Harry was considered a workaholic and slept only short periods at night. However, this restlessness was forced upon him due to the truck accident in Mexico that left him in considerable pain. Another reason for Harry's tremendous productivity was that he took full advantage of postal services (before e-mail) to persuade anyone working in tropical countries to send him ticks they had collected. He also kept up-to-date with his correspondence (150–200 letters/week), which often kept three or four secretaries working full time to keep up with him. Harry would have the ticks sent to him identified and catalogued, or refer them to Kaiser in Cairo or Clifford and Keirans (in Montana), and then correspond with the collector regarding their identification, often requesting more material. For example, Dr. Alex Fain (Belgium) sent Harry males and larva of an argasid tick from fruit bats that were collected in Zaire (1956) but Harry needed the other tick stages so when the late Dr. Robert Usinger, on sabbatical leave from University of California was planning a trip to Africa to collect cimicid Heteroptera, Harry asked him to look for more material of this tick; subsequently, Usinger collected females and nymphs that turned out to be a new species, *Ornithodoros* (now *Carios*) *faini*, from roosts of *Rousettus* fruit bats in the Congo. Usinger sent a sample of the live ticks to Harry in pouch-mail from Zaire and hand carried another sample to Cairo to ensure their survival for rearing purposes so that all of the stages (larva, nymph, male, female) could be described and illustrated in the published manuscript. Harry, as well as his colleagues in Montana, didn't wish to describe new species of ticks based on only one of the stages. When a particular tick was collected it would be catalogued and compared with closely related material that was often laboratory reared. Previously, tick workers had described ticks based on finding one sex (the male, for example) and confusion could later result when other stages were collected. Harry would not describe a species based on only a single specimen.

Harry also did not believe in what he called "tampering with present concepts of tick genera," something done in present day with the discovery of RNA/DNA and molecular studies. He believed that phylogenetic trends among ticks, especially in the genus *Argas*, were lucidly demonstrated on a subgeneric level.

A portion of the ticks collected would always be preserved and portion "ground up" by his associates in Cairo or at the Rocky Mountain Laboratory (Montana, USA) and tested for arbo-viruses. This was undertaken before the tick arbo-viral activities of the U.S. Public Health Service were phased out.

Robin Rice (Hawaii) was an individual Harry recruited to collect ticks for him on Peruvian cliffs, in the Galapagos of South America, in coastal Texas of the USA, and in southeastern Kenya of East Africa. Some of the African material that Rice collected remains undescribed to this day, as more material was needed by Harry before publication to be sure that they were new species. This author (E.R.E) accompanied Harry to an escarpment south of Nairobi near Lake Kwenia to search for argasid ticks of the Griffon vulture (1975). There we examined the massive thorn-stick nests of the red-billed buffalo weaver in Baobab trees (Kiboko Range Research Station) for a tick previously collected there by Rice and tentatively known as *A. bubalornis*; it remains undescribed.

His enormous tick collection was combined with the Rocky Mountain Laboratory collection and his material is currently housed at the U.S. National Tick Collection, currently on loan with Georgia Southern University in Statesboro.

Harry was a complex man, having many interests, including sculpture and culture of cacti. He died in his sleep in Cairo on his 69th birthday, on February 24, 1986.

Hooktip Moths (Lepidoptera: Drepanidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Hooktip moths, family Drepanidae, comprise 812 species worldwide, but predominately Oriental (647 sp.); none are known for the Neotropics and only a few are in the Nearctic; the actual fauna probably exceeds 950 species. Three subfamilies are known: Drepaninae, Oretinae, and Nidarinae (the latter only from Madagascar). The family is in the superfamily Drepanoidea, in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults small to medium size (18–66 mm wingspan), with head scaling normal; haustellum small or absent in some species; maxillary palpi vestigial; antennae bipectinate to filiform; body sometimes somewhat robust. Wings broadly triangular, usually with the forewings falcate; hindwings mostly rounded (Fig. 40). Maculation mostly shades of brown to yellow with various markings, sometimes more colorful, or hyaline to white with tan bands. Adults nocturnal. Larvae are leaf feeders. Host plants include a variety of plants in Anacardiaceae, Betulaceae, Caprifoliaceae, Fagaceae, Myrtaceae, Rosaceae, Theaceae, and others. A few are economic.

Hope, Frederick William

Frederick Hope was born in London on January 3, 1797. In 1817 he entered Oxford University, and graduated in 1820 with a B.A. degree in classics, and in 1823 obtained an M.A. The intent was that he should enter the church, and he was presented with a curacy in the county of Shropshire, but his health did not allow this to continue. While he was an undergraduate, he became fascinated with the natural sciences and spent much time studying geology and entomology. After leaving Shropshire, he returned to London and,ww later aided by Ellen Meredith, the wife he married in 1835, began to collect natural history objects into his own private museum. He built his collections not just by his own collecting, but by purchase, gifts and exchange, such that he acquired materials from Britain and abroad. He travelled in France, Germany, Holland and Switzerland in the 1830s. He was elected fellow of The Royal Society in 1834. He was one of the founder members of the Entomological Society of London in 1833, and served as president in 1835–1836, 1839–1840, and 1845–1846. He also published mainly taxonomic works on insects, especially Coleoptera, and many in the pages of the journals of the Entomological Society of London. These works included descriptions of some of the insects collected by Charles Darwin. In 1855, Oxford University began to build a new museum to house scientific collections, and Frederick Hope's collections and personal library were promised to that museum by deed of gift, with the stipulation that a conservator of his collections should be appointed by the university. Thus, the position of Hope Professor of Zoology was created, and this position was held first by J. O. Westwood. Frederick Hope died on April 15, 1862. A few entomologists (faculty, technicians, and graduate students) associated with the Hope Professor of Zoology (Entomology) remained housed with the Hope Entomological Collections and Hope Library in the University Museum, as the Hope Department of Entomology, until 1978. Then, the name Hope Department of Entomology disappeared, merged into Oxford University's Zoology Department. The title of Hope Professor of Zoology (Entomology) disappeared in 1995. But, the name "Hope Entomological Collections" still persists for the insect collections housed in the University Museum, and a curator and assistant curator are responsible for them. The lecture room of the University Museum, on Saturday June 30, 1860, was scheduled to be the site of the now-famous debate between Thomas Henry Huxley, a staunch supporter of Darwin, and Samuel Wilberforce, Bishop of Oxford and creationist. Wilberforce "begged to know, was it through his [Huxley's] grandfather or grandmother that he claimed descent from a monkey." Huxley replied that he would not be ashamed to have a monkey as an ancestor, but he would be "ashamed to be connected to a man who used great gifts to obscure the truth." It would be expected that Hope and Westwood would have been present at that meeting of the British Association. Their reactions were not recorded. Neither had accepted Darwin's theory, although both had been correspondents of his, and both described species that he collected during the voyage of the Beagle.

A. D. Hopkins, a pioneering entomologist, is generally considered the "father of forest entomology in North America." He was born in Harrison County, Virginia (now Jackson County, West Virginia) on August 20, 1857. Though he never received much formal education, Hopkins showed an interest in natural history at an early age, spending many hours collecting and studying rocks, plants, and animal life in the rural West Virginia landscape where he grew up. His formal education ended at age 17, though he would receive an honorary doctoral degree in 1893. As a matter of fact, Hopkins appears to have had a relatively low opinion of formal education, and espoused the opinion that "college is a place where pebbles are polished and diamonds dimmed." His lack of formal training certainly did not prevent him from becoming an eminent scientist and ushering in the discipline of forest entomology in the United States.

Hopkins was deeply involved in the agricultural activities of West Virginia, and organized one of the first farmer's cooperatives in the state, the Farmers' Institute Society. He was an accomplished agriculturalist himself, developing a superior strain of timothy hay through plant breeding, and introducing purebred sheep and cattle to the area. Through his activities with the Society, he became acquainted with Dr. John Myers, the first director of the West Virginia Agricultural Experiment Station. In 1889 Hopkins wrote Dr. Myers, volunteering to be the entomologist for the Station, but was politely rebuffed due to his lack of formal training. Not one to be easily discouraged, Hopkins wrote back, offering to work on a trial basis for $1.00 a day. Dr. Myers offered him the job on trial for 3 months at $50.00 per month. Hopkins officially began work on March 1, 1890.

Hopkins early research projects (Fig. 41) involved a large bark beetle outbreak in the pine and spruce forests of eastern West Virginia, and Hessian fly as a pest of wheat. His seminal work on the Hessian fly showed that delayed planting could control the fly, and he produced appropriate planting dates for West Virginia and much of the United States as well. This work was the foundation for a lifelong interest in bioclimatics, the study of the relationships among life, climate, and the seasons.

Hopkins' discovery of a massive bark beetle outbreak in the pine and spruce forests of Randolph County and his subsequent investigations of this group of insects launched his career as a forest entomologist, and marked the beginning of forest entomology as a distinct discipline in the U.S. It was for this work that Hopkins would receive his honorary Ph.D. degree in 1893 from West Virginia University. After extensive sampling, Hopkins concluded that the southern pine beetle, *Dendroctonus frontalis*, was the major cause of tree mortality. Hopkins initiated an early forest entomology importation biological control program, importing the clerid beetle *Thanasimus formicarius* from Germany for release against the beetles. However, there was no evidence that the clerids became established, and the bark beetle epidemic subsided following a severe winter in 1893–94. Interestingly, Hopkins and his clerid release received credit for ending the bark beetle epidemic, even though Hopkins emphatically denied that the clerids had become established.

Hopkins, Andrew Delmar, Figure 41 **Andrew D. Hopkins, the Father of American Forest Entomology.**

During his 12 years with the Experiment Station, Hopkins published scientific papers and bulletins at a prodigious rate. In addition to his papers on the southern pine beetle outbreak, his most important forest entomology works included the "Catalog of West Virginia Scolytidae (Bark Beetles) and Their Enemies" and "Catalog of West Virginia Forest and Shade Tree Insects." As an indicator of Hopkins' productivity, during a single year with the Experiment Station he described 196 new species and six genera of insects, and this was primarily background work for his studies of insect biology and pest control. In addition to his research work, Hopkins duties included answering hundreds of extension-type questions from citizens on a wide variety of entomological subjects.

Hopkins expertise in forest entomology was recognized by the U.S. Department of Agriculture, and Gifford Pinchot, head of the Division of Forestry, hired him to conduct special investigations of insect problems in forests of the western U.S. Hopkins had traveled through parts of the far west in 1899, and made observations on stand characteristics of ponderosa pines that became the basis for a risk rating system for this species. In barely over 2 months, Hopkins correctly identified and detailed most of the important forest insect problems of the far west. In October 1901, he was sent to the Black Hills region of South Dakota to investigate bark beetle problems there. Though he was in the Black Hills for only 4 days, Hopkins collected an incredible amount of information on the mountain pine beetle, *Dendroctonus ponderosae*, which he published in a bulletin only 3 months later.

In 1902, Hopkins took a position with the U.S. Department of Agriculture Bureau of Entomology in Washington, D. C., initially working under the famous entomologist C. V. Riley. Within 2 years, however, he was named head of the Division of Forest Insects, a position he would hold for 21 years until his retirement in 1923. Among those who worked under his direction during this period were F. C. Craighead, H. E. Burke, J. M. Miller, F. P. Keen, and W. F. Fiske, a virtual "Who's Who" of forest entomologists in the early twentieth century.

Characteristically, Hopkins remained quite active after his retirement from the Bureau of Entomology. He quickly resumed pursuit of his lifelong interests in plant breeding and bioclimatics. One well-known product of this research is Hopkins' Bioclimatic Law, which states that elevational decrease in temperature is mirrored in latitudinal decrease in temperature as one moves away from the equator. His Wood County, West Virginia farm was designated a special field station of the Department of Agriculture, "The Kanawha Farms Intercontinental Base Station for Bioclimatic Research." Hopkins was married in 1880 to Adelia Butcher, and they had four children, including W.B. Hopkins, who became a well-known petroleum engineer and was listed in "Who's Who in American Men of Science." A. D. Hopkins died in 1948, truly one of the outstanding scientists of his time.

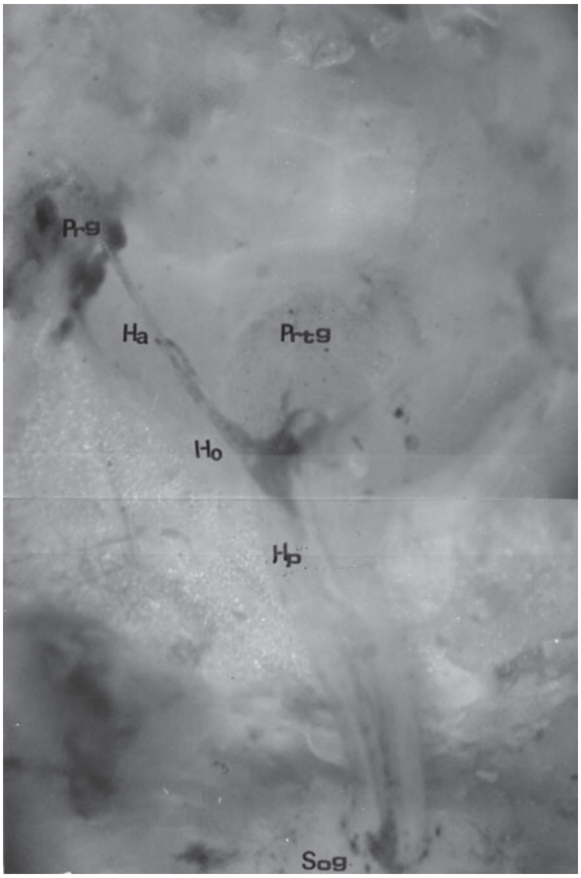
H-Organ

SERAP MUTUN
Abant Izzet Baysal University, Bolu, Turkey

H-organ is a neurohaemal organ associated with the perisympathetic organs of the ventral nerve cord. The H-organ was first discovered in 1986 in various Lepidopteran species and later was studied in some Orthopterans. It is named the H-organ due to its shape, resembling the letter H. It is located in the prothoracic region between the subesophageal ganglion and prothoracic ganglion. It is approximately three times smaller than a single prothoracic gland. It extends across the narrow cervical region and is exposed to good hemolymph flow. The organ consists of three parts: anterior arms, posterior arms and a central region. The anterior arms stretch out laterally toward the prothoracic glands and consist of two types of nerve fibers. The posterior arms are composed of nerve axons extending backward and to the lateral arms. The central part of the organ is connected with the prothoracic ganglion via median nerves. The organ includes abundant nerve fibers, invaginated neurilemma, neurosecretory products and irregularly distributed glial cells. The H-organ is very similar to the regular metameric perisympathetic organs. However, the organ has a very complex structure, differing from other regular perisympathetic organs in its appearance, and consisting of two fused perisympathetic organs. The first belongs to the subesophageal ganglion attached from its rear, and the second is in the frontal part of the prothoracic ganglion. The most complicated part appears in the middle region. In this branching area between the anterior arms, transverse nerve of the H-organ (Fig. 42) and the posterior arms, an organ that seems like the corpus cardiacum was found. The H-organ receives neurosecretory product from both subesophageal and prothoracic ganglia.



H-Organ, Figure 42 **The H-organ in the prothoracic region of an insect: Prg = prothoracic gland; Ha = anterior arm of the H-organ; Ho = H-organ; Hp = posterior arm of the H-organ; Prtg = prothoracic ganglion; Sog = subesophageal ganglion.**

The H-organ often shows species-specific variations in its shape. Within the order Lepidoptera, in *Pieris brassicae* and some other members of the family Pieridae and Nymphalidae, the organ is almost rectangular or square. In *Actias selene* and several other members of the family Saturniidae, it shows a tracheolized structure projecting from the prothoracic ganglion where posterior arms seem absent. In *Barathra brassicae* and *Noctua pronuba* (Noctuidae) it has rather narrow anterior and posterior arms and a more compact central region. In this case, the anterior arms are well developed so that the organ provides neurosecretory products and neurosecretory axons to the prothoracic glands. Studies in some Orthopteran species show that both *Locusta migratoria* and *Acrida bicolor* have a triangular shaped H-organ composed of a central body with its extensions connected to the subesophageal ganglion by two thick bundles of nerve fibers, and by a single thick connection to the prothoracic ganglion. The organ is connected to the prothoracic glands at the laterals by its anterior arms.

Together with other perisympathetic organs, as a translucent and poorly visible structure, the H-organ is important in insect development and it is the main source of innervation and neurosecretory material for the prothoracic glands, which secrete ecdysone, a hormone that stimulates larval molts and metamorphosis in insects. It has direct neurosecretory connections with the prothoracic gland and the prothoracic spiracle, and may control metabolism in the prothoracic gland. The H-organ shows more-or-less a continuous growth without apparent cyclic changes. This acyclic growth and other nervous characteristics of the H-organ suggest that the physiological nature of the H-organ be predominantly of a nervous rather than glandular character.

The H-organ is well developed in all instars. During metamorphosis, the H-organ starts to retreat gradually, and disappears during adult development. The middle part of the H-organ appears to be hypertrophied during the molting periods, containing material in the form of clusters or droplets, and then atrophied during interecdysis. Histofluorescence studies indicate the presence of catecholamines and indolealkylamines, and some other neurosecretory products that are azocarminophilic in their nature. These are found in the lateral parts of the H-organ surrounding the central region, a region called the corpus prothoracale. The lateral branching area with the corpus prothoracale is richly supplied with trachease, indicating a high metabolic activity in this region of the organ. Although the function of the H-organ is not yet clear, it has been suggested that the central region of the organ with the corpus prothoracale is the most important neurohaemal area among the whole ventral nerve cord among the studied insect species.

Horizontal Gene Transfer

The transfer of genetic information from one species to another.

Horizontal Transmission

This is movement of a pathogen among members of a species within the same generation, or within the same season. In contrast, transmission of a pathogen between members of an arthropod species by movement from parent to progeny (transovarial or transovum transmission) or between instars within a generation (trans-stadial transmission) is called vertical transmission.

Hormoligosis

Subharmful quantities (low, sublethal exposure rates) of stress agents (e.g., temperature, radiation, minor injuries, chemicals) can be stimulatory to organisms in a stressful environment. In entomology, this usually is seen in the increased development rate of insects or mites, or increased reproduction, following exposure to insecticides and reared under suboptimal conditions. It is derived from the Greek words "hormo" (to excite) and "oligo" (minute quantities). Hormoligosis is sometimes used to explain population resurgence of insects and mites following insecticide treatment. It is important to separate direct physiological (horm oligotic) effects from indirect effects related to the destruction of natural enemies by low doses of pesticides; either can cause increases in abundance. Also, the response of insects to such stressors may be delayed.

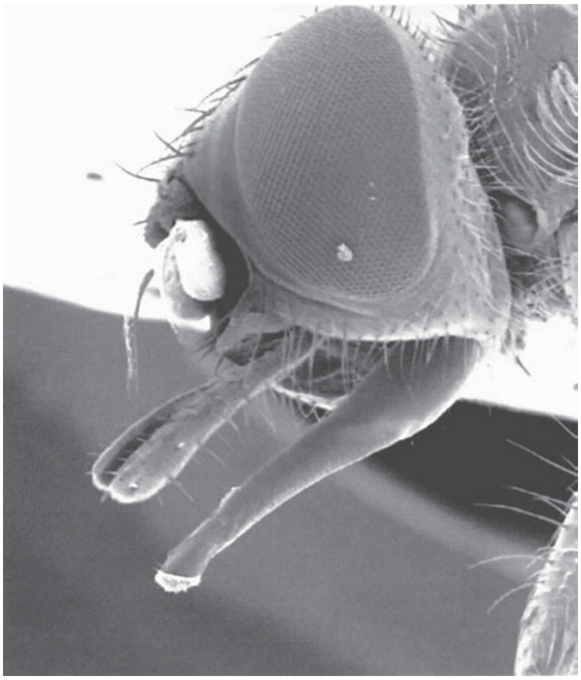
Horn Fly, *Haematobia irritans* (L.) (Diptera: Muscidae)

TIM LYSYK
Agriculture and Agri-Food Canada Lethbridge, Lethbridge, AB, Canada

The horn fly is a significant pest of cattle throughout much of the world. The fly occurs throughout Europe, Asia and North Africa, and was accidentally introduced to North America in the 1880s. It was first reported in Canada in the early 1890s. It colonized most of the continent, and had reached Venezuela by the 1930s. Horn fly arrived in Brazil in the mid 1980s and has spread through much of the cattle -producing areas of South America.

The adult horn fly lives in close association with cattle. The fly is about 5 mm long; gray, with four dark stripes on the top of the thorax. The wings are broad and held in a V-shape at rest (Fig. 43). The eyes are large and red, widely spaced in the females and close together in the males. The mouthparts are similar to the stable fly's with a heavily sclerotized labium that forms the sheath of the proboscis (Fig. 44). The food canal is formed by the labrum-epipharynx and the hypopharynx forms the salivary canal. The labium ends in a pair of labella that bear sharp teeth used for cutting the host's skin. The maxillae are greatly reduced and only the maxillary palps are visible at the proximal end of the proboscis. The maxillary palps are longer than half the length of the proboscis.

Horn Fly, *Haematobia irritans* (L.) (Diptera: Muscidae), Figure 43 **Horn fly, *Haematobia irritans*.**



Horn Fly, *Haematobia irritans* (L.) (Diptera: Muscidae), Figure 44 Head and mouthparts of horn fly.

The adult flies spend most of their lives in close contact with cattle. Adults are most abundant on bulls, followed by steers, cows and calves. The adults are quite mobile and the distribution of flies on the cattle body will change markedly during the day as adults move from the backs and sides of the animals to the belly. The proportion of flies on the belly shows a distinct seasonal trend, and is highest in late summer and lowest in the spring and fall. This movement may be in response to increasing numbers on an animal, environmental fluctuations, increasing proportion of gravid females in the population, and the presence of lesions along the belly. Both sexes feed on cattle by cutting the skin with the labellar teeth and ingesting the resulting blood and tissue. Flies can ingest from 11 to 21 mg of blood per day. The irritation resulting from feeding activity of a relatively few flies (12–25 flies per animal) is believed to be responsible for an immediate decline in animal productivity associated with behavioral changes that reduce forage utilization and feed efficiency. Horn fly infestations of yearling cattle have been responsible for 18% reduction in weight gains. When fly numbers exceed 200 flies per animal, cattle will undergo physiological changes that result in further reductions in productivity that increases with fly numbers. Horn fly infestations on cows can indirectly reduce weaning weights of calves by reducing milk production by the cow. Every 100 flies per cow can reduce calf weaning weights by 8%, with reported decreases ranging from 3 to 16%.

