long time, conferring some benefit to its microbial hosts.

Polydnaviruses as Symbionts

A particularly interesting example of an intimate relationship between insects and symbionts is illustrated by the relationship between polydnaviruses and some parasitoids. Polydnaviruses are relatively newly-recognized viruses that are found only in the Braconidae and Ichneumonidae among the parasitic Hymenoptera. Polydnaviruses are symbiotic proviruses that have double-stranded circular DNA genomes; they are literally poly-DNA-viruses, having segmented genomes composed of several circular DNA molecules. For example, the genome of the virus within the parasitic wasp *Campoletis sonorensis* consists of 28 DNA molecules ranging in size from approximately 5.5–21 kb, with the total genome size approximately 150 kb.

Polydnaviruses are important in ensuring that some species of braconids and ichneumonids are able to successfully parasitize their insect hosts. At least fifty species of parasitic wasps have been shown to contain polydnaviruses and over 30,000 species are thought to carry polydnaviruses. Polydnaviruses alter the host insect's neuroendocrine and immune responses, prevent encapsulation of wasp eggs and larvae by host hemocytes, and influence development of the host to benefit the wasp. Genera of parasitoids containing polydnaviruses appear to have more species and have broader host ranges than sibling groups lacking them, suggesting the viruses contribute to the evolutionary success of their hosts. The two polydnaviral groups, Ichnoviridae and Brachoviridae, are phylogenetically and morphologically distinct and use different mechanisms to inhibit host immunity and development. The association between braconid parasitoids and their viruses appears to have lasted at least 60 million years. Thus, the viruses and braconid parasitoids appear to have a long association and have evolved a variety of interactions with their lepidopteran hosts.

Polydnaviruses replicate only in braconid or ichneumonid wasp ovaries and are secreted into the oviducts from where, during oviposition, they are injected into host lepidopteran larvae. The viruses appear to be vertically transmitted and integrated into the chromosome of the wasp. Each wasp species appears to carry a polydnavirus characteristic of that species. If one species within a particular genus carries a polydnavirus, they all are likely to do so.

Insects possess immune mechanisms that protect them from microorganisms, other invertebrates, and abiotic materials. Protection occurs through constitutive factors or by inducible humoral and cellular responses. Many parasitoid wasps are internal parasites and spend part of their lives in the bodies of other insects. Many behavioral, morphological, nutritional, and endocrine factors determine whether the interactions between a host and a parasitoid will lead to development of the parasitoid or to its destruction. The polydnavirus influences the immune system of the insect host, which allows the parasitoid eggs and larvae to survive. The virus replicates asymptomatically in the parasitoid but causes a pathogenic virus infection in the wasp's lepidopteran host. The virus alone can induce altered immune responses in some hosts, but in other hosts the venom injected by the wasp also must be present for the full effect of the virus to occur. Parasitoid wasps thus appear to benefit significantly from the polydnaviruses that replicate in their reproductive tracts. The virus also clearly benefits if the wasp is able to reproduce, because polydnaviruses are known to replicate only within their wasp hosts.

The polydnavirus-parasitoid-lepidopteran host system provides an unusual example of an obligate mutualistic association between a virus and a parasitoid that functions to the detriment of the parasitoid's lepidopteran host. The origin of polydnaviruses is unknown, as is how they became established in the parasitoid genome. It has been speculated that polydnaviruses may have potential value in agricultural pest management programs if genetically engineered pathogens (viruses, bacteria, fungi) containing polydnavirus genes could produce products that immunosuppressed the target pest, making the pathogens more effective. Alternatively, genetically engineered parasitoids could be developed that exhibit a modified host range, making them more effective in controlling pests.

Symbiosis

A close association of two different organisms in which some benefit is derived from the association. A special type of symbiosis is mutualism, in which both organisms benefit.

Symbiosis Between Planthoppers and Microorganisms

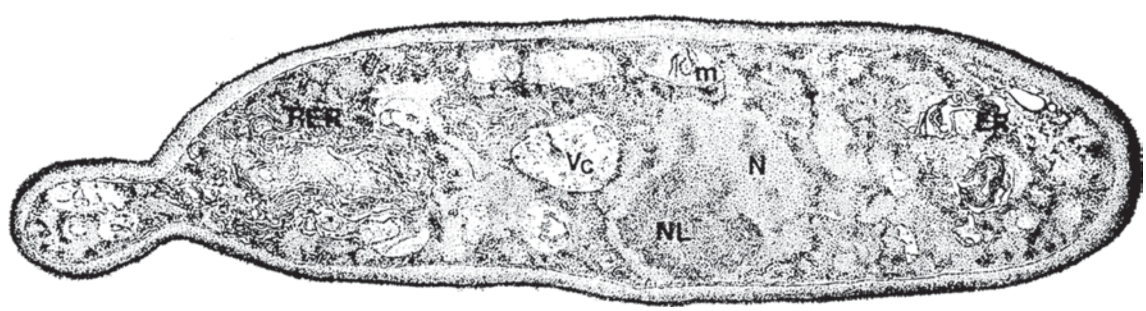
ROGER F. HOU
National Chung Hsing University, Taichung, Taiwan

Symbiosis is a rather common biological phenomenon and is defined as living together intimately between two or more dissimilar organisms. At least nine orders of insects possess symbiotes, which may be different in forms and are located in various organs (mycetoms) or cells (mycetocytes). Many plant-sucking hemipterans harbor intracellular symbiotes. For example, aphids have symbiotic bacteroids, leafhoppers have rickettsia-like organisms in addition to bacteroids, and planthoppers harbor mostly the yeast-like symbiote. The brown planthopper, *Nilaparvata lugens* Stål, is one of the most destructive pests of rice in Asia, and is extensively studied on its symbiotic association with microorganisms.

The yeast-like symbiote of *N. lugens* is located in fat body cells of the abdomen, but never in the head or thorax. It measures 2.5 × 8–10 μm in size. This symbiote is bacilliform and unicellular, has a two-layered cell wall, and reproduces by budding, forming a convexity at the budding site. The fat body in the abdomen (Fig. 166) is full of yeast-like symbiote, as observed by histological sectioning. Ultrastructural observations showed that the yeast-like symbiote has a large nucleus, ribosomes, rough endoplasmic reticulum, Golgi apparatus, and many mitochondria in cytoplasm. Its morphology resembles cellular structure of the yeast. Because it is not cultured in vitro, this microorganism is named the yeast-like symbiote. However, a phylogenetic study based on direct sequencing of its 18S rRNA genes showed that the yeast-like symbiote in three planthoppers (*N. lugens*, *Sogatella furcifera*, and *Laodelphax striatellus*) is placed in the class Pyrenomycetes of the subphylum Ascomycotina. Therefore, the taxonomic position of the yeast-like symbiote is at present uncertain.

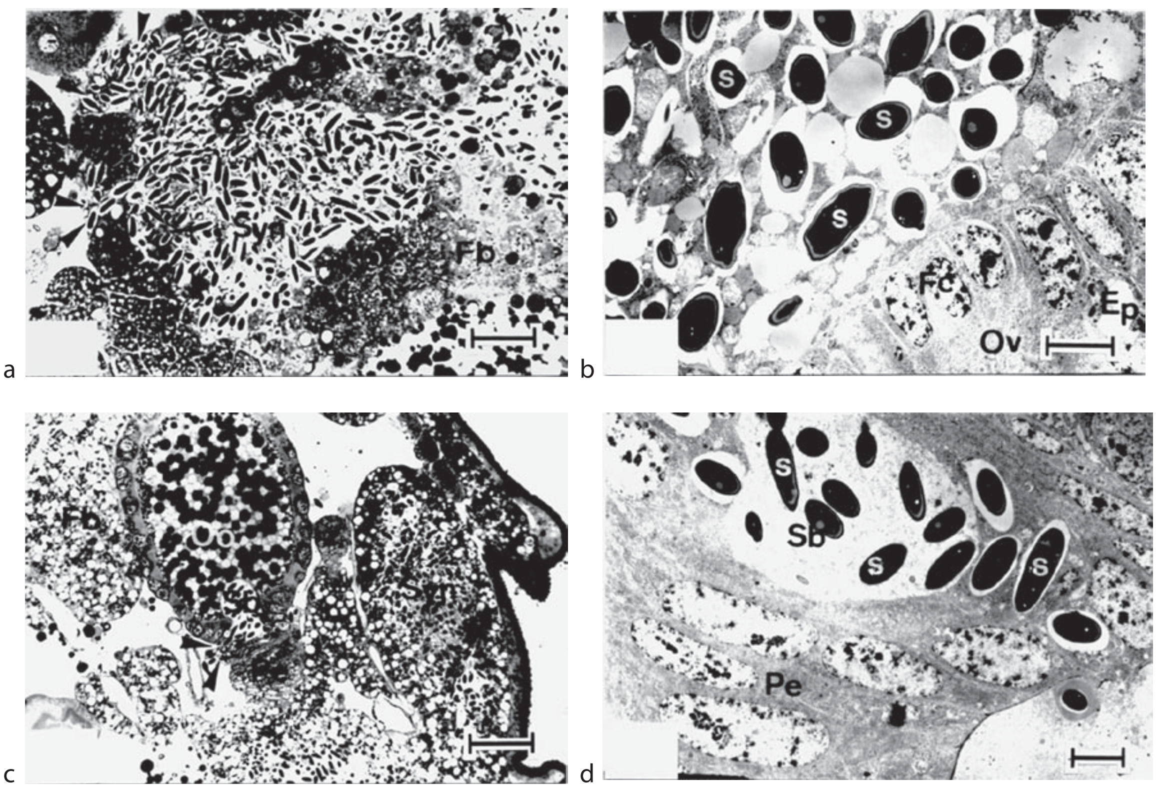
The population of yeast-like symbiote increases through nymphal development of *N. lugens*. The total number reaches a peak before oviposition in female adults and then declines, while the maximal number in males is at the fifth nymphal instar. The females harbor more yeast-like symbiote than the males, especially at the fifth nymphal and adult stages. The population declines drastically by incubating the neonate nymphs at 32°C, or above, for 3 days or longer, resulting in subsymbiotic or aposymbiotic insects (insects with less symbiotes or without symbiotes). Incubation at 32°C causes some cellular changes, such as disintegration of its cell wall, degeneration of nucleus, and loss of cytoplasm. The reduction in yeast-like symbiote number caused by high-temperature treatment (at 32°C) could be due to these cellular changes. In addition, treatment of yeast-like symbiote with some antibiotics also may result in lowering the symbiote number. For example, 0.3% Polyoxin S and 0.1% chlamphenicol as well as 0.1% cycloheximide may reduce yeast-like symbiote number, and thus kill the insects due to loss of the symbiotes.

The physiological roles of yeast-like symbiote can be studied by comparing normal with subsymbiotic or aposymbiotic insects. The brown planthopper eggs treated with high temperature



Symbiosis Between Planthoppers and Microorganisms, Figure 166 **Schematic diagram of a yeast-like symbiote in the brown planthopper, *Nilaparvata lugens* (after Cheng and Hou, 1996). Abbreviations: N, nucleus; NL, nucleolus; m, mitochondrium; r, ribosome; RER, rough endoplasmic reticulum.**

on day 1, 4 or 7 after oviposition display reduced hatchability only on day 7, indicating that the symbiote is more significant in the late embryonic development than the earlier stages. The eggs within the high-temperature treatment harbor only a few of the symbiotes, and their symbiote ball in eggs through embryonic development is free of symbiotes. The embryos of subsymbiotic eggs cannot undergo blastokinesis and dorsal closure, and fail to hatch due to lack of differentiation of the abdominal segments. Electrophoretic profile of the eggs laid by the subsymbiotic females showed the absence of several minor proteins, which are usually found in the fat body of normal females. A protein of 131 kDa is barely detectable in the subsymbiotic insects, and is not found in the ligated eggs in which the symbiote ball is completely separated from the developing germ band. Therefore, the symbiote seems to supply its host with proteins for normal embryonic and postembryonic development. The yeast-like symbiote number in females may be reduced after injection with lysozyme solution, and some of the eggs are unable to hatch due to failure in blastokinesis. The embryos of ligated eggs could complete segmentation and differentiation normally before 110 h of embryonic development, but the abdominal segments fail to



Symbiosis Between Planthoppers and Microorganisms, Figure 167 Histological micrographs showing transovarial transmission of yeast-like symbiote in *Nilaparvata lugens* (rearranged from Cheng and Hou, 2001). (a) The yeast-like symbiote moves out of the syncytium by exocytosis. Bar = 10 μm; (b) The free yeast-like symbiote in hemolymph approaches to the ovarioles near pedicel. Bar = 10 μm; (c) The yeast-like symbiote enters follicle cell around the primary oocyte by endocytosis (arrow heads) at epithelial plug. Bar = 10 μm; (d) The yeast-like symbiote aggregates at the posterior end of the mature egg after entering, forming a symbiote ball. Bar = 10 μm. Abbreviations: Ep, epithelial plug; Fb, fat body; Fc, follicle cell; Oo, oocyte; Ov, ovariole; Pe, pedicel; S, symbiote; Sb, symbiote ball.

differentiate after dorsal closure, forming the head embryos. Partially ligated eggs harbor some symbiotes and may produce normal larvae. Hence, the yeast-like symbiote is significant in abdominal segmentation and differentiation of the planthopper embryo.

The yeast-like symbiote of *N. lugens* passes to progeny by transovarial transmission. The symbiotes in mycetocytes move out of the syncytium, which is formed from a layer of fat body cells, by exocytosis, and are released (Fig. 167) into hemocoel in females. Then, the free yeast-like symbiote in hemolymph approach to the ovarioles near the pedicel and are enclosed by follicle cells. They enter the follicle cells around the primary oocyte by endocytosis at epithelial plug of the ovariole. The yeast-like symbiote aggregates at the posterior end of the mature egg after entering, forming a symbiote ball, and finally complete the transovarial transmission. Therefore, the yeast-like symbiote is intimately associated with the brown planthopper through generations and is indispensable for its host life.

Symbiotic Viruses of Parasitic Wasps

PAULINE O. LAWRENCE
University of Florida, Gainesville, FL, USA

Parasitic wasps (parasitoids) have been extensively used as biological control agents against veterinary and agricultural pests. Over the past several years, it has become increasingly evident that many of these parasitoids, particularly members of the Ichneumonoidea, have silent partners that play a major role in their success as biological control agents. These third party entities consist mainly of viruses and virus-like particles (VLPs, lacking nucleic acid or for which the nucleic acid composition is not yet known) that are presumed or determined empirically, to enhance the survival of the parasitoid within its host.

More than 80% of the Hymenoptera consist of parasitic species but little is known about their viral or VLP symbionts. It has been suggested that symbiotic viruses and VLPs influence the host range of their wasp, influencing the types of hosts they infect. Nevertheless, very little is known about the distribution and types of viruses and VLPs that occur in different species and families of the parasitic Hymenoptera. An understanding of the distribution of symbiotic viruses within parasitic wasps would provide valuable insights into which wasps may be most effectively utilized as biological control agents of insect pests. It would also further our understanding of the co-evolutionary relationships that may have arisen between hymenopteran families and particular genera of viruses.

Several factors influence the successful development of the immature wasp within its host. These include the fluctuations in the host's endocrine system, the biochemical and nutritional status of the host, as well as its physiological ecology. An equally important but more immediate factor that influences the wasp's developmental success is its ability to avoid or circumvent the host's cellular defense responses, particularly during the wasp's egg development. Substances from the venom gland of the wasp, proteins and other secretions from extra-embryonic membranes of wasp first instars, as well as ovarian proteins injected with the wasp egg play various roles in enhancing development/survival of the wasp egg and larva. The VLP of the ichneumonid wasp *Venturia canescens* was one of the first to be identified as protecting the oviposited wasp egg. However, the subsequent discovery and characterization of polydnaviruses (PDVs), double stranded DNA viruses with unusual segmented circular genomes, followed by discoveries of even more PDVs, RNA and unipartite DNA viruses, and VLPs, brought into focus the widespread distribution of wasp-associated viruses and their impact on the host's immune response and survival of the developing wasp.

The availability of molecular tools has facilitated the sequencing and comparative analyses of the genes and/or genomes of several PDVs, as well as their phylogenetic relationships within the Ichneumonoidea. Consequently, PDVs are the best studied wasp-associated third party entities. PDVs belong to the genera *Ichnovirus* and *Bracovirus* from the Ichneumonidae and Braconidae wasps, respectively. Bracoviruses appear to share one evolutionary origin but apparently are distinct from ichnoviruses. Nevertheless, the genomes of both groups are integrated into their wasp genomes as a provirus and are transmitted as such to the next wasp generation. These PDVs replicate as virions within the epithelium of the ovarian calyx (swollen base of the ovary) but not in the host. Over 30 bracoviruses and more than 20 ichnoviruses have been described from different wasp species. Their genome organization is complex and thought to be more eukaryotic than viral, and is considered to be highly evolved packages of wasp genes.

The major focus of this overview is on viruses other than PDVs, with emphasis on those that belong to recognized/established taxonomic virus families, based on characteristic morphology and/or empirical molecular data. The overview will address basic characteristics of the family of viruses and will discuss reported findings on the biology, location, and putative role of the virus in wasp survival within the host. Where available, aspects of the molecular characterization of genes from relevant viruses will be addressed.

While PDVs are more widely studied, several types of RNA viruses and unipartite double stranded DNA viruses and VLPs have been described from parasitic wasps and are known or presumed to be transmitted to their hosts during oviposition. Some of these belong to six known virus families (Ascoviridae, Baculoviridae, Picarnoviridae, Poxviridae, Reoviridae, and Rhabdoviridae) but fewer than 20% of these viruses have been characterized, in whole or in part, at the molecular level. Most VLPs have been described only by their shape and size, with no demonstrated relationship to known virus families. No nucleic acids have been detected in some of these, suggesting that VLPs vary in their evolution from true viruses to other entities that have co-evolved with the parasitic wasp. All viruses and VLPs described to date were reported from either the epithelium of the ovarian calyx or the lumen of the poison gland apparatus of the female wasp, but most are presumed to be transmitted to the host during oviposition since these sites are confluent with the oviducal canal. Fewer, however, have been traced to the parasitized hosts as well, providing direct evidence of transmission from the wasp. Following is an overview of wasp-associated viruses from recognized virus families excluding the PDVs and unclassified VLPs that lack morphological or molecular relationship to recognized virus families.

Ascoviridae

Ascoviruses are a recently established group of large (400 × 130 nm), double-stranded, enveloped DNA viruses with an electron dense core and are all presumed to have a circular genome of about 100–180 kb. The virions vary in shape from allantoid to reniform and bacilliform and infect primarily noctuid larvae. The noctuid-attacking ascoviruses of *Spodoptera frugiperda* (SfAV1), *Trichoplusia ni* (TnAV2), and *Heliothis virescens* (HvAV3) are mechanically transmitted by ovipositing wasps and are highly pathogenic to their hosts. They presumably retard and even kill developing parasitoid larvae within infected hosts, are therefore not beneficial to the parasitoid and are not considered here among the symbiotic viruses.