Female horn flies use ingested blood for egg production. Females feed for 2–3 days before oviposition, and lay from 8 to 13 eggs per day. Eggs are laid every 1–2 days until death. As females become gravid, they move to the rear and underside of the cattle, and leave to lay eggs on the undersides of newly deposited cattle manure. Although female may live a maximum of 21 days, the average female lifespan is generally <1 week. Females could lay 100–200 eggs if they reach the maximum lifespan, but few do. On average, a female will contribute 20–25 eggs to the next generation.

The eggs are 1.2 mm in length and reddish-brown in color. Eggs hatch within a day and the first instar larvae enter the pat. Larvae feed on bacteria within the manure and pass through three instars. The third-instar larvae are easily identified. These are typical maggots with a reduced head and an anteriorly tapering body. The posterior spiracles have a characteristic pattern with a button located on the inside margin surrounded by three sinuous slits. Larval survival is influenced by chemical factors such as manure pH, nitrogen content, and moisture; physical factors such as temperature; and biotic factors such as predation. Larvae survive best in feces from animals feeding on forage compared with those fed concentrated or grain-based diets, hence the greater occurrence of this pest in pasture or rangeland systems. The larval stage is completed in 1–2 weeks depending on temperature. Larval development requires 9 days at 20°C and 4 days at 30°C.

The pupal stage is formed beneath the pat (feces). Pupae weight about 6 mg and develop within a reddish brown puparium formed by the last larval skin. The duration of the pupal stage is strongly influenced by temperature, requiring about 12 days at 20°C and 5 days at 30°C. The pupal stage occupies about 55% of the total immature developmental time. Pupae can be attacked and killed by a variety of hymenopterous parasitoids. When pupal development is complete, the adults emerge, find a host, mate and continue the life cycle.

The entire life cycle is completed in 2–4 weeks under field conditions. Reproduction is continuous, and there are several overlapping generations. The number of generations per season increases with warmer climates. In northern areas, there may be 3–5 generations per year, and 5–8 generations per year in southern regions. Populations generally show a major peak in mid-summer in northern areas, and may show spring and fall peaks in southern climates.

In the fall, environmental cues trigger the production of diapausing pupae, the overwintering stage. The increasing proportion of diapausing pupae produced in the fall results in reduced recruitment to the adult stage and adult populations decline. Earlier research suggested that diapause is induced by declining photoperiods acting on female flies causing them to produce eggs that are predisposed to enter diapause when they reach the pupal stage, and that temperatures to which the immatures are exposed mediate the proportion of pupae that enter diapause. More recent work has indicated that diapause occurs in response to reduced temperatures experienced by the larvae during a diapause-sensitive period and that maternal influences play little role in diapause induction.

The diapause sensitive period begins when immatures have completed 10% of their development to the adult stage, and ends when 82% of the immature developmental period is completed. The incidence of diapause increases as temperatures decline and a greater number of days are spent in the diapause sensitive period. In warmer climates, temperatures may not be low enough for diapause to occur, and generations may occur the entire year. Temperatures experienced during the diapause sensitive period are correlated with overwintering success. Overwintering survival is low when temperatures average <10°C during the diapause sensitive period, and greater when temperatures range from 10 to 23°C. Diapause is not induced at temperatures above 23°C. Once diapause is induced, overwintering survival is relatively uninfluenced by ambient temperatures. The diapausing pupae can survive extended periods of exposure to −5°C, and temperatures below the pats rarely drop below −10°C, even when air temperatures reach −30°C.

Diapause is terminated gradually throughout the winter, and post-diapause development begins in the spring when temperatures increase. The rate of completion of post-diapause development is temperature-dependant and adults emerge during a 3–4 week period in the spring. Flies colonize cattle, and begin the life cycle again. The flies that emerge in the spring are produced during a 3–6 week window the previous fall.

Most methods for controlling horn flies are oriented towards treating cattle, as this is the commodity that is affected. The population of adult flies is in constant association with cattle, and is a convenient target. Immature stages are typically not targeted for control as these are protected within the manure pat and are dispersed throughout the pasture. Chemical control options are most frequently used and may be applied to the cattle in several ways. Direct applications, in the form of sprays or pour-ons can be used when the animals are gathered. These will provide 1–2 weeks control of the adults, but after this period cattle can be re-colonized by newly emerged adults that were in the immature stages when the treatment was applied. Reapplication requires gathering the animals for treatment, and this may not always be practical. Self-application devices can be placed in the field so that cattle will receive a dose of insecticide when they contact the application device. These devices must be placed in areas such as watering sites or salt licks where they cattle will contact them, and are most effective in forced-use situations. The most common method for controlling horn flies is the use of insecticide-impregnated ear tags. These tags are applied in the spring before cattle are turned out to pasture, and release insecticides over the animals' bodies for the entire fly season. Initially, these provided season-long control, but horn flies quickly developed resistance to the commonly used chemicals. Use of ear tags should be managed to delay the development of resistance. This can be accomplished by applying tags to all animals, removing tags at the end of the season, using tags containing different classes of chemicals in successive seasons, and alternating tag use with other application methods. Relatively few non-insecticidal options are available for horn fly control. Various traps have been designed to remove the adult flies from cattle when cattle walk through the trap. These can be effective, especially when used in situations such as dairies where cattle must walk through the trap routinely.

Horn, George Henry

George Horn was born in Philadelphia on April 7, 1840. He was interested in entomology and other areas of natural history by the time he completed high school. He entered the University of Pennsylvania, and obtained a medical degree in 1861. In the American Civil War he served as surgeon to the infantry of the California Volunteers in 1862–1866. This allowed him to collect insects in California, Arizona, and New Mexico. Then he returned to Philadelphia and excelled in obstetrics. But he was elected president of the American Entomological Society in 1866 and, because he was unmarried, was able to devote all his spare time to the study of beetles. He obtained greater fame in entomology than in medicine, publishing 265 papers, and describing 154 genera and 1,682 species. His entomological papers included syntheses of genera and higher taxa, and several of them stood for about a century before being bettered. He was closely associated with the American Philosophical Society and was awarded honorary memberships in several entomological societies. He died on November 24, 1897, nearly a year after suffering a debilitating stroke. His collections are now in the Museum of Comparative Zoology of Harvard University.

Horn, Hermann Wilhelm Walther

Walther Horn was born in Berlin on October 19, 1871. By the age of eight he already was building an insect collection. In the late summer of 1889 he made the acquaintance of Gustav Kraatz, who influenced his entomological training. In 1891 he and his schoolfriend Hans Roeschke published an entomological paper, a monograph of palearctic tiger beetles, the first for either of them. Following his father's wishes, he studied medicine, obtained his medical degree in 1893, and took his medical practitioner's examination in 1895. By this time he had published 39 entomological papers, and in 1896 took his first foreign collecting trip, to Italy, Tunisia, Algeria, Portugal, and France, lasting 9 months. In 1899, he took his second trip, to Ceylon and India, lasting 8 months. His third trip came in 1902, to South, Central, and North America. In 1904, he was appointed by Gustav Kraatz to the position of director of the entomological museum that Kraatz had founded. In a private house in Berlin, it was first called Deutsche Entomologische National museum and in 1920 was renamed Deutsche Entomologische Institut. Walther served in the German army during World War I, and was posted to the eastern front. Inflation in Germany after the war caused great financial difficulties for the institute which, like some in Britain and the USA, was privately financed [compare with the American Entomological Institute]. In 1922, Walther arranged the institute's affiliation with the Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften ["Kaiser Wilhelm association for the advancement of sciences"] which made funding more secure, at least until circumstances changed again. In 1934, the institute was made part of a national institute for systematic and applied entomology. Walther's taxonomic contributions were almost entirely on tiger beetles (Carabidae: Cicindelinae), on which he published 284 papers. His was the work on tiger beetles in "Genera insectorum" (1908–1915), and in "Coleopterorum catalogus" (1926). He nevertheless published 51 papers on insect studies, 19 on museum studies, and six bibliographies. His (1935–1937) work "ű ber entomologische Sammlungen, Entomologen und Entomo-Museologie" (on entomological collections, entomologists, and entomological museum methods), together with a work coauthored with Schenkling (1928–1929) "Index literaturae entomologicae" (index to the entomological literature) were and still are of worldwide importance to entomologists. They are still of worldwide importance because although computerized bibliographies exist to the literature from some time (variously) after 1970, the older literature is not thus computerized, so Horn's works are invaluable. With such interest in bibliographies, he built the institute's entomological library to be the best in continental Europe. He died on July 10, 1939.

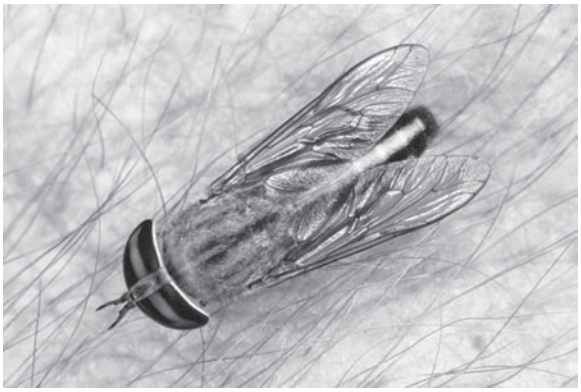
Horse Flies and Deer Flies (Diptera: Tabanidae)

JAMES E. CILEK
Florida A & M University, Panama City, FL, USA

The family Tabanidae is primarily composed of two fairly large groups of biting flies known collectively as horse flies and deer flies. They occur worldwide and are represented by 4,300 species and subspecies from 137 genera. Generally, the wings of deer flies possess a vertical dark band from the mid-line of the wing down to the margin, while wings of horse flies can be entirely dark, mottled, or completely clear. Horse fly wings never possess a vertical band down the mid-line of the wing. Members of this family have large eyes; the females are dioptic (eyes widely separated) and the males are holoptic (eyes contiguous). Adult size range varies tremendously. Some deer flies, *Chrysops* sp., are as small as 6 mm, while some of the larger horse flies, *Tabanus* sp., can be up to 25 mm in length (Fig. 46).

Horse Flies and Deer Flies (Diptera: Tabanidae), Figure 45 **Adult deer fly, showing the vertical dark band of wing (photo, J. Castner, University of Florida).**

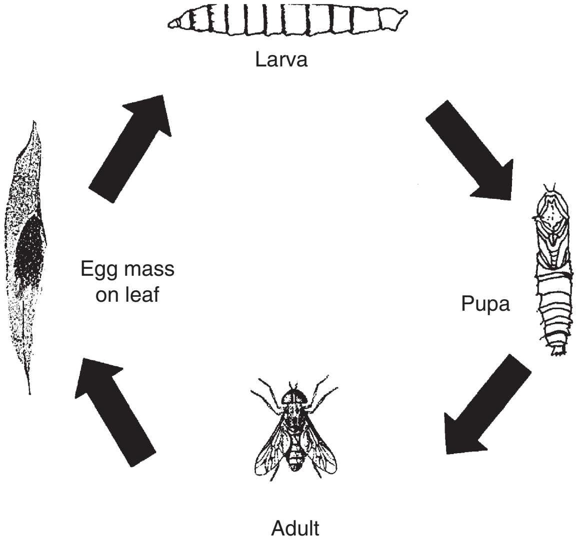


Horse Flies and Deer Flies (Diptera: Tabanidae), Figure 46 **Adult horse fly (photo, J. Castner, University of Florida).**

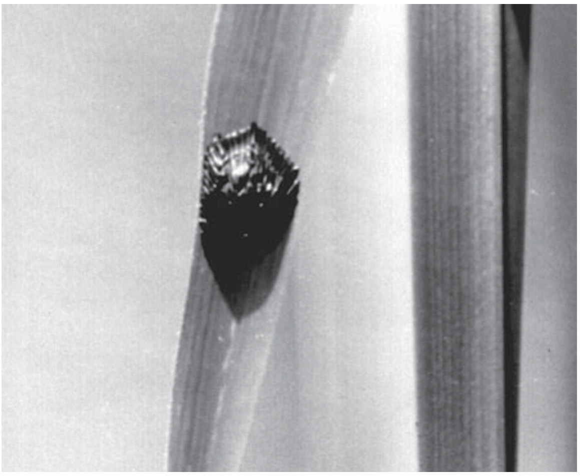
Only females feed on blood to mature their eggs, while both sexes feed on nectar sources that provide carbohydrates. Males cannot bite because they lack mandibles. Blood-seeking adults can be severe pests of humans as well as animals.

Tabanids go through complete metamorphosis, i.e., egg, larva, pupa and adult (Fig. 47). Generally, the eggs are deposited in layers on vegetation or other objects hanging over the water (Fig. 48). The eggs range in size from 1.0 to 2.5 mm and vary in number from about 100–1,000 depending on the species. After oviposition, the female will deposit a waterproof secretion that covers the eggs to prevent desiccation and parasitization by wasps. Once the egg shells harden, they will turn black and sometimes appear as "tar spots" on vegetation. The eggs hatch in 5–12 days.

Newly hatched larvae will drop immediately into the water and burrow into the mud to feed upon organic matter. Developmental habitats for most horse flies and deer flies are primarily aquatic to semi-aquatic. However, some species of horse fly larvae can develop in open pastures or rotted logs (Fig. 46).



Horse Flies and Deer Flies (Diptera: Tabanidae), Figure 47 **Generalized life cycle of Tabanidae. (Source, redrawn and reproduced from Harwood and James, and University of Florida).**



Horse Flies and Deer Flies (Diptera: Tabanidae), Figure 48 **Egg mass of *Hybomitra lasiophthalma* (source, J. V. Freeman).**

The larvae are cylindrical and tapered at one end. The number of larval instars (stages) and duration are profoundly influenced by weather conditions. Several tabanid species have been reported to be predators of a variety of invertebrates including insect larvae, crustaceans, snails and earthworms. Sometimes even small vertebrates can be preyed upon, such as the unique case of the predatory capture of adult, newly emerged spadefoot toads, *Scaphiopus multipicatus*, by horse fly larvae, *Tabanus punctifer*, on an Arizona mudflat.

In most temperate climates, tabanids usually have one generation per year. In more southern regions, a few species may have two generations per year. But there are exceptions, for some species take 2 or 3 years to complete development.

Tabanid bites usually cause mild irritation in most humans. But some deerfly species (*Chrysops* sp. and a closely related species *Diachlorus ferrugatus*) have been reported to cause allergic reactions that, in extreme cases, can result in hospitalization. Allergic reactions occur as the body reacts to the anticoagulant injected into the feeding wound by the female fly in order to stop blood from clotting and facilitate the uptake of blood from the host.

Horse flies and deer flies have been incriminated in the transmission of a number of protozoan, helminthic, bacterial and viral organisms that cause human and/or animal disease. Some pathogenic microorganisms, such as the protozoans *Trypanosoma theileri* and *Haemoproteus metchnikovi*, require the adult fly as a multiplication source in their life cycle in order to infect animals.

Most disease causing organisms are transmitted by the contaminated mouthparts of the fly. Several species of horse flies (*Tabanus* sp.) have been incriminated in the transmission of *Trypanosoma evansi* in Africa, southern Asia and Central and South America. This protozoan is frequently fatal to horses, camels and dogs, although it appears to be non-pathogenic to cattle and buffaloes.

Certain species of deerflies from the genus *Chrysops* can transmit the African eye worm, *Loa loa,* to humans. Members of the genus Tabanus have been implicated in transmitting the rickettsial agent that causes anaplasmosis (*Anaplasma marginale*) in cattle. In the southern U.S., a few species of *Tabanus* have been found to transmit a viral infection in horses referred to as equine infectious anemia. Transmission occurs by the interrupted feeding of horse flies, via their contaminated mouthparts, between infected and non-infected horses. *Francisella tularensis*, the bacterial agent of tularemia, is sometimes transmitted to man by a few species of *Chrysops*. Tularemia primarily appears during summer months and occurs in the Northern Hemisphere between latitudes 30° and 71°.

Control

Currently, there are no effective long-term methods to control horse fly and deer fly populations. Over the years, a variety of non-toxic traps (often supplemented by a carbon dioxide source as an attractant) have been developed, but most have proven suitable only for sampling populations.

Because tabanids are attracted to movement, it is possible to lure and trap them with suspended dark spherical objects such as black beach balls coated with an adhesive. Many tabanids are collected by this method, but it remains to be proven whether or not they actually reduce local populations. Box traps are another method (Fig. 49) that have been used for a number of years to reduce greenhead adults, *T. nigrovittatus*, in the salt marshes around Cape Cod, Massachusetts.

Larval control, through habitat modification of wetlands or direct application of insecticides to developmental sites, is not an option because of state and federal regulatory issues. Insecticide application against adult horse flies or deer flies has met with only limited success.

Control of horse flies and deer flies on cattle, horses and other animals primarily consists of direct application of over-the-counter insecticides labeled for such use. However, the effectiveness of the insecticide to kill tabanids resting on the hair coat can be reduced by the animal's grooming behavior as well as environmental factors, e.g., rain and/or sunlight. Repellents for humans or animals do not offer more than brief relief, at best, from biting annoyance. Efficacy is often dependent upon the number of horse flies/deer flies in the immediate area that are seeking a blood meal.

Horsehair Worms (Nematomorpha)

A phylum of insect-parasitic invertebrates known as nematomorphs, Gordian worms, and hair snakes, the Nematomopha are named after the tendency of these worms to be long and thin, resembling the hairs of horses. Also, these invertebrates are commonly found in water sources where livestock such as horses drink. In most cases this is due to the tendency of common hosts such as grasshoppers to leap into water troughs and then be unable to escape. The horsehair worms contained within the bodies of the grasshoppers then emerge and swim around in the water

Horsfall, William R

William Horsfall was born in the state of Missouri on January 11, 1908. He received a bachelor's degree in 1928 from the University of Arkansas, and a master's degree the following year from Kansas State University. Then he entered Cornell University as a graduate student, and received a Ph.D. in entomology in 1933. His employment as a teacher and researcher began at Cornell, continued at the University of Arkansas, then South Dakota State University and finally, beginning in 1947, at the University of Illinois at Urbana-Champaign. But World War II interrupted his academic work. He served in the South Pacific as commander of a U.S. military malaria survey unit for 3 years. At the University of Illinois in 1947–1976, he published five books (including, in 1955, "Mosquitoes. Their bionomics and relation to disease" and in 1962. "Medical entomology. Arthropods and human disease") and 140 scientific papers, taught medical entomology and insect bionomics, and won a citation for outstanding teaching. His research was on the bionomics of meloids, grasshoppers, chinch bugs, bean weevils, scarabs, and mosquitoes. He was an elected fellow of the American Association for the Advancement of Science. He received awards of merit from the American Mosquito Control Association, the Zoological Society of Finland, the Entomological Society of America, and the Illinois Mosquito Control Association. After retirement, he continued to work as a consultant and to publish. He died in Illinois on November 18, 1998, survived by his wife, Annie Laurie.

Horticultural Oil

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Oils have long been used for their insecticidal properties, including application of oil to plants to kill plant-feeding species. Most oils used for insect control are petroleum products, and are also known as mineral oils. However, oils are also derived from plants, and usually referred to as vegetable oils. Historically, the greatest use of oils was a winter application to twigs and trunks of fruit trees and ornamental plants, and this product is called dormant oil. However, more highly refined, lighter-weight oils have become available for use during the growing season, and these are called summer oils. Both mineral and vegetable oils, properly refined and applied, can be used for winter or summer applications.

Dormant Oils

The use of dormant oils was popular because it addressed some difficult insect control problems, mostly involving aphid and caterpillar eggs, mites (both adults and eggs), and scale insects (usually eggs). Also, the treatments could be made during a relatively slow season (winter) when there was not much else that could be done to fruit and ornamental crops (except perhaps for pruning). Application of dormant oil to trees and shrubs before bud swelling and bud break poses little risk of injury to the plant, and yet kills many insects and mites. Both eggs and active forms of small arthropods are susceptible to oil because the oil apparently inhibits air exchange, often by clogging the air passages (spiracles) through which arthropods breathe. Dormant oils are relatively heavy-weight products, and often contain aromatic compounds such as sulfur that can cause toxicity to vegetation, hence the timing of application to avoid active growth by the plant. Heavy oils evaporate slowly, which is a good characteristic for insect control, but which can be damaging to plants. Dormant oils are normally mixed with an emulsifying agent that allows the oil to mix with water and be dispersed uniformly. Upon mixing, the oil solution typically turns white due to actions of the emulsifying agent; this is the basis for one of the names applied to dormant oil spray, "white oil." Oil is normally diluted to about 2% of the spray mixture. Oils are not applied before winter hardening has occurred, if the weather is below freezing, or if the plants are beginning to grow. Some plants are sensitive to oil, so the product label should be consulted for precautions.

Summer Oils

Summer oils are lighter in weight, less contaminated with residues that may prove phytotoxic, and useful for many more plants than are dormant oil sprays. They are also called superior, supreme or ultra-refined oils. Summer oil is often applied to control aphids, whiteflies, leafhoppers, thrips, mealybugs, mites, and the early stages of many other insects, usually at concentrations of 1–4%. Damage can occur when too much oil is applied, the plants are under water stress (inadequate soil moisture), the temperature is high (32°C or 90°F), or the humidity it too high (the oil cannot evaporate). Vegetation with hairy leaves (dense trichomes) may be more prone to damage because more oil is held on the leaf. It is advisable to test a few leaves if you are uncertain about the safety of application, and wait a few days to see if damage occurs. Summer oils are not selective, and will kill most small insects, including beneficial species. However, once they are dry they are no longer toxic, so relative to traditional insecticides they are relatively non-toxic to beneficial insects. Also, they tend to impart a shine or sheen to treated plants, so they are popular because they improve the appearance of ornamental species.