The *Diadromus pulchellus* ascovirus (DpAV4) is 220 × 150 nm and replicates in both the ichneumonid wasp vector *D. pulchellus* and its noctuid host *Acrolepiopsis assectella* and enhances the development of the wasp larva. DpAV4 is the first unipartite DNA symbiotic virus to be characterized, in whole or in part, at the molecular level. It has a 116 kb circular genome and replicates extra chromosomally in the nuclei of the ovarian calyx of the wasp and of various somatic tissues of male and female wasps, suggesting that the virus is transmitted as an episome. This is in contrast to the PDV proviruses within the wasp's chromosomal DNA. The DpAV4 genome contains several highly conserved (77%) repeats of 494 bp containing sequences similar to the DNA-binding motifs of baculoviruses, herpesviruses, and adenoviruses, although the same viral replication functionality of those motifs cannot be ascribed with certainty. Phylogenetic analysis of the d-DNA polymerases of DpAV4 with those of the noctuid ascoviruses and other DNA viruses, suggested that DpAV4 belongs to a different clade, and likely a different family, from the noctuid ascoviruses and are close relatives of iridoviruses. It is also interesting that motifs known to be conserved within the d-DNA polymerases of baculoviruses, herpesviruses, adenoviruses, and entomopoxviruses also occur in DpAV4 and the other noctuid Ascoviridae. The presence of such motifs may either be a result of viral acquisition of housekeeping genes from their hosts, conservation of original genes from a common ancestral virus, or convergent evolution. Given the paucity of information on the origin and/or evolution of viral symbionts, these and other molecular similarities to known viruses are potentially fruitful avenues of inquiry in the future.

The DpAV4 ascovirus is presumed to have either no effect on, be pathogenic to, or mutualistic with, its host, depending on the species of *Diadromus* wasp that carries it, and this variable relationship is presumed to be regulated by some suppressive/permissive factor found in the wasp females. There is limited evidence of similarities between ichnoviruses and DpAV4, leading to speculation that they may constitute an intermediate in the evolution from the pathogenic ascoviruses to symbiotic form and further, to ichnoviruses.

DpAV4 replicates within host hemocytes and disrupts their encapsulation response, presumably by destroying their intercellular communication and inducing hemocyte segregation. This mechanism, no doubt, enhances the survival of the developing parasite within the host. However, DpAV4 does not benefit all parasitoids that co-occur in the *A. assectella* host. Indeed, it enhanced the development of *D. pulchellus* and its close relative *D. collaris* but retarded and sometimes killed larvae of another but unrelated ichneumonid *Itoplectis tunetana*. In the latter wasp, developmental retardation and death were concomitant with fast replication of DpAV4. The authors therefore hypothesized that the *D. pulchella* and *collaris* female wasps regulate the rate of viral replication to the benefit of the wasp. It is presumed that these wasp females express virus controlling/regulating factors without which viral replication is unchecked, and thereby induce premature death of the host before the wasp completes its development. If this is the case, what is this female factor? Do parasitic wasps that lack this presumed factor also lack symbiotic viruses and if so, what mechanisms do they use to overcome host defenses? Studies on the relationship between

DpAV4 and the three ichneumonid parasitoids raise interesting questions about the biochemical basis of virus acquisition by and compatibility with parasitic wasps and should form the basis for related studies in other host-parasitoid systems.

Baculoviridae

Baculoviruses characteristically have large circular double stranded DNA genomes of 90–160 bp. The enveloped nucleocapsid is rod-shaped and has occluded and non-occluded (budded) forms. The two main members of the group include the granulovirus genus (GVs), distinguished by its granular appearance, and the nucleopolyhedrovirus genus (NPVs) which has a more crystalline structure. GVs only contain a single virion per inclusion body. Prior to the establishment of the Polydnaviridae, VLPs were described from several parasitoid and lepidopteran species as baculoviruses or baculovirus-like. However, most of these have since been reclassified as PDVs. Similarities (multiple nucleocapsides within a viral envelope and virus localization within the host nucleus and replication in the ovarian calyx) between baculoviruses and bracoviruses raise the question of whether PDVs arose from baculoviruses. Baculoviruses in parasitoids are poorly studied, but molecular analyses and other experimental studies could shed further light on the relationships between these two groups.

Poxviridae

Entomopoxviruses (EPVs) represent a subfamily of the Family Poxviridae that are large (200–400 nm in diameter), enveloped, double stranded DNA viruses with unipartite linear genomes of 130–380 kilobase pairs (kbp). EPVs are characterized by a biconcave central core and two lateral bodies and the mature virion is included in a large crystalline proteinaceous matrix called spheroidin, that surrounds and protects the virions from UV damage in the external environment.

The *Diachasmimorpha longicaudata* entomopoxvirus (DlEPV) is the first symbiotic EPV from a parasitoid to be described and for which genes have been sequenced. This virus was first described as an entomopoxvirus-like particle (Fig. 168) in hemocytes of the parasitized tephritid host *Anastrepha suspensa* and was subsequently traced back to the poison gland of the *D. longicaudata* braconid wasp female where they were first shown to undergo morphogenesis and assembly in the gland filaments and the mature virions stored in the gland reservoir. A similar 200 nm membrane-bound particle reported from the poison gland reservoir of the same wasp species was referred to as "irregular" but not described as a virus. The "irregular" description was likely based on the biconcave core, typical of dipteran entomopoxviruses and is most likely DlEPV.

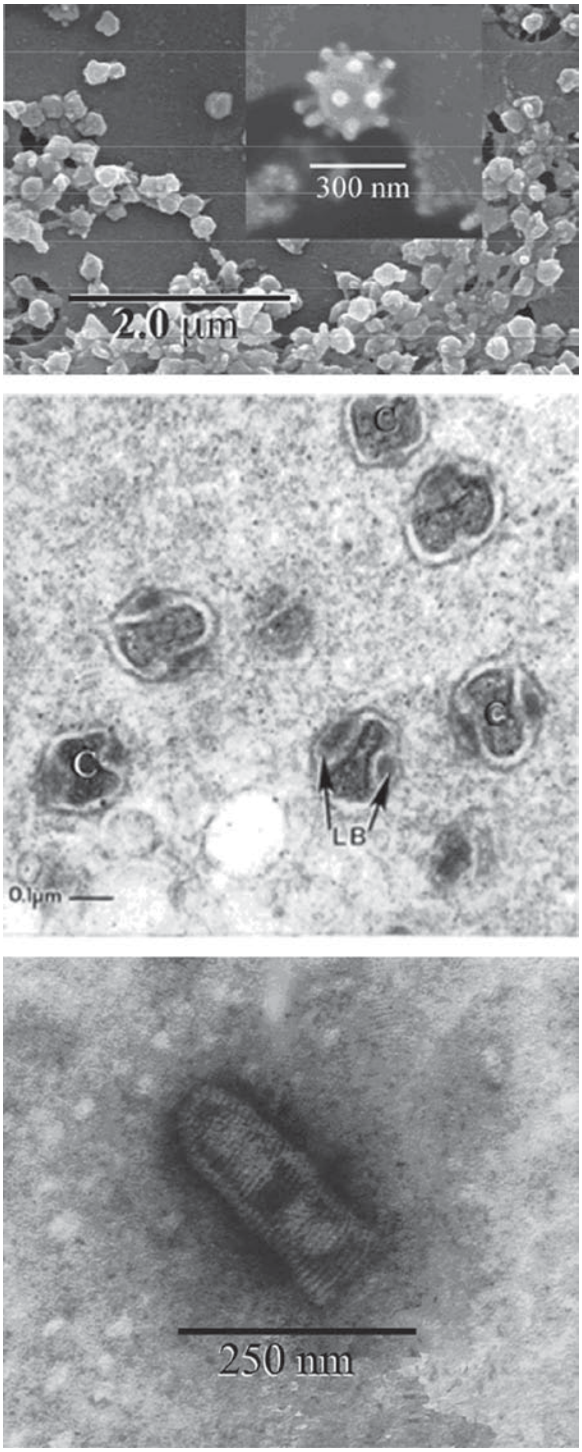
DlEPV has a large (250–300 kb) unipartite DNA genome. Nucleic acid and deduced amino acid sequences of several open reading frames (ORFs) from a DlEPV EcoRI genomic library have facilitated comparisons with other members of the Poxviridae and confirmed its position within the Entomopoxvirinae subfamily. Indeed, DlEPV genes encoding putative proteins such as DNA-directed RNA polymerase, DNA helicase, transcription factors, membrane proteins and RNA polymerase, and a poxvirus rifampicin resistance proteins, have been identified and share up to 60% sequence homology with those of other poxviruses. Thus, DlEPV is included in the subfamily Entomopoxvirinae (ICTVdB, 2002). While it is believed to be the first member of the Group C (Dipteran) EPVs to be characterized, DlEPV genes must first be compared with those from gammaentomopoxviruses. Unfortunately, none have as yet been sequenced.

DlEPV infection inhibits encapsulation of wasp ovarian eggs by inhibiting the cellular encapsulation response of the host. The virus also induces the expression of a host-encoded parasitism-specific protein (PSP24) when the purified virus is injected into healthy fruit flies. DlEPV proteins and DNA also occur in male wasps, suggesting that the virus is transmitted vertically. It remains to be determined whether transmission is as an intact virion or episome within the egg or whether it is eaten by the developing larvae with the virus-infected host hemolymph.

Picornaviridae and Picornalike Viruses

Picornaviruses are isometric/icosahedral virions that lack an envelope and are among a group of small RNA-containing viruses (SRVs) of <40 nm that occur in insects. They have a non-segmented, linear positive-sense, single-stranded RNA genome of about 10 kb. The 5´-end of the negative-sense strand has a covalently attached terminal protein. The 3′-terminus has a poly (A) tract. Some insect viruses with similar characteristics have been described but their fidelity to true Picornaviridae of mammals remains in doubt and as a consequence, are referred to as Picornalike.

Recently, a picornalike virus was found in the *V. canescens* parasitoid and confers protection on the developing parasitoid egg within their lepidopteran host *Ephestia kuehniella*. This small RNA-containing virus was designated VcSRV and co-occurs with the *V. canescens* VLPs (VcVLP) in the lumen of the wasp's ovarian calyx. Upon injection into the larval host, VcSRV invades the hemocytes of the host. The virus induces no obvious pathology to the host but a beneficial role in parasitoid development has not yet been identified.



Symbiotic Viruses of Parasitic Wasps, Figure 168 **(*top*) Electron microscopy (EM) of the *Diachasmimorpha longicaudata* entomopoxvirus (DlEPV). Scanning EM of virion purified from the poison glands of female wasps by sucrose density gradient centrifugation and processed for SEM as previously described (Lawrence and Matos, 2005). The virions are 250–300 nm in diameter from the base of the spikes. (*center*) Transmission EM of DlEPV showing the characteristic biconcave core and two lateral bodies (arrowheads) of poxviruses. (*bottom*) Negative stain of the *Diachasmimorpha longicaudata* rhabdovirus (DlRhV) purified by sucrose density gradient centrifugation. Virions are 60–70 nm in diameter and 250–300 nm long. Note cross striations typical of rhabdoviruses.**

Analysis of the RNA-dependent RNA polymerase protein sequence of VcSRV indicated that the virus is probably related to the infectious flacherie virus [Iflavirus (IFV)] genus and is now recognized as an unassigned member of the Iflavirus genus within the Picornavirales superfamily. Members of the genus Iflavirus have similarities to other picornaviruses but appear to occur primarily in insects.

Picornalike viruses in insects have been reported from dipterans, particularly from *Drosophila* and tephritid fruit flies such as the Mediterranean fruit fly, *Ceratitis capitata*, Queensland fruit fly, *Bactrocera* (*Dacus*) *tryoni*, and the olive fruit fly, *B. olea* and still others occur in Hemiptera and Lepidoptera. Since dipterans, hemipterans, and lepidopterans represent the largest insect orders that contain agricultural pest species, and given the large numbers of parasitoids known to attack them, we should anticipate that many more small RNA viruses will be found in parasitoids. Careful molecular characterization of these viruses should elucidate the possible evolutionary pathways from plant-infesting viruses (of which many picornalike viruses are known), to viruses of plant feeding insects, and ultimately to being beneficial viruses of parasitoids.

Reoviridae

Members of the Reoviridae characteristically have icosahedral virions of 60–80 nm in diameter and lack an envelope. The 2–3 layered nucleocapsid contains a linear genome of 10–12 segments of double-stranded RNA varying from about 18 to 31 kb. Each segment has a duplexed positive and negative strand. The termini of the negative strands are phosphorylated while the 5′ end of the positive strand is capped. Particles matching the description of reoviruses (RV) that appear to be symbiotic to parasitoids include DpRV-1 and DpRV-2 found in *D. pulchellus*. DpRV-1 occurs along with the ascovirus DpAV-4a (see above) and is hypothesized as benefiting the developing wasp indirectly by slowing down the rate of the ascovirus replication within the host. DpRV-2 is beneficial to certain *D. pulchellus* wasp populations by being immunosuppressive to their lepidopteran host.

The reovirus McRVLP found in the braconid *Microplitis croceipes*, and HeRV from the ichneumonid *Hyposoter exiguae*, are morphologically distinct and are regarded as "non pathogenic commensals" of the wasps. This is because they are not only found in reproductive tissues of female wasps but also in non-reproductive tissues of both sexes (though not in all strains of the parasitoid) and cause no pathology or obvious benefit to the parasitoid. A reovirus-like particle (OpRVLP) also occurs in the poison gland apparatus of *Opius* (now *Psyttalia*) *concolor*, a braconid parasitoid of tephritids. The uncharacterized OpRVLP is a double enveloped icosahedral particle, 72 nm in diameter, and possesses an "inner shell" with "hollow spikes at the vertices" and occurs in the poison gland lumen in association with secretory vesicles. There is no direct evidence that this VLP is transmitted to the tephritid host or what role, if any, it plays in the survival of the *O. concolor* immatures within the tephritid host. However, its presence within the lumen of the poison gland suggests that it is injected into the host during oviposition. As has been observed with most of the viruses and VLPs reported to date, OpRVLP co-occurs in the poison gland with a second, slightly smaller VLP, presumably a coronavirus-like particle. No nucleic acid characterization of these particles has been done. However, reoviruses have been found in the gut of one of the hosts, *C. capitata*, of *O. concolor*. This system could be a candidate for studies on the evolution of symbiotic wasp viruses through initial contamination by pathogenic viruses of their hosts. It is apparent that molecular characterizations of these reoviruses are needed along with a detailed analysis of their replication in wasp and host. The results could provide meaningful insights into the potential of these viruses as microbial control agents against tephritid pests.

Rhabdoviridae

Rhabdoviruses are enveloped, negative sense, non-segmented single stranded RNA viruses. They replicate in the cell cytoplasm of numerous plants, insects, and vertebrates. Several are vectored by insects. Virions are usually bullet-shaped and are about 180 nm × 70 nm, with some phyto rhabdoviruses being bacilliform and more than 300 nm long. Virions characteristically have spike-like projections arising from the major membrane glycoprotein that are apparent in negatively stained virions.

The *D. longicaudata* rhabdovirus originally described as a rod-shaped particle has been shown to replicate in the cytoplasm of accessory gland filament cells of the poison gland apparatus of the parasitoid and in vesicles of the epithelium of parasitized *A. suspensa* puparia, an indication of direct transmission from wasp to host. While the nucleic acid of this virus (called DlRhV) has not yet been characterized, negative stain and transmission electron microscopy reveal typical rhabdovirus morphology and replication within both the wasp and the *A. suspensa* tephritid host. DlRhV morphogenesis is evidenced by the presence of paracrystalline arrays of the immature particles. The replication and aggregation of mature virions are associated with secretory vesicles, as has been reported for other rhabdoviruses.

Within 24 h of injection into its host, DlRhV particles affix to cells associated with the tracheae and invade hemocytes where they replicate but after 30–40 h post infection, disappear from the hemolymph and migrate to the epidermal cells where they traverse the basement membrane and aggregate in the epidermal cell vesicles from which they bud to invade new cells. In superparasitized hosts, virus overload of vesicles is presumed to inhibit the migration of vesicles containing molting fluid, and hence inhibit apolysis. DlRhV is the first rhabdovirus reported from a parasitic wasp but its specific role in the virus-wasp relationship needs to be clarified.

DlRhV is transmitted vertically as intact virions in the subchorionic spaces of postvitellogenic eggs in the ovary. Although virions are observed in the midgut of first instars of the wasps during feeding on infected host hemolymph, it is not clear whether these virions are able to penetrate the midgut and enter the hemocele and ultimately, enter the poison gland as a secondary avenue of virus transmission to wasp offspring.

Summary and Conclusion

There is either direct or reasonable circumstantial evidence that several types of viruses enhance the survival of the immature wasp within their insect hosts. Here are discussed the wasp viruses that, on the basis of either characteristic virion morphology and/or molecular characterization of one or more viral genes, can be placed in established/recognized virus families and, as such, are regarded as true viruses. Because PDVs are the best studied parasitoid-associated "viruses," a synopsis of the group is provided here but the reader is encouraged to consult recent reviews as well as other papers describing more detailed molecular characterization of the many PDVs that have been described. PDVs are regarded either as viruses that are so highly co-evolved with their parasitoids that they no longer exhibit true viral characteristics (e.g., virions do not replicate within the host insect) or are packaged wasp genes that have evolved to manipulate the host and enhance the survival of the wasp's offspring. Numerous other viruses and VLPs reported from parasitoids remain unclassified due to lack of molecular characterization of their nucleic acids or the absence of nucleic acids, as in the case of *V. canescens*.

This overview of parasitoid viruses from six established virus families (Ascoviridae, Baculoviridae, Poxviridae, Picornaviridae, Reoviridae, and Rhabdoviridae) demonstrates that much remains to be done to better characterize these viruses at the molecular level. There is preliminary evidence that parasitoids of the same host or faunistic complex of hosts probably contain the same or closely related viruses and lend support to the hypothesis that symbiotic viruses of wasps may have arisen through contamination by viral pathogens from insect hosts. The presence of viruses from taxonomically established virus families, with relatives in plants or in non-parasitoid insects, provides an exciting opportunity for developmental and molecular studies on the evolution of virus-wasp-pest host relationships. This is especially true with RNA viruses that have wide distribution among plant, insect, and vertebrate hosts. It is hoped that this overview will stimulate further study of this topic as it is also likely to lead to novel approaches to agricultural pest control either through use of the viruses directly, or through molecular manipulation that would render parasitoids more effective biological control agents. Some parasitoids may lack VLPs or viruses altogether. Nevertheless, they are able to circumvent the host's immune system and develop successfully.

Sympatric

Possessing the same geographic range as a related organism without loss of genetic identity (contrast with allopatric)

Sympatric Speciation

Speciation that occurs in the same place, due to such factors as consumption of different food (allophagic speciation) or occurrence at different times (allochronic speciation).

Symphylans (Class Symphyla)

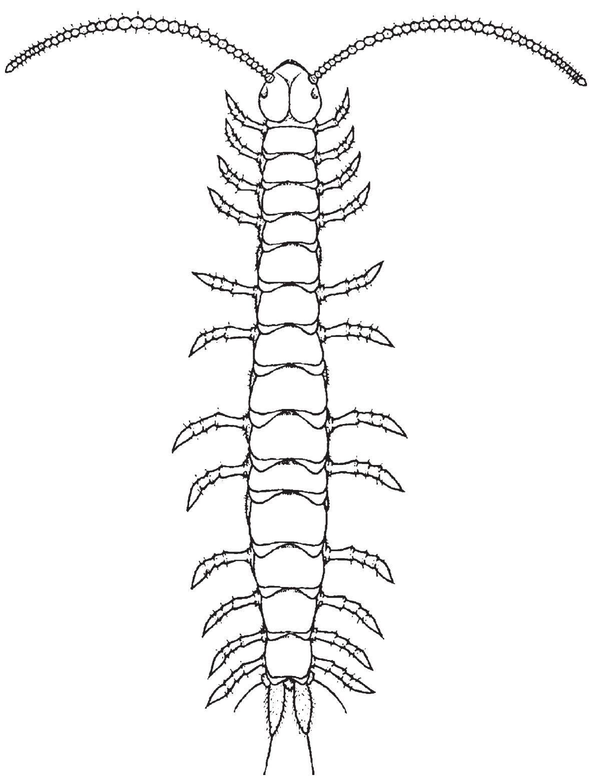
BEVERLY BURDEN
Louisiana State University-Shreveport, Shreveport, LO, USA

Symphylans are insect relatives in the subphylum Atelocerata (Myriapoda), and are related to centipedes (Chilopoda) and millipedes (Diplopoda). They possess a single pair of Malpighian tubules, no median simple eyes, and have tomosvary organs (humidity and/or chemoreceptors). They also have musculated antenna and diffuse nervous systems. There are approximately 160 species within the single order.

Phylum: Arthropoda
Subphylum: Atelocerata
Class: Symphyla
Order: Scolopendrellida

The apterygotes (wingless insects) may be derived from ancestral symphylans via paedomorphosis (juvenile characteristics are retained in the adult.).

Symphyla are <10 mm long, slightly dorsoventrally compressed, and white or colorless with a slender, soft body. They resemble small centipedes without the fangs found in Chilopoda. The head is distinct and well-developed, and the mouthparts are endognathous (mouthparts are concealed by the labium or cranial folds). Symphylans resemble the apterygotes with a single pair of long antenna with many segments and a single pair of spiracles are open on the head. They lack eyes and are blind. There are 15–22 body segments present, with an average of 15. Each body segment has one pair of hook-like legs. Immatures begin with 6–7 pairs of legs. All legs on one side move simultaneously, alternating side to side (Fig. 169).



Symphylans (Class Symphyla), Figure 169 An adult symphylan (original by M. L. Baker, Louisiana State University-Shreveport).

There are two legless caudal segments at the tip of the body, which may posses a pair of spinnerets for silk production. The number of dorsal tergites (14–24) exceeds the number of true segments. The fourth segment has a gonopore. In an unusual fertilization ritual, the egg is taken from the gonopore and stored in the mouth, where it is exposed to sperm from a spermatophore. Spermatophores are generally deposited on the ground. Ten to twenty eggs are laid in clusters on the soil. Symphylans do not dig tunnels, but take advantage of naturally occurring cracks and worm burrows for shelter. Symphylans inhabit soil that is rich in organic material, particularly humus and decaying wood. They feed on plant material, especially the roots. They can become a pest in greenhouses and in the field. They are cosmopolitan, yet concentrated in the tropics. Garden symphylan, *Scutigerella immaculata* (Newport), is the best known of the pests species, and has a wide host range. Though likely originating in Europe, it is now widely distributed.

Symptom

Any aberration in function (including behavior), indicating disease. (contrast with sign)

Synanthropic

Living in association with humans, without actually feeding on humans.

Synapse, pl., synapses

The narrow gap between two nerves, or between a nerve and a muscle, that is bridged by a chemical neurotransmitter. Acetylcholine is a major synaptic transmitter in the insect central nervous system.

► Nervous System

Synchroa Beetles

Members of the family Synchroidae (order Coleoptera).

► Beetles

Synchroidae

A family of beetles (order Coleoptera). They commonly are known as synchroa beetles.

► Beetles

Synchronous Muscle

Muscle in which the frequency of contraction is controlled directly by nervous impulses, with each contraction caused by nervous stimulation. (contrast with asynchronous muscle)

Syndrome

A group of signs and symptoms characteristic of a particular disease.

Synecology

Study of groups of organisms in relation to their environment (population, community, and ecosystem ecology).

Synergism

KUN YAN ZHU
Kansas State University, Manhattan, KS, USA

Chemical interactions may occur when two or more toxic chemicals are given to a living organism simultaneously or sequentially. Such interactions may result in a toxicity that is additive of individual toxicities of the chemicals or that is greater or less than the additive toxicity of these chemicals if administrated separately. Generally, the effects of chemical interactions can be divided into four types, including additive effects, synergism, potentiation and antagonism (Table 28).

Both synergism and potentiation refer to the action or phenomenon in which two or more chemicals (e.g., insecticides) administered simultaneously

Synergism, Table 28 Effects of chemical interactions on chemical toxicity

Chemical effect	Characteristics of chemical effect
Additive toxicity	The combined toxicity of two chemicals administered together is equal to the sum of the toxicities of the chemicals administered separately.
Synergism	The combined toxicity of two chemicals administered together is greater than the sum of the toxicities of these chemicals, one of which has little or no intrinsic toxicity, if administered separately.
Potentiation	The combined toxicity of two chemicals administered together is greater than the sum of the toxicities of these chemicals; both have appreciable toxicities if administered separately.
Antagonism	The combined toxicity of two chemicals administered together is less than the sum of the toxicities of these chemicals administered separately.

or sequentially achieve a greater toxicity than the sum of the individual toxicities of the chemicals administered separately. However, the term synergism is reserved for the case in which one chemical has little or no toxicity if administered alone, whereas in the case of potentiation both chemicals have appreciable toxicities.

A relatively non-toxic chemical substance applied with an insecticide to increase the toxicity of the insecticide against insect pests is known as a synergist. Different synergists may confer their synergistic effects on an insecticide through different mechanisms. They may inhibit the metabolic detoxification of the insecticide, increase the penetration of the insecticide through the insect cuticle, or act at the binding site(s) of the insecticide on the receptor proteins in target insects.

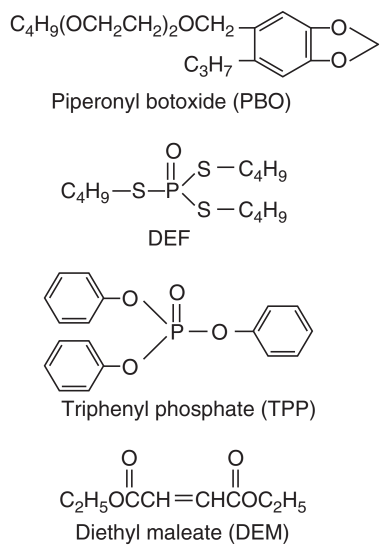
The most commonly used insecticide synergists are metabolic inhibitors that block certain detoxification enzymes so that insecticide detoxification in target insects is abolished or significantly reduced. Such synergists may serve as research tools to help determine the mechanisms of insecticide detoxification in a living organism and as control agents to increase the efficacy of insecticides in a pest management program. For example, the insecticide synergist piperonyl butoxide (PB or PBO) is a rather potent inhibitor of cytochrome P450-dependent polysubstrate monooxygenases (PSMOs, formerly known as mixed-function oxidases or MFOs), a major group of detoxification enzymes in living organisms. Both DEF (*S,S,S*-tributyl phosphorotrithioate) and triphenyl phosphate (TPP) inhibit various esterases that may be involved in detoxification of various insecticides including organophosphates, carbamates and pyrethroids. Currently, there is no specific inhibitor available for glutathione *S*-transferases (GSTs). However, diethyl maleate (DEM), which conjugates with and rapidly depletes glutathione, has been commonly used as a synergist to suppress the GST activity (Fig. 170).

The degree of synergism is often determined by two parallel but separate bioassays for an insecticide. One bioassay treats insects with mixtures of the insecticide and synergist or pretreats the insects with synergist and then with insecticide. The other bioassay treats the insects with insecticide only. If both bioassays determine the LD_{50} (lethal dose for 50% of the target insect population) values for the insecticide with and without the synergist, the level of synergism, which often is presented as the synergism ratio (SR), can be calculated:

$$SR = LD_{50}\text{ (Without synergist)}/LD_{50}\text{ (With synergist)}$$

Insecticide bioassays with synergists can help researchers learn possible detoxification mechanisms for a particular insecticide in a target population. For example, Yang et al. (2001) evaluated the susceptibility and possible detoxification mechanisms of the Banks grass mite (BGM), *Oligonychus pratensis* (Banks), and the two-spotted spider mite (TSM), *Tetranychus urticae* Koch, to three selected insecticides with three synergists (TPP, DEM and PBO) (Table 29). Their study suggests that esterases, GSTs, and PSMOs all play important roles in the detoxification of the pyrethroid bifenthrin in the two-spotted spider mite because TPP, DEM and PBO enhanced the toxicity of bifenthrin by 6.2-, 4.1- and 4.5-fold, respectively.

► Synergist



Synergism, Figure 170 Chemical structure of some commonly used insecticide synergists.

Synergism, Table 29 Effect of three synergists (TPP, DEM, and PBO) on bifenthrin toxicity against the two-spotted spider mite using glass vial residual contact bioassay

Chemical	LC50 (95% CI) (μg/ml)	DF	Slope + SE	P(x^2)	SR
Bifenthrin	114.0 (92.3–144.0)	5	0.42 ± 0.03	0.35	—
Bifenthrin + TPP	18.5 (13.9–23.6)	5	0.37 ± 0.03	0.32	6.2
Bifenthrin + DEM	27.5 (20–5–36.8)	4	0.34 ± 0.03	0.45	4.1
Bifenthrin + PBO	25.1 (19.8–31.0)	5	0.42 ± 0.03	0.20	4.5

Synergist

Synergists are chemicals that lack pesticidal properties on their own but increase the toxicity of pesticides (other chemicals). They inhibit degradative enzymes (mixed function oxidase, or MFO) such as P450 monooxygenases. Examples of synergists include sesamex, *n*-propyl isome, sulfoxide, piperonyl butoxide, and MGK 264. Initially used extensively to increase the toxicity of pyrethrum, and used to some degree with other pesticides (the effectiveness varies among insecticides), synergists have become of increased importance in recent years as pyrethroid insecticides have increased in use.

The most common synergist is piperonyl butoxide, which was developed in 1947. It functions by inhibiting the breakdown of pesticides by insects. Without piperonyl butoxide, insects may degrade the insecticide before mortality can occur, and recover from the poisoning. In addition to reducing the ability of insects to recover from insecticide poisoning, addition of piperonyl butoxide to insecticide formulations usually reduces the amount of active ingredient needed in the formulation, thus reducing pesticide load in the environment and potentially reducing cost. It is applied to all types of insecticide formulations, especially household pesticides and livestock treatments. Piperonyl butoxide alone has very little toxicity. It is not persistent in the environment. Long-term exposure may have effects on the liver, however.

Systematics

In entomology, an abbreviated form of "biosystematics," the relationships of taxa based on study of their genetics and evolutionary history.

Systematic Sampling

A method of allocating sample units within a sample universe in which sample units are collected at fixed intervals along a predetermined pattern. Examples include sampling along transects or along V or X shaped patterns in crop fields. Often, the starting point of the pattern is determined randomly. Systematic sampling is probably the most common method for allocating sample units in most agricultural systems because it is simple and time-efficient.

► Sampling Insects

Systemic

Absorbed and translocated through the vascular system of plants or animals.

► Insecticides
► Insecticide Formulations

Szent-Ivány, József Gyula Hubertus

George Hangay
Narrabeen, NSW, Australia

József Szent-Ivány was born on the 3rd of November 1910 in Budapest, Hungary. He matriculated in Rimaszombat and from 1928 he continued his studies in Vienna, Austria. Between 1933 and 1936, he was a student at the Budapest University of Science, where he completed his studies and received his doctoral degree of zoology, geography and mineralogy. In 1936, he joined the staff of the Hungarian Natural History Museum, where he primarily worked on Lepidoptera. In 1938, he established Fragmenta Faunistica Hungarica, a zoological journal, and from 1937 until 1944 he was the editor of Folia Entomologica, the official publication of the Hungarian Entomological Society. He collected huge numbers of Lepidoptera for the museum and during World War II, at his own cost, he translocated the entire collection from Budapest to Tihany, a small town where it was safe from bombing raids. The war disrupted his scientific work and as the Russians occupied the country, he fled to the West. In 1950, he migrated to Australia but it took another 4 years before he could continue with his entomological work. He gained employment as government entomologist in Papua New Guinea. He spent 12 years there, building an insect collection of more than 100,000 specimens, which formed the basis of the Papua New Guinea Entomological Institute. His entomological activities were not restricted to collecting and taxonomy alone. He took active part in running the Institute and conducting numerous studies in the field of crop protection against insect pests, projects of medical and forest entomology, environmental studies and a whole host of other scientific activities. He published a great number of papers, mostly in English, German and Hungarian. After his retirement in 1966, he remained active as an entomologist, taking on many assigments, consultation projects and honorary positions. From 1972–74 he was the president of the committee which investigated and found the lost grave of Sámuel Fenichel at Stephansort. In 1975, the newly established entomological research station in Wau was named Szent-Ivány Laboratory. In 1985, he received from Queen Elizabeth II the Order of Australia. In 1988, he was admitted into the Hungarian Academy of Science. A few days after this honor, on the 8th of June 1988, József Szent-Ivány passed away.

Tachinid Flies (Diptera: Tachinidae)

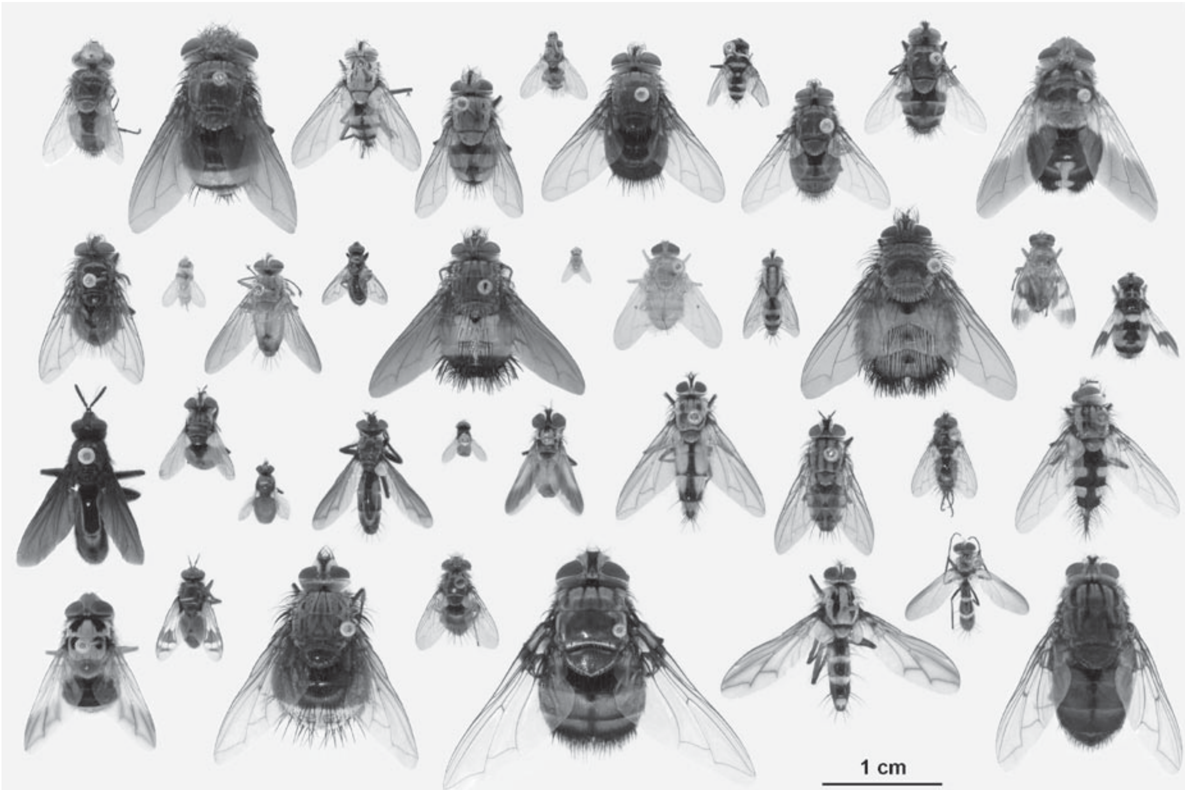
JAMES E. O'HARA
Agriculture and Agri-Food Canada, Ottawa, ON, Canada

There are well over 100 families in the order Diptera, or true flies, and most of them are comprised entirely of species with free-living larvae. There are, however, about 20 families with at least some species classed as parasitoids, species that live within other animals as larvae and kill their hosts before progressing on to the adult stage. It is estimated that this type of parasitic life style evolved over 100 times in the Diptera and multiple times within certain families. About 16,000 of the approximately 120,000 described species of Diptera are parasitoids, and about 10,000 of them belong to a single family, the Tachinidae. All tachinid flies are parasitoids in their larval stage and their hosts all belong to the Arthropoda, almost exclusively the Insecta. The true diversity of the Tachinidae is likely many thousands of species higher than the 10,000 currently described, making this family a good candidate for the most speciose family of Diptera and without question the most successful with a parasitic way of life.

Most tachinid flies are larger than a house fly and noticeably more bristly, but they range in size from 2–20 mm and across the family there is a tremendous variety of shapes, colors and degree of bristling. The features upon which the family is founded and that support its monophyly (descent from a common ancestor) are rather subtle. In addition to features shared with other families of the Oestroidea (Rhinophoridae, Sarcophagidae, Calliphoridae, and Oestridae), adult tachinids possess a well developed postscutellum (a rounded bulge below the hind part of the thoracic dorsum) and the labrum (or mouth hook) of the first instar larva is fused with the cephalopharyngeal skeleton. The family is cosmopolitan in distribution and most diverse in the subtropics and tropics.