Stylet Oils

Lightweight oils also are sometimes recommended for disruption of plant virus transmission by insects such as aphids; such formulations are called stylet oils. The oil interferes with transmission of virus on the stylets of the insects. Such viruses are the non-persistent types. Persistent viruses, which are harbored within the insect, are not affected by stylet oils.

Vegetable Oils

Vegetable oils do not really originate with vegetables. The common sources are oil seed crops such as soybean, canola and cottonseed. Other sources include neem seed, sesame seed, rosemary, and other plants. Like petroleum-based oils, they can cause phytotoxicity. Neem seed is well known as a source of azadirachtin, a growth regulator-based insecticide and feeding deterrent. However, some neem products contain mostly neem oil and are relatively free of azadirachtin.

Phytotoxicity

Among the plants that are known to be sensitive to oil are:

Azalea, *Rhododendron* spp.
Beech, *Fagus* spp.
Black walnut, *Juglans nigra*
Douglas-fir, *Pseudotsuga* spp.
Hickory, *Carya* spp.
Japanese holly, *Ilex crenata*
Juniper, *Juniperus*
Cedar, *Cedrus* spp.
Maple, *Acer* spp.
Redbud, *Cercis* spp.
Smoke tree, *Cotinus coggygria*
Spruce, *Picea* spp.

Also, neem oil is reported to affect several plants, including:

Impatiens, *Impatiens* spp.
Fuchsia, *Fuchsia* spp.
Some roses, *Rosa* spp.
Olive, *Olea europaea*
Some carnations, *Dianthus caryophyllus*

As noted previously, if there is uncertainty about phytotoxicity of an oil product to a crop, it is better to test and watch for several days for toxic effects rather than treat an entire tree or crop with a product of unknown phytotoxicity. If phytotoxicity is not a problem, then oils are a great pest control technique to consider for small arthropods. Oils are relatively harmless to everything except small arthropods and some aquatic insects, and of course some plants.

► Neem

Horticultural Oil

Petroleum or botanical oil that is used to control pests on plant.

Host

An organism that provides food and/or shelter for another organism. In entomology, it also is the insect that supports a parasitoid or pathogen.

Host Feeding

A behavior displayed by a parasitoid when the adults feed on insects that normally are used for larval development.

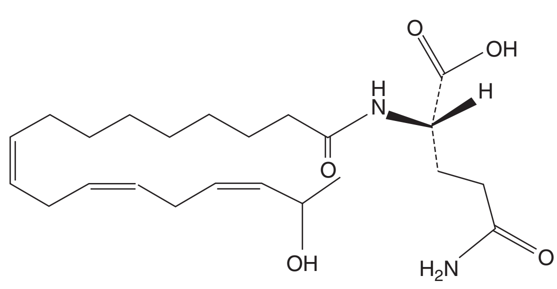
Host Location in Parasitic Wasps

M. L. HENNEMAN
University of Bristol, Bristol, United Kingdom

Generally, three steps are recognized in host location and acceptance by parasitic insects (parasitoids) which reproduce by oviposition on or in the bodies of other insects. First, parasitoids must locate the proper habitat in which their host is found. Second, within the habitat they must find the proper microhabitat. Within that microhabitat, they must locate the host itself, and decide whether or not to accept it (i.e., whether or not to oviposit), generally using cues obtained from physical contact with the host.

Most studies have focused on the last two stages, orientation toward the microhabitat and host location within the microhabitat. Microhabitat location has been examined using laboratory equipment such as wind tunnels and olfactometers – branched tubes in which an insect is required to make a decision leading to one of two or more odor sources. A few have determined specific compounds to which antennal sensilla are sensitive, using a combination of a gas chromatograph and electroantennogram (EAG). The chromatograph separates volatile complexes into constituent compounds, and the signal as each compound comes into contact with the insect's antenna is recorded.

As a result of these studies we can draw several general conclusions about parasitoid odor discrimination and learning. First, biochemical analysis (using chromatography to separate individual compounds) shows that feeding by herbivorous insects on their host plants induces systemic production of specific volatile compounds that are not induced by artificial damage alone. Most commonly found are the two homoterpenes 4,8-dimethyl-1,3(*E*),7-nonatriene and 4,8,12-trimethyl-1,3(*E*),7(*E*),11-tridecataene. These have been found to be produced by several species of herbivore-infested plants from agricultural systems, including lima bean, apple, cucumber, corn, and cotton. These compounds are induced during feeding (at least by beet armyworm caterpillars) by a compound that was isolated from their saliva, *N*(17– hydroxylinolenoyl)-L-glutamine, known as volicitin (Fig. 50).



Host Location in Parasitic Wasps, Figure 50 **Volicitin, a compound in the saliva of beet armyworm larvae, that induces production of volatiles attractive to wasps. (After Alborn, H. T., T. H. Jones, G. S. Stenhagen, and J. H. Tumlinson. 2000. Identification and synthesis of volicitin and related components from beet armyworm oral secretions. Journal of Chemical Ecology 26: 203–220.)**

Parasitoids, in general, seem to be able to exploit these specific induced compounds to more accurately locate their hosts. They orient upwind preferentially to plants damaged by herbivores, over artificially damaged and undamaged plants. Parasitoids also learn odors, which increases their foraging efficiency. They are more responsive and more accurate in host location when a host is associated with an odor that a parasitoid has encountered before in the presence of a host. This is true not only of plant odors, but is extendible to novel, artificial odors such as vanilla and chocolate.

Because a reduction in herbivore feeding is beneficial to plants, it has been suggested that systemic odor production by plants may have evolved to exploit odor-orientation abilities of the natural enemies of herbivores; in effect, plants are "calling" wasps to come and attack the insects feeding upon them. Several authors, however, have also pointed out that such an effect could also be explained by wound response. For example, damage accompanied by the presence of insect saliva could make a plant more susceptible to infection by a pathogen, and the systemically released compounds are antipathogenic. Research to this point has not ruled out either of the explanations, which are not mutually exclusive.

Significantly less is known about the use of visual cues by foraging female parasitoids. Most parasitoids studied are wasps, and wasps are believed to rely more on odor for orientation, as they usually have long antennae and small eyes. Research indicates, however, that parasitic wasps orient to, and learn preferentially, certain colors and patterns associated with hosts. For example, wasps may show a preference for a pattern of feeding damage on a leaf that is unique to its host. Parasitoids attacking frugivorous (fruit-feeding) species may only be attracted to colors similar to those of the fruits which its host infests. Within the range of a meter or two, visual cues are likely more useful than odors, which might not be as easily traceable in turbulent air currents.

We lack information about the host-locating abilities of most parasitoids in their natural environments, especially at the level of habitat location. A few studies that have examined microhabitat location in the field, however, have reinforced findings in the laboratory. But the mechanism by which a parasitoid flying through a forest locates a small egg cluster or first-instar larva under a leaf, for example, remains a mystery.

Host Plant Resistance

Any host plant-related factor that disrupts the host selection process or causes the plant to be less suitable for insect growth, survival or reproduction than is normal among plants.

► Plant Resistance to Insects

Host Plant Selection by Insects

S. FINCH, R. H. COLLIER
Horticulture Research International Wellesbourne, Warwick, United Kingdom

Host plant selection by insects is often divided into "host plant finding" and "host plant acceptance." While the two are easy to separate conceptually, in practice, they are really part of a continuum of three, rather than two, inextricably bonded links. However, the central link of host plant finding, thought previously to be governed by volatile chemicals, has, until now, proved intractable to scientific experimentation. Thus, the focus here is on host plant selection by insects associated with cruciferous plants as, since the classical work of Verschaffelt in 1910, most theoretical studies on herbaceous plants have used the interaction between insects and cruciferous plants as their test system. Such a selection is logical, as cruciferous (Cruciferae) vegetable and oilseed crops are of high economic importance and are now cultivated on large farms in most parts of the world. In addition, cruciferous plants are ideal for biological studies, as their chemistry is well understood and they support pest species from a wide range of insect orders.

Many researchers have shown that the numbers of pest insects found on cruciferous crop plants are reduced considerably when the background of the crop is allowed to become weedy, when the crop is intercropped with another plant species, or when the crop is undersown with a living mulch. Obviously, if placing non-host plants in the vicinity of host plants reduces the numbers of insects that actually find their host plants, then this could provide a clue as to how insects find their host plants. It has been suggested that when the background of crop plants growing in bare soil is made more diverse by allowing other non-host plant species to grow in the inter-row spaces, that the additional diversity "disrupts" insects from selecting otherwise acceptable host plants. Such disruption is considered to be mediated through the non-host plants providing (i) physical obstruction, (ii) visual camouflage, (iii) masking of host plant odors, (iv) repellent chemicals, or through (v) the non-host plants altering the physiology of the host plants. Two other suggestions, named by Root (1973) as the "Resource Concentration Hypothesis" and the "Enemies Hypothesis," have also been used to explain why fewer phytophagous insects are found on host plants growing in diverse backgrounds than on similar plants growing in bare soil.

A discussion of the seven hypotheses put forward to date is presented here, followed by a description of a theory based on "appropriate/inappropriate" landings, which the authors believe is the key, or "missing link," to host plant selection by phytophagous insects. Finally, the new theory will be used (i) to discuss the type of information required to make intercropping, undersowing and companion planting more successful, (ii) to suggest how insect biotypes could develop, and (iii) to describe why wild host plants are not decimated by pest insects.

Description and Discussion of the Seven Earlier Hypotheses

Physical Obstruction

This hypothesis was used to describe those situations in which the host plants were, in effect, hidden physically by using larger or taller non-host plants. For example, tall maize plants were used to protect bean plants from pest infestations. Tall plants were considered to be effective because they obstructed the movement of the pest insect within the cropping system.

It could be argued that there is an element of physical obstruction when clover disrupts host plant finding by pest insects of brassica crops as, to have maximum impact, the foliage of the clover has to surround much of the host plant. Although clover growing in such close proximity to the host plant will obviously obstruct the searching insects, no suggestions have been made as to how this mechanism might operate.

However, a mechanism relying solely on physical obstruction is not supported by recent findings in which clover plants were desiccated so that they retained the same architecture as the living plants and differed only in color, being brown rather than green. When the cabbage root fly (*Delia radicum*), the diamondback moth (*Plutella xylostella*) and the large white butterfly (*Pieris brassicae*), were presented with host plants surrounded by desiccated (brown) clover, the number of eggs laid did not differ from the numbers laid on host plants presented in bare soil. Hence, the physical presence of the clover was not sufficient on its own to reduce the numbers of eggs laid, a reduction occurred only when the surrounding clover was green.

Visual Camouflage

This hypothesis was based on the two types of visual stimuli that induce low-flying insects to land on plants. The first is a directed response to the color of the plant, which, in most cases, means green, and the second is an optomotor response in which landing is provoked by plants "looming up" along the path of the flying insect. Anything that competes with such stimuli, such as other green plants, or raising the height of the overall background with weeds so that the distance over which the host plant can be separated from the background is foreshortened, helps to visually camouflage the host plants. This makes the host plants less "apparent" among the foliage of the non-host plants.

Although many authors showed clearly that aphids, whiteflies and certain Lepidoptera preferred plants that stood out against a background of bare soil, no attempts were made to determine how such a mechanism might operate.

Masking of Host Plant Odors

The release of "odor-masking" substances into the air by non-host plant species is considered to confer some protection to the associated host plants. Although this "associational resistance" seems a plausible hypothesis, few data have been collected during the last 25 years to support it.

The possibility that the odor of the host plant could be masked by that of the non-host plant now seems much less likely, though not impossible. For example, host plant selection by the cabbage root fly was disrupted when its host plants were surrounded by a range of different plants including the weeds fat-hen (*Chenopodium album*), fumitory (*Fumaria officinalis*) and spurrey (*Spergula arvensis*); and cultivated plants such as pea (*Pisum sativum*), onion (*Allium cepa*), carrot (*Daucus carota*), rye-grass (*Lolium perenne*), or clover (*Trifolium*). As each of these non-host plants has a different odor profile, it seems highly improbable that they would all be capable of preventing an adapted specialist insect from finding its host plants. Furthermore, observations made in wind tunnels revealed that brassica plants growing in clover were approached by cabbage root flies as readily as brassica plants growing in bare soil, indicating that the odors from the clover did not mask those of the flies' host plants. More striking, however, was that the same disruptive effect could be produced by surrounding the host plants with plant models made from green cardboard, or simply with sheets of green paper, neither of which were releasing plant chemicals. It seems that once the characteristic host plant chemicals stimulate the insects to land, the disruption is caused simply by providing the insects with a greater number of green surfaces on which to land.

Repellent Chemicals

It is implicit in this hypothesis that the odors given off by the non-host plants are sufficiently strong to actually repel the searching insects. It was suggested that the diamondback moth could be repelled from cabbages by intercropping the cabbages with tomatoes (*Lycopersicon esculenta*) and that the highly odorous ragweed (*Ambrosia artemisifolia*) could be used to repel the cabbage flea beetle (*Phyllotreta cruciferae*) from crops of collard (*Brassica oleracea* var. *acephala*). Such suggestions were made to describe why pest insect numbers were different in the two situations. They were not based on scientific experimentation. Whether or not true deterrency is a mechanism still needs to be proven. Deterrency usually involves highly aromatic plants that often have to be crushed and tested in small, confined spaces in the laboratory to show that they are actually capable of repelling pest insects. As such tests are far from natural, the validity of using such data during the synthesis of new behavioral mechanisms is questionable. In reality, no experimental evidence has been produced during the last 15 years to support the hypothesis that plants produced effective levels of chemical repellents.

Plants chosen for their odorous nature, such as French marigolds (*Tagetes patula*), failed to deter the carrot fly (*Psila rosae*) when used as the intercrop in carrots. In addition, oviposition by the diamondback moth was similar on Brussels sprouts (*Brassica oleracea* var. *gemmifera*) plants intercropped with plants of sage (*Salvia officinalis* L.) and thyme (*Thymus vulgaris* L.), two plant species selected for their pungent odors. Extracts of the essential oils of sage and thyme were shown to reduce oviposition by the diamondback moth, but the effect resulted from contact stimuli and not from repellent volatile stimuli. Doubtless, many contact chemicals play a major role during host plant acceptance, but as these come into play only after an insect has landed, they are included only in the second part of this review, which is concerned with host plant acceptance.

Altering the Profiles of the Host Plant Odors

While this seems a novel mechanism, it relies upon the host plants' inability to metabolize certain chemicals they take up from the soil, so that such chemicals, in effect, change the subsequent physiology of the plant. Many claims are made that African marigolds (*Tagetes* spp.) planted between rows of crop plants reduce pest numbers. It is clear from the earlier discussions that this is unlikely to be a direct effect of the odors of the African marigolds repelling the colonizing insects. However, it is well known that species of African marigolds release large amounts of root exudates, which can be taken up by adjacent plants. It is possible, therefore, that any host plant growing in an intercrop could be affected directly by chemicals taken up through its roots rather than by having its odor masked.

To test whether the uptake of such chemicals was responsible for the differences in plant colonization, several batches of the host plants were left in their pots throughout the test periods. As the effects of the clover were still evident, and often within minutes of starting an experiment, a generic mechanism based on the non-host plants (here, clover) causing physiological changes in the host plants cannot be supported.

The Resource Concentration Hypothesis

The last two hypotheses are the ones quoted most frequently. Both were derived from one study in which Root monitored insect distribution during three field seasons in pure stands of collard plants and in single rows of collard plants bounded on each side by diverse meadow vegetation.

The "Resource Concentration Hypothesis" states that phytophagous insects are more likely to find and remain on host plants that are growing in dense or nearly pure stands. Phytophagous insects that arrive in a clump of host plants, by whatever means, and find conditions suitable, will tend to remain in the area. This "arresting effect" of host patches will depend upon several factors such as the size and the purity of the plant stand and the type of host plant required by the phytophagous insect. In many cases, this accumulation of specialist insects on a concentrated resource (here, cultivated *Brassica* plants) will be sufficient to increase the numbers of phytophagous insects in that locality. Again, this hypothesis describes simply the effect of changes in the purity of a host plant stand on insect numbers and does not include any attempt to develop a general theory to describe how phytophagous insects select their host plants.

The Enemies Hypothesis

Contrary to five of the earlier hypotheses, which claim that the differences are due to the direct effects of the diverse backgrounds on the behavior of the pest insects, this hypothesis, like hypothesis 5 (altering the profiles of the host plant odors), proposes that the effects are indirect. In essence, this hypothesis proposes that lower numbers of phytophagous insects are found in complex environments because predators and parasitoids are more effective in such situations. Thus, outbreaks of phytophagous insects are checked early by the higher numbers of enemies that can be supported by the diverse resources available in complex environments. Unfortunately, Root found that the effectiveness of the "enemies" did not differ significantly between collards grown as pure stands and those grown in single rows among diverse meadow vegetation. Nevertheless, Root pursued this "enemies hypothesis" by discussing sets of data collected mainly in England. His own, more extensive data, however, indicated clearly that the diversity of both predators and parasitoids was higher in the pure stands, probably because more prey/host species were also present in that habitat. Consequently, he concluded that factors other than natural enemies were responsible for much of the differences in insect numbers recorded between simple and diverse habitats. Although Root himself discounted the "enemies hypothesis," many subsequent scientists have championed the cause of predators, often on the flimsiest of evidence, or without collecting the data necessary to support their claims.

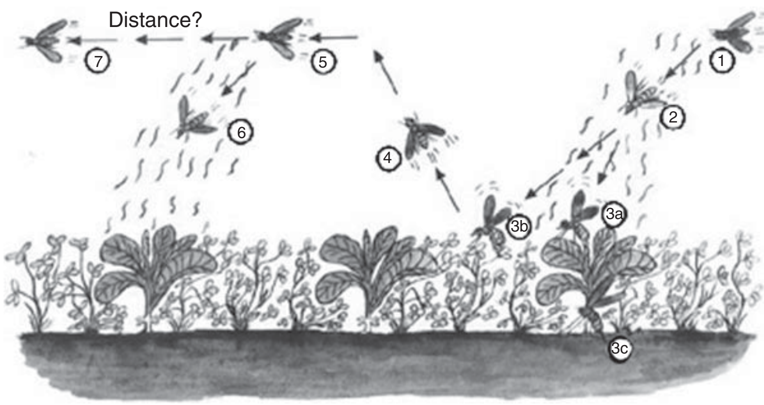
Conclusions From Recent Work

Although authors have indicated that diverse backgrounds can affect host plant selection in the seven ways described above, it is hard, from the results presented in recent publications, to refute the more simplistic view that one mechanism is operating against all species. Recent work published by Finch and Collier (2000) included experiments on the cabbage moth (*Mamestra brassicae*), the diamondback moth, the garden pebble moth (*Evergestis forficalis*), the small white butterfly (*Pieris rapae*), the large white butterfly, the cabbage aphid, the cabbage root fly and the mustard beetle (*Phaedon cochleariae*). Despite these eight test species being from four insect orders, the ability of each of them to find host plants was affected adversely, though to differing degrees, when their host plants were surrounded by clover. It appeared that differences in the initial rates of colonization were the factor that regulated the numbers of phytophagous insects found on host plants growing in bare soil or clover, as differences between the two situations were often apparent within minutes of starting an experiment.

Description and Discussion of the New Theory

Unfortunately, no one has yet developed any of the earlier hypotheses into a robust general theory, they are still only hypotheses. Hence, we have generated our own theory from detailed studies of insect behavior.

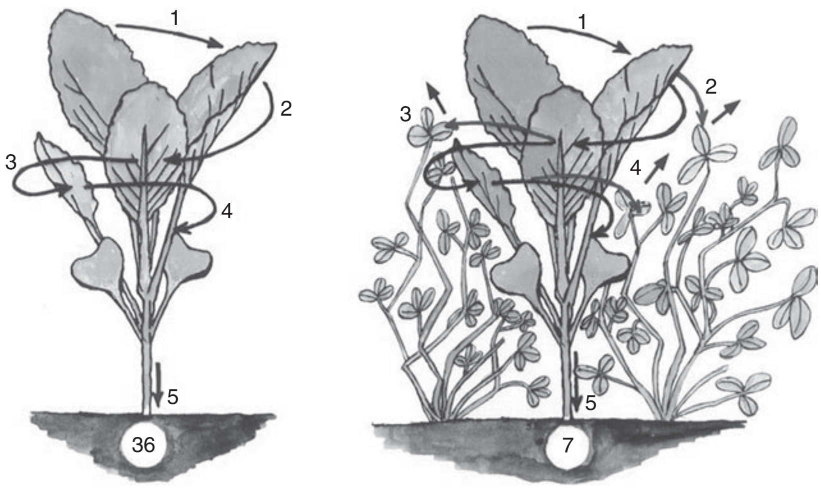
Instead of the seven hypotheses described previously, we believe that a mechanism that we have described as "appropriate/inappropriate landings" is the central link in host plant selection by insects. In the overall system, the new theory of host plant selection can be divided into a chain of actions involving just three links. In the first link (Link 1; Fig. 51), volatile chemicals emanating from plants indicate to flying, receptive insects (action 1) that they are passing over suitable host plants. Once the odor of the host plant in the air becomes sufficiently concentrated, it induces the insect to land (2). In this way, the volatile chemicals bring the insects into the close vicinity of the host plants. However, during the last few milliseconds, when the insects are only a short (often <1 m) distance away from the plant, instead of maintaining their directed response to



Host Plant Selection by Insects, Figure 51 **Schematic diagram to illustrate how diverse backgrounds, here represented by clover (*Trifolium* spp.), influence host plant finding by the cabbage root fly. Numbers represent insect actions 1–7 (see text).**

volatile stimuli, phytophagous insects switch to a directed response to green objects, which, in most cases, means to plant leaves. It is logical that vision takes over at this stage, as most flying animals use vision to "pin-point" a suitable object on which to land. Therefore, insects that fly over plants growing in bare soil will be stimulated to land on host plants, the only green objects available to them (3a), as most phytophagous insects avoid landing on brown surfaces, such as soil. When host plants are growing in bare soil, most landings will be what we have classed as "appropriate," and so, the host plants will, in effect, "concentrate" the insects. In contrast, insects flying over host plants surrounded by clover land in proportion to the relative areas occupied by leaves of the host and non-host (3b) plants, as specialist phytophagous insects do not discriminate between the two when both are green. Hence, any landings made on the non-host plant (3b) are classed as "inappropriate." The amount of time the insects spend on the leaves of the non-host plants before taking off again (4) is governed by whether the insects receive acceptable or antagonistic stimuli through their tarsal receptors. Once the insects are again airborne, if they are stimulated to land after flying only a relatively short distance, they could land on a host plant (5, 7). In all situations, however, the plant on which the insect first lands, even if it is a "host plant," may not stimulate the insect sufficiently to cause it to remain on the plant, and the overall process will be repeated. If this represented the complete system, then under "no-choice" situations in the field, it would just be a matter of time before the numbers of eggs laid on host plants growing in diverse backgrounds were similar to those laid on host plants (3c) growing in bare soil. However, this does not occur, as there is a second phase to host plant finding.

This second phase can be illustrated (Fig. 52) most clearly by data collected from a detailed study of the cabbage root fly. Before accepting a host plant as a suitable site for oviposition, receptive female cabbage root flies make, on average, four spiral flights before laying eggs beside the plant. Hence, the insects stand a much greater chance of "losing" the host plant in a diverse background as, on average, they repeat the initial appropriate/inappropriate landing procedure an additional three times. Observations under laboratory conditions showed that for every 100 females that landed on a brassica plant surrounded by bare soil, 36 received sufficient stimulation from the plant to be induced to lay eggs. In contrast, only seven out of 100 females that landed on host plants surrounded by clover managed to lay eggs. Fewer flies managed to lay eggs in this

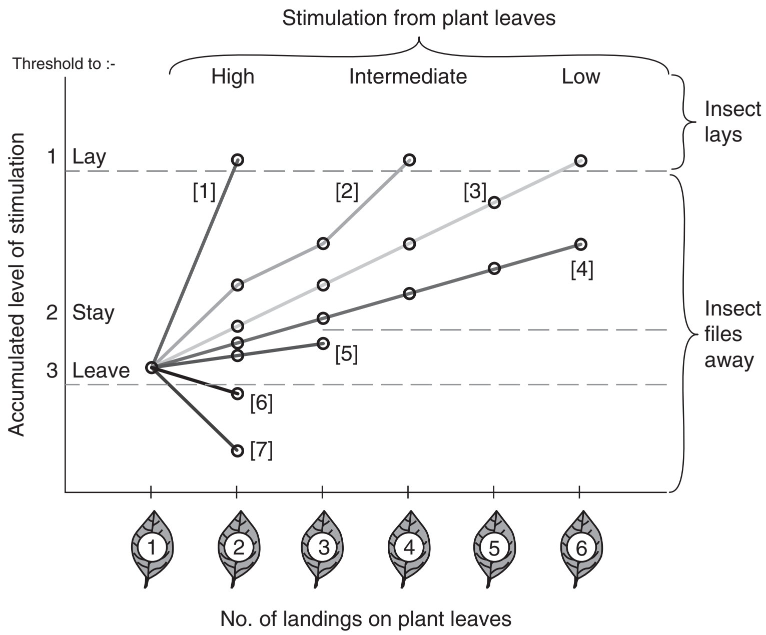


Host Plant Selection by Insects, Figure 52 **Schematic diagram to illustrate how diverse backgrounds, here represented by clover (*Trifolium* spp.), influence host plant acceptance by the cabbage root fly. Numbers represent the four (mean no.) leaf-to-leaf flights made by the fly to ascertain whether the plant is a suitable site to lay its eggs.**

situation, because following each short spiral flight, a proportion of the flies landed on the leaves of the surrounding clover plants. This failure to re-contact a leaf of a host plant after any spiral flight prevented the females from accumulating, within the allotted time, sufficient stimulation from the host plant to be induced to lay eggs. Hence, the barrier that this fly faces when its host plants are grown in diverse backgrounds is not chemical nor mechanical, but behavioral, simply because during the innate series of spiral flights, the fly must continue to accumulate more positive host plant stimuli each time it lands.

The amount of stimulation the female picks up on each landing is crucial, and this is where the phase of host plant finding (Link 2) becomes truly integrated with host plant acceptance (Link 3). In essence, the complete system really involves finding and refinding the host plant. Obviously, the insect can re-find the host plant quite easily in bare soil situations, but not as easily when the plant is growing in a diverse background of other plants. The schematic representation shown in the final figure indicates that the female cabbage root fly may only have to visit two leaves of a highly stimulating plant [1] compared to six leaves on a poorly-stimulating plant [3] before finding it an acceptable site to oviposit. Other insects, however, may accumulate sufficient stimuli to keep them searching [4], but not sufficient stimuli to induce oviposition and so will fly away. A similar outcome results when insects visit several leaves but do not manage to accumulate sufficient stimuli in the allotted time to be induced to stay [5]. Two other variations occur when the insects land initially on a stimulating leaf, but subsequently on a non-stimulating leaf. It does not matter whether this leaf is from a host [6] or a non-host plant [7], as anything that interrupts (Fig. 53) the rate of accumulation of positive stimuli causes the insect both to abort its attempt to lay and to move elsewhere. In addition, interspecific competition may also become important. At any stage during the host plant selection process, many of the new immigrants may not remain on otherwise acceptable plants if those plants are colonized already by certain, but not all, of the other insect species present in the pest complex.

The physiological status of the insect, which depends partly on its age and also on how long it has been deprived of a suitable oviposition site, also has to be superimposed upon this already



Host Plant Selection by Insects, Figure 53 **The number of leaf landings a cabbage root fly may have to make before accepting a plant as a suitable site for oviposition or deciding to fly elsewhere. The numbers in [] represent seven possible variations in the pattern of insect behavior.**

complex system. With time, phytophagous insects tend to become less discriminating in their choice of oviposition sites. The condition of the plant is also extremely important, as some cruciferous plant species are more highly preferred than others, and during their phase of exponential growth, many individual plants become highly stimulating to insects. However, even when the insect and the plant are both in the appropriate physiological state, it counts for nothing the moment the insect makes a wrong choice and alights on any green object other than a leaf of a host plant. This, however, is tempered by the fact that when the host plant is highly stimulating, the insect has to visit fewer leaves and so has less chance of making an inappropriate landing. In addition, the highly stimulating plants invariably induce the individual insects to lay more eggs. Detailed descriptions of the multitude of other factors involved during host plant acceptance can be found in many of the papers published in 1999 in the proceedings of the Tenth International Symposium on Insect-Plant Relationships.

Although the other seven test species mentioned earlier have not been studied in detail, records of the movements of the small white butterfly in the field showed that it always made contact with several leaves, interspersed with short flights, before laying an egg. Although the original author concluded that this butterfly needed some flight time to get the next egg ready, these short flights could also represent a behavioral repertoire similar to that of the cabbage root fly. It seems likely, therefore, that the relative differences in the effects that diverse backgrounds have on host plant selection by the test species may simply reflect the numbers of contacts/re-contacts the insect has to make to accumulate sufficient positive stimuli to lay eggs. Results from recent experiments indicated that the diamondback moth was the species affected least by diverse backgrounds. It raises the question of whether the diamondback moth has become such a major pest of cruciferous crops simply because it has a limited behavioral repertoire prior to oviposition, and so, lays eggs on more or less the first host plant leaf it encounters.

General Discussion

The "appropriate/inappropriate landing" theory (Fig. 53) can be used to explain why certain aspects of host plant finding by phytophagous insects, supposedly regulated by volatile plant chemicals, proved intractable to scientific experimentation in the past.

Compared to our simple theory of host plant finding, other theories invoke complex processes involving volatile chemicals to guide phytophagous insects to their host plants. For example, it is known that the odorous environment of a given insect is a shifting maze of overlapping active spaces. Therefore, it was suggested that it is in this shifting maze that the insect must find the active space containing those few signals that will lead it to its host plant. However, in the open air, it is turbulence rather than diffusion that determines the distribution of odorous molecules, and there is nearly always a prevailing wind to blow the odorous molecules away from the plant. Registering directional cues from odorous molecules is even more complicated for flying insects, as the movement of the air relative to the insect depends on the insect's own activity, and the wind direction has to be determined by the insect in the absence of fixed markers.

The evidence that volatile chemicals are the main regulatory stimuli in the central link of host plant finding is weak, as the maximum distance recorded for insect orientation to host plant volatiles in the field is only a few meters. In wind tunnel experiments, cabbage root flies flew upwind to a cruciferous plant odor released at 2.5 g/day, a rate similar to that dispensed from field traps. This rate of release is at least 105 times higher than the amount of chemical released from a healthy cruciferous plant. Although the flies moved upwind in response to this odor, $<10\%$ of the flights lasted more than 0.5 m. While the shortness of such flights was described as unexpected, it would not have been unexpected had the chemicals involved been regarded as arrestants rather than attractants. Similarly, with insect traps releasing large amounts of chemical to provide directional cues in the field, many insects miss the trap and subsequently fail to enter, suggesting again that stimuli other than volatile chemicals take over once the insect nears the source of the odor. The current mechanism seems much more robust than one based on volatile chemicals, as the sooner an insect lands, the sooner it is freed from the plethora of problems it faces while still in the air.

The "appropriate/inappropriate landing" theory works equally well for generalist feeders, where the decision of whether to stay is determined primarily by the chemicals the insect detects via its contact chemoreceptors once it has landed on a leaf. However, it should be remembered that if an insect that is considered to be a "generalist" has been stimulated to land by volatile chemicals released from a specific plant species, the insect may continue its search for such a plant rather than choosing the first acceptable plant it encounters.

Finally, the "appropriate/inappropriate landing" theory appears to apply equally well to nocturnal insects, as oviposition by the diamondback moth and the cabbage moth was not disrupted when their host plants were surrounded by brown clover. Although both of these moth species are considered to be nocturnal, much of their oviposition activity is concentrated at, or shortly before, dusk. The above results indicate that during this period, both species of moth appeared to be able to discriminate between green and brown objects.

From a crop protection standpoint, the more non-host plants removed from any crop area, the greater chance an insect has of finding a host plant. Hence, current cultural methods are exacerbating pest control problems, as "bare soil" cultivation ensures that crop plants are exposed to the maximum pest insect attack possible in any given locality.

Future Work

If the theory based on "appropriate/inappropriate landing" is accepted, it raises searching questions regarding several aspects of entomological research.

In the first instance, we have expressed considerable doubts about whether host plant volatile chemicals on their own are capable of guiding phytophagous insects to their host plants. Most of the detailed experiments with host plant volatile chemicals have been done by releasing plant odors from a point source sited at one end of a wind-tunnel, introducing responsive insects and then recording whether the insects move upwind to the source of the odor. Results from this approach have been disappointing. Often, the only way to obtain data is to place a visual stimulus, normally a green object, alongside the site where the volatile chemical is being released.

If, as the "appropriate/inappropriate landing" theory suggests, it is only the number of green objects surrounding a host plant that reduces colonization by pest insects, then it should not be too difficult in the future to quantify the type and number of plants needed for the diverse background to reduce pest insect numbers in any given crop. If several plant types proved appropriate for a given cultivated crop, it would then simply be a case of choosing the one that caused the least reduction in yield to the harvested product.

There is also a need to obtain a better understanding of "companion planting" a practice used frequently by organic growers. Recent data show that there is no scientific evidence proving that the odors from highly aromatic plants can actually deter pest insects. This, therefore, brings into question how these aromatic plants produce their effects. A survey of the literature should help to show whether such systems are effective only when the companion plants possess relatively large amounts of foliage when compared to the crop plants. If this idea can be substantiated, the differences recorded may simply be a reflection of appropriate/inappropriate landings, and, again, have little to do with volatile chemicals, no matter how pungent the plant odors might appear to the researcher.

Apart from its impact in practical pest control situations, the "appropriate/inappropriate landing" theory helps also to explain why wild host plants growing among other plants in natural vegetation are rarely decimated by pest insects. However, some insects that are considered to be pest species do develop on wild-host plants. The question then, is do such insects prefer to remain on the wild host plants in subsequent generations, a situation that could give rise to biotypes? The answer to this question is of considerable practical importance. Future work is required to determine what proportion of any given pest population develops on wild-host plants, and whether such insects readily switch back to the cultivated crop plants. If they do not, then it should be possible to control certain pest insects by isolating new crops from earlier infestations.

Additional work is required also to determine whether appropriate/inappropriate landings influence the overall distribution of the parasitoids of the pest species. It is well documented that such insects use both host plant chemicals and kairomones to locate their host insects. Research in the 1940s in which cabbage plants infested with the larvae of the small white butterfly were placed in bare soil crop fields and in hedgerows, showed clearly that one specific parasitoid, *Apanteles rubecula*, was also affected adversely when the plants on which its host insects were feeding were placed into a diverse background. Further work is needed on other parasitoids to determine whether this is a general phenomenon. If it is, then the suggestions of some researchers that diverse backgrounds have adverse effects on pest insects and no effect on their parasitoids warrant further study.

Similarly, with respect to the "Enemies Hypothesis," it should not be too difficult to show whether predation is higher on infested plants surrounded by non-host plants, than on similarly infested plants surrounded by bare soil.

As much of the aforementioned work has been based on detailed information on the cabbage root fly, work is needed to determine the detailed activity of each of the other pest species. It appears that diverse backgrounds may have a greater effect on the cabbage root fly than on the diamondback moth simply because, before acquiring sufficient stimulus to oviposit, the cabbage root fly repeats the sequence of host plant finding four times, but the diamondback moth only once. It would be difficult to prove that once the cabbage root fly starts one of its spiral flights it is again stimulated to land (arrested) by volatile chemicals, as the distances between taking-off and landing again are extremely short. However, olfaction is considered to be used by phytophagous caterpillars in choosing their feeding sites, so the intervention of olfactory stimuli again at this stage cannot be ruled out.

The hypothesis of "appropriate/inappropriate landings" does appear to provide a robust description of host plant selection by insects under a wide range of different conditions. It shows how elements of all the earlier hypotheses can be incorporated into the overall system, and in particular, how the lack of detailed research on insect behavior, and in particular, on visual stimuli, has led to many of the current anomalies. Apart from the future work proposed, it will be interesting to determine whether the same theory regulates host plant selection by specialist insects found associated with plant families other than the Cruciferae. While we believe the simplicity of our theory makes it all-embracing, only time will tell whether our optimism is justified.

Host Specific

An organism that is monophagous, feeding only on a certain host.

Host Specificity

The degree of specificity of an animal preying on hosts. Levels of host specificity include monophagous, stenophagous or oligophagous, and polyphagous.

Host Specificity of Weed-Feeding Insects

LUCA FORNASARI
Montpellier, France

The understanding of evolutionary processes is necessary when considering biological diversity and the relationships existing between insects and plants. The major forces in structuring the populations of phytophagous insects act vertically through trophic levels (e.g., from natural enemies of phytophages to phytophages, and from these to host plants), rather than horizontally through interspecific competition. Therefore, due to the selection pressure by phytophagous insects, plants evolved – and sometimes co-evolved with them – interspecific negative or positive interactions. These are expressed by a gradient of interactions. At one end of the spectrum, negative interactions are seen in defense mechanisms; at the other end of the spectrum, positive interactions can be seen in obligate mutualistic interactions. Both are a result of reciprocal, repeated intimate adaptations and counteradaptations. This is exemplified in phototoxic plants, which developed very effective defense mechanisms, and in entomophilous plants, which conversely are extremely specialized and could not even survive without a given species of insect.

Adaptations of Insects to Plants, and of Plants to Insects

The adaptations in insect-plant relationships involve behavioral, phenological, physiological, morphological and biochemical traits of phytophages and plants, which ultimately determine the success and fitness of species. The attack by herbivores induces production of allelochemicals in plants. In turn, the selection pressure driven by plant resistance, especially through allelochemicals, results in patterns of specialized insect natural enemies, whose success is enhanced by the reduced competition for food that they encounter once they overcome plant defenses. These evolutionary adaptations especially involve the feeding and oviposition habits of phytophagous insects, leading to a high level of specialization for their host plants, and also defense mechanisms that allowed them to be resistant. Resistance is expressed as being non-palatable, repellent, digestion-inhibiting, or toxic to other species of insects. Besides toxic chemicals, plant defenses also include physical (morphological) structures, and low levels of available nitrogen, or water/nitrogen ratios. On the other hand, insects develop specific morphological, biochemical and behavioral adaptations, and synchronize their life histories with their hosts.

Host Selection

The ability of specialist weed-feeding insects to identify, locate and select the proper host as breeding substrate, is critical to the performance and survivability of a given species of insect. All phytophagous insects show some degree of selectivity for their food-plants, and possess a definite host range. The host selection behavior includes a specific sequence of activities and responses to environmental cues, principally orientation, feeding and/or oviposition. Adults usually must choose the right host for oviposition, thus facilitating the development of immature stages, which often have limited mobility. Nevertheless, also immature stages of insects are capable of displaying host selection behavior. For oviposition, adults may not only choose the host plant species, but also a suitable individual plant, the most favorable geographical area, the site, the habitat, plant density, and the size and the part of the plant. Even subtle factors such as the degree of protection from biotic or abiotic damage to eggs, the correct micro-environmental conditions for the development of eggs and immatures, and the nutritional status of the food supply affect host selection. The spatial pattern of the host plant can affect oviposition behavior, and plant shape can modify its attractiveness to insects. Adults also regulate their oviposition behavior in terms of the number of eggs oviposited per plant, and in some cases will avoid oviposition on plants where other eggs have already been laid. This behavior facilitates a regular distribution of eggs on the plants, and regulates the effect of insect feeding on the host plants. In some species, adults are deterred from laying eggs if the plant has already been fed upon by other insects.

The selection of a suitable species of plant by phytophagous insects is guided by a combination of physical and chemical stimuli. The sensorial selection of the host plant by insects involves the senses of smell, sight, touch, taste and other forms of contact chemoreception, and may be facilitated by activity and behavioral patterns typical for a given species of insect (e.g., pattern of flight). Plant-produced volatile semiochemicals such as kairomones and allomones, as well as nonvolatile secondary chemicals and interactions with microorganisms, play a major role in determining insect behavior. The sense of smell is highly developed in insects, and the olfactory signal is usually the main indicator of an appropriate host, often complemented by visual elements. Leaf surface contact cues are then important in the host selection process. Insects also respond to the hardness of tissue, which is usually associated with lessened feeding. In general, the balance between phagostimulatory and deterrent compounds contained in the ingested plant tissues determines the acceptance or rejection of the plant by polyphagous insects. In contrast, for monophagous and many oligophagous species, the perception of a single, specific, chemical, or group of chemicals of the plant seems to trigger feeding. A complex of factors and interactions may ultimately cause the association of the herbivore with the target plant. The characteristics of the plant causing it to be unsuitable for insects are described as "xenobiosis" (also called antibiosis); the subset of plant characteristics that cause an insect not to accept a prospective host plant are described as "antixenosis" (nonpreference).

Learning

Experience may play a role also in the host selection process, although differences seem to exist between polyphagous and oligophagous insects. It is necessary to consider the importance of the physiological conditions of plants and insects, abiotic factors, presence of other plants species and other biotic factors, as these can greatly influence the behavior of the insect during the host selection process, and largely modify the host range that the insect has under standard conditions.

Plant Defenses

The great genetic plasticity and biological diversity in insects is amply seen in their specialization on the most diverse species of host plants. This is clearly shown also by insects that attack weeds. The species of weed-feeding insects have a wide array of relationships with their food-hosts and several mechanisms to overcome plant resistance to attack. Most phytophagous insects are relatively specific for their hosts, and generalists represent a minority. However, it is possible to distinguish different levels of specificity, in a continuum of patterns of resource use, ranging from species that are strictly monophagous, to polyphagous species. The degree of specificity varies, with exceptions, among orders of insects, but also among lower taxonomical levels, including species and even sub-specific entities. The host range depends on characteristics intrinsic and extrinsic to a species of insect. In the first category fall all the biological, biochemical and ecological characteristics of the weed-feeding insect and its responses to environmental stimuli, whilst in the second category fall the characteristics related to the life history, phenology and physiology of the species of plant considered. For instance, because of the life history of the plant considered, a species of insect may not be present at the time of the year when the plant, or plant part, is susceptible of being attacked. The fact that narrow host specificity is prevalent among phytophagous insects means that most of them developed mechanisms allowing to overcome hurdles to phytophagy in the food web represented by the defensive evolutionary barriers of plants. Land and aquatic plants, including weeds, show a great biochemical diversity, growth forms, leaf shapes and seasonal phenologies, and the reciprocal (coevolutionary) influences between these diverse forms of plants and insects, led to the specificity of weed-feeding insects for their hosts. This was achieved in various ways by specialized insects. They alternatively developed the ability to (i) detoxify and metabolize xenobiotic compounds contained in the tissues of the host plant; (ii) sequester toxic secondary plant metabolites; (iii) rapidly excrete the toxicants ingested; or (iv) attack poisonous plants without ingesting an overdose of the toxic allelochemicals, as a result of behavioral defenses. On the whole, specialists are more efficient in the use of resources and better competitors than generalists. Specialized monophagous and oligophagous insects, rather than polyphagous insects, have the major effect in the regulation of the abundance of their host plants.