Classification

The Tachinidae are currently divided into four subfamilies, the Phasiinae, Dexiinae, Exoristinae and Tachininae (see Fig. 1 for representatives of each). The smallest of these in terms of species,



Tachinid Flies (Diptera: Tachinidae), Figure 1 **Representative Tachinidae. Row 1 (top), left to right: Exoristinae, *Gonia porca*, *Belvosia bifasciata*, *Calolydella lathami*, *Chrysoexorista ochracea*, *Cyzenis browni*, *Leschenaultia fusca*, *Trigonospila* sp., *Lespesia stonei*, *Winthemia vesiculata*; Tachininae, *Microtropesa* sp. Row 2: Tachininae, *Chrysotachina* sp., *Siphona (Siphona) lutea*, *Genea* sp., *Euscopolia dacotensis*, *Xanthoepalpus bicolor*, *Siphona (Baeomyia) xanthogaster*, *Ormia reinhardi*, *Vanderwulpia sequens*, *Paradejeania rutilioides*, *Oestrophasia* sp., *Neximyia* sp. Row 3: Phasiinae, *Penthosia satanica*, *Gymnosoma par*, *Besseria brevipennis*, *Cylindromyia (Cylindromyia) euchenor*, *Phasia aldrichi*, *Trichopoda* sp.; Dexiinae, *Zelia vertebrata*, *Billaea* sp., *Periscepsia (Ramonda) clesides*, *Uramya halisidotae*. Row 4: Dexiinae, *Amphitropesa* sp., *Euthera tentatrix*, *Euchaetogyne roederi*, *Voria aurifrons*, *Rutilia (Donovanius) regalis*, *Euantha litturata*, *Cordyligaster septentrianalis*, *Trixodes obesus*.**

the Phasiinae, is possibly but not demonstrably a monophyletic lineage in which all species are parasitoids of Hemiptera-Heteroptera, or true bugs. The Phasiinae are morphologically diverse and include most of the tachinid species that lack strong bristling. The Dexiinae are the next largest subfamily and the only one widely regarded as monophyletic, a belief based on shared derived features of the male terminalia. In particular, male dexiines possess a hinged connection between the basiphallus and distiphallus of the phallus (or aedeagus) that is not found in other tachinids. Some of the most visually stunning tachinids belong to the dexiine tribe Rutiliini, an Oriental and Australasian group of mostly large and metallic-colored flies. The Exoristinae and Tachininae are the most speciose subfamilies. The former is more homogeneous in appearance, with many species grayish black in color and moderately bristly. Given this combination of homogeneity and diversity, the Exoristinae are, as a group, the most taxonomically difficult of all Tachinidae. The Tachininae are more morphologically diverse and include some of the largest, most colorful, and most bristly of tachinids. The subfamily also includes some of the smallest and least conspicuous tachinids.

The phylogenetic relationships within the Tachinidae are unclear at the higher levels. There are currently about 40 tribes recognized, but not all are monophyletic and the relationships within and between them are poorly known. Many of the main characters used to distinguish tachinid species are not unique to particular lineages, thus inhibiting attempts to infer relationships through parsimony analysis of external morphological traits. It is possible that more detailed study of male and female terminalia and immature stages will provide better, less homoplastic, characters for phylogenetic analysis. Molecular systematics is beginning to show promise in the elucidation of tachinid relationships but there have been few studies to date.

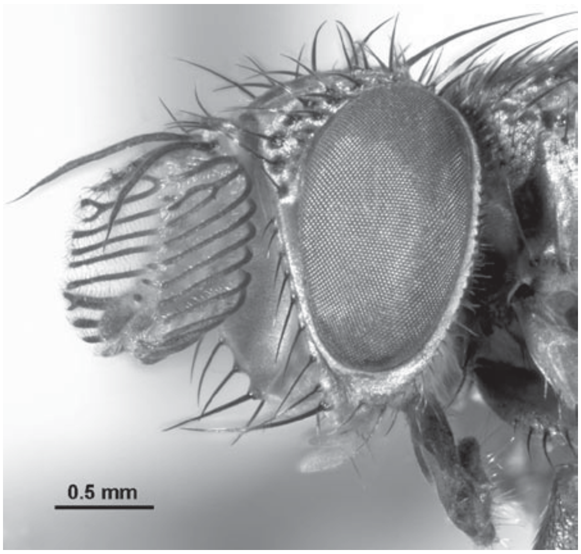
The classification at the generic level is relatively stable in the Nearctic and Palearctic regions where the tachinid faunas are fairly well known. There are literally thousands of undescribed species in the other regions, and until those species have been better studied the genera of those regions will remain poorly characterized. Certain authors in the first half of the 1900s had a tendency to oversplit the Tachinidae to the extent that each genus would often comprise only one or two species, and this legacy is still in evidence today in less studied parts of the world. For example, the Neotropical Region has nearly 30% of all described tachinid species but over 50% of all genera.

Life Stages

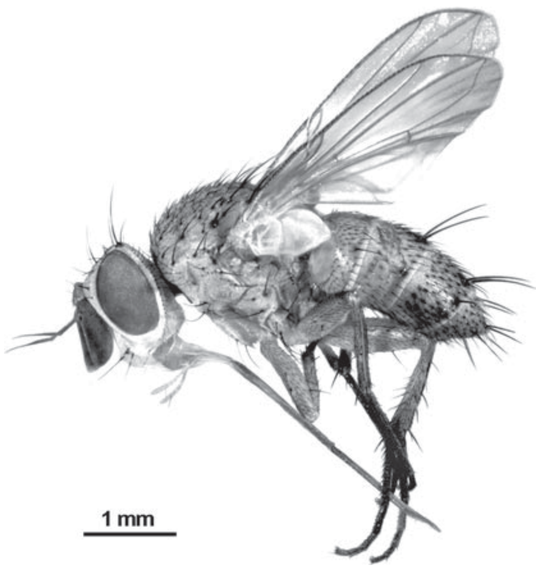
Adult

The variation in size and shape of adult tachinids has been mentioned above and is evident in the specimens shown in Figure 1. Tachinids range in color from pale yellow to jet black, with some species shiny metallic blue or purple (e.g., *Gymnocheta*), or brilliantly metallic and multicolored (many Rutiliini). Wings are usually clear but are darkened or patterned in some species, or even bicolored. Despite the huge range in size, shape and color within the family, the majority of tachinids are grayish black and 5–10 mm in length. Many species have four black longitudinal stripes on the thorax, in contrast to members of the closely related family Sarcophagidae that usually have three stripes.

The head is about the width of the thorax, with compound eyes that vary in size from about half head height to almost head height. Eyes are only rarely holoptic (meeting above) and range from bare to densely haired. Antennae range from tiny to enlarged and in certain species (males only) are bifid, trifid, or elaborately branched (Fig. 2). Mouthparts are present and functional, apically padlike for feeding on liquids (e.g., nectar and honey dew), and occasionally greatly elongated (up to length of body) (Fig. 3). Chaetotaxy (arrangement of setae) on the head is greatly varied and very useful for the identification of species.



Tachinid Flies (Diptera: Tachinidae), Figure 2
Head of male *Borgmeiermyia* sp., illustrating elaborately branched antenna.



Tachinid Flies (Diptera: Tachinidae), Figure 3
***Siphona pisinnia*, illustrating unusually long proboscis.**

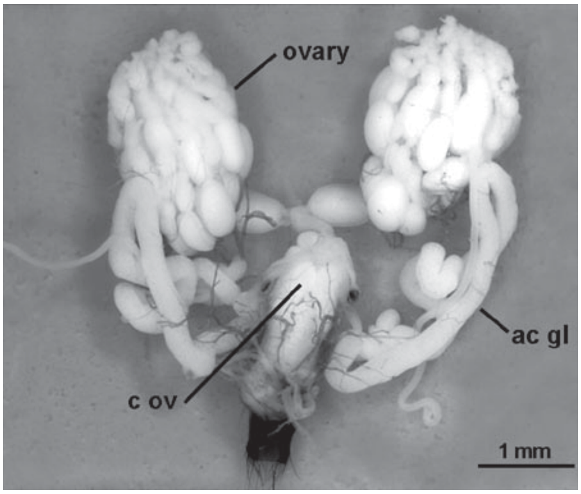
The thorax is slender to broad, typically setose but almost bare dorsally in many Phasiinae. The prosternum between the fore legs is typically haired in Exoristinae, bare in Phasiinae and Dexiinae, and varied in Tachininae. Legs are setose and in some groups elongated, without elaborate modifications except for the flattened, feather-like setae on the hind tibia of *Trichopoda*. Wings are well developed, haired along several veins in a few species, and show some variation in venation. Vein *M* in the center of the wing has a bend near the wing margin (bend rarely absent, e.g., *Cinochira*) and the vein may terminate in vein R_{4+5} or the wing margin. Very rarely, vein *M* fades out at about the usual location of the bend. Chaetotaxy of the thorax, especially the arrangement of setae on the upper surface (i.e., scutum and scutellum), is taxonomically and diagnostically very important.

The abdomen is greatly varied from narrow and long to short and round, and from nearly bare to thickly setose. A few species are very good wasp mimics (e.g., *Cylindromyia* (*Ichneumonops*) *mirabilis*) with a wasp-like abdomen. Males of some *Uramya* species have the tip of tergite 5 constricted and lengthened posteriorly into an almost cone-like appendage that can be nearly as long as the rest of the abdomen (slightly developed in *Uramya halisidotae,* see Fig. 1). Segments 6–11 comprise the terminalia and are highly varied morphologically in both sexes. The female terminalia show obvious modifications related to oviposition: short unspecialized ovipositors in most species that lay eggs on foliage, tubular telescopic ovipositors in some species that lay eggs with great precision on their hosts, and piercers of varied shapes and sizes derived from different sternites in different lineages. The terminalia, particularly those of the male, provide some of the best characters for interpreting the phylogenetic relationships within the Tachinidae and are helpful for identifications at the species and genus levels.

Egg

Modifications to the female reproductive system, egg, and ovipositor permit tachinids to parasitize hosts in a wide variety of ways. In the primitive condition, an unembryonated egg is deposited directly on a host by means of an extensible ovipositor. The egg is typically thick and convex on its upper surface and thinner and flatter on its under surface, and is attached to a host with a glue-like substance. Tachinids employing this mode of attack are termed oviparous because the egg is undeveloped when laid and the first instar is not fully formed for several days. The first instar may then burrow directly through the underside of the egg and through the host's integument, or may exit the egg through an operculum and then burrow into the host. Certain oviparous tachinids, including most Phasiinae, inject an egg directly into a host by means of a piercing ovipositor. Oviparous tachinids comprise the Phasiinae and some Exoristinae (Exoristiini, Winthemiini, and a few species of Blondeliini and Eryciini). The female reproductive system of an oviparous tachinid is shown in Fig. 4.

The majority of tachinids are ovolarviparous, depositing eggs that contain fully developed first



Tachinid Flies (Diptera: Tachinidae), Figure 4 **Female reproductive system of an oviparous tachinid, *Smidtia fumiferanae*. Not more than one fertilized egg is retained in the common oviduct at a time. Abbreviations: ac gl, accessory gland; c ov, common oviduct.**

Tachinid Flies (Diptera: Tachinidae), Figure 5 **Female reproductive system of an ovolarviparous tachinid, *Lypha fumipennis*. Fertilized eggs form tightly packed rows within a coiled ovisac.**

instars. The female reproductive system of these flies is modified to retain fertilized eggs in an ovisac or uterus until they are ready to hatch. The ovisac stretches and forms a coil as hundreds to thousands of fertilized eggs are added to it (Fig. 5). The females of numerous ovolarviparous species still deposit eggs directly on a host, but other strategies, some quite ingenious, are used as well. In most cases the eggs have a thin chorion and hatch almost immediately after deposition. The eggs of many species are laid near a host or are broadcast on its food plant and the motile first instar either crawls to a host or waits for one to pass by. The eggs of Dexiini and most Rutiliini (Dexiinae) are deposited on the ground and the first instar burrows into the soil in search of a beetle host. A few ovolarviparous species have the unusual habit of ovipositing an egg into the mouth of a host. Members of the Goniini (Exoristinae) have tiny "microtype" eggs that they scatter on the food plant of a host, usually in the vicinity of feeding damage, and these eggs hatch only after being ingested by a host. Various types of piercers have evolved in different lineages of ovolarviparous tachinids to inject an egg into a host.

The number of eggs produced by a tachinid is roughly proportional to the likelihood of a first instar infecting a host. Species that oviposit directly on or in a host have a high success rate and low fecundity, generally less than a few hundred eggs. Species that oviposit in the vicinity of a host often produce many hundreds of eggs, and species with microtype eggs or that oviposit rather indiscriminately on a host's food plant have the highest fecundity of all, with the number of eggs produced numbering into the thousands.

Some tachinids are cited in the literature as larviparous, meaning in the strict sense of the term that their eggs hatch internally and first instars are oviposited instead of eggs. However, the term larviparous has also been used in a looser sense to describe tachinids that deposit fully developed eggs that hatch immediately after deposition (i.e., ovolarviparous tachinids). The eggs are frequently so thin and membranous as to be almost invisible. In some cases, first instars inside a freshly killed female will break free of their thin-walled eggs and escape through the ovipositor, giving the impression that the species is normally larviparous. Dissections of killed females may also reveal first instars free in the ovisac that would, under normal circumstances, remain in the egg until after oviposition. Although there may be species that are truly larviparous, they have yet to be reliably documented.

The eggs of tachinid flies are not intended to provide long term protection for a first instar. Tachinids do not overwinter in the egg stage or as free-living first instars.

Larval instars

Tachinids, like other cyclorrhaphan flies, have three larval instars. The first instar is remarkably varied externally, adapted to cope with the different circumstances under which eggs are placed in the environment. First instars that must search for hosts on their own have evolved a number of specializations to aid movement and avoid desiccation. Their bodies are often adorned with bands of small spines or sclerotized plates, in some instances displaying more morphological variation between species than the bodies of their adults. First instars of ovolarviparous species can be removed from pinned adult females in museum collections and rehydrated for morphological study. Research into the diversity of first instars is expected to contribute valuable characters for tachinid taxonomy and for phylogenetic analyses of tachinid relationships.

First instars that enter a host on their own do so with the cutting action of a sharp labrum that is varied apically from pointed to axe-like. The labrum is scraped against the host's integument with a back-and-forth motion until a hole is created, likely aided by an enzymatic substance in the saliva. Once inside the host, the first instar may attach itself posteriorly to its entrance hole or to the host's tracheal system, or it may remain free in the host's body. First instars that remain free usually attach themselves to the tracheal system when they become second instars to provide an adequate supply of oxygen for developmental needs. A first instar may start to feed immediately and can pass through all three instars in as little as a few days, but in most species the larval stage lasts a few weeks. Not uncommonly, the first instar delays development until the host reaches a particular stage. It might migrate to specific places within the host during its period of inactivity, such as the salivary glands, ganglia or muscles, where it is able to evade the host's immune system. It is generally hormonal signals within the host that trigger the first instar to relocate and continue development. Some tachinid species overwinter as first instars within their hosts.

A first instar feeds on host hemolymph and carefully avoids damaging any vital organs, living more like a parasite than a host-killing parasitoid. This changes during the second instar when rapid feeding and growth begin. If a larva did not form a connection to tracheal or outside air during its first instar, then it typically does so as an early second instar. At the same time as the tachinid larva is attempting to feed and obtain oxygen, the host is attempting to kill it through an immune response termed encapsulation. In the early stages of encapsulation, a thin membrane forms around the larva. A first instar can be almost completely encased, but if this happens then it can usually still feed on hemolymph that filters through to it. The larger second instar frees itself anteriorly and begins to feed more aggressively on non-vital tissues, at the same time continuing to stay attached to an air supply posteriorly. The capsule that forms around the larva is termed a respiratory funnel and it becomes larger and thicker as time passes. The ability of the Tachinidae to thwart the encapsulation process is one of the keys to their success. This ability does not afford total protection and some larvae are killed by encapsulation even in suitable hosts. Other potential hosts that are seldom successfully parasitized may have immune systems that are more effective at combating tachinid invaders or there may be other incompatibilities between parasitoid and host.

The primary cutting structure in the first instar, the labrum, is replaced in later instars by paired mandibles. The second instar is a voracious feeder that selectively consumes non-vital tissues, especially fat stores. The host may appear normal or somewhat lethargic, or may display atypical behavior induced in some way by the parasitoid.

The third instar leaves the respiratory funnel and feeds less discriminately. Except in rare cases, the host is killed and the third instar continues to feed until fully grown or until the food supply is exhausted. The latter situation is not uncommon among tachinids that develop gregariously within a single host and the tachinid adults that develop from under-fed third instars can be half or less the size of typical adults.

Puparium

Pupation in tachinid flies takes place within a puparium, the hardened shell of the third instar. Most commonly the third instar crawls away from the host and pupariates in the soil or ground litter, but in some species pupariation takes place within the host. A few species that pupariate within adult beetles strategically cut openings in the host's integument to facilitate respiration and the eventual exit of the adult (Fig. 6). Quite a few tachinids overwinter in the pupal stage.

The puparium is roughly cylindrical with two small anterior spiracles and generally two conspicuous and darkened posterior spiracular discs, for respiration. The posterior spiracular discs can be flush with the surface of the puparium or raised above it, and directly level with the midline or above or below it. In a few species the spiracular discs are fused into one. Quite often there are three or four spiracular slits on the upper surface of each spiracular disc. The morphology of the spiracular discs is highly varied and provides useful characters for the identification of species. An adult tachinid emerges from its puparium by inflating a balloon-like ptilinum from behind its face to force open the anterior end of the puparium along a circular line of weakness.

Tachinid Flies (Diptera: Tachinidae), Figure 6
Puparium of *Myiopharus neilli* within remains of its host, an adult sunflower beetle (*Zygogramma exclamationis*). Anterior and posterior ends of puparium are visible. The beetle is typically decapitated between the prothorax and mesothorax. Underside of beetle is shown with legs removed. Abbreviations: a spr, anterior spiracle; p spr ds, posterior spiracular disc.

Distribution and Evolution

The Tachinidae are well distributed throughout all zoogeographic regions of the world (see Table 1), although poorly represented on smaller islands that are distant from larger land masses (e.g., Hawaiian Islands, Galapagos Islands). The total number of described species is about 10,000, but this number is misleading because only the Nearctic and Palearctic faunas are relatively well known. The Neotropical Region has the largest number of described species at about 3,000, almost twice that of any other region and representing 30% of the world's fauna, yet there are so many undescribed species and the region is so vast and under-collected that the actual number is probably well over 5,000. Similarly, Australia has a described fauna

Tachinid Flies (Diptera: Tachinidae), Table 1
Number of tachinid species and genera in each biogeographic region and the world

Biogeographic region	Genera	Described species
Neotropical	822	2,864
Nearctic	304	1,345
Palearctic	405	>1,600
Afrotropical	213	1,006
Oriental	264	725
Australasian	230	808
World	1,523	about 10,000

Numbers for genera follow O'Hara (2007) and for described species follow the most recent regional catalogues. Actual number of tachinid species (described + undescribed) in the world is likely greater than 15,000. Some species and many genera are found in more than one region so the values for the world are not the sums of the regional numbers.

numbering about 500 species but the actual fauna has been estimated at 3,500–4,000 species. The tachinid faunas of the Afrotropical and Oriental regions have not been well studied and also contain many undescribed species. Given these circumstances, it is likely that the total number of tachinid species in the world is in excess of 15,000.

Some older insect groups show an interesting pattern of distribution that links the faunal elements in South America, Australia and sometimes southern Africa. These relationships are thought to date back to Gondwanaland when the southern continents were fused into a single land mass. By the end of the Cretaceous Period about 65 million years ago, Africa was drifting northward and the connection between South America and Australia (via Antarctica) was becoming cooler and more tenuous. If the Tachinidae began their radiation in the Cretaceous then evidence of this might be sought in the fossil record and modern distribution patterns. However, no fossil Tachinidae are known from the Cretaceous and there is no clear evidence of southern relationships, so the family is assumed to be of Tertiary origin.

The sister group to the Tachinidae has not been determined but is to be found among the families Sarcophagidae, Calliphoridae, Rhinophoridae and Oestridae. These five families are united by their possession of a row of setae on the meron (a sclerite above the hind leg) and together comprise the superfamily Oestroidea.