Weed-Feeding Insects

Host specific weed-feeding insects can be used as beneficial organisms in programs for the biological control of weeds, as an alternative to chemical herbicides, or other forms of control. Therefore, they may be a component of integrated pest management programs and in some cases may represent the best, if not the only effective solution to control exotic weeds introduced in a new geographical area. This is the case in particular for rangeland weeds, and weeds that represent an environmental problem, for example in protected areas and where the area infested is very large. Nevertheless, biological control can be successfully applied also against weeds infesting crops. This form of control offers many important advantages, being effective, selective, environmentally sound, self-perpetuating and cost-effective, especially in the long term. Information about the host range of a weed-feeding insect is essential for organisms that have prospective use as biological control agents. It is necessary that, in addition to being effective in controlling the target plant, it does not harm other plants such as agricultural crops, ornamental plants, or plants of ecological value. Therefore, studies must be conducted to be able to predict the effectiveness of the biological control agent, and to determine which plants are likely to be attacked in the region where the insect should be released. Several approaches were considered to study the level of specialization of a candidate agent in order to define its host range and in general these methods include tests on (i) species of plants taxonomically related to the target plant for biological control; (ii) plants attacked by other species of insects related to the candidate agent; (iii) cultivated plants of economic importance in the region of release; (iv) threatened, endangered, or other native plants of ecological value present in the area of release; (v) plant species with an increasing phylogenetic distance from the target plant; and (vi) unrelated plants with biochemical, or morphological characteristics in common with the target plant. The evaluation of the safety and future performance of candidate biological agents in the release environment depends on a complex of biotic and abiotic factors and has to be considered for each specific situation. In order to assess the degree of specificity of a species of insect, studies can be conducted in the laboratory and in the field on the test plant species. The ability of the insect to feed, produce fertile eggs and oviposit on the test plants is verified. Also, the ability to complete its development under no-choice and multiple-choice conditions is studied. Once this information is available, studies on the following generations can show if the test plant affects their biology, and if there are variations in fertility, or other key biological traits. Studies conducted in the field will complement the information obtained in the laboratory and will help to define the true host range of the insect. Depending on the nature of the weed problem, it may be necessary to use organisms with various degrees of specialization for their hosts, ranging from highly specific (e.g., attacking exclusively a variety of the weed species), to less specific insects. In-depth studies on the life history of these insects are also required, since often these weed-feeding insects being considered as candidate agents for biological control are new to science, and even when they are not new species, their biology is usually very poorly known. Due to intraspecific variability among insects, host range studies should include a sufficiently large sample of insects to be representative of that species, and it is preferable that they are conducted on precise, geographically distinct populations. The biology, habits, degree of host specificity and, if necessary, genetics of populations of different origin are compared.

House Dust Mite

Several species of mites in the family Pyroglyphidae are considered to be dust mites.

► Mites

House Fly, *Musca domestica* L. (Diptera: Muscidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

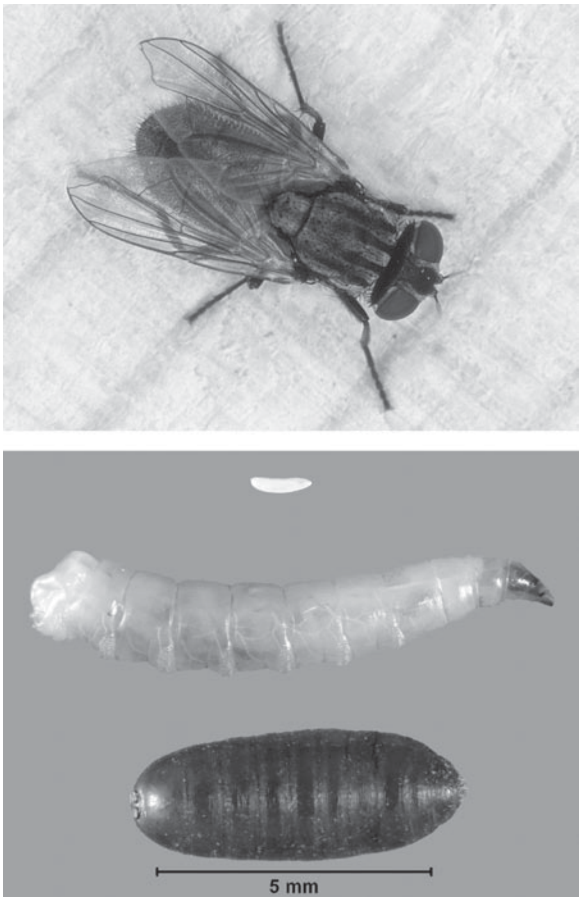
This common fly originated on the steppes of central Asia, but now occurs on all inhabited continents, in all climates from tropical to temperate, and in a variety of environments ranging from rural to urban. It is commonly associated with animal feces, but has adapted well to feeding on garbage, so it is abundant almost anywhere people live. It is the most common fly to invade homes, and often is the dominant species around livestock and poultry. Despite its inability to bite, it is both a nuisance and a public health problem.

Life History

The life cycle of the house fly may be completed in as little as 6 days, but under suboptimal conditions may require up to 2 months. It breeds continuously in warm climates such as in the tropics and subtropics, producing more than 20 generations annually. Even in more temperate areas they commonly undergo ten generations. In cooler areas they overwinter as larvae or pupae, but adults perish when exposed to cold. In heated areas in cold climates, however, they breed throughout the winter months if the adults have access to food and larvae to suitable developmental media.

The cylindrical-oval eggs (Fig. 54) are white, and 1.0–1.2 mm long. Eggs typically are laid in clusters, often numbering 75–150 eggs per cluster. A female normally deposits 2–6 clusters of eggs during her life span. Maximum egg production occurs at intermediate temperatures, 25–30°C. Often, several flies will deposit their eggs in close proximity, leading to large masses of larvae and pupae. Eggs must remain moist or they will not hatch. Egg hatch usually occurs within 8–20 h. Due to its rapid development time and high reproductive capacity, the house fly has the capacity to increase in abundance rapidly. Indeed, scientists impressed with its reproductive capacity have calculated that, lacking mortality, a single pair of flies could grow to a population of 191,010,000,000,000,000,000 in only 5 months, enough to cover the entire earth in a layer of flies several meters deep!

The larvae are creamy white, cylindrical, legless, and taper to a point at the head. The head of larval house flies, like most maggots, have dark mouth hooks. There are three larval instars. The optimal temperature for larval development is 35–38°C, though larval survival is greatest at 17–32°C. Larvae complete their development in 4–13 days at optimal temperatures, but require 14–30 days at temperatures of 12–17°C. The moisture level of the food affects larval survival, and 50–70% moisture content favors survival, though some survival can occur at almost any moisture level. Nutrient-rich substrates such as animal manure provide an excellent developmental substrate. Very little manure is needed for larval development, and sand or soil containing small amounts of degraded manure allows for successful belowground development. At maturity, larvae are 7–12 mm long, and prefer to disperse to a dry location to pupate.



House Fly, *Musca domestica* L. (Diptera: Muscidae), Figure 54 House fly stages of development: *above*, adult; *below* (top to bottom), egg, larva and pupa. Note that the eggs are normally deposited in clusters. (Upper photo by Jim Castner, lower by Lyle Buss, both of the University of Florida).

The mature larva pupates within the cuticle of the last larval instar (this structure is called the puparium), though the shape of the pupa is quite different from the larva, being bluntly rounded at both ends. It is about 8 mm long. The color of the pupa changes from yellowish, to reddish brown, to dark brown or black over the course of the pupal stage. Pupae complete their development in 2–6 days at 32–37°C, but require 17–27 days at about 14°C.

The adult is about 4–7.5 mm long. The female is typically larger, and can be distinguished from the male by the relatively wide space between the eyes (in males, the eyes almost touch). The dull, grayish fly bears four narrow dark stripes on the thorax. The abdomen may be gray, but often is yellowish, and has a narrow dark line dorsally. The wings are transparent except for the dark veins. They have sponging mouthparts, which allows them to lap up liquid food. Thus, they cannot bite animals and humans. Flies regurgitate readily, secreting saliva onto solid foods so it can be liquefied and ingested. Adults may live up to 2 months, but more typically live 2–3 weeks. Without food, they survive only 2–3 days. Longevity is enhanced by availability of suitable food, especially sugar. Access to animal manure does not lengthen adult life and they live longer at cooler temperatures. They require food before they will copulate, and copulation is completed in as few as 2 min or as long as 15 min. Oviposition commences 4–20 days after copulation. Female flies need access to suitable food (protein) to allow them to produce eggs, and manure alone is not adequate. They prefer sunlight, and are active fliers during warm days. They are inactive at night, and commonly can be seen perching on the ceilings of barns or other shelters. Lacking buildings on which to perch, flies rest on trees, poles, wires, and other elevated objects. If adequate food and oviposition sites are available, emerging flies generally remain in the area. Lacking these conditions, however, flies will easily disperse a kilometer or more in search of food.

According to a study conducted in Texas, USA, breeding site suitability (in descending order), was horse manure, human excrement, cow manure, fermenting vegetable, and kitchen waste. However, another study found that structures containing swine, horse, sheep, cattle, and poultry varied in fly abundance, with swine facilities containing the most and poultry the least. Fruit and vegetable cull piles, partially incinerated garbage, and incompletely composted manure also are highly favored sites for breeding.

Damage

House flies are mechanical vectors of animal and human pathogens, particularly enteric diseases. At times, they have been found contaminated with viruses, bacteria, fungi, protozoa, and nematodes. These microbial organisms adhere to their tarsi, legs, mouthparts, and elsewhere as the flies move about their environment, and then these microbes can be relocated when the flies move to new food sources. Of particular concern is their movement from animal or human feces to food that will be eaten uncooked by humans. Also, when consumed by flies, some pathogens can be harbored in the mouthparts or alimentary canal for several days, and then be transmitted when flies defecate or regurgitate. In situations where plumbing is lacking, such as open latrines, serious health problems can develop, especially if there are outdoor food markets, hospitals, or slaughter houses nearby. Among the pathogens commonly transmitted by house flies are *Salmonella, Shigella, Campylobacter, Escherichia, Enterococcus, Chlamydia*, and many other species that cause illness. These flies are most commonly linked to outbreaks of diarrhea and shigellosis, but also are implicated in transmission of food poisoning, typhoid fever, dysentery, tuberculosis, anthrax, ophthalmia, and parasitic worms.

In addition to disease transmission, house flies can be a severe nuisance. These flies alight on and near people where they can be an irritant, especially for people who cannot wave them away, such as infants and the asleep or infirm. If left undisturbed, the flies may feed on the secretions of the mouth, nose and eyes. When human habitations are in close proximity to animal production facilities, the flies emanating from such operations usually prove to be a point of contention, sometimes resulting in legal actions.

Management

Tolerance of flies depends greatly on circumstances. In sensitive environments such as food preparation and packing facilities, restaurants, and hospitals, even small numbers of flies cannot be tolerated. In the context of livestock or poultry production, however, some flies are inevitable. Serious problems occur when cities or suburban development occur near poultry production facilities, as residents usually will not tolerate the large numbers of flies emanating from such facilities.

Fly populations are commonly monitored directly using sticky tapes or ribbons, or baited traps, to capture flies. Densities are also assessed indirectly using spot cards to assess the number vomit or fecal spots. Traps can be baited with molasses, sugar, fruit or meat, and often are used in combination with a device that captures the attracted flies. The sex pheromone (Z)-9-tricosene also functions as an aggregation pheromone, and is called muscalure. Muscalure is formulated with sugar as a commercially-available fly bait for local population suppression, as well as an enhancement for population monitoring.

Ultraviolet light traps can be used to assess population levels, but also serve as a non-chemical control technique that can be used indoors in both agricultural and non-agricultural areas. They normally function by electrocuting flies that enter the trap, though those used in restaurants typically have a sticky panel. Flies do not orient to traps from a great distance, so several are normally needed for them to be effective. Placement should include within 4–8 m of entryways, and within 1.5 m of the floor, to take advantage of fly flight behavior. They should be operated continuously, although they are most effective when the room lights are off.

The most important approach for fly management is sanitation. Flies should be deprived of suitable oviposition sites, and larval environments should be eliminated or made too dry for high levels of survival to occur. To accomplish this, removal of fecal material, agricultural refuse, spilled feed, soiled animal bedding, and food wastes should occur at least twice per week. Around homes and businesses, screening or covering of windows, doors or air doors, and trash containers proves useful in denying access of flies to breeding sites. Packaging household trash in plastic bags, and burying trash under at least 15 cm of soil and in sanitary landfills also helps to eliminate breeding. Trash cans and dumpsters should have tight-fitting lids; failing this, slow release fumigant insecticide dispensers are sometimes installed on the inside of the lids to reduce fly survival.

In agricultural areas, manure can be scattered over fields so that it quickly dries and becomes unsuitable for egg and larval survival. Composting of manure can be effective if the compost is properly maintained, including regular turning. Manure can also be liquefied and stored in lagoons anaerobically, though at some point the solids need to be separated. Manure can also be treated with an insecticide, though this method is highly discouraged as it interferes with biological control of flies, often resulting in a rebound of the fly population. More commonly, insecticides (especially insect growth regulators) can be fed to livestock, and residual insecticide in the manure inhibits fly breeding. In animal facilities, insecticides are often applied to the favored resting places of adults, or bait stations established to poison adults with either solid or liquid formulations. Continuous exposure of flies to insecticides has led to development of insecticide resistance to many insecticides.

Natural biological suppression of the house fly results primarily from the actions of certain chalcidoid wasps (Hymenoptera: Pteromalidae), of which many species have been associated with house fly around the world. Among the more important are *Muscidifurax* and *Sphalangia* spp. Ichneumonids and other parasitoids, as well as some predatory insects (especially histerids [Coleoptera: Histeridae] and staphylinids [Coleoptera: Staphylinidae]), also contribute to fly mortality, but under optimal fly breeding conditions the house fly quickly builds to high numbers. Augmentative biological control using insectary-reared parasitoids has been quite successful in some dairies, feedlots and poultry house situations. The species most often released for biological suppression in North America are *Muscidifurax raptor* Girault and Saunders, *M. raptorellus* Kogan and Legner, *Spalangia endius* Walker, and *S. nigroaenea* Curtis. These different species function better under different conditions, some performing better under cooler or warmer conditions, others parasitizing flies near the surface or deeper in the pupation medium.

► Flies

Howard, Leland Ossian

Leland Howard was born in Illinois on June 11, 1857, but moved with his parents to New York state when he was young, and it was in the vicinity of the town of Ithaca that he grew up. His interests in natural history were encouraged by his parents. However, when he entered Cornell University, it was to study civil engineering at the insistence of his mother, who by then was a widow. Leland transferred to the natural sciences without telling his mother, studied botany, geology, and chemistry, and worked in the laboratory of Henry Comstock. He graduated in 1877, and the following summer was contacted by Charles Riley to persuade him to go to Washington, DC, and work for the U.S. Department of Agriculture. The offer was accepted, and Howard moved there and worked on numerous projects in applied entomology, including brown-tail moth, gypsy moth, European corn borer, Japanese beetle, and scale insects, and taxonomy of Hymenoptera including Ichneumonidae, Braconidae, Chalcididae, and Prototrupoidea. He received an M.S. degree from Cornell University for his thesis "The morphology of Chalcididae." He and Riley were among the founders of the Entomological Society of Washington in 1884. He married in 1886. In 1894 after the resignation of Riley, Leland Howard was appointed Division Chief in his place. Books followed, such as (1901) "Mosquitoes, how they live, how they are classified, and how they may be destroyed," (1901) "The insect book," (1911) "The housefly – disease carrier," (1912–1917) with Dyar and Knab as coauthors "The mosquitoes of North and Central America and the West Indies," (1930) "A history of applied entomology," (1931) "The insect menace," and (1933) "Fighting the insects: the story of an entomologist." Awards followed in the form of honorary doctoral degrees from Georgetown, Pittsburgh, California, Toronto, and Rutgers universities, as well as an honorary M.D. degree from Georgetown University. In 1894 he became president of the American Association of Economic Entomologists, and in 1898 permanent secretary of the American Association for the Advancement of Science. He retired in 1927 and died on May 1, 1950, perhaps the most respected entomologist in American history.

Hübner, Jacob

Jacob Hübner was born in Augsburg, Germany, on June 20, 1761. His early life seems unrecorded. His great works were (1786–1790) "Beiträge zur Geschichte europäischer Schmetterlinge," (1793) "Sammlung äuserlesener Vogel und Schmetterlinge," (1805–1824) "Sammlung europäischer Schmetterlinge," (1806–1818) "Geschichte europäischer Schmetterlinge," and (1806–1824) "Sammlung exotische Schmetterlinge," (1806) "Tentamen determinationis, digestionis atque denominationis singularum stirpium Lepidopterorum…," and (1816) "Verzeichniss bekannter Schmetterlinge." All of the works deal with Lepidoptera (the second also with birds). Some of the works are magnificently illustrated with copper plates, making identification easy. The (1806–1824) "Sammlung exotische Schmetterlinge" deals with exotic species of Lepidoptera [meaning those that occur abroad] and includes several North American species, some of which are pests. The (1806) "Tentamen" was a work distributed to just a few entomologists, in which the author tried to fix scientific names, whose validity was subsequently hotly debated. He died in Augsburg on September 13, 1826. This man was the world's first great lepidopterist.

Huffaker, Carl Barton

Carl Huffaker was born in the state of Kentucky, USA, on September 30, 1914. His B.S. (1938) and M.S. (1939) degrees were from the University of Kentucky, with a Ph.D. from Ohio State University in 1942. His career began as medical entomologist with the U.S. Health and Sanitation Division of Inter-American Affairs, in Colombia, Haiti, and the Dominican Republic. He was recruited in 1946 by the Division of Biological Control of the University of California, stationed in Berkeley, and remained in Berkeley for the rest of his career. His work emphasized the biological control of weeds, and a major one was control of *Hypericum perforatum* (perforated St. Johnswort, or Klamath weed) in the Pacific coastal states of the USA. He published over 200 papers. In 1970–1983 he was director of the University of California's International Center of Integrated and Biological Control. He was co-leader (with Paul DeBach) of the Integrated Pest Management Project, sponsored by the U.S. Department of Agriculture, U.S. Environmental Protection Agency, and National Science Foundation, involving scientists from 18 universities. This project was so much associated with his leadership that it was widely known as "The Huffaker Project." He served as president of the Entomological Society of America and was elected to the National Academy of Sciences. He died on October 10, 1995, after a prolonged illness, and was survived by his wife and four children.

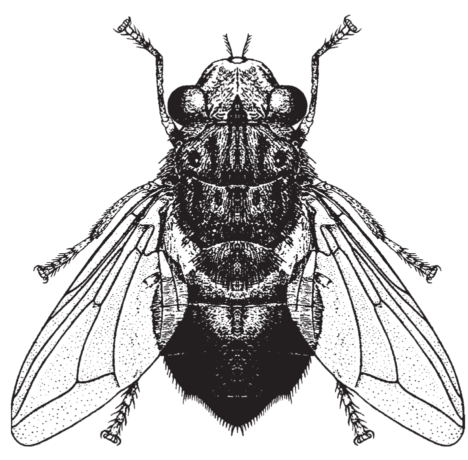
Human Botfly, *Dermatobia hominis* (Linneaus, Jr.) (Diptera: Oestridae)

EUGENE J. GERBERG
University of Florida, Gainesville, FL, USA

This large (approximately 12 mm) metallic blue fly is also known as tropical warble fly, human warble fly, and torsalo. The fly occurs in Mexico, Central and South America from approximately 25°N to 32°S latitude. The fly, which does not feed, is found primarily along the margins of forested areas. It affects livestock, pests and other mammals in addition to humans. On occasion birds are affected, and young livestock in Central and South America can be so heavily infested that they are killed by this fly. The life cycle is unusual, as the adult female botfly (Fig. 55) lays its white eggs on day-flying flies, particularly mosquitoes, usually of the genus *Psorophora*. The mosquito then inadvertently transports the eggs of the botfly to distant vertebrate hosts. The female lays 14–200 eggs on the ventral surface of the transport insect, usually mosquitoes, but sometimes ticks serve as hosts. The eggs are 1 mm in length. When the egg-bearing transport insect feeds on a warm-blooded host, the heat stimulates the *Dermatobia* eggs to hatch, the larva emerges and bores into the skin. They usually penetrate at the feeding site of the mosquito, but also can penetrate unbroken skin at the hair pore. This botfly has also been known to lay eggs on wet laundry. When a person puts on the egg-infested clothes, the larvae emerge from the eggs and bore into the skin. Within the skin, the larva grows, molts, and forms a cyst, boil or warble. In humans, lesions develop mainly in



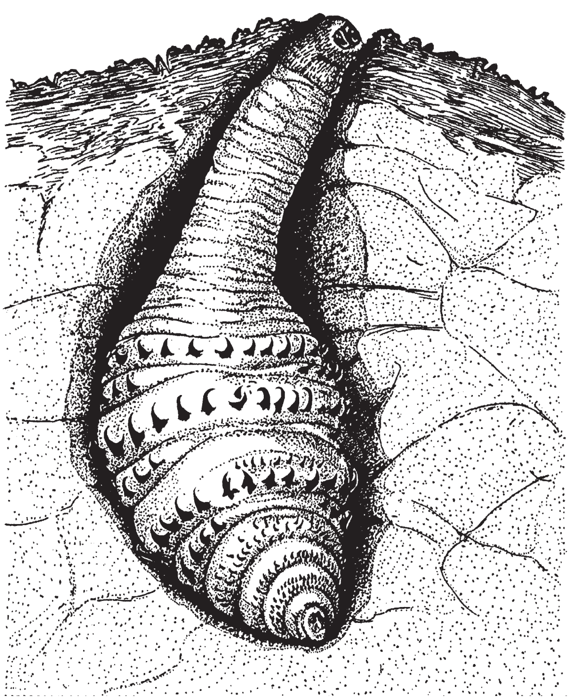
Human Botfly, *Dermatobia hominis* (Linneaus, Jr.) (Diptera: Oestridae), Figure 55 Adult female human botfly, *Dermatobia hominis* (adapted from James 1947).

the hands, wrists, ankles, neck, face and head, but occasionally also in the brain. Several larvae can inhabit the host simultaneously, and they normally stay close to the site of entry, using the entry pore as a breathing site. The inflamed pocket may itch, larval movement is painful, and eventually discharge emanates from the swelling. Larval development time is about 1–4 months. Though not generally considered life-threatening, it can be fatal to very young children (<5 years of age). The adult lifespan is brief, usually only a few days.

Treatment of humans usually involves exercising pressure on or around the lesion, resulting in expulsion. This may not be effective, however, and excision follow by treatment to prevent secondary infection may be preferable. Secondary infection is common.

The larva has twelve body segments. The first segment has mouthparts with hooks. Most of the body segments have spines. The larva pushes its posterior spiracles through the aperture in the skin to maintain a hole open to the external air. After several weeks the mature larva (Fig. 56) emerges during the night or early morning, and drops to the ground to pupate. The larval period lasts approximately 40 days. The last larval skin serves as a shell for the pupa. The pupal period lasts from 14 to 24 days, and then the adult emerges. The emerging females mate and seek a transport insect.