Hosts

The evolutionary success of the Tachinidae is closely tied to their exploitation of arthropods as a source of hosts. The family is a difficult one taxonomically and a relatively young one, suggesting that it is still undergoing rapid radiation within its specialized niche. The life of an endoparasitoid is a complex one with strong selective pressures centered around finding and parasitizing a host. In some cases selection has produced generalists that attack many species of hosts, in others selection has produced specialists that attack only one or a very few host species.

Hosts of Tachinidae are all arthropods, almost exclusively insects. For many tachinid species the hosts are unknown. The non-insect hosts comprise only a few species in the Chilopoda (centipedes), Scorpiones (scorpions), and Araneae (a single record from a spider). These hosts are attacked by a few species of Tachininae, mostly within the Polideini.

The majority of hosts of tachinids are Lepidoptera, mostly caterpillars that feed on foliage in exposed situations but also others that are concealed, such as leafrollers and stem borers. Lepidoptera represent the main hosts of the two largest tachinid subfamilies, Exoristinae and Tachininae, and are also significantly attacked by the third largest subfamily, the Dexiinae. The smallest subfamily, the Phasiinae, attacks only Heteroptera and there is only one genus outside the Phasiinae (*Euthera* in the Dexiinae) that also attacks heteropteran bugs.

Larval and adult Coleoptera of about 20 families are attacked by a small number of species in the Exoristinae and Tachininae and by the majority of species in the Dexiinae. The greatest number of beetle hosts belong to the Scarabaeidae, larvae of which are parasitized by nearly all members of the sizable dexiine tribes Dexiini and Rutillini; adult scarabs are parasitized by members of the small dexiine tribe Palpostomatini.

Hymenopteran hosts are chiefly larval Symphyta, many of which are exposed defoliators like larval Lepidoptera. A small number of wasps (Vespoidea) and ants (Formicidae) also serve as hosts. Hymenopteran parasitoids belong to the Exoristinae and Tachininae. The remaining hosts of tachinids are also parasitized by members of these two tachinid subfamilies and include the Orthoptera (crickets, grasshoppers, katydids), Blattaria (cockroaches), Mantodea (mantids), Phasmatodea (leaf and stick insects), Dermaptera (earwigs), Diptera (flies), and Embioptera (webspinners).

Some tachinids are solitary endoparasitoids and will fight one another within a host until a single larva remains alive. Other species, especially those that parasitize larger hosts, are not aggressive toward one another and numerous individuals can successfully develop into adults. If conditions are crowded, then some maggots may die and the rest may produce stunted adults. Multiparasitism, the development of more than one larva within a host, also can result in more than one tachinid species successfully parasitizing a single host.

There are a variety of factors that determine how many host species a tachinid species will parasitize. The adult female plays a large role in host range by deciding where to oviposit. If eggs are laid on or near a host or injected into it, then the host range is determined by the specificity of the ovipositing female and the ability of the larva to develop in the selected host. Females of some species search for a particular microhabitat and once in it (e.g., a particular plant species) will oviposit on different potential host species encountered there. One tachinid species, *Compsilura concinnata*, has become well known because it is highly indiscriminate in its selection of hosts and its larvae are capable of developing in many different species. The female fly injects an incubated egg into a host and the larva escapes the defenses of its varied hosts by living and feeding in the midgut between the peritrophic membrane and gut wall. *Compsilura concinnata* has almost 200 recorded hosts in numerous families of Lepidoptera and also parasitizes sawflies and a species of weevil.

Host Location

The ancestral mode of host finding in Tachinidae likely involved a series of cues, olfactory and visual, that guided a searching female to the right microhabitat and host plant and then to an exposed host, where perhaps tactile stimuli initiated oviposition behavior. This method of host location is still common, but there are many sophisticated behaviors that have evolved to aid the searching tachinid. For example, oviposition in numerous tachinids does not involve the visual sighting of a host. In the case of Goniini, microtype eggs are deposited on the food plant of a host, usually in response to plant volatiles released at the site of feeding damage, and the eggs do not hatch until ingested by a host. Many other tachinids also oviposit on the food plant of a host or in a specific microhabitat (e.g., those that parasitize litter insects like cockroaches and earwigs), not necessarily within sight of a host, and the first instar locates a host on its own or lies in wait for one to pass by. Certain tachinids (e.g., *Lixophaga diatraeae*) are stimulated to oviposit near the burrow of a concealed host by the odor of the frass that has accumulated at the entrance. Members of the Dexiini oviposit on the ground, leaving the task of finding a soil-dwelling scarab host to their first instars.

The importance of visual cues varies in different tachinids. Those that search for hosts at night must rely mostly on other sensory cues to find an acceptable place to oviposit. Some tachinids that lay eggs on exposed caterpillars not only select hosts of a particular size, presumably by sight, but may also place the eggs near the front of the host where they cannot be reached by the host's mandibles. A few species that parasitize adult beetles assist their first instars by ovipositing near natural openings such as the mouth, anus and spiracles. Not uncommonly, females that oviposit on a specific part of a moving host have a telescopic ovipositor that can be brought forward under the body and in front of the head to permit egg placement to be visually guided. Some tachinids attack their hosts on the wing, requiring acute vision as well as maneuverable flight.

In most instances where olfaction is involved, the chemical cues that attract a female tachinid to an oviposition site are the standard odors of a host or host plant, or odors (volatiles) given off by a damaged plant that is being fed upon. More unusual are the cues that attract certain Phasiinae to their hosts; these species use the pheromones of their heteropteran hosts as host-finding kairomones. The antennae of these tachinids are up to 10 times more sensitive to the bug pheromones than are those of the bugs.

The vast majority of Tachinidae are incapable of hearing, but members of the tribe Ormiini have evolved an inflated prosternum between the front legs that functions as a tympanal organ. This structure allows these tachinids to locate their orthopteran hosts at night by homing in on their mating calls. So effective are these parasitoids in finding their calling hosts that some hosts have evolved strategies to reduce their susceptibility. The tympanal organs are different in male and female ormiines, with those of the female very receptive to the low frequency calls of hosts and to sounds in the ultrasonic range, whereas males are only sensitive to ultrasonic sound. It has been suggested that the sensitivity of these nocturnally active flies to high frequency sound helps them avoid predators such as insectivorous bats.

Mate Finding

Male and female tachinids that are commonly found in meadows and along roadways, particularly on wildflowers, probably mate in those places, e.g., Phasiinae, larger Tachinini, most Siphonini. There are other tachinids that go to species-specific aggregation sites to find a mate. The most noteworthy of all aggregation phenomena is "hilltopping," where males of certain tachinid species fly to the tops of hills or mountains to await the arrival of females. Each species has its own predetermined time of day during which it will hilltop, with some species preferring the morning, others the afternoon, and the night-active *Ormia* hilltopping at dusk. On hot days the activity begins earlier than on cool days, and on cloudy days there are fewer flies. A good hilltop on a hot and sunny day is a frantic place, with anywhere from a few tachinid species to 75 or more (in exceptional habitats) visiting the hilltop by mid afternoon, after which fly activity drops off considerably. Virtually all the observable individuals are males, presumably because they remain on the hilltop for some time whereas females stay only long enough to find a mate. Males of each species are guided by instinct to a particular place on a hilltop and successive generations will return to the same spot year after year. One species may prefer a sunlit spot on the ground at the base of a bush, another will alight on tree trunks, and others will sit on foliage to one side of the hilltop or buzz around the topmost branches of a bush at the hilltop's center, etc. Males of some species spend most of their time perched at preferred locations, darting out frequently to inspect passing insects. Males of other species are in almost constant motion as they fly from point to point but seldom alight.

Aggregation sites for male tachinids are not always on hilltops. The branches of an isolated tree, or shrubs alongside a stream, or a patch of ground below a bush, are a few of the places where males of one or more species may congregate to await a potential mate, nearly always in sunlit situations. Tree trunks also serve as aggregation sites for a number of species. Often several males will occupy the same tree trunk, but the males of some species (e.g., *Trixodes obesus*) are always found singly. Generally only one or a few trees in an area are attractive to aggregating males and these trees will be frequented by the same species year after year. Some species do not alight on a tree but instead fly in a zig-zag pattern up the trunk for a few moments before flying to another tree to repeat the behavior.

It is not uncommon for the antennae of male tachinids to be larger than those of females, but usually this difference is slight. Rarely, the difference is dramatic with the first flagellomere greatly enlarged over that in its conspecific female, or even bifid or multi-branched. Since antennae serve a mostly olfactory function, it is presumed that such antennae help in the location and/or courtship of females. Very little is known about courtship and mating in tachinids, especially under natural conditions.

Ecology

The vast majority of hosts of tachinid flies are plant-feeding insects. As a result, parasitism by tachinids has two major effects at the community level: a reduction of host populations, and an indirect reduction in feeding damage to plants used by hosts. The level of parasitism can vary greatly, from less than 1% to approaching 100%, depending on such factors as the size of a host population, size of the parasitoid population, and environmental conditions. Parasitism levels usually vary locally from one portion of a host's range to another. Parasitism rates are quite dynamic and rise and fall through the generations and from area to area in cycles that both influence, and are influenced by, host populations. The net effect is generally low rates of parasitism (under 5%) with occasional generations where parasitism is significantly higher. Most of the studies into parasitism rates by tachinid flies have involved pest insects, some of which cause damage to crops or forests on an annual basis and some of which are only of economic concern during outbreaks. How quickly a tachinid population can take advantage of an increase in host numbers is dependent on a number of factors but is influenced in part by the oviposition strategy and fecundity of the tachinid species involved.

Tachinid species can be broadly divided into two types, specialists and generalists. As the names imply, specialists attack one or a few host species and generalists attack multiple hosts. On the whole, tachinids tend to be less host specific than hymenopteran parasitoids. Factors affecting tachinid host range include, but are not limited to, habitat choice, host searching strategy, oviposition strategy, method for coping with physiological defenses of host, and developmental synchrony. There is recent evidence from large scale, long term rearings of Tachinidae from Lepidoptera in Costa Rica that some supposedly generalist tachinid species actually comprise a group of specialist cryptic species (species that are difficult to separate morphologically). Although it is likely true that cryptic species are more common in the Tachinidae than previously thought and these species may have narrow host ranges, there are still many tachinid species that are clearly generalists. Most generalists have fewer than 20 recorded hosts, but some have over 50 and a very few have over 100. The hosts of many tachinid species are either unknown or poorly known and are not completely known for the vast majority of species.

Tachinid flies and other parasitoids exert selection pressures on their hosts to evolve ways in which to minimize parasitism. The more obvious may involve the evolution of cryptic coloration, specialized feeding strategies such as concealed feeding or feeding at night, or evasive maneuvers that are evoked when a host is attacked. Less obvious, but quite important at the community level, are the effects of tachinid parasitism on host and host-plant interactions (i.e., tritrophic interactions). Insect herbivores do not always feed preferentially on plant species that provide the highest nutrition. Certain insect herbivores will feed on less preferred host plants if such feeding reduces their level of mortality due to parasitism. The investigation of enemy-free space as an important component of tritrophic interactions is an active area of research.

Biological Control

Potential insect pests are kept largely in check by their natural enemies in their native habitats, but the spread of agriculture and the introduction of insects into new areas has resulted in a steady increase in the number of economically important insect pests attacking crops and forests. Control measures continue to be largely chemical-based, but the benefits of biological control or integrated pest control (control by chemical, biological and other means) have long been recognized. By the early 1900s there was an increasing realization that some insects unwittingly transported to new places by sea vessels were causing considerable damage in their new locations. An early example concerns the gypsy moth (*Lymantria dispar*) and browntail moth (*Euproctis chrysorrhoea*), two forest pests introduced into eastern North America from Europe prior to 1900. In one of the earliest cases of a classical biological control program, several tachinid parasitoids of these pests were imported into eastern USA from Europe in huge numbers in the early 1900s. Although the program was not a complete success, it laid the groundwork for future studies of tachinids as biological control agents. In recent years, one of the tachinid species introduced against those forest pests, *Compsilura concinnata*, has been implicated in the decline of giant silk moths (Saturniidae) in northeastern United States.

Some of the best known success stories of tachinid biological control programs have been reviewed many times. They include: the release of *Cyzenis albicans* from Europe against the winter moth (*Operophtera brumata*) in Canada; release of *Lixophaga diatraeae* from Cuba and elsewhere and *Lydella minense* from Brazil against sugarcane borers (*Diatraea* spp.) in the Caribbean; release of *Bessa remota* from Malaysia against the coconut moth (*Levuana iridescens*) in Fiji; and release of *Ceromasia sphenophori* from Papua New Guinea against the New Guinea sugarcane weevil (*Rhabdoscelus obscurus*). More recently, *Ormia depleta* from Brazil has been implicated in the control of pest mole crickets (*Scapteriscus* spp.) in Florida, USA. Similarly, several species of *Trichopoda* from the southern United States and South America have been introduced recently into Hawaii, Australia, Italy (accidentally), South Africa, and other places for control of the southern green stink bug (*Nezara viridula*), with mixed results.

Some tachinid species have been successfully mass-produced for biological control programs whereas others have proved difficult or expensive to rear under laboratory conditions. The in vitro propagation of tachinids on artificial diets has been achieved for a very few species in laboratory experiments but has yet to be employed in a biological control program.

Tachiniscidae

A family of flies (order Diptera).

► Flies

Taenidium (pl., Taenidia)

Cuticular ridges that strengthen and support the walls of the trachae.

Taeniopterygidae

A family of stoneflies (order Plecoptera). They sometimes are called winter stoneflies.

► Stoneflies

Tagma (pl., Tagmata)

One of the major body regions. In insects, this is the head, thorax and abdomen. In many other arthropods it is the cephalothorax and abdomen.

Taiga Tick, *Ixodes persulcatus* Schulze (Acari: Ixodida: Ixodidae)

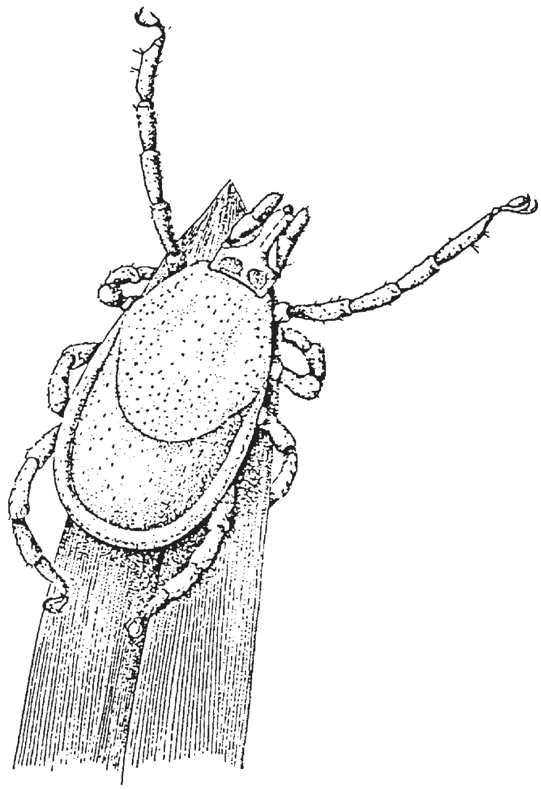
IGOR USUPENSKY
The Hebrew University of Jerusalem, Jerusalem, Israel

This is one of the most well-studied species among hard ticks. Intensive study of *Ixodes persulcatus* was initiated in the late 1930s when this tick was found to be the main vector and reservoir of a virus causing a severe human disease, tick-borne encephalitis (Russian spring-summer encephalitis, Far Eastern encephalitis), that occurs throughout the range of the tick. Two other viruses responsible for human pathogenicity were isolated from the taiga tick: Powassan virus in the southern Russian Far East, and Kemerovo virus in Western Siberia and the European part of Russia. Later, *I. persulcatus* was found to be the main vector of Lyme borrelioses, caused by *Borrelia garinii* and *B. afzelii*, over the entire range of the tick. Recently, *I. persulcatus* was found to be a vector of a number of agents of human and animal diseases: babesiosis (*Babesia microti*), human monocytic ehrlichiosis (*Ehrlichia muris*) and human granulocytic anaplasmosis (*Anaplasma phagocytophilum*). Also, two new agents were isolated from *I. persulcatus* in Siberia: *Bartonella henselae* responsible for cat-scratch disease, and a new rickettsia of unclear pathogenicity (*Rickettsia tarasevichiae*). This tick plays some role in mechanical or biological transmission and maintenance of agents of some other human diseases (salmonellosis, tularemia, Omsk hemorrhagic fever, Q-fever). Transovarial and/or transstadial passage of many pathogens has been proved. Thus, this tick is one of the most important vectors and reservoirs of human pathogens from various groups. Mixed infections in the same populations of ticks, as well as in the same individuals, were documented. A double infection of humans was recorded, and this event may dramatically change the clinical course of human illness.

The range of *I. persulcatus* covers a huge territory of boreal coniferous (taiga) forests, from the Baltic Sea to the Pacific Ocean, extending as a large strip through Estonia, Latvia and the entire Russian Federation. In the west, the tick range includes the eastern parts of Lithuania and some spots in Finland, Poland, Belorussia and in Ukrainian and Hungarian parts of the Carpathians. In the east, the range includes the northern part of Mongolia, the northwestern and northeastern parts of China, North and partly South Korea, as well as a part of Hokkaido Island and several smaller nearby islands in Japan. In the south, there are findings of the taiga tick in limited areas of Kazakhstan, Uzbekistan and Kyrgyzstan. The spread of *I. persulcatus* to the north of its reproductive range is limited by low temperature, and to the south by low humidity. The single findings of the tick to the north of its reproductive range are explained by its introduction by birds during spring migrations from their overwintering areas to the breeding sites. Thus, cases of tick findings on humans and animals even within the Arctic Circle have been documented. The routes of bird migrations are influenced by various geomorphological formations including the valleys of large rivers. Evolutionarily, the taiga tick is one of the youngest representatives of the closely related species in the subgenus *Ixodes* that are united in the *I. persulcatus* group or *I. ricinus* complex, but its range is the largest one among all ticks of this group.

As is the case with most species of ticks living in the temperate zone, *I. persulcatus* has a well-defined seasonality. The unfed ticks search for hosts (questing or host seeking) during the spring-summer season of the year. They use a so-called "ambush strategy" for seeking hosts: unfed ticks are positioned on the vegetation, from the litter layer to the tips of stems or branches, scanning nearby spaces with their chemoreceptors (part of Haller's organs, located on the dorsal surface of tarsus I). They spend from several hours to several days in questing position (Fig. 7) depending on particular environmental conditions. Adult ticks sense the host stimuli from a distance of 5 to 10 m. They can also detect paths of regular host migration, which explains their high concentration nearby. Questing ticks either catch onto a passing host or, sensing it from a distance, move in its direction. Ticks cannot constantly be in a questing position because their water reserves would become depleted. To maintain their water balance, ticks must regularly migrate down to the litter and soil where the temperature is lower and humidity higher. During the day, unfed adults have two peaks of activity: in the morning (8–10 a.m.) and in the late afternoon (after 4 p.m.). Nymphal activity is maximal at dusk and the beginning of the night. Cloudy weather, rain or warm nights may significantly change this pattern. However, if a host appears close to an unfed tick, it may be attacked at any time.

The capacity of *I. persulcatus* for active migration is limited. The questing larvae usually can move up to 20 cm, nymphs up to 40–50 cm, and adults up to 1.0 m. The height of vertical movement is directly correlated with the air humidity. Ticks also are unable to carry out long horizontal migrations: mean 5 m (up to 10 m) for adults and 0.5 m (up to 1.5 m) for larvae. The rate of adult movement may be as high as 30 cm/min at 23°C but generally is lower, decreasing with decreasing



Taiga Tick, *Ixodes persulcatus* Schulze (Acari: Ixodida: Ixodidae), Figure 7 **Unfed adult female of the taiga tick on foliage, seeking a host (after B. I. Pomerantsev and G. V. Serdyukova 1947).**

temperatures. The taiga tick has no eyes, though it can distinguish between more or less illuminated areas, preferring the latter. Photosensitive cells were found approximately in the same area where eyes might be, and their response to light is no less pronounced than in some species of ticks having eyes.

The season of adult activity lasts for 3–6 months, from the time of snow melt (April–May) until July-September, depending on the conditions of a particular region. The season of activity for unfed subadults (larvae and nymphs) principally corresponds to that for adult ticks, though it may be longer. The activity period does not correspond to the life span of individual ticks. After hatching or molting, unfed subadults live about 14–15 months and unfed adults live about 12 months, including post-molting development and behavioral diapause during hibernation, when ticks do not seek hosts. The life of active (host-seeking) ticks is much shorter, from 1 day to about 75 days for unfed adults. The unfed ticks do not become active immediately after post-molting development or diapause but gradually, during the main part of the activity season. Most adults become active during the first 15–30 days of the season. The adults that become active earlier in the season live longer than ticks that become active later. The abundance of active adults sharply increases during the first third of the season (often during a shorter period) and then gradually diminishes until the end of the season. Unfed ticks that do not find a host and cannot feed during the activity period die due to complete expenditure of their nutritional reserves.

The taiga tick is a typical exophilic three-host tick. Each parasitic stage feeds on a vertebrate host only once: the larva feeds for 3–5 days, the nymph for 3–6 days and an adult female for 6–10 days. The duration of feeding strongly depends on the host species. Males feed several times during their active life for 15–30 min each time, and even these brief periods are sufficient for infection of hosts with viruses. The obligatory condition for normal female engorgement is its insemination. The female *I. persulcatus* can be inseminated not only on a host, but also in nature before finding a host. In some populations, about 50% of unfed females collected from vegetation are inseminated. The larvae and nymphs increase their weight during feeding 15- to 30-fold, while engorged females are heavier than unfed females 100- to 150-fold. The mass of an unfed larva is 0.03–0.045 mg, whereas the mass of fully engorged females reaches 250–470 mg. Females lay from 2,000 to 4,000 eggs. The minimal weight of engorgement, after which females are capable of laying single eggs, is about 20–35 mg. The heavier the engorged female becomes, the greater the ratio of the number of laid eggs/mg of the female's weight, until the female weight reaches 140–200 mg, after which the dependence of egg number/mg of engorged female becomes linear and equals approximately 8.5–9.5 eggs/mg of the female weight. Values of all these parameters differ for tick populations from different parts of the range of *I. persulcatus*.

The engorged ticks drop off the host into the litter where they develop before molting, or where the females oviposit and the eggs develop. The engorged subadults feeding in the late summer have no time to undergo the necessary metamorphosis by the autumn; they enter the morphogenetic diapause and molt into the next stage only in the second part of the summer of the following year. The possibility of nymphal diapause during 2 years is rather questionable and needs further study. The molted unfed individuals hibernate, being in behavioral diapause, and become active next season. Only eggs and engorged adults cannot hibernate. The general duration of the entire life cycle (from eggs to eggs) may fluctuate from 2 years under most favorable conditions (the southern part of the Russian Far East) to 5 years. In most cases, the tick populations consist of ticks of different cohorts (having life cycles of different durations). These two factors make *I. persulcatus* a unique reservoir for pathogenic agents.

The taiga tick is one of the most opportunistic (generalist) tick species, using as hosts nearly 300 species of different vertebrates (about 100 species of mammals, more than 175 species of birds and a few species of reptiles). Larvae principally feed on small mammals (rodents and insectivores), nymphs on medium-sized mammals (rodents, lagomorphs, some carnivores) and birds, and adults on large mammals. The questing height of ticks of each stage coincides with the size and location of their main hosts. In years of depression of the abundance of small mammals, or under specific environmental conditions, subadults may change their hosts for larger ones or for hosts less typical for them under normal conditions. Adults actively attack people and are the main source of human infection by different pathogens; nymphal attacks toward humans have been recorded extremely rarely. *Ixodes persulcatus* adults are more aggressive than adults of the closest relative, the sheep tick *I. ricinus*. Their efficient attachment to the host body is enhanced by a long hypostome covered with numerous recurved teeth, preventing tick removal.

A number of parasites and predators of the taiga tick are known. However, the prospects of their use for tick control are rather slim. The taiga tick is a member of some rather complicated forest communities formed long ago, and there is little chance of destroying a well developed balance of such communities by introducing new agents. The high stability of adult tick abundance from year to year (the difference is not more than one order of magnitude) indicates the extreme fitness of this species. This stability is provided for by a number of factors, such as a complicated life cycle, existence of different types of diapause, numerous hosts from various groups, and a high level of aggressiveness of adults toward potential hosts.

The simplest mode of human protection from taiga tick attacks and bites is proper clothing when in forested areas, and regular self- and cross-inspections followed by tick removal. A wide-scale educational program (lectures, leaflets, articles in newspapers, etc.) just before and during the season of tick activity may increase public awareness of tick attacks and personal motivation for self-protection. There are data on the protective effect of some repellents which can be used on clothing or applied directly to the skin to reduce tick infestation. Large-scale treatment of tick-populated forest areas by persistent acaricides, which were used in the 1950s to 1970s, is now banned. The only target for treatment with non-persistent acaricides might be the popular sites of human relaxation during the summer months.

Tally Threshold

In binomial sampling, the number of individuals required to be present per sample unit to consider the sample unit infested. Proper selection of the tally threshold can improve the accuracy of classification sampling.

► Sampling Arthropods

Tanaostigmatidae

A family of wasps (order Hymenoptera).

► Wasps, Ants, Bees, and Sawflies

Tandem Running

A from of communication among some ants, wherein ants trail one another, with each ant maintaining contact with the preceding individual by means of its antennae.

Tangle-Veined Flies

Members of the family Nemestrinidae (order Diptera).

► Flies

Tanning

The process of sclerotization (hardening) of the cuticle after an insect molts; tanning involves the cross-linking of proteins, aided by quinones. Darkening may accompany tanning. Transparent cuticle can be tanned (hardened), as occurs over the compound eye, though in the absence of darkening.

Tanoceridae

A family of grasshoppers (order Orthoptera). They commonly are known as desert longhorned grasshoppers.

► Grasshoppers, Katydids and Crickets

Tanyderidae

A family of flies (order Diptera). They commonly are known as primitive crane flies.

► Flies

Tanypezid Flies

Members of the family Tanypezidae (order Diptera).

► Flies

Tanypezidae

A family of flies (order Diptera). They commonly are known as tanypezid flies.

► Gladiators (Mantophasmatodea)

Tarnished Plant Bug, *Lygus lineolaris* Palisot De Beauvois (Hemiptera: Miridae)

N. J. BOSTANIAN
Agriculture and Agri-Food Canada, Horticultural Research and Development Center, St. Jean-sur-Richelieu, QC, Canada

The tarnished plant bug, *Lygus lineolaris* (Palisot de Beauvois) is a widely distributed mirid, known from Alaska to southern Mexico. It is a pest of a wide range of seed, vegetable, fruit, fiber and forage crops. More than 600 different plant species have been reported as potential hosts for this insect. Its ability to cause economic losses is often related to the migratory behavior of the adult and the phenology of the host plant. Depending on the host plant species, feeding may cause any of the following injuries: malformation of fruit, abnormal growth habits, necrosis, abscission of fruiting structures, or production of shriveled or embryoless seeds.

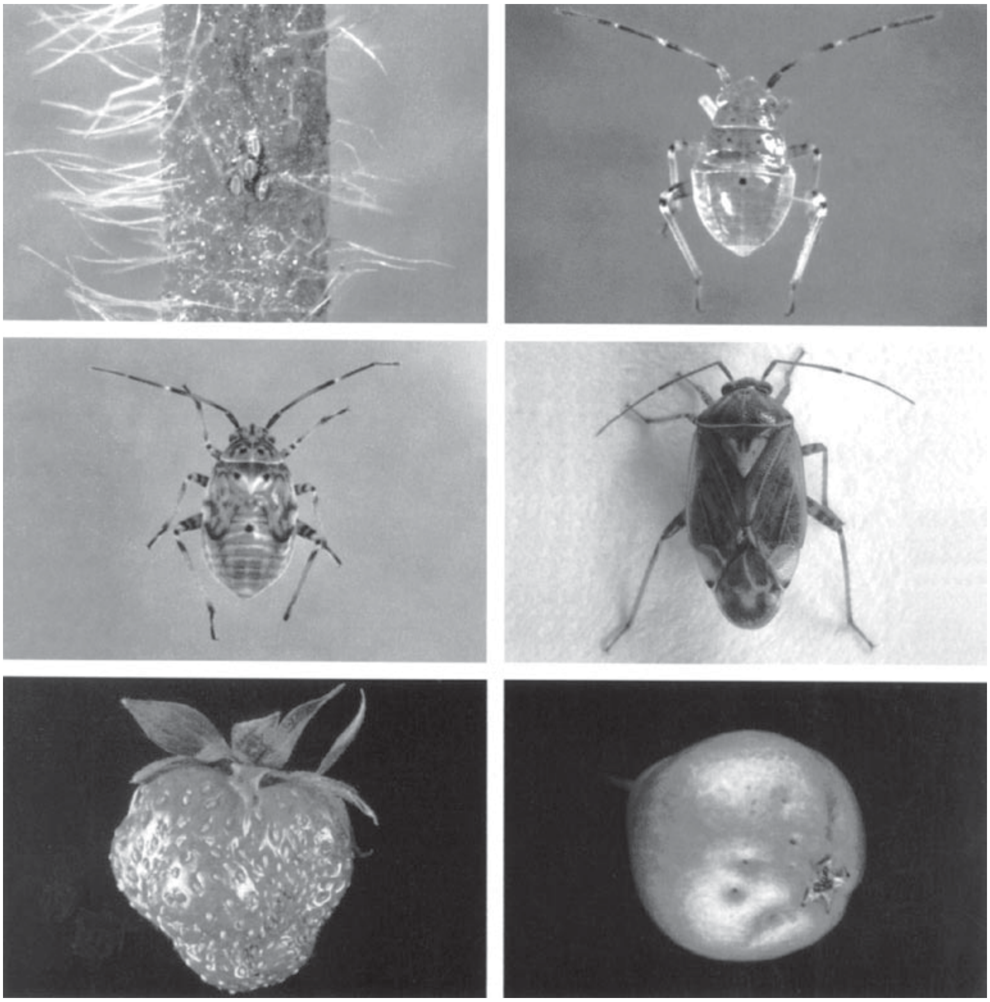
Life Stages

Egg

A freshly laid egg is translucent. Later it is yellowish. It is oval and slightly curved on one side. One end is obtuse and broadly rounded, whereas the other end is almost squarely truncated. The hardened egg shell (chorium) is smooth. Each is 0.85–1.6 mm long and 0.22–0.28 mm wide.

Nymphs

The five instars (Fig. 8) are very similar in form and all are yellowish-green. They walk rapidly and drop readily when disturbed.



Tarnished Plant Bug, *Lygus lineolaris* Palisot De Beauvois (Hemiptera: Miridae), Figure 8 Tarnished plant bug, *Lygus lineolaris*: *upper left*, eggs; *upper right*, third-instar nymph. Note the black spot of the abdominal gland; *second row left*, fifth-instar nymph. Note the four black spots on the thorax. The wing pads are yellowish with irregularly marked brown lines and extend to the fifth and sixth abdominal segments; *second row right*, the adult, dark brownish; *lower left*, a berry injured by tarnished plant bug nymphs. Note the closeness of the achenes where the bug has fed; *lower right*, a pear injured by tarnished plant bug. Note the "pit."

First Instar

The yellowish-green body has a pale orange spot in the middle of the caudal margin of the third abdominal segment. The body length is 0.85–1.10 mm and the body width is around 0.40 mm. The width of the head at the eyes is 0.34–0.36 mm.

Second Instar

The body is yellowish to yellowish pea-green. The third abdominal segment exhibits a bright orange-yellow spot with a slightly smaller spot at the posterior margin. The body length is 1.30–1.65 mm and the body width is about 0.60 mm. The width of the head at the eyes is 0.45–0.52 mm.

Third Instar

The body is green. The abdominal gland is indicated by a black spot. Toward the end of this stage, four dark thoracic spots begin to appear. Wing pads also appear and extend on to the second abdominal segment. The body length is 1.7–2.2 mm and the body width is about 1 mm. The width of the head at the eyes is 0.58–0.60 mm.

Fourth Instar

A great variation of color exists and green, red, white and black predominate. The four black thoracic spots are more prominent. The caudal margin of the third abdominal segment bears a large black spot. Two prominent reddish bands appear on each femur. The wing pads extend to the third abdominal segment. The body length is 2.1–2.7 mm and the body width is about 1.5 mm. The width of the head at the eyes is 0.78–0.80 mm.

Fifth Instar

The color is variable, but greenish in general. The yellowish head has five longitudinal brownish stripes converging behind, but not attaining, the posterior margin of the vertex. The thorax and wing pads are yellowish with irregularly marked brown lines. The abdomen is yellowish or greenish yellow. The wing pads extend onto the fifth or sixth abdominal segment. The veins begin to appear in the pads. Four black spots are conspicuous on the thorax. The dorsal abdominal gland is indicated by a conspicuous black spot on the caudal margin of the third abdominal segment. The legs are variable in color. The body length is 3.2–4.2 mm and the body width is about 2 mm. The width of the head at the eyes is 0.94–0.96 mm.

Adult

The color is variable, usually greenish or brownish, with reddish brown markings on the wings. The thorax has five longitudinal dark stripes. The scutellum has two medium and two lateral black or reddish lines. Eleven segments comprise the abdomen, although some of these are considerably modified. The first ventral segment is reduced to an elastic membrane that joins the abdomen to the thorax. In the female, the seventh segment is named the subgenital plate, as it extends posteriorly in the midventral region to cover the base of the ovipositor. The body length is 4.9–5.7 mm for males and 5.2–6.0 mm for females. The body width is 2.4–2.8 mm for males and 2.4–3.0 mm for females. Moreover, around the base of the ovipositor on the ventral surface of the abdomen, there is usually a dark brown patch that may extend to the thorax.

Life Cycle

Tarnished plant bugs overwinter as diapausing adults either beneath plant litter or duff ground cover, or between the leaves of plants and long dry grasses. In piled leaves and rubbish, winter survival is about 29%, whereas in orchard sod it is only 6%. Overwintering adults start emerging in mid-April at temperatures as low as 8°C. These adults feed first on the opening buds of trees such as apple, peach and shrubs. A little later they migrate to early appearing annual plants. The favorite spring food plants include black current (*Ribes nigrum* L.), wild currents (*Ribes* spp.), common mullein (*Verbascum thapsus* L.), sheep sorrel (*Rumex acetosella* L.), yellow rocket (*Barbarea vulgaris* R.Br.), and strawberries (*Fragaria* spp.) (Table 2).

Overwintering adults gradually disperse on these spring plants as the temperature increases and then migrate to other favorable emerging weeds or cultivated plants. The bugs usually feed on the sap of growing tips or the reproductive parts of a plant, such as the buds of flowers, or the

rapidly growing meristematic tissue of such plants as asparagus, alfalfa and other forage crops.

Tarnished plant bugs generally migrate to a host only when the plant enters its reproductive growth stage. There is a seasonal succession of hosts as the bugs feed on different plants from spring to fall (Table 3). Nymphs can disperse long distances (15–20 m) within a short time and adults

can travel at least 5.1 km in sustained flight. Most adults fly no higher than 1 m from the ground, although some adults have been collected at elevations as high as 1,500 m. Multiple matings occur, but a single mating is sufficient for a female to lay viable eggs throughout her entire life. In Canada, overwintering females oviposit from the first week of May to the third week of June (about 50 days). Optimal oviposition occurs between 21°C and 27°C and oviposition does not take place below 16°C. Eggs can sustain low temperatures of 10°C for 15 days without adverse effect. Eggs are embedded in the stem, in the petioles, or in the midribs of leaves. They may be deposited singly or sometimes in groups of two or three in close proximity.

Following eclosion, the nymphs feed immediately on the succulent parts of the host plant and molt five times. The choice of the host plant dictates significantly the duration of each stage. Laboratory studies, with the temperature fluctuating irregularly between 17°C and 30°C, showed that female longevity ranged from 31 to 68 days, whereas male longevity ranged from 19 to 41 days. In southern Quebec, Canada, adults of the first generation appear about mid-June and reach maximum abundance around mid-July. During this time, adults migrate in great numbers from early season hosts, e.g., June bearing strawberries toward other host plants such as the following: raspberry (*Rubus* spp.), garden beans (*Phaseolus vulgaris* L.), potato (*Solanum tuberosum* L.), pepper (*Capsicum annuum* L.), turnip (*Brassica napus* L.), sugar beet (*Beta vulgaris* L.), red clover (*Trifolium pratense* L.), celery (*Apium graveolens* L.), wild mustard (*Sinapsis arvensis* L.), brown knapweed (*Centaura jacea* L.), and lamb's-quarters (*Chenopodium album* L.). This list is by no means complete. Eggs laid by summer adults produce adults 20–25 days later. For a given area, the seasonal sequential presence of tarnished plant bugs on wild plant hosts is practically the same year after year. The first generation adults mate when they are 4–6 days old. The pre-oviposition period varies between 9 and 13 days, with individual ranges from 5 to 29 days. The fecundity may reach up to 140 eggs per female with an average oviposition of 0–3.4 eggs per female per day. The population dynamics of the second generation nymphs is a function of the immigration time of the adults, the oviposition period of each individual and the nutritive quality of the different host plants. With the season progressing, more and more overlapping occurs between the developmental stages and the different generations of the tarnished plant bug. The overlap results in a smooth exponential growth pattern as opposed to a stepwise pattern. From the end of July to the second week of September, all stages of the bug can generally be found in the field. First generation adults that emerge in mid-June oviposit on several hosts and lead to a continuous emergence of second generation summer adults from the beginning to the end of August. A third generation of nymphs could occur on some cultivated hosts such as alfalfa and asparagus, and on wild plants such as common ragweed (*Ambrosia artemisiifolia* L.), Canada goldenrod (*Solidago canadensis* L.), rough goldenrod (*Solidago rugosa* Mill.), tall white aster (*Aster simplex* Willd.), stinging nettle (*Urtica dioica* L.), Canada fleabane (*Erigeron canadensis* L.), and the red-stemmed aster (*Aster puniceus* L.). In the fall, 25–30 days are needed for the tarnished plant bug to complete its life cycle. In southeastern Canada there are two generations per season whereas in the cotton belt in the southern USA, there are four to seven generations. Past the second generation, it is difficult to distinguish the generations. For example, on lamb's quarters characterized by continuous germination, second and third generation adults and larvae are found on the same plant. Therefore, the extended vegetative and flowering period of this weed contributes to the build-up of tarnished plant bugs in adjacent fields.