Management includes using mosquito repellents on the skin and clothing, and mosquito netting around beds. This benefits not only human botfly management, but helps prevent mosquito-vectored diseases such as dengue, yellow fever, and malaria.



Human Botfly, *Dermatobia hominis* (Linneaus, Jr.) (Diptera: Oestridae), Figure 56 **Mature larva of human botfly, *Dermatobia hominis*, shown infesting its host, with the posterior spiracles protruding from a hole in the host's skin (adapted from Craig and Faust 1940).**

Human Lice

TERRI L. MEINKING
University of Miami School of Medicine, Miami, FL, USA

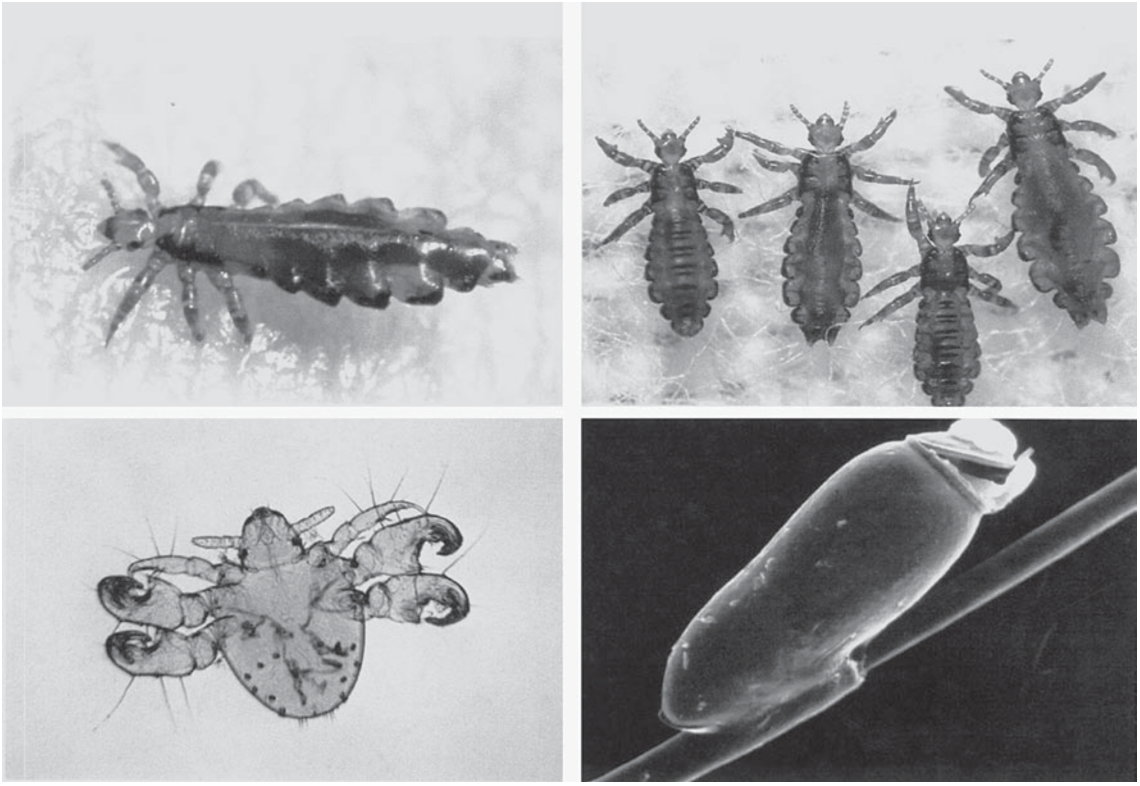
Lice are wingless, six-legged, bloodsucking insects that belong to the order Siphunculata (also called Anoplura, or combined with the chewing lice and called Phthiraptera). There are nearly 4,000 species of lice recognized, although only 560 species suck blood and feed on mammals. Lice are very host specific; therefore, human lice cannot be transmitted between mammals. There are only three species of lice that infest humans: *Pediculus humanus humanus*, the body or "clothing" louse; *Pediculus humanus capitis*, the head louse; and *Phthirus* (or *Pthirus*) *pubis*, the pubic or "crab" louse (Fig. 57).

Biology

Lice are hemimetabolic, meaning that they do not go through a complete metamorphosis like mosquitoes or fleas. After a 7–12 day incubation period, nymphs are hatched from eggs or "nits." Almost immediately, the nymph must feed on a human host to avoid death from starvation and dehydration.

Nymphs resemble miniature adults and undergo three nymphal instars before maturation. Several feedings occur between each molt of the chitinous exoskeleton. When feeding, the body structure of the louse is capable of expanding by one third of its body weight per meal. Crab and head lice feed regularly every 4–6 h, although the body louse can survive several days without a blood meal.

It is not until the 3rd and final molt that the sex is determined. It is more difficult to identify the gender of *P(h)thirus* than *Pediculus*. Within 2 days of maturation, the female will feed several times, copulate, and begin laying eggs. The female head louse lays an average of 3–6 eggs per day, with crab lice laying fewer and body lice laying more. The female louse attaches nits to hairs



Human Lice, Figure 57 **Human lice. *Upper left*: adult female head louse with blood meal; *upper right*: alternating male and female head lice (male-female-male-female); *lower left*: nymph of crab louse; *lower right*: scanning electron micrograph of head louse egg (nit).**

(or ibers in the case of body lice) by secreting a glue that hardens on contact with air.

In each species, females are usually 20% larger than males, with longer, wider, and rounder bodies. Only males have dark brown stripes on their back. Only females, however, have an invaginated V-shape located on the posterior end of their body, in order to deposit eggs on the hair shaft or cloth fiber. The average life span of a louse is 30–42 days.

Habitat and Epidemiology

Pediculus humanus

The body louse does not live on the body, but in clothing or bedding, and only travels to the host to feed. Nits are laid on cloth fibers, particularly in the seams and collars. Although people associate all lice with poor hygiene, only body lice infestations are due to lack of cleanliness. Infestations are common in individuals who are unable to change or wash their clothing. Frequently, these people are forced to live in crowded, unsanitary environments, such as those exposed to war, natural disaster, refugee status, or homelessness.

Pediculus capitis

Head lice are 25% smaller than body lice, but otherwise are identical in appearance. Head lice live on the scalp, preferring a clean, healthy head. Nits are usually laid close to the scalp for warmth, although in tropical climates, they can be found anywhere on the hair shaft. The female louse deposits nits on the hair shaft with a biological adhesive for which there is no known solvent. Hair debris such as gel, spray, and dandruff, are often mistaken for nits. However, hair residue slides easily off the hair, whereas nits are firmly cemented to the hair shaft. Head lice infestations are most common in children aged 3–11 due to their frequent head to head contact during play. Other close contacts, such as family members, teachers and day care workers, may also become infested. Head lice transmission can also occur by sharing of brushes, combs, hats, helmets, and other headgear and hair accessories.

P(h)thirus pubis

Crab lice are not discriminatory in host choice, and are found in all levels of society and various ethnic groups. Crab lice are typically located in the pubic and perianal areas, but can be also found on any hairy part of the body. Secondary sites of infestation commonly include beards, mustaches, scalp, eyebrows, eyelashes, and axillae. Transmission generally occurs by sexual contact, although crab lice can also be transmitted by infested towels and bedding. It is not uncommon to find crab lice with their craws caught in the fiber loops of a towel recently used by an infested individual. Fomite transmission occurs more commonly than originally thought because adult crab lice are viable off the host for at least 36 h.

Disease Transmission

Pediculus humanus

Disease transmission is not caused by the bite of the louse, but by infected fecal pellets that can be scratched into the bite site or by an abrasion in the skin. The body louse is known to transmit the following diseases: epidemic typhus (caused by *Rickettsia prowazekii*), murine typhus (caused by *Rickettsia typhii*, trench fever (caused by *Bartonella quintana*), and relapsing fever (caused by *Borrelia recurrentis*).

Pediculus capitis and *P(h)thirus pubis*

Head and crab lice are known to mechanically transmit group A *Streptococcus pyogenes* and *Staphylococcus aureus*. Head and crab lice have not yet been investigated as transmitters of blood borne diseases.

Treatment

Pediculus humanus

Treatment of body lice includes washing clothing and bedding in hot water and then drying in a hot cycle (65°C, 149°F). Drug therapies, such as permethrin or malathion dusting powders, are effective treatment methods in instances of mass infestation. In individual cases, prescription permethrin 5% topical cream or oral ivermectin are recommended treatments.

Pediculus capitis

Treatments for head lice include lindane, malathion, permethrin or natural pyrethrin products. Lindane products demonstrate resistance and may have harmful toxicity effects to the central nervous system (CNS). Over-the-counter treatment with 1% permethrin or natural pyrethrin products can be used, but resistance has been reported in the United States and other countries. Currently, the most effective treatments for head lice include prescription malathion lotion, oral ivermectin (off-label), certain products with anise oil and alcohol, and nit combs as adjunct therapy.

P(h)thirus pubis

Although head lice products may be used in treating crab lice, 5% permethrin cream (prescription treatment for scabies) or oral ivermectin are the most effective treatments. Medication should be applied to all hairy areas of the body, including the scalp.

Phthiriasis palpebrarum

Topical treatments should not be used around the eye area. Vaseline is an effective treatment for crab lice of the eyelashes, as it suffocates lice and eggs and lubricates the lashes, making nit removal easier and is non-toxic.

Human Lymphatic Filariasis (Elephantiasis)

JAI K. NAYAR
University of Florida, Vero Beach, FL, USA

Human lymphatic filariasis (elephantiasis) is a debilitating and deforming disease caused by infection with parasitic round worms belonging to the phylum Nematoda, order Spirurida, superfamily Filarioidea, and family Filariidae, genera *Wuchereria* and *Brugia*, species *W. bancrofti* and species *B. malayi* and *B. timori*. Humans are the final and exclusive host of *W. bancrofti*. *Brugia malayi*, in addition to infecting humans, has other strains that infect some feline and/or monkey species, but the life-cycles in humans and in these other animals generally remain epidemiologically distinct. These parasites complete their development in two host types, the human (the final and definitive host) or other vertebrates, and the mosquito (the intermediate host). The disease spreads from person to person by the bites of infected mosquitoes.

Approximately 120 million people are infected in at least 80 countries of the world throughout the tropics or subtropics (41 North latitude to 31 South latitude), that include South America, Cuba, Puerto Rico, West Indies, Africa, Spain, Turkey, Asia, Australia, and many South Pacific Islands. It is estimated that one billion (20% of the world's population) are at risk of acquiring infection. Ninety percent of these infections are caused by *W. bancrofti*. The remaining 10% of infections caused by *B. malayi* are restricted to southeast Asia, including India, Thailand, Vietnam, southern China, and the south Pacific islands, and by *B. timori* in the Lesser Sunda Islands of eastern Indonesia.

Both *W. bancrofti* and *B. malayi* have four types based on the density of microfilariae in the peripheral circulation: nocturnally periodic, nocturnally subperiodic, diurnally subperiodic and diurnally periodic. Nocturnally periodic type of *W. bancrofti* is generally found in the slum areas of cities (urban type) and rural areas (rural type). A nocturnally subperiodic type is found in Thailand and Vietnam. The diurnally subperiodic type is rural and found in the eastern Pacific islands and the diurnally periodic type of *B. malayi* is mostly found in areas with irrigated rice fields.

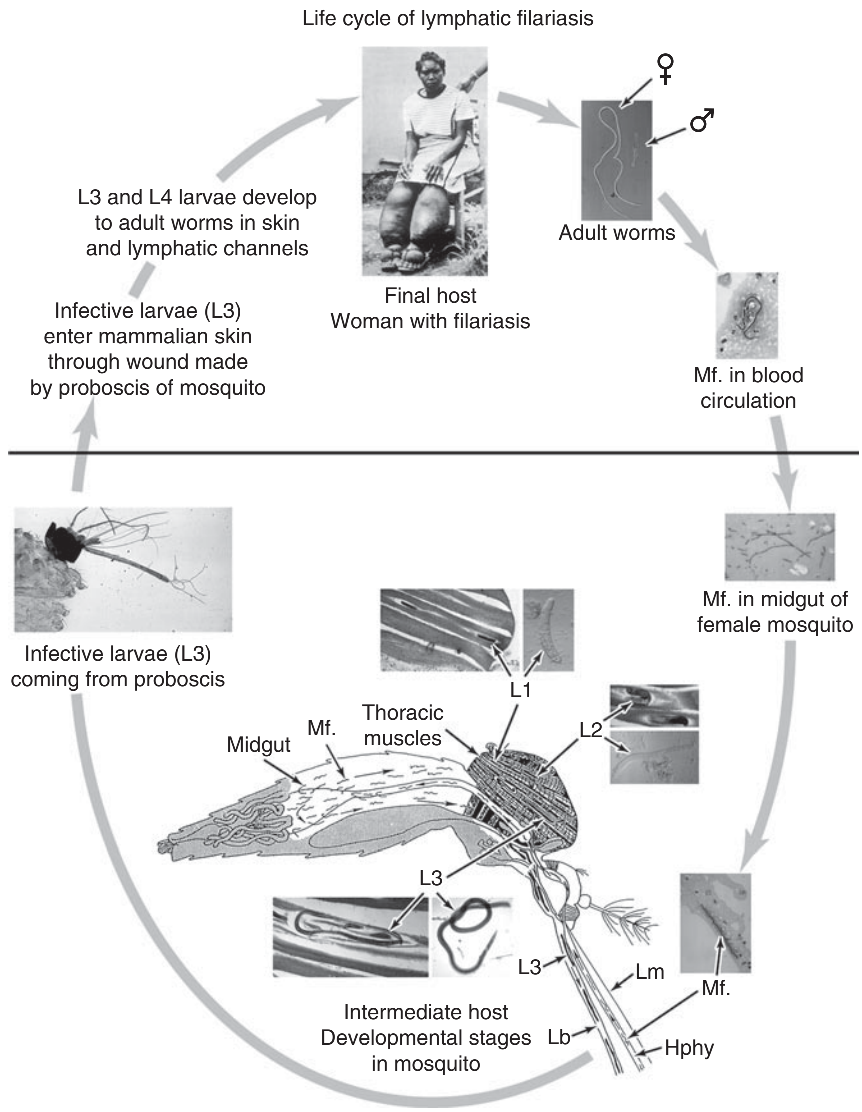
The adult worms that cause the disease live for 7–10 years in the victim's lymph vessels, near to and in lymph nodes. Adult females are long and slender (*W. bancrofti* – 6–10 cm long and 300 μm wide, *B. malayi* – 48 mm long, and *B. timori* – 40 mm long) with a smooth cuticle and bluntly rounded ends. The head is slightly swollen and bears two circles of well-defined papillae. The mouth is small; a buccal cavity is lacking. Males are much smaller (mean length for *W. bancrofti* – 40 mm, *B. malayi* – 18 mm, and *B. timori* – 15 μm) with a fingerlike tail. The vulva of the female is near the level of the middle of the esophagus. Adult females, after mating, produce microfilariae (mean length for *W. bancrofti* – 290 μm, *B. malayi* – 222 μm and *B. timori* – 310 μm) which are found in the blood and peripheral circulation. In endemic areas, in the nocturnally periodic type, the level of microfilariae in the peripheral circulation of humans is controlled by a circadian periodicity or 24 h light-dark cycle, that is, the numbers of microfilariae in the peripheral circulation show a marked peak during the night. In the day time the microfilariae move mainly to the pulmonary capillaries and very few are found in the peripheral circulation. The appearance of large numbers of microfilariae in the peripheral circulation at night coincides with the biting activity of the local mosquito vector. In the nocturnally subperiodic, diurnally subperiodic and diurnally periodic types, microfilariae can be found in the peripheral circulation at all hours of day and night. The microfilariae do not develop further in humans, but only in susceptible species of mosquitoes.

Development of microfilariae to the L_3 or infective larval stage in mosquitoes is identical in all three species (Fig. 58). In mosquitoes, ingested microfilariae in the blood meal do not multiply but grow to the L_3 stage after two molts with 2 weeks. Within a day after the microfilariae are ingested, they shed their sheath and penetrate the midgut wall, move in to the hemocoel, then migrate to the thoracic muscles and lodge themselves intracellularly. The slender active microfilaria transforms to the short thick inactive sausage-stage or L_1 larva within the next 2–4 days. The L_1 larva has a cuticle which forms a conspicuous tail, characteristic of this stage. In the genus *Brugia* one to two nuclei are present in the tail. Five to six days after being ingested as microfilariae, the L_1 larva molts to the L_2 stage. The L_2 larva grows rapidly and has a thin cuticle which can be seen at the caudal end as a short tail. There are one or two papillae at the caudal end. During the second molt the larva sheds its cuticle and becomes the infective L_3 larva. The L_3 larva grows further in length but not in width, moving actively to the hemocoel of the mosquito, first towards the abdomen and later to the head and proboscis. The caudal end of *W. bancrofti* is characterized by having three teat-like papillae of equal size, whereas in the *Brugia*, the central papilla is the most prominent. The duration of larval development in mosquito vectors is affected by the ambient temperature; generally, the warmer it is the more rapid the development. It usually takes 10–14 days for *W. bancrofti* to reach the infective stage, and 7–10 days for *Brugia* species.

When the now infective mosquito bites a human, some or all the infective larvae escape from the proboscis onto the skin and actively enter the wound made by the mosquito. The L_3 larvae move to the lymphatic system and start to develop and molt to the L_4 stage followed by the L_5 or young adults and finally to the mature male and female worms. After fertilization, the female worms produce microfilariae, which find their way from the lymphatic system to the blood circulation. The pre-patent period from the entrance of L_3 when the mosquito bites the human to the appearance of microfilariae in the peripheral blood, is about 3–4 months for *Brugia* sp. and about 8–9 months for *W. bancrofti*.

The intermediate hosts (mosquitoes belonging to the genera *Aedes*, *Culex*, *Anopheles*, and *Mansonia* – about 77 species) become infected when they take an infective blood meal from an infected definitive host (man). Urban *W. bancrofti* with noctural periodicity is transmitted mainly by *Culex quinquefasciatus* in tropical regions, by *Culex pipiens pallens* in China and Japan, and *Culex pipiens molestus* in the eastern Mediterranean. Rural *W. bancrofti* that is nocturnally subperiodic over most of its range is mainly transmitted by several species of *Anopheles* in the western Pacific islands and Africa, occasionally *Aedes* spp. in eastern Pacific islands, and rarely by *Mansonia uniformis* in Sri Lanka. The diurnally subperiodic type is transmitted predominantly by several species of *Aedes,* and the nocturnally subperiodic type by the mosquitoes of the *Aedes niveus* group. The nocturnally periodic type of *B. malayi* is transmitted in certain regions by *Mansonia* spp. and in other regions by *Anopheles barbirostris* or *An. campestris* in Indonesia and Malaysia. *Aedes togoi* is a vector in coastal parts of the Republic of Korea, and parts of southern China. The nocturnally subperiodic type of *B. malayi* is transmitted by *Mansonia* spp. *B. timori* is transmitted by *Anopheles barbirostris*.

Clinical course of lymphatic filariasis in humans can be divided into three distinct stages, asymptomatic, acute and chronic, generally progressing in that order. The asymptomatic stage is characterized by the presence of microfilariae in the peripheral blood, although there are no clinical manifestations of filariasis. The acute symptomatic



Human Lymphatic Filariasis (Elephantiasis), Figure 58 **Life cycle of lymphatic filariasis. Stages of filarial worm in human: L_3 = third stage larvae and L_4 = fourth stage larvae. stage is characterized by recurrent attacks of fever associated with inflammation of the lymph nodes (lymphadenitis) and lymph vessels (lymphangitis). In bancroftian filariasis recurrent attacks of fever associated with lymphadenitis are less frequently seen than in brugian filariasis. In addition to the lymph nodes in the inguinal, axillary and epitrochlear regions, the lymphatic system of the male genitalia is frequently affected. Typically, each attack of fever and lymphadenitis lasts for several days or weeks and usually subsides spontaneously following bed-rest. The chronic signs of filariasis do not develop usually before the age of 15 years and only a small portion of the community is affected. During the chronic stage microfilariae are usually absent from the blood.

In bancroftian filariasis, the occurrence of the major chronic signs are accumulation of serous fluid in the body cavity (hydrocele), appearance of microfilariae in urine (chyluria), swelling of body parts (lymphodema) and hardening and thickening of the skin of swollen body parts (elephantiasis), which may differ from one area to another. The most common are hydrocele and swelling of the testis, followed by elephantiasis of the entire lower limb, the entire arm, the vulva, and the breast, in descending order of frequency. In brugian filariasis, the leg below the knee or the arm below the elbow are characteristically affected. Genital involvement has not been reported for brugian filariasis.

The worms in the lymphatic system cause tissue changes which restrict normal flow of lymph and result in swelling, fibrosis and eventually secondary infections in the affected tissues. The lower extremities and groin are the parts most likely to be affected. In its severest form, lymphatic filariasis causes elephantiasis, or dramatic swelling of limbs (usually the leg) and genitals (usually the scrotum). These conditions have a devastating effect on the quality of life of those affected, impacting them not only physically, but also emotionally and economically.

Human lymphatic filariasis is a disease which develops over several years and is localized in communities. Individuals can be treated with albendazole plus either diethylcarbamazine (DEC) or ivermectin (Mectizan®), which have been shown to be effective in removing microfilariae from the blood for a full year after treatment and slowly killing the adult stage of the parasite. Recently, the World Health Organization has adopted the policy of a Global Program to Eliminate Lymphatic Filariasis by 2020. The strategy for such a program is based on two concepts: first, to interrupt transmission of infection and second, to alleviate the suffering of infected individuals through management of the disease. The first concept includes treatment of each individual in the community with a single dose of either of the two-drug combinations, albendazole and DEC or albendazole and ivermectin, once a year for several years and to implement vector control practices in each infected community. The second concept is to alleviate the suffering caused by the disease by educating the community about the programs to raise awareness in affected patients. This would promote the benefits of intensive local hygiene, vector control and possible improvement, both in the damage that has already occurred, and in preventing the debilitating and painful, acute episodes of inflammation.