Despite some variations, the sex ratio is 1:1 irrespective of the host plant. The bugs are mainly phytophagous; however, they can sometimes feed as facultative predators on soft-bodied arthropods such as aphids and mites, or as scavengers on dead nymphs and adults of their own species.

As fall progresses, the testes and ovaries atrophy and the adults enter diapause. Exposure of nymphs of the first four stages (the photosensitive stages) to photoperiods of 12.5 h or less induces diapause in the adult stage. Rearing these nymphs to a photoperiod of 13.5 h or more will prevent the adults to enter diapause. Continuous light prevents diapause in young adults and terminates diapause in diapausing adults. Fifth-instar nymphs and adults are not sensitive to diapause-inducing photoperiods.

Attractants

There is now some evidence that virgin female tarnished plant bugs release an attractant to males. However, the attractant has not yet been isolated and identified. The presence of an aggregation pheromone that attracts both sexes also has been suggested. In any case, there are still no practical applications for these findings.

Pest Host Relationships

In southeastern Canada and northeastern United States, adults are subject to late fall temperatures that induce the tarnished plant bug to hibernate until the following spring. Management practices to control this bug in fields must consider plant hosts as reservoirs for the build-up of adults and nymphs in the vicinity of cultivated fields. Any flowering plant seems to attract the tarnished plant bug. Nevertheless, there are a few exceptions such as dandelions, sowthistle, milkweed and dogbane, which are all sap latex-type plants. Goldenrod is one of the rare latex-type sap plants which is very attractive in the fall to field populations of this bug.

Plant hosts range from highly attractive to highly resistant to the tarnished plant bug. Resistance to *Lygus* has been reported in some cultivars of celery, alfalfa, cotton, beans and carrots. Some plants do not attract the bug at all. For example, outbreaks have never been reported on wheat, rye and turf grass.

Although the tarnished plant bug is able to develop on a wide range of hosts, field observations show that some plants consistently support much higher populations than others. Management on selected hosts at particular growth stages over a short time, e.g., before the nymphs become adults, may result in lowering bug populations in crop agro-ecosystems. Sites with ephemeral, lush growth that dries out quickly provide a release of tarnished plant bugs and are of immediate concern during the cropping season. In uncultivated fields, weeds growing in sequence that are acceptable to tarnished plant bug development will retain their bug populations throughout the year without any activity of dispersion toward the surrounding crop lands, as long as the site is not disturbed or dried up.

Natural Enemies

Presently, it seems that natural enemies (Table 4), other than a few species of insect parasitoids, are not capable of checking a *L. lineolaris* population once it begins to build up. Endemic populations of *L. lineolaris* are under tremendous environmental pressure that checks their populations. In such instances, natural enemies play an important role. We do not yet have quantitative analyses of the intricate relationships between prey (*L. lineolaris*) and their natural enemies. In addition to parasitic Diptera and Hymenoptera, an identified species of nematode has been reported to rarely parasitize *L. lineolaris* adults in Quebec. Several predators are known to attack *L. lineolaris*, including damsel bugs (*Orius* spp., Anthocoridae), leaffooted bugs (Coreidae), stink bugs (Pentatomidae), lacewings (Chrysopidae), solitary wasps (Sphecidae), robberflies (Asilidae), lady beetle larvae (Cocinellidae), and spiders (Oxyopidae, Tetragnathidae and Thomisidae).

Damage

In southeastern Canada and northern United States, overwintering adults are pests of fruits such as apple, peach and pear. The adults injure the buds causing a circular depression referred to as "pit" in apples and pears (Fig. 8). In peaches, the fruit

Tarnished Plant Bug, *Lygus lineolaris* Palisot De Beauvois (Hemiptera: Miridae), Table 4 Known parasitoids of *Lygus* bugs

Parasitoid name	Family	Target	Comments
Indigenous species			
Polynema pratensiphagum Walley	Mymaridae	Egg	72% *Lygus* mortality in Quebec
Anaphes iole Girault	Mymaridae	Egg	
Anaphes ovijentanus Crosby Leonard	Mymaridae	Egg	50–85% *Lygus* mortality widespread
Erythmelus miridiphagus Dozier	Mymaridae	Egg	
Telenomus spp.	Scelionidae	Egg	
Peristenus pallipes (Curtis)	Braconidae	Larvae adults	First generation May–June; second generation Aug.–Sept. combined 15–20% *Lygus* mortality in Quebec; 38% in Ontario and 22% in Saskatchewan-Alberta
Alophora opaca (Coquillett)	Tachinidae	Adults	7% *Lygus* mortality in Quebec
Alophorella sp.	Tachinidae	Adults	0.8% *Lygus* mortality in Ontario
Imported species			
Peristenus stygicus Loan (USA, Sask., Alta.)	Braconidae	Larvae	Diapausing race from France and a nondiapausing race from Turkey; polyvoltine
Peristenus rubricollis (Thomson) (USA)	Braconidae	Larvae	From Poland; univoltine
Peristenus digoneutis Loan	Braconidae	Larvae	From France (potato, alfalfa rye fields) released in alfalfa field in New Jersey 1979–1988; 36% parasitism of first generation and 29% parasitism of second generation; released in seed alfalfa, Saskatchewan, and strawberries, Quebec, in 1991, 1992; Currently, descendents from the New Jersey releases are collected at St. Clothilde Qc. It is bivoltine; population at maximum abundance about same time as Lygus populations; attacks early stage nymphs of *Lygus*.

appears as if it has been gouged when small and the injury is called "cat facing." Furthermore, a certain percentage of fruit drop occurs following *Lygus* attack. The nymphs that will comprise the first generation attack strawberries causing malformed berries where the achenes are very close to each other and straw-colored. Similar to peaches, the injury is called "cat facing." Several vegetables such as celery, tomato, eggplant and pepper are also attacked by first generation adults and second generation nymphs and adults, causing flower abscission, which reduces yield in some years. In celery, early injuries to the stalk are of no economic consequence. However, near harvest, injury to petioles and necrosis of leaflets leads to secondary infections by bacteria. The damage is called black joint. It is serious and causes unacceptable economic losses. Though cotton is not its preferred host, the tarnished plant bug is a serious pest of cotton. Migration occurs when the wild hosts have dried along cotton fields. Following the completion of the second generation, the bugs enter the cotton fields and damage all fruiting forms of cotton. Early to mid-June pinhead squares (immature flower buds) are attacked and turn yellowish, dry up and eventually drop off the plant. In addition to feeding on pinhead squares, tarnished plant bugs also feed on terminal shoots. This activity results in several physiological changes caused by the toxins injected into the meristematic tissue of the plant terminal. The tall, fruitless plant is characterized by shortened internodes, swollen nodes and excessive lateral branches. This condition is often referred to as "crazy cotton." Later, damage to larger squares shows up as darkened anthers in white blooms resulting in poor pollination and deformed bolls. These are called "dirty blooms." Eventually, the tarnished plant bugs even attack the bolls causing small, dark, sunken spots on the outside of the boll and brownish discoloration inside the boll.

Taro Caterpillar or Rice Cutworm, *Spodoptera litura* (Fabricius)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

This insect occurs in Asia, Australia, and Oceania. There are reports that it invaded many locations outside its natural range and was eradicated, but it is not certain that such eradications involved this species. A very similar but allopatric insect, *Spodoptera littoralis* (Boisduval) (cotton cutworm), is found in Africa, Madagascar, Europe and the Middle East. For many years these two species were thought to be the same, and although they have been considered to be separate species by most authorities since 1962, confusion lingers. Other common names applied to *S. litura* include rice cutworm, tobacco budworm and common cutworm.

Life History

The number of generations displayed by this species depends on temperature. A generation can be completed in less than a month, and 12 generations have been reported annually in India, though 8–10 generations is more common in the wet tropics. Development ceases when temperatures are less than about 8°C, and the upper limit for development is about 37°C.

Eggs are spherical, somewhat flattened, and measure about 0.4–0.6 mm in diameter. They are deposited in clusters of 200–300 eggs, in fairly regular rows comprising three layers, and covered with whitish scales from the abdomen of the female moth. The eggs are orange or pink initially, but turn black before hatching. Eggs persist for 2–3 days in the summer, but considerably longer under cooler conditions, up to 25 days. Females have been shown to produce 2,000–2,500 eggs.

Larvae initially are blackish green with black heads. The older larvae are more variable, often appearing gray, brown or almost black and with dark markings. The latter instars bear triangular spots laterally on each body segment, and a yellow dorsal stripe. They attain a length of 40–50 mm. Young larvae feed in groups, but as they mature they become more solitary. However, at high densities they may disperse in large groups from field to field. Normally there are six instars. Larvae are inactive during the day, with the older instars seeking shelter in the soil but the younger larvae remaining motionless on the foliage. Larval development may require only 12–18 days under hot conditions.

Larvae burrow into the soil to a depth of 3–5 cm in preparation for pupation. Pupae are dark red to reddish brown, and are found in cells buried in the soil. The pupae are 15–22 mm in length, and the last segment bears two hooks. Pupal development time is only 7–10 days under warm conditions, but requires up to 30 days under cool conditions.

The appearance of adults are typical of *Spodoptera* moths, with the forewings bearing gray, brown, yellow and white markings, and the hind wings whitish with a brown or gray margin and dark veins. The wing span is about 30–38 mm. It is nearly identical to the yellowstriped armyworm, *S. ornithogalli* (Guenée), of North America. Adults are active at dusk and during the evening. They mate immediately upon emergence and can begin to deposit eggs within 2 days of mating, though sometimes several days elapse before egg deposition. The adults are short-lived, rarely surviving 7 days under warm conditions, though persisting for 3 weeks under cool conditions. Sex pheromones are produced and have been identified for use in traps.

Damage

This is one of the most serious crop pests in the Asian tropics. It is highly polyphagous, feeding on numerous vegetables, herbs, flowers, and field crops including soybean, cotton, maize, sunflower, rice, and grasses. Plants are often entirely defoliated, and bolls or flower buds can be eaten. Young plants may be severed at the soil surface.

Management

This species is often heavily parasitized by wasps and tachinid flies. Both eggs and larvae are affected. Numerous diseases also are known. However, management generally depends on use of chemical insecticides. Insecticide resistance is an increasing problem, however. In India, integrated management is promoted using trap crops (sunflower and castor plants) around crop fields, clean cultivation, prediction of egg laying by using pheromone traps for capture of moths, and application of neem and nuclear polyhedrosis virus for suppression of larvae. Resistance has been identified in some varieties of peanuts.

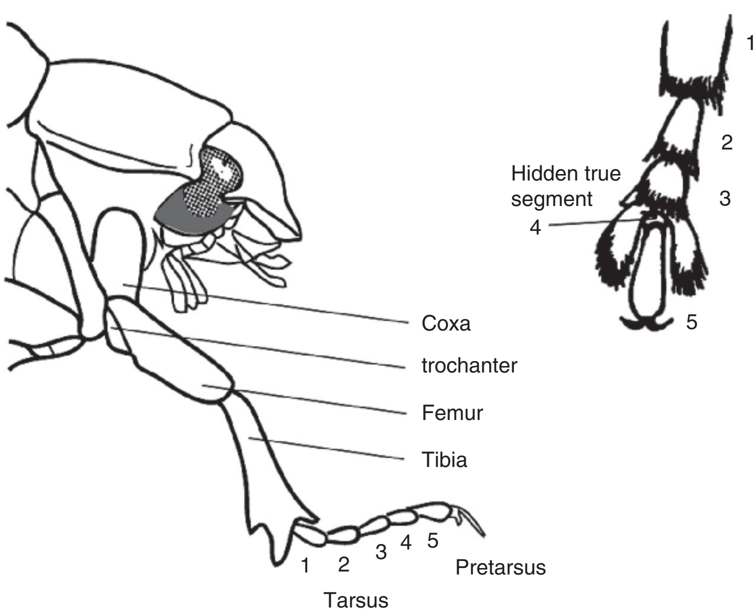
Taste and Contact Chemoreception

REG CHAPMAN
University of Arizona, Tucson, AZ, USA

The sense of taste provides animals with the ability to identify potential food by the perception of certain nutrients, and also to detect potentially toxic materials. Insects are no exception, but unlike most other animals their taste receptors are not restricted to the region around the mouth and they may be able to recognize oviposition cues, and, occasionally, intraspecific signals as well as food. In addition, whereas in vertebrates the taste receptors are stimulated by chemicals in solution, insects have the capacity to perceive chemicals on dry surfaces. For this reason, it is referred to as "gustation" or "contact chemoreception" rather than "taste."

Insect contact chemoreceptors are usually in the form of hairs, or conical projections from the cuticle, with a pore at the tip. The pore permits chemicals to pass through the cuticle to the sense cells beneath. Each hair, or cone, contains the sensitive endings (dendrites) of (commonly) four sensory cells, and each of these responds to a different range of chemicals. The ranges of chemicals reflect the habits of the insect and also the position and specific function of a particular hair.

Very little is known about why an insect chemosensory cell responds to one, or some chemicals and not to others, but it is probable that, as in other animals, this is determined by receptor molecules in the cell membrane of the dendrite just inside the pore in the cuticle. A taste receptor cell may have only one type of receptor molecule, in which case, its response is limited to one, or a few, structurally similar chemicals that interact with the receptor. Other cells have more than one type of receptor molecule, and so have the capacity



Tarsus (pl., Tarsi), Figure 9 Leg of a beetle (Coleoptera: Scarabaeidae) leg showing its component parts, and a close-up of one type of beetle tarsus (foot).

to respond to a range of structurally different chemicals. Some cells that are presumed to have these different characteristics are described below.

The interaction of the appropriate chemical with a receptor molecule leads to changes in the electrical potential across the cell membrane and an electrical signal is sent along the axon that connects each sensory cell to the central nervous system. Connections within the central nervous system determine whether the insect responds positively or negatively to the stimulating chemical, that is, whether it accepts or rejects food, or an oviposition site. In practice, how the insect responds nearly always depends on the integration of signals from a number of receptors.

Contact chemoreceptors are found primarily on the mouthparts, the labrum, maxillae, labium, and hypopharynx, and they may be especially abundant on the maxillary and labial palps when these are present. A small number are present on the epipharynx (the inside surface of the labrum) just outside the mouth in all insects that have been investigated. Many insects also have contact chemoreceptors on the tarsi, and on the antennae, although most of the chemoreceptors on the antennae are olfactory receptors. Females of some Orthoptera, Diptera, Hymenoptera and Lepidoptera have contact chemoreceptors on their ovipositor, but this is not a general characteristic of females even within a group.

The numbers of contact chemoreceptors associated with the mouthparts is very large in cockroaches, grasshoppers and related insects. An adult of the migratory locust, *Locusta migratoria*, for example, has about 3,000 contact chemoreceptors on the mouthparts. In these insects, additional receptors are produced at each molt. By contrast, much smaller numbers are present in sucking bugs. Aphids have no contact chemoreceptors on the exposed parts of the proboscis, but they have a few on the epipharynx. As a result, aphids must draw fluid into the cibarial cavity before they are able to taste it. This is not true of all sucking bugs, however, many of which have contact chemoreceptors on the tip of the labium, which is the first mouthpart structure to contact the food prior to feeding. Holometabolous insects also generally have few mouthpart contact chemoreceptors, especially in larvae. Caterpillars have only 16–20 contact chemoreceptors and this number does not change throughout development. In grasshoppers, species with more restricted diets tend to have smaller numbers of contact chemoreceptors on the mouthparts than polyphagous species. Among caterpillars, however, this is not true. The numbers are similar irrespective of feeding habit.

Feeding

The primary function of contact chemoreceptors on the mouthparts is the selection of food. Once the insect bites into food, some receptors become immersed in the juices released from the food and so function very much like taste receptors in vertebrates by detecting compounds in solution. However, the receptors on the maxillary and labial palps often come into contact with food before the insect bites. They can detect compounds on the dry surface of a leaf, for example. In grasshoppers, crickets and cockroaches, the palps are vibrated rapidly so that the contact chemoreceptors at their tips are brought into a rapid series of brief contacts with the surface. As many as 15 contacts per second may be made, and each period of contact probably lasts less than 20 ms. This behavior, known as palpation, probably serves two functions. It allows the insect to receive a more sustained flow of information from the receptors than would be possible if contact were maintained because the receptors become adapted (as our taste receptors do after the first mouthful of a sweet drink), and it also allows the insect to sample a larger surface area than if the palps remained stationary. The information provided by palpation before an insect starts to feed enables it to make feeding decisions more rapidly and also, perhaps, to avoid the possible intake of noxious compounds if the food contains toxins.

Insects, like other animals, can taste the major nutrients essential for their development, survival and reproduction: sugars (as a source of energy), amino acids (the building blocks for protein), and inorganic salts and water. There is no direct evidence that insects are able to taste proteins. The specific chemicals to which an insect's taste receptors respond, however, vary with the feeding behavior of the insect. It is common for one of the sense cells in a contact chemoreceptor to be sensitive to some sugars, and another to be sensitive to some amino acids. Some insects have also been shown to possess a "water cell," that is, a cell that responds to water and very dilute salt solutions, and it is possible that this type of cell is of widespread occurrence. All insects appear to have a cell responding to inorganic salts, but this cell exhibits increased activity as the salt concentration increases (unlike the "water cell" whose activity declines with increased salt concentration), and it is probably a cell that inhibits further feeding, ensuring that the insect does not ingest excessive amounts of salt. The other nutrients such as sterols, fatty acids and vitamins appear to be acquired as a result of their widespread occurrence in the insect's food and do not require specific taste receptors.

A cell responding to sugars does not necessarily respond to all sugars, nor does an amino acid-sensitive cell respond to all amino acids. In the woolly bear caterpillar of the moth, *Grammia geneura*, for example, a sugar-sensitive cell in one hair only responds to the fruit sugar, fructose. This cell probably has only one type of receptor molecule that only reacts with fructose. However, a cell in another hair close by responds to sucrose and glucose although not to fructose. This cell probably also has a single type of receptor molecule that reacts with both sucrose and glucose because of similarities in their molecular structure. In the same way, cells in different hairs may respond to different ranges of amino acids. This probably allows an insect to detect food of different qualities. Even so, not all different types of sugar or amino acids are tasted by any one insect even though some of them are essential for its development. It obtains a balanced diet mainly because a food with some nutrients, which it can taste, will generally contain most of the others, which it cannot taste.

In addition to nerve cells that respond to nutrient compounds, many plant-feeding insects possess sensory cells that respond to plant secondary compounds. These compounds, alkaloids, terpenoids, and many others, are produced by plants outside the normal primary metabolic pathways (hence "secondary") and are important in the plant's ecology. Many of them inhibit feeding by herbivorous animals, including insects, and the human interpretation is that they taste "bitter." Sometimes they are also toxic. In a majority of plant-feeding insects, stimulation of a cell by these secondary compounds inhibits, or deters feeding, and the cells are usually called "deterrent cells." A deterrent cell usually responds to several different secondary compounds, but by no means all the different types. This almost certainly reflects that fact that it has several different types of receptor molecules.

Because all plants contain secondary compounds, whether or not an insect feeds on a particular plant and the amount it eats is dependent on the balance between information received from taste cells signaling the presence of nutrients, and deterrent cells signaling the presence of secondary compounds. However, in some insect species that feed only on particular plant species or groups of plants, characterized by a specific chemical, it is common for the deterrent cells to have lost any sensitivity to that chemical so the plant is no longer "distasteful." Correspondingly, some now have a sensory cell that responds only to that compound or class of compounds and which indicates "acceptability" rather than "distastefulness" to the insect. The best-known example of this is the response to glucosinolates. These are sulfur-containing compounds characteristic of the cabbage family. For most plant-feeding insect species, these compounds stimulate deterrent cells and inhibit feeding, but in many species that feed habitually on plants in the cabbage family, the deterrent cells are not affected. Instead, another sensory cell responds to the glucosinolates, indicating acceptability so that the insects are stimulated to feed or oviposit.

In species that feed on vertebrate blood, the contact chemoreceptors have a sense cell that responds to adenine nucleotides such as ATP and ADP. These compounds are released when the insect probes into the host's blood vessels and damages blood cells. They provide the insect with an unequivocal signal that appropriate food is available.

Not only the chemoreceptors on the mouthparts are involved in feeding decisions, however. This is most obvious in fluid feeding insects like flies and bees, where extension of the proboscis, which is necessary before the insect can feed, is induced if chemoreceptors on the tarsi are stimulated with sucrose. In the tsetse fly, *Glossina fuscipes*, similar receptors respond to some of the common components of human sweat, such as uric acid and the amino acids leucine and valine. Stimulation with these compounds causes the insect to probe with its proboscis and is presumably part of the normal host recognition process. Tarsal receptors are also involved in host recognition by plant-feeding insects.

Oviposition

It is common for contact chemoreceptors to be involved in oviposition, although attraction to the oviposition site often depends on the sense of smell. Contact chemoreception in this context has been most thoroughly investigated in some flies such as the cabbage fly, *Delia radicum*. The tarsal receptors on this fly respond to glucosinolates on the leaf surface of the host plant. Other insects, like the imported cabbage butterfly, *Pieris brassicae*, and the cabbage looper, *Trichoplusia ni*, that lay their eggs on cabbage plants also have tarsal receptors responding to glucosinolates. Contact with these compounds induces the insects to lay eggs. A number of butterflies drum on the leaf surface with their fore tarsi when selecting a leaf for oviposition. This appears to be a process analogous to palpation, bringing the contact chemoreceptors on the tarsi into a series of brief contacts with the leaf surface. There is no evidence that the leaf surface is broken by these activities, so the insect does perceive chemicals on the surface, not from within the plant.

Although contact chemoreceptors do occur on the ovipositors of some insects, there is not yet clear evidence of their roles in oviposition.

Pheromone Detection

Contact chemoreceptors are sometimes important in the perception of pheromones involved in sexual recognition, prevention of oviposition, and trail following. In the tsetse flies, *Glossina* species, the male recognizes a female by touching her with contact chemoreceptors on his fore tarsi. This contact also enables him to determine whether or not she has mated through the perception of specific molecules in the wax on the surface of the female's cuticle. Changes in the proportions of some components occur at the time of mating because wax from the male contaminates the female, and the male is able to detect the difference with his tarsal receptors. A similar process occurs in *Drosophila* fruit flies, except that in this case, the female wax alters as a result of changes in synthesis in the female following mating. Females of the German cockroach, *Blattella germanica*, also have sex specific compounds in their cuticular wax which function as a sex recognition pheromone. At the start of courtship, the male touches the female with his antennae, presumably detecting the compounds with contact chemoreceptors on the antennae.

Contact chemoreceptors are used by the adults of some flies to detect oviposition deterrent pheromones laid down by previously ovipositing females to reduce the likelihood of competition with their larvae. This is known to be the case in adults of the apple maggot fly, *Rhagoletis pomonella*, and the cabbage butterfly. The cabbage seed weevil, *Ceutorhynchus assimilis*, however, detects its oviposition deterrent pheromone with contact chemoreceptors on the club of the antenna. Although contact chemoreceptors are common on insects' antennae, this is one of the few instances where their function is known. Many insects are known to make rapid vibrations of the antennae when they encounter a potential food or prey item. This process is known as antennation, and it is probably analogous to palpation with the insect bringing contact chemoreceptors at the tip of the antenna into brief contacts with the substrate. Parasitic Hymenoptera, for example, are commonly seen doing this when they encounter a potential host.

Tent caterpillars follow chemical trails deposited by conspecifics. The trails are detected by contact chemoreceptors on their maxillary palps.

It is almost certain that there are many situations in which insects use contact chemoreceptors on their antennae or tarsi for the perception of intraspecific signals.

Taxis (pl., Taxes)

A directional movement in response to an environmental stimulus, directed toward or away from a stimulus. A movement toward the stimulus is considered to be a positive taxis, a movement away is a negative taxis. Types of taxes include anemotaxis, astrotaxis, chemotaxis, geotaxis, hygrotaxis, phonotaxis, phototaxis, rheotaxis, and thermotaxis.

Taxon (pl., Taxa)

A group of organisms, populations or taxonomic groups considered to be sufficiently different from other groups to be treated as a unique group from the perspective of classification or taxonomy. For example, a species is a taxon when it is compared to another species; likewise, higher level groups such as families and orders can be referred to as taxa.

Teaching and Training Entomology: Institutional Models

CARL S. BARFIELD, MARILYN E. SWISHER
University of Florida, Gainesville, FL, USA

Research on insects, whether to understand basic biology or to provide management strategies, most often occurs within thef context of an institutional paradigm. Precisely the same is true for teaching/training programs and extension. The structure of an organization in which researchers, trainers or extension specialists work is crucial to understanding the goals, motivations and successes of those human resources. Understanding the institutional framework within which programs are developed and delivered is therefore an important consideration when evaluating program effectiveness.

There are five principal models of institutional and procedural frameworks within which research, teaching and/or extension programs associated with entomology occur. Three are fairly widely used and two have the potential to become global.

The very framework chosen within which to pursue entomology may well affect the types and quality of information developed. Evaluating the effectiveness of entomological programs cannot be complete without recognizing the institutions within which such programs are developed and reside.

The degree to which entomological programs developed under one paradigm can function successfully when transferred to another is therefore an important and an intriguing issue, but one that has been virtually ignored on a global basis. Each of the five major models currently used has advocates and critics, and each has relative strengths and weaknesses. However, discussion of program strengths and weaknesses most often fails to consider the institutional context in which they have developed historically, and thus fails to provide a comprehensive analysis of when, how and why these programs succeed or fail.

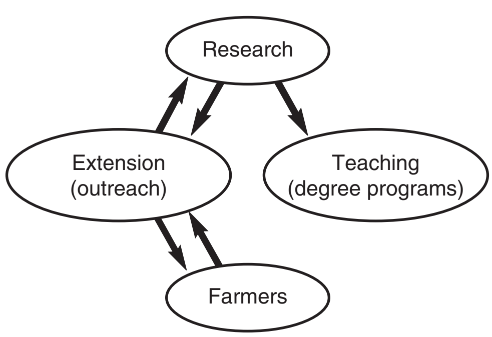
The Land Grant System: USA

During Abraham Lincoln's presidency, the United States Congress was moved to provide legislation directly aimed at assisting farmers. This made both practical and political sense, as some 65% of the U.S. population was involved in agriculture in one way or another. Under Lincoln's guidance, the United States Department of Agriculture was established in 1861. Then, four successive Federal Acts (Morrill Land Grant Act, Hatch Act, second Morrill Act and Smith-Lever Act), dating from 1862 to 1914, set aside lands for agricultural research and put the infrastructure and human resources in place to conduct that research. The second Morrill Act (1890) set aside a second set of lands and infrastructure for the development of what are often termed Historically Black Colleges and Universities (HBCUs), and the Smith-Lever Act (1914) created the Federal Extension System.

The Land-Grant system is based on the concept of combining teaching, research, and extension within a single institution, and it took about 50 years to establish all three functions. All 50 states and U.S. protectorates and territories employ the system. America has led the world in agricultural production since the Land Grant system was established.

Proponents of the Land-Grant model point to the productivity of American agriculture and the associated research infrastructure. Indeed, due in part to the Federal and state investment in this institutional model, the USA is today the world's leading producer of food with only about 1.8% of the population involved in food production. The USA grants more graduate degrees in the agriculture-related disciplines than any other nation, and more international students seeking advanced degrees in agriculture choose to study in the United States than anywhere else. Including extension in the model indicates the importance of a forward and backward link between farmers and researchers. Finally, this model ensures that advances in agricultural technology to find their way into the classroom very quickly, ensuring that future generations of agricultural professionals and farmers are able to apply the new technologies (Fig. 10).

Not everyone agrees that this model is ideal. Critics of the Land-Grant model point out several weaknesses in the system:



Teaching and Training Entomology: Institutional Models, Figure 10 **Basic structure and flow of information in a Land-Grant Institution as originally conceived.**

1. Over the years, extra-mural grants have supplanted Federal and state direct support for agricultural research and extension. Grants programs are fickle and trendy. Land-grant institutions have a long history of "following" extra mural priorities (integrated pest management in the 70s, sustainable agriculture in the 80s, and genetic engineering now). The wholesale commitment to these types of trends by significant percentages of land-grant scientists is indicative of how susceptible this model is to abrupt shifts in priorities in the quest to acquire funds and publish. Research is driven more by granting agency priorities than by farmer needs.
2. Due in part to the emphasis on extra-mural funding, Land-Grant institutions tend to recruit faculty with ever-narrowing expertise so they can compete successfully for grants. As a result, the system lacks scientists who have either the skills or the incentives to integrate knowledge across disciplines. Individuals who are capable of critically analyzing the potential impacts of new technologies in a broader social, economic and ecological framework are rare.
3. The departmental and college management structure of Land-Grant institutions is, in many ways, the antithesis of the type of holistic program structure needed to resolve real problems. University units are rewarded for their individual productivity, not for their collective cooperation. While universities constantly discuss the need for inter-disciplinary approaches, their very structure often prevents them from implementing effective cross-disciplinary solutions.
4. The ability of the USA to capitalize on the high productivity of Green Revolution agriculture is as much attributable to good fortune as to agricultural research, and it is likely not sustainable. Green Revolution agriculture depends on high levels of off-farm inputs that make successful farmers more dependent on a few transnational corporations that supply seed, fertilizers, equipment, and chemicals while also increasing the farmers' debt. Other farmers simply cannot obtain these inputs. There appears to be an internal conflict of priorities in the Land-Grant Model. One priority is to feed the masses at any cost. The other is to keep small farmers in business for the social good.
5. Teaching in Land-Grant institutions often is the single least rewarded activity. Reward and professional advancement depend largely on the amount of grant dollars obtained and the number of publications produced. Relevance to real farm problems may not rank high among the factors taken into consideration for faculty promotion.
6. Extension often does not work as it was conceptualized. The fundamental idea was for extension to serve as the voice of the farmers and to vocalize the research needs seen by farmers as priorities. That extension voice would then explain those priorities to university researchers who, using their research expertise, would investigate the issues, develop solutions and have the extension voice deliver those solutions back to the farmers. In reality, researchers are driven by grant priorities, rather than extension-relayed farmer needs.
7. Finally, critics point out that the USA has moved from an original farm policy designed to keep farmers on the farm and farming profitable, to a "cheap food" policy designed to feed urban populations who, by and large, elect Federal officials. The Land-Grant infrastructure evolved to pay little attention to the promotion of agricultural procedures that would make farming sustainable and conserve natural resources.

While the debate continues, the sheer volume of output from Land-Grant programs is impressive. In the USA, the Land-Grant system encompasses a wide range of farming enterprises. Large scale, corporate farming often becomes a source of information for Land-Grant scientists as corporations have the capital to invest in staff and research on their crops and pests that tax-based Land-Grant institutions do not. Small farmers often cannot afford to adopt the technologies proposed by Land-Grant scientists and tend to utilize a mix of modern science and traditional farming practices.

The system has not gained acceptance outside the U.S. and, in fact, has really not ever been replicated elsewhere, although components of the system have been implemented in other places. This model depends greatly on a collaborative relationship among peers for its success. Peer review, for example, is a major factor in evaluating the quality of teaching, research and extension. Similarly, funding for the system involves Federal, state and local support, and farmers must be empowered to ensure that their problems and priorities are imposed on the entire structure. All of these characteristics are typical of the social and political structure in the United States. The poor "transportability" of the U.S. system, especially to non-European based cultures and to nations where democracy is not the norm, may be due, in large part, to the absence of an appropriate social, cultural and political context for the system. The Land-Grant model may be culturally insensitive, but not necessarily wrong. Agricultural productivity appears to be like every other increasingly globalized activity: one cannot compete if one doesn't play the top-level game. This, of course, is not highly acceptable to politically sensitive people who want to maintain local culture and merely improve agricultural productivity. Global competition likely will demand local cultural changes in the way farmers and governments spend their time and money.

Training and Visit (T&V): World Bank

T&V is a child of the World Bank, and this model was conceptualized and first utilized in Asia in the 1970s. This hierarchical system began in India, Turkey, Burma, Nepal, Sri Lanka and Thailand, and today exists in more than 40 nations. The basic premise of the T&V system is that much more information and technologies exist than are used by farmers, and the principal reason for this is the ineffectiveness of extension delivery systems. T&V thus places major emphasis on training and outreach. Research is most often limited to site-specific adaptive research of existing technologies. While more recent T&V programs have tended to re-emphasize the research component, the approach continues to focus heavily on outreach.

T&V is a top-down approach. A subject matter specialist trains a limited number of regional extension agents who, in turn, provide training to local extension agents who, in turn, train farmers. This approach emphasizes the timeliness of actions, and the progress of agricultural productivity at the farm and regional levels is "tracked" by the training process. For example, training on improved seedbed preparation will be delivered just before the time when seedbed preparation is to occur. Frequent, regular reporting from the bottom up is a key feature of the T&V model. The Land-Grant system has "field days" and "demonstration plots" where farmers can come to witness innovations. While not hierarchical in nature, as is T&V, the idea is somewhat the same.

Proponents of T&V argue that the system is ideal because it focuses on those human resources that are native to indigenous cultures, provides a "filter" to take existing technology and adapt it to local conditions, and it is both relevant and timely. T&V takes complete advantage of cultural and social hierarchies already in place. The fact that T&V is currently utilized in over 40 nations, so say the proponents, is indicative of its relevance. Simply put, it works.

Critics of T&V point to several shortcomings:

1. Methods are geared to the top, best-educated, most articulate facilitators (regional extension personnel). Most T&V programs end up with a paltry number of highly capable facilitators. The methods that are emphasized both confuse and leave behind the other participants in the system. One result is that the less capable extension agents train their local agents poorly, and the farmers who rely on them, in essence, receive poor advice.
2. In the same vein, T&V historically has not sanctioned facilitators for not attending all training sessions. One result is poorly equipped facilitators, and the problem progresses down the hierarchy.

3. This approach, in many ways, "force fits" the T&V timetable into an often-unreceptive farmer schedule resulting in poor adoption of advice.
4. T&V programs historically are narrow in perspective and not linked to broader, yet relevant, issues of great concern to farmers. Timely seedbed technology is useless if not linked to socially relevant local schedules and to lending periods and priorities of local banks.
5. T&V programs were developed for irrigated systems where water was controlled and never attempted to develop procedures exportable to rain fed agriculture.
6. Many analyses have shown T&V approaches to be overly costly and non-sustainable.

T&V differs from the Land-Grant system in its almost sole focus on a hierarchical extension-training approach. An interesting note is that virtually all the countries where T&V is employed are in World Bank-funded efforts in Asia. T&V does not appear to have been widely adopted elsewhere. However, the essence of T&V sometimes is practiced in other countries like Jamaica despite no formal funding of projects actually called T&V.

Once again, cultural and social factors may play an important role in determining how well this system "travels" from its Asian heartland to other parts of the world. The very hierarchical model that assumes that knowledge flows "downward" from more educated and knowledgeable experts to practitioners (farmers) would not, for example, be very acceptable to many farmers in the United States or perhaps in most societies where egalitarian norms are strong.

Farming Systems: United States Agency for International Development

The farming systems model originated from programs in Latin America and, over the last two decades, has been promoted by a variety of international development agencies. The single largest advocate of this model in the 1980s was the United States Agency for International Development (USAID). Many of the CGIAR centers (notably CIP, CIMMYT and IITA) also have used this model.

The farming systems model differs widely from T&V in that farming systems primarily emphasizes research, not extension. Underlying the farming systems model is the assumption that most existing technology has not been adapted to specific regional or local conditions. Farmers are, therefore, unable to adopt and utilize what would be useful methods. The major emphasis of farming systems is on site-specific, adaptive research. While there is episodic invention of "new technology," the major emphasis focuses on local tests of existing technologies. Proponents of this model argue that there are major differences between the farming systems model and the Land-Grant model. In practice, those differences are often hard to discern. Both models depend on strong linkages between research and extension and are difficult to implement in places where the two functions are not housed in the same institution. Further, many advocates of the Land-Grant system argue that both models emphasize features such as on-farm research, site-specific testing and multidisciplinary research teams. There is, in practice, one major difference between the two models. The farming systems model emphasizes research much more than extension, and farming systems projects that demonstrate mass dissemination of information are rare.

A basic tenet of the farming systems model is that many global farmers have been by-passed by the Green Revolution. Their land holdings or their economies were too poor to take advantage of high-yielding agriculture and its associated inputs. Thus, the advocates say the most relevant approach is the use of a multidisciplinary "rapid rural appraisal" team to ask farmers' opinions, followed by research aimed at tailoring existing technology to individual farmers' fields (Figs. 11 and 12).

Critics of the farming systems model point to a number of constraints on its effectiveness:

Teaching and Training Entomology: Institutional Models, Figure 11 **Farming systems training effort in The Gambia, West Africa.**

Teaching and Training Entomology: Institutional Models, Figure 12 **Farming systems project to teach proper goat-dipping techniques for tick control in Kenya. Slide provided by Dr. Sandra Russo, International Programs, University of Florida.**

1. The disciplinary make-up of the initial rapid rural appraisal team can severely bias what the team determines is pertinent research.
2. Farming systems teams have often been unable to define their tasks and, consequently, served only to "spread the gospel" of farming systems rather than to provide holistic solutions for real problems. Farming systems failed in Africa for precisely this reason.
3. Many farming systems projects to date have focused on crop variety and/or fertilizer trials – the very things that these farmers supposedly could not afford, thus giving rise to the farming systems model in the first place.
4. To date, adherents of the farming systems model have been primarily economists, anthropologists and a few agronomists. The broad spectrum of agricultural disciplines apparently has not b ought into the basic premise of farming systems.