Human Scabies

JOHN P. SMITH
Florida A & M University, Panama City, FL, USA

Scabies is a skin condition, also known as “7 year itch” or “Norwegian itch,” produced by almost invisible parasitic mites commonly referred to as “itch mites,” *Sarcoptes scabiei* (DeGeer).

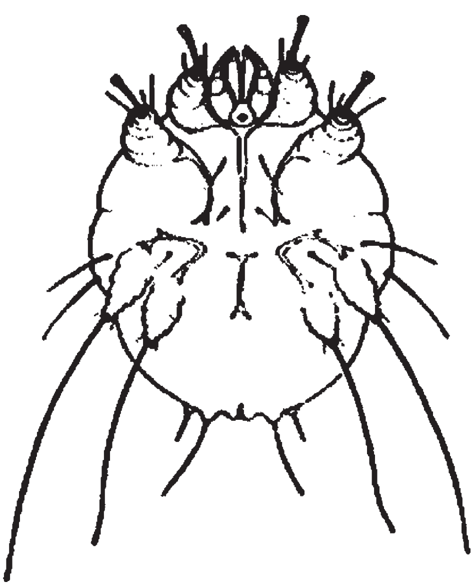
There are several varieties of itch mites that can be distinguished only by the host they attack. Dog, pig, horse and human itch mites are known to exist. Though it is possible for people to be infested with non-human species, usually little to no adverse effect is produced.

Biology

Itch mite nymphs and adults are whitish in color and have eight short, pointed legs equipped with suction devices on the two front pairs and long hairs on the remaining hind legs (Fig. 59). The life cycle of the human itch mite consists of the egg, six-legged larval, eight-legged nymphal and adult stages. The period from egg to mature adult takes 10–14 days at body temperature. Itch mites seldom survive more than a few hours off the host.

Injury and Spread

Mature female mites are responsible for the majority of the skin irritation caused by tunneling in the upper skin layer. Eggs are deposited in these tunnels that extend over one inch in length at 2–3 day intervals over a 2-month period. Once the eggs hatch in 3–8 days, emerging larvae exit the tunnels and remain on or near the skin surface until they reach adult stage. During this time, male mites move about the surface where it is thought they mate with females. These newly fertilized female mites are highly active and are thought to be the contagious stage. Itch mites are primarily transmitted through close personal contact, though bed linens and clothing may serve as secondary sources.



Human Scabies, Figure 59 The human itch mite, *Sarcoptes scabiei* (actual size about the size of this period ".").

Signs, Symptoms and Diagnosis

Red patches of skin on various regions of the body characterize scabies. The most common infested areas include: wrists, elbows, breasts, penis, bends of the knees, between the fingers, and between the buttocks. Sometimes the actual raised tunnels or bumps produced by the mites can be seen. Tunneling mites may release toxic substances that produce severe itching. Often, constant itching causes the individual to become pale and haggard from loss of sleep. Scratching to relieve itching frequently leads to secondary bacterial infections that may become more serious than actual scabies. Widespread allergic reactions also may occur due to the mite presence.

First-time infestations often cause no immediate itching, although sensitivity normally occurs after 1 month. Thereafter, subsequent infestations result in reactions within the first 24 h. Infestations producing these symptoms typically involve less than 12 adult mites. Diagnosis is best made by applying mineral oil to the affected skin surface where tunnels occur, scraping the skin with a scalpel, and examining for the mites under a microscope.

Control

Recognize signs and symptoms of a possible infestation and attempt to recover mites for identification.

Inspect all individuals coming in contact with infested person(s).

Treat all infested persons with one of the recommended miticides listed in the following treatment section. Prophylactic treatment of non-infested persons should be avoided unless screening programs are not effectively suppressing an outbreak.

Isolate infested person(s) for 24 h after treatment has been applied.

Machine wash bed linens, clothing and all other possible contaminated articles in hot (130°F) water and soap, or tightly seal non-washables in plastic bags for 2 weeks.

Treatment

Ointments containing 5% permethrin cream (Elimite®), benzyl benzoate, malathion (Derbac-M®), crotamiton (Eurox®), tetraethylthiuram monosulfide (Tetmosol®), sulfur, thiabendazole, or 1% lindane (Kwell®) are the most widely recommended medications for itch mite control. These products are available only through a physician by prescription and should be applied strictly according to labeled and/or prescribed directions.

► Mites

Hungerford, Herbert Barker

Herbert Hungerford was born in Kansas on August 30, 1885. He grew up on a farm and trained as a teacher, becoming teacher, principal, and superintendent of schools between 1904 and 1909. Having married in 1905, he entered the University of Kansas in 1909 and obtained a bachelor's degree in 1911. He immediately became a member of the university faculty, and in 1924 was appointed head of the Department of Entomology and State Entomologist. His research interest was the taxonomy, ecology and behavior of water bugs, especially Corixidae and Notonectidae. He built a large collection of aquatic and semiaquatic Hemiptera on which he continued working after retirement in 1956. In 1936, he was elected president of the Entomological Society of America and in 1953 of the Society of Systematic Zoology. He died on May 13, 1963.

Hydropsychidae

A family of caddisflies (order Trichoptera). They commonly are known as net-spinning caddisflies.

► Caddisflies

Hydropyle

Hydropyles are structures that allow the uptake of water, and are found on some eggs. Water is absorbed when the embryo is rapidly growing, and the egg enlarges in size. The eggs of most aquatic insects absorb water, but terrestrial insects that deposit their eggs where moisture may occur (e.g., grasshopper eggs in soil) also may have eggs that enlarge. The hydropyle is formed interiorly from the serosal layer, but may be visible externally by an extension of the chorion.

► Eggs of Insects

Hydroscaphidae

A family of beetles (order Coleoptera). They commonly are known as skiff beetles.

► Beetles

Hydrostatic Skeleton

Maintenance of body form in soft-bodied insects such as caterpillars by muscles exerting pressure on the fluid-filled body.

Hygrokinesis

A kinesis response with respect to moisture.

Hygrotaxis

A taxis response with respect to moisture.

Hymenopodidae

A family of praying mantids (Mantodea).

► Praying Mantids

Hymenoptera

An order of insects. They commonly are known as wasps, ants, bees and sawflies.

► Wasps, Ants, Bees and Sawflies

Hypericin

CYRUS ABIVARDI
Swiss Federal Institute of Technology, Zurich, Switzerland

Hypericin, well known for its photodynamic action, is an aromatic polycyclic compound (a highly condensed quinone) mainly synthesized by plants of the genus *Hypericum* (family Hypericaceae). A survey covering 200 species within the family Hypericaceae, revealed that ca. 60% of these plants contained Hypericin. It is usually confined to certain species of the genus *Hypericum*, e.g., the St. John's worts, a common pasture weed throughout the world. While this compound is found in the leaves, stem and flowers of *Hypericum perforatum*, it occurs only in multicellular trichomes of the calyx of *H. hirsutum*.

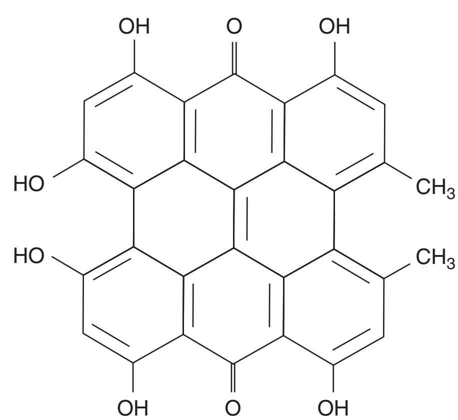
Hypericin (Fig. 60) and its derivatives have also been recorded from other sources. Hypericin has been found in the chromophore of the photoreceptor of *Stenor coeruleus* (a blue-green ciliate) and in the integument of an Australian insect (*Nipaecoccus aurilanatus*). Fagopyrin (a derivative of hypericin) is found in buckwheat (*Fagopyrum esculentum*). In addition, pencilliopsin, which can be oxidized and irradiated to form hypericin, has been isolated from a mold (*Penicilliopsis clavariaeformis*).

Biological Activity

Effects on Insects

Although photodynamic reactions are generally not species specific, the phototoxicity of hypericin is known in only a few systems. Its phototoxicity toward grazing animals, antiviral activity against HIV-1, and insecticidal effect on Aedes mosquito larvae have been reported.

It is well established that the active wavelengths in hypericin toxicity are greater than 500 nm. For larvae of the sphingid *Manduca sexta*, the LD_{50} of purified hypericin was 16 μg/g larval initial fresh weight in constant light (22 W/m^2), but reduced irradiance resulted in decreased mortality. Sublethal applications of



Hypericin, Figure 60 **Structure of hypericin ($C_{30}H_{16}O_8$). an aromatic polycyclic compound mainly synthesized by plants of the genus *Hypericum* (family Hypericaceae).**

hypericin retarded larval growth (body fresh weight) in a dose-dependent manner. While the phototoxic effect was lost when larvae were maintained in darkness for more than 8 h before irradiation, the potential for light-dependent mortality was retained if larvae were starved before irradiation.

Interestingly, several insects with different lifestyles have been reported to overcome the phototoxic effects of hypericin by appropriate behavioral and biochemical strategies: (i) by avoiding light, (ii) by feeding on the plant parts lacking hypericin, or (iii) by decomposing hypericin. Studies on the behavioral and biochemical adaptations of generalist and specialist herbivorous insects feeding on *Hypericum perforatum* (Guttiferae) have revealed that the generalists *Tettigonia viridissima* L., *Ruspolia nitidula* Scopoli, and *Conocephalus discolor* Thunberg preferentially fed on the part of the leaf lacking the phototoxic, hypericin-laden dark glands. In contrast, the specialists *Galeruca tanaceti* L., *Chrysolina geminata* Paykull, and *Cloantha perspicillaris* Boisduval showed no discriminatory feeding pattern but exhibited a negative phototaxis that is presumed to be an efficient strategy to overcome the light-induced toxicity of hypericin.

Another mechanism of defense for insects feeding on phototoxic plants may be the presence of antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPOX), and glutathione reductase (GR). The activities of these enzymes were examined in the larvae of three lepidoptera: *Ostrinia nubilalis*, *Manduca sexta*, and *Anaitis plagiata*. The highest levels of antioxidant enzyme activity were found in *A. plagiata*, a specialist feeder on *Hypericum perforatum*, a plant which contains high levels of the phototoxin hypericin. Larvae of *A. plagiata* that were fed leaf discs treated with hypericin exhibited a short-term, concentration-dependent decline in enzyme activity. Longer term studies with *A. plagiata* fed either the phototoxic *H. perforatum*, or the closely related but non-phototoxic *H. calycinum*, resulted in increased CAT and GR activity in the larvae that were fed the phototoxic plant whereas SOD activity was not significantly different. These results suggest that CAT and GR may be inducible defenses against phototoxins.

Similar results also have been reported for other generalist and specialist herbivorous insects feeding on *Hypericum perforatum* (Guttiferae). The specialist insects had lower constitutive activities of two antioxidant enzymes, glutathione S-transferase and glutathione reductase, than the generalists. Both enzymes are considered to be biochemical adaptations used by phytophagous insects to attenuate the oxidative stress caused by photosensitization.

Medicinal Use and Potential

H. perforatum is presently a source for the preparation of several herbal drugs. There is increasing interest in use of the herbal preparation St. John's wort (*Hypericum perforatum*). Hypericin, the major active ingredient, has many psychoactive properties. The herbal preparation is sold as a nutritional supplement and is recommended for numerous conditions, including depression, anxiety, insomnia and inflammation.

Hypericin, and the structurally related quinone, pseudohypericin, have also been described as having potent antiviral effects, in that they could inhibit both retroviral replication in cell culture and could also control the symptoms of retovirus-induced disease in mice. It has been shown to have impressive light-mediated antiviral activities against different viruses including human immunodeficiency virus type 1 (HIV-1).

Strategies have been studied using hypericin to inactivate enveloped viruses in red blood cell concentrates. Photodynamically induced virus inactivation appears promising in preventing transmission of enveloped virus infections in transfusible blood products. The results of studies on the practical potential of hypericin as a photosensitizer to inactivate key enveloped viruses in packed red blood cell concentrates (PRC) are promising. Also, hypericin induces differentiation and apoptosis in neoplastic cells and exerts phototoxic effects on two cancer cell lines: (i) PC-3, a prostatic adenocarcinoma non-responsive to androgen therapy and (ii) LNCaP, a lymphonodal metastasis of prostate carcinoma responsive to androgen therapy. The results suggest that photodynamic therapy with hypericin could be an alternative approach to the treatment of prostatic tumors, and could be beneficial in tumors that are non-responsive to androgen therapy.

Effects on Domestic Animals

Recently, it has been found that the photosensitization of grazing animals following the ingestion of certain *Hypericum* species is due to the presence of hypericin. This disease which is known as hypericism (or "bighead" in sheep) is manifested by skin irritation and inflammation. It is most commonly caused by the ingestion of *H. perforatum*.

Hypericin must be ingested by mammals to result in hypericism. Unlike the furanocoumarins, it does not appear to be absorbed through the outer layer of the epidermis. After ingestion of the plants, animals remain sensitive to sunlight for a week or more. Skin irritation and inflammation is most severe in regions of unpigmented skin devoid of hair (e.g., the mouth, nose and ears). Other effects are central nervous system disturbances and increase in body temperature. It is, however, rarely fatal and does not appear to deter grazing animals. Nevertheless, sunlight-associated hyperthermia is a consistent and rapidly developing clinical sign in sheep intoxicated by St. John's wort.

Mode of Action

Many secondary plant compounds are capable of photoactivation, resulting in the production of toxic oxygen. Early studies on mammals have shown that the photosensitizing action of hypericin requires both visible light and oxygen. Hypericin promotes Type II photodynamic reactions. Hypericin is known to generate singlet oxygen, and possibly other reactive species, in the presence of light (650–700 nm). It is thought that such photoproducts inactivate viruses by damaging the membrane, since non-enveloped viruses appear to be resistant to hypericin.

Hypermetamorphosis

A type of development in which there is more than one distinct form of the larval stage. For example, in the Meloidae, young larvae must locate a food source, but older larvae remain and feed on that source; thus, the long-legged, mobile young larvae are replaced by sessile older larvae with shorter, less functional legs.

Hyperparasitoid

An insect parasitoid that parasitizes another parasitoid. A secondary parasitoid.

Hyperplasia

An increase in the number of functional units of an organ (organelles, cells, tissues), excluding tumor formation.

Hypertely

PIERRE JOLIVET
Paris, France

The concept of hypertely, a non-Darwinian concept, has been mainly developed by Lucien Cuénot and René Jeannel in France, though originally advanced by certain stubborn lamarckists of the middle of the last century. It can be defined as an excessive development of certain organs, in size and complexity, mostly among males, and was attributed to orthogenesis. The theory of orthogenesis was an alternative to Darwinian natural selection, and at one time found support in the USA and Germany, especially among palaeontologists and developmental biologists. Orthogenesis can be defined as evolutionary change proceeding consistently in one direction, resulting from a tendency to accumulate similar mutations in successive generations rather than by natural selection. Thus, the purported result of hypertely was the development of certain organs (horns, tusks, legs, antlers, etc.) up to the extent of a certain monstrosity.

Such a concept is very much debatable and may be explained as the result of a normal Darwinian selection and just part of natural biodiversity. Such organs are often useful or at least harmless, and the best proof of it is that the animals endowed with them survive, multiply and do not seem to be ill at ease with them. Beetle horns help the males when fighting over access to females, long legs of Sagrines help them, when mating, and also to clutch on the stems, thoracic extensions among the Membracidae or certain Curculionidae can help in camouflage and, in all cases, the insects survive well and reproduce. The extreme flattening of the *Mormolyce* (Carabidae) in Indonesia allow them to hide under loose pieces of bark during the day, and similarly the aberrant tenebrionid *Cossyphus* can easily slide under the bark of *Acacia* trees in the Sudan. *Hololepta plana* (Histeridae) lives under the loose bark of felled trees; it is so flattened that its height is only a small fraction of its width. Of course many beetles are flattened, but this is an adaptation to their habitat. Mimicry and camouflage are not hypertely, and may provide protection for the animal against his predators. It has been demonstrated recently that pronotal horns help some beetles during ecdysis, at least among *Onthophagus* (Scarabaeidae), which means that allometry or differential growing is not just a meaningless developmental process. An apparently non-adaptive organ is often an organ not functionally well understood, or at least an organ that was adaptive before some change occurred in the environment (Figs. 61 and 62).

Hypertely can be defined as "beyond the bounds of the useful." Some dictionaries give the following definition: "excessive development of certain organs, in size and complexity, among certain species, mostly among males." The horns of the Scarabaeidae and the mandibles of the Lucanidae might sometimes appear excessive, but they help in defense, and during the fight among males the winner is often the most well equipped with such a horn. The thoracic prolongations of the Membracidae can seem a bit odd, but they serve as camouflage. The long thoracic horn of the *Cranopoeus* (Curculionidae) mimics the seeds of the host tree. The excessive development of certain organs (antennae, legs) of cavernicolous (cave-dwelling) insects compensate for the loss of eyes. The pseudophysogastry (artificial swelling of the abdomen, not connected with ovary development) of some cavernicolous insects is more difficult to interpret, but it increases the isolation of the abdomen against cold or humidity. Pseudophysogastry is known also among termiticolous (living in association with termites) insects, also living in a close and isolated world. The long rostrum of the Brentidae help in digging their tunnels. The enormous legs of certain weevils such as

Thailand (figs. a and b, after Paulian, 1988; c, after Cuénot and Tétry, 1951; d, e, f, after Grassé, 1951; g, after Jolivet and Verma, 2002).**

neotropical Cerambycidae (*Acrocinus*), Malagasy eumolpines (*Arsoa*; Chrysomelidae) and the big femora of the sagrines (Chrysomelidae), are used for holding on to the stems or mating. The sternal horn of certain *Doryphora* (Chrysomelidae) is used as a weapon in fighting between males. It is also evident that sensorial dimples on the abdomen of many beetles have their usefulness in detection of humidity or mates. Examples are many of those organs which appear excessively developed, but they are not functionally meaningless.

For Darwinists, the concept of hypertely is a mistake of interpretation, because although the character may look functionless, it is not without its functional significance. The phenomenon seems coherent and related to some function such as sexual selection, mimicry, self defense, clutching, lodging, etc. Some French zoologists such as Jeannel, Cuénot, and Grassé could, in the past, see hypertely as the result of extreme orthogenesis. Cases of hypertely were suggested to include the bent tusks of the mammoths, the bent canines of the babirussa, the teeth of the *Machairodus* or *Smilodon*, the antlers of the Irish deer, the horns of the Tithanotherians, the sword of the saw fish (*Pristis*) and the swordfish (*Xiphias*), the long spines of certain urchins (Cidarids), the dermic armor of the Stegosaurians, the complex septa of certain Ammonites, the thoracic expansions of the Membracidae, the horns of the Scarabeids, the mandibles of the Lucanids, the foliaceous expansions of the legs of certain Hemiptera or Diptera, the reduced hind wings of the Nemopteridae, and even the long legs of the Tipulidae. However, these seemingly unusual structures can be explained. For example, the long legs of those Diptera prevent them from getting captured on spider webs when they dance rhythmically, and the mandibles of the Lucanidae and the horns of the Scarabeidae help them when fighting (and those organs have some other functions too, recently decrypted). Some beetles have a very elongated body, but this form is useful for digging and living in tunnels. Others, as the *Cychrus* (Carabidae) have the head and pronotum elongated and narrow, but this is an adaptation used to penetrate snail shells. The long proboscis of certain Diptera or moths are needed to penetrate some deep flowers. All those modifications of the morphology seem to be functional specializations, not meaningless exaggerations.

All modern authors see in the so-called hypertely of the carabeid horns a case of allometry, sometimes under the influence of hormones or food. Individuals are able to express different morphologies in response to environmental conditions during their development. Recently, it was suggested that pronotal horns among *Onthophagus* are crucial during ecdysis of the larval head capsule during the larval-to-pupal molt. This function in molting seem unrelated with fighting and defense, but all criteria are positive and useful for the insect.

Additional examples of exaggeration include organs used in reproduction; often, the male genitalia of certain beetles are very big, while other species of the same genus have a normal aedeagus. That is the case among the galerucines of the genus *Monoxia* (Chrysomelidae), where only one species, *Monoxia puncticollis*, has an enormous intromittent organ, but its body size is not much bigger than the body of other species with a normal aedeagus. The mating is done and successful with the female of *M. puncticollis*, which probably has some kind of adaptation. There is also the case of *Hydrochus interruptus* (Hydrophylidae), an aquatic beetle, which is provided with so complex an aedeagus that some entomologists have doubted its real sexual function. Very often, the beetles or other insects are gifted with so complicated aedeagi that one wonders how they work. But such aedeagi function, and the insect reproduces normally. Also, sometimes the spermatozoa are enormous. This is the case of many Alticinae (Chrysomelidae) or the *Drosophila* flies (Drosophilidae), for instance. However, it appears that, in the case of the Alticinae, the role of the long sperm is in forming a vaginal plug. It seems also that the males of *Drosophila* which have developed those long spermatozoa have an increased chance to fertilize the eggs successfully.

As far as we can see, the concept of hypertely is obsolete. All those so-called exaggerated morphologies have a function and the animals survive, multiply and they do not seem to suffer from those "monstrosities." As a rule, handicapped specimens are eliminated and only the fit ones survive. A non-adaptative organ is an organ not understood. So-called hypertelic insects are just part of the biodiversity, having evolved through selection.

A family of bugs (order Hemiptera, suborder Fulgoromorpha). All members of the suborder are referred to as planthoppers.

Hypodermosis in Deer

JAVIER MARTÍNEZ, IGNACIO NAVARRETE,
DAVID REINA, SANTIGO HERNÁNDEZ
Universities of Cordoba and Extremadura,
Madrid, Spain

Hypodermosis is a common myiasis produced by flies of the genus *Hypoderma* (Diptera: Oestridae), affecting a wide variety of hosts, but specially important in domestic animals like cattle and goats. It is spread over almost all the northern hemisphere, and these flies produce serious economic losses in hosts, especially in herds reared for meat and dairy production. Little research has been directed, however, at wild and semi-wild animals such as deer. Nonetheless, existing studies have pointed out just how serious this infestation may be in these hosts, because widespread parasitosis currently affects deer in numerous Palaearctic countries. The situation is truly worrying, due to the high degree of prevalence and intensity of parasite infestation.

Effects of Hypodermosis

Little is known about the infestation of deer, and few studies have discussed the influence of environmental factors on the biology of flies and their resulting distribution. At the same time, the pathogenicity of larvae for host deer remains unknown. Although it is patently clear that, in deer, this disease should be classed as critical, since it affects:

Deer Health

The *Hypoderma* life cycle in deer is still not well known, but due to the similarities with cattle myiasis, it is thought to have an internal migratory cycle that affects the health of the host. There is a decrease in meat production, retarded growth and reduction in skin quality (Fig. 63).

Rural Development in Poor Areas

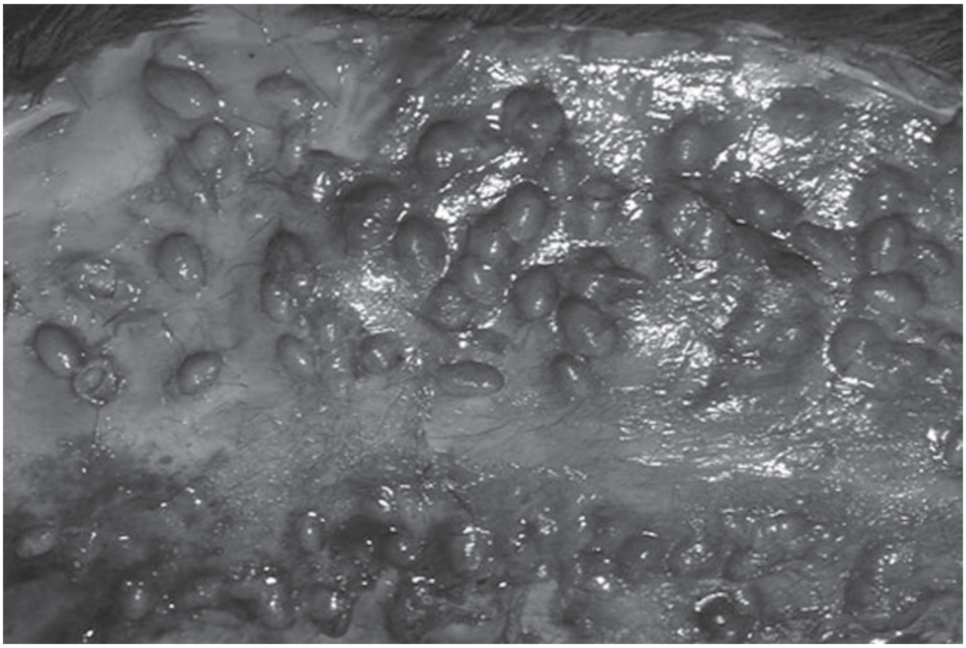
Deer hypodermosis affects the economic development of many poor areas due to repercussions on the hunting-based economy. In social terms, hunting is a developing force in depressed areas, where it provides a major source of income through the employment of local labor.

Deer Farming

This is a growing farming activity, and venison offers an alternative to beef, pork and lamb.

Species and Hosts of *Hypoderma* spp.

Several *Hypoderma* species are found in deer, but the three main parasites are *H. diana*, *H. actaeon* and *H. tarandi*. *H. diana* is euryxenic and affects, in addition to red deer (*Cervus elaphus*), a range of other hosts including roe deer (*Capreolus capreolus*), fallow deer (*Dama dama*), elk (*Alces alces*)



Hypodermosis in Deer, Figure 63 Myiasis in deer caused by *Hypoderma*.

and reindeer (*Rangifer rangifer*), and lives in a great diversity of ecosystems.

Host specificity is strong in *H. actaeon* and *H. capreolus*, as the former only affects red deer and the latter roe deer.

Morphological differentiation between *H. diana* and *H. actaeon* is made according to the pattern of spine morphology and morphology of spiracular plates.

H. (*Oedemagena*) *tarandi* shows greater specificity, affecting only *R. rangifer*, and is found within the subarctic region.

Biology

Biology of deer-infesting *Hypoderma* spp. is still a relatively unknown aspect of myiasis. Some particulars are important in deer hypodermosis. For example, *H. diana* is present in a great variety of habitats, and also of hosts, and this departs from the principle of host specificity of warble flies, maintained by a complicated equilibrium with its host by means of internal regulatory systems. It is spread throughout Europe and Asia, from 30° to 60° north, and lives in several different ecological zones such as mixed, deciduous and coniferous forests, wooded steppes and wetlands, overlapping the territory of its hosts and adapted to the wide variety of ecosystems in which live the parasite's hosts.

Flight and oviposition of female flies are conditioned by air temperature and ambient light, so they are most active at midday. In contrast, their endogenous cycle has yet to be fully described, although some authors claim that they arrive at the dorsal area via the spinal canal, exhibiting a cycle similar to that of *H. bovis*. Resistance and susceptibility to infection has to be studied, as previous studies have demonstrated that the extent of parasitism and prevalence are higher in younger animals, possibly due to a measure of resistance built up through repeated contact with the parasite.

Pupation is highly influenced by the nature of the land, pupae being more viable when produced in areas where there is at least some grass. This viability decreases depending on to what extent the land freezes or frosts over.

Hypoderma tarandi is more specific and is found in just one host (*R. rangifer*); it has thus adapted itself to live in the same habitat as its host, usually subarctic regions. Its biology has been studied in great detail due to the importance of the reindeer in cold northern countries. Two different habitat are occupied by these flies, one of wooded regions, and other of wide open or mountainous areas with plentiful water courses. Usually only the female approaches the host; the male rarely does so, and is usually found in sunny, rocky areas. The flight range of females is absolutely astonishing, as they can fly as far as 600–900 km. Males, however, tend to fly for shorter distances and times, although they may achieve a radius of 400 km.

The degree of parasitism in male deer is usually higher than in females and castrated animals; thus, resistance to this disease is greater in females than in males. Prevalence is higher in herds which did not move to new pastures after calving than in those continually changing their grazing grounds. When deer are led to new pastures, the number of infested animals and the degree of parasitism drops substantially.

Hypoderma actaeon is confined to one host, red deer (*Cervus elaphus*), and it seems to be restricted to Europe. Little is known about the biology of this parasite, but it has been observed that yearling hosts are more parasitized than older ones, and it suggests the development of resistance by repeated contact with the parasite. The internal life cycle of *H. actaeon* lasts up to 9 months, as subcutaneous stages are found from September to May, with the presence of first instar larvae for a period of 2–3 months, and then the second (L2) and third (L3) instars.

Chronobiology

The seasonal dynamics of *H. diana* adapted to central European countries are as follows: larva migration and growth take place in the host until April, pupation lasts for 26–33 days, and flying is observed in May and June. In eastern countries (Czech Republic), L1 larvae develop from November to March, L2 from December to April, and L3 from January to June. Flies have been observed from April to June. By contrast, in southern European countries such as Spain, this cycle is brought forward by 2–2.5 months. L1 may be observed September to December, L2 October to January, and L3 onwards of December.

Hypoderma tarandi, owing to its northern ecology, does not develop until later, beginning in October and with L3 appearing June to July; flying takes place between June and September.

Chronobiology of *H. actaeon* is similar to that described to *H. diana*, with L1 larvae developing in September to November, second instar larvae from September to December and L3 from December to May.

Prevalence

Hypoderma diana is widely distributed throughout Europe, and cases of parasite infestation as high as 100% have been reported, such as those recorded in Russia. In Bulgaria, parasitism ranges from 48 to 66%, whereas in Spain there is a mean of 90%.

The other important species in red deer is *H. actaeon*, which reach very high levels of prevalence in southern and central Spain, ranging from 44 to 92%, with a mean intensity of parasitization of near 40 larvae per animal (1–317).

The extent of parasitism with regard to the number of larvae per animal varies greatly in *H. diana* and *H. actaeon*. In Spain, values ranging from 1 to 400 larvae per animal have been recorded, where over half of the animals contained more than 50 larvae. In the former Czechoslovakia, cases have been reported of up to 300 larvae per animal, in Germany 300–500 larvae, in Bulgaria up to 150 larvae, and in France up to 200. *H. tarandi* has also reached levels of 99.9%.

Other Negative Effects of Hypodermosis

It has been shown that *H. diana* can infest other hosts in addition to deer. In the United Kingdom, cases have been reported of sheep living near deer-populated forests being affected. Cases of ophthalmomyiasis produced by *H. tarandi* have been described in children, in dogs and in horses, and always in the vicinity of deer-populated areas.

The cost of the damage caused by *Hypoderma* spp. is difficult to calculate although, as occurs in bovines, losses are incurred both in reduced meat yield and in depreciation of skins and horns/antlers.

Control

It is never easy to develop strategies for the control of disease in wild and semi-wild animals, and deer are no exception. Any such controls also must be based on a total respect for the environment, since the quality of their surroundings plays an important role in the welfare of not only deer but all wild animals living on the same biotope.

It should be borne in mind that ecological or "organic" meat such as venison, supplied to a gourmet market, must satisfy sophisticated organoleptic criteria and its quality must never suffer. Thus, the use of medicaments and pharmacological substances has to be strictly controlled in order not to affect meat quality.

There are only a few studies about the treatment of warble flies in deer, but we can assume that the same drugs used in other species should be useful in deer, i.e., some organophosporous, avermectines and milbemicynes.

Handling practices may be modified through a knowledge of the parasite cycle and ecology. Animals could enjoy greater protection by being herded into corrals, or at least into the shelter of shaded areas to reduce the risk of infestation when adult flies are active.

In domesticated animals or semi-domesticated animals living on the range, such as reindeer, the rate of infestation may be reduced when, after giving birth, the herd migrates to fresh pastures or is led to new pastures away from those frequented during the muddy season. The aim is to distance the deer from the pupae and flies. These measures are not particularly effective, however, so greater control of parasitism will still depend on pharmacological treatment.

For free-range deer, and only when they cannot be captured for the administration of treatment, food may be supplemented with oral forms of antiparasite preparations. The problem arises, however, in choosing a suitable vehicle for the anti-parasitic treatment, because it cannot be freely distributed around the environment due to the danger of its being consumed by other animals. Neither could the ingested volume be controlled. Experimental trials with rafoxanide and ivermectin in the daily salt pellets required by the animals' diet have yielded promising results.

Farm-raised animals are obviously easier to control, and a program of preventative medicine may be applied, with regular treatment in accordance with the local chronobiology of *Hypoderma*.

Identification of Insects

Usually the first question that comes up when someone encounters an insect is: "What is it?" Answering this question can be a difficult or simple process. It can be difficult because insects are incredibly diverse, with nearly one million described species. On the other hand, within a 300 km radius there may be only about 15,000 species (fewer in cooler climates, more in tropical areas). So it is possible for a person to have a reasonable grasp of the local fauna, especially the more common or distinctive species.

In the process of identification, one common mistake is to consult an illustrated book of national or international scope, particularly one that treats the entire class of insects, matching pictures with specimens. Though this can work with the most common insects, it usually is doomed to failure. There are entirely too many insects, and too many are similar in appearance (differing only in minute detail) for this approach to be very successful. Greater success can be attained with books of regional scope, or books that treat smaller groups. Thus, "Grasshoppers of the United Kingdom," "Butterflies of Costa Rica," or "Plant bugs of the Prairie Provinces" will prove to be more useful than more general treatments. In the hands of specialists who have reasonable grasp of the diversity, or in the case of specialty publications that are comprehensive in treatment, picture books are useful. However, in most cases, accurate determination of insects requires the use of diagnostic aids called "keys."

Insect Keys

Keys are arrangements of taxa, with similar taxa (usually based on external morphology, or appearance) clustered together. Thus, insects with wings

Identification Key to the Classes of Adult Arthropoda

P.M. Choate

Insects represent one **Class** of animals within the **Phylum *Arthropoda***. If you do not immediately recognize an insect you may need to identify some arthropods to first determine if they are in fact insects before proceeding further.

Biologists have adopted the use of *dichotomous keys* to identify organisms. Starting at couplet 1, decide which of the first 2 choices best fits the organism you are trying to identify. Proceed by going to the couplet indicated at the end of your choice. By process of elimination you will arrive at an identification. Compare your results with pictures and notes in this handout and in your books to see if you have arrived at a likely identification. If you are satisfied with your result, proceed to the next key that you wish to use and follow the same process. As you move from **Class** to **Order** to **Family** and perhaps to **Genus** and **Species** you will notice that choices may become more difficult. This is due to the details necessary to separate these categories. Since this key is designed to help you recognize insects, and to also recognize Arthropods that might be confused with insects, we will start with an obvious and surefire couplet, #1. There are many insects which do not appear to have wings or actually lack wings. However, many have easily observable and functional wings which immediately identify the creature as an insect.

1. With 1-2 pair of obvious, visible, usually transparent wings (**Fig. 1**). (*If it's not a bird or a bat then it is an insect*) .... **Insecta**

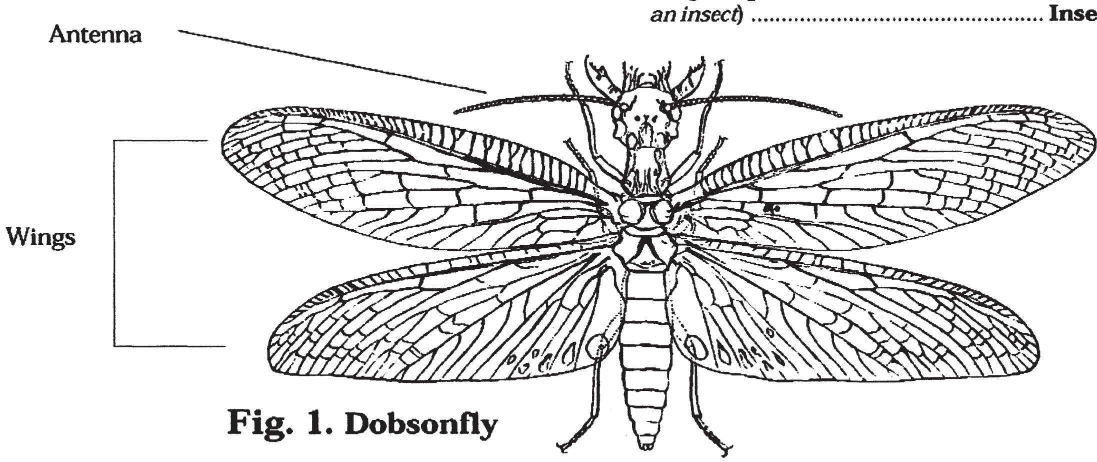

Fig. 1. Dobsonfly

- Without obvious wings 2

2. With 1 or 2 pairs of antennae ("segmented feelers") of various shapes (see **Figs. 1, 3-5**) inserted on front of head, usually between the eyes. Antennae may be inconspicuous, hidden beneath head when viewed from above, or small and more bristle-like than typical segmented structure. ***Note***: some non-insects carry their front legs or modified mouthparts (pedipalps, **Fig. 2**) in a manner resembling antennae 3

- Lacking segmented antennae and always lacking any suggestion of wings. 8

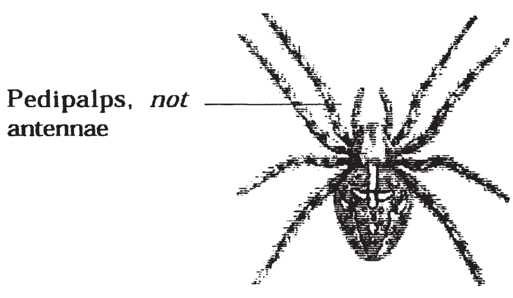

Fig. 2. Spider

3. With 2 pairs of antennae (one pair may be smaller than the other; *2nd pair is vestigial in terrestrial Isopoda* (pillbugs, **sowbugs**); body usually with 2 distinct regions (**Figs. 3-4**), **cephalothorax** and

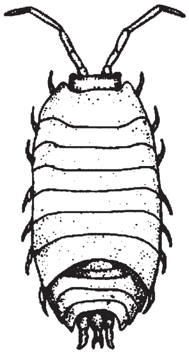

Fig. 3. sowbug

abdomen; variable number of legs on cephalothorax, abdomen with or without appendages which when present are not leg-like; (amphipods, sowbugs, lobsters, crayfish) .... **Crustacea**

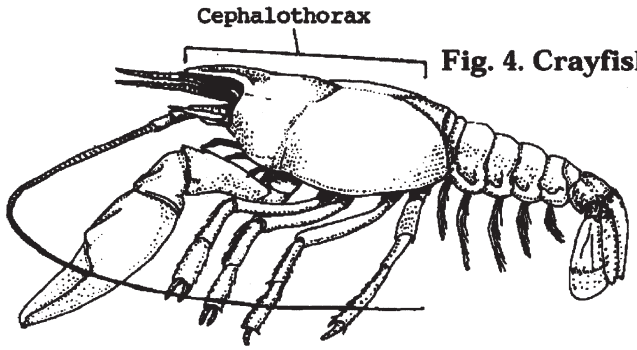

Fig. 4. Crayfish

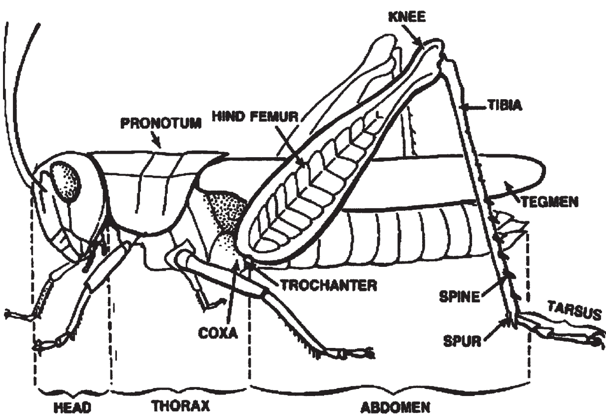

Fig. 5. Grasshopper

- **Always** with **only 1 pair** of antennae; body regions and numbers of legs variable; appendages not biramous 4

4. With only 3 pairs of legs and often with 1-2 pairs of wings; 3 body regions (**Fig. 5**). Abdomen without segmented legs but may have appendages; body shape variable .... **Insecta**
- With 9 or more pairs of legs (**Figs. 6-7**) which are on most segments posterior to head; head distinct; wings absent; body elongate and wormlike 5

5. Legs evenly spaced along body, usually 1 pair of legs per segment 6
- Legs arranged in pairs, 2 pair per segment (**Fig. 6**) (millipedes) .... **Diplopoda**

6. Body flattened, with 15 or more pairs of legs; size variable but usually longer than 25mm. (**Fig. 7a**) (centipedes) .... **Chilopoda**
- Body cylindrical; *minute* forms with 9-12 pairs of legs 7

7. Antennae branched (**Fig. 7b**); 9 pairs of legs ....
.... **Pauropoda**
- Antennae not branched; 10-12 pairs of legs (**Fig. 7c**) ..
.... **Symphyla**

Key to the Orders of Insects Normally Found in Insect Collections

P.M. Choate

Once you have determined that the organism you have before you is an insect you may wish to further identify it. This means that you may have to use additional keys to determine the Order of that specimen. Some insects will be immediately recognized as insects but you may not be familiar with the oder to which it belongs. The key that follows will help you determine many of the more commonly encountered orders of insects. Not all insects will be able to be determined here. If you decide that your specimen may not be included here, use the reference books. These should permit identification of any specimen you happen upon.

Once you have determined the Order, the next step is to determine the Family within that order to which the insect belongs. This may mean an increase in complexity for you, and will usually require additional knowledge about specific types of structures and the variation that exists within these structures. Once the family of an insect has been determined you are left to hunt for literature that will permit identification to genus and species. Not only may this prove difficult, it may prove impossible. Not all insects are discussed or are identifiable to species. Literature may be scattered, outdated, or non-existent. You may have to call upon specialists for help. This is a normal part of the identification process. For our purposes here we will concentrate upon keys that should help you arrive at an Order level identification, and within a few of these Orders, some of the more commonly encountered families.

The following key to orders begins with a couplet that asks you to determine whether or not the insect has wings. This may be a confusing beginning for you. Many insects have flight wings which are hidden beneath another set of modified wings called elytra. Elytra are wings which act as protection and covering for the flight wings of beetles. At first glance there is little to indicate to you that these insects have wings. To further confuse the issue there are many beetles that lack flight wings, and whose elytra are fused to form a solid cover. Similar modifications may occur in such diverse groups as grasshoppers and the true bugs.

A similar point of confusion may be the determination of presence or absence of antennae. Antennae come in a variety of sizes and shapes . Dead insects may have antennae hidden or broken. If antennae are not apparent check to see if attachment "sockets" are visible on the insect's head in front of and beneath the eyes.

These two characters (antennae and wings) are mentioned here to emphasize the point that it is almost impossible to generalize about the characteristics that make up an insect order. There are many exceptions. With this in mind, proceed to identify specimens, using your book and examples here to help arrive at your final determination. When you have finished you should go to a museum or reference collection and compare your results. With practice you may find that the identification of insects will become a challenging avocation.

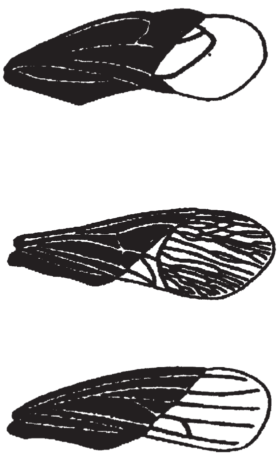

Fig. 8. Hemelytra

Fig. 9. Tegmen

1. Wings present (wings may be hidden under external elytra (p. 10-11), hemelytra (Fig. 8), or tegmina (Fig. 9) such that "wings" do not appear to be present) 22
— Wings absent or reduced to small pads; many abdominal segments visible from above 2

2. Antennae absent; body slender and whitish in color. Very small (Fig. 10) (1mm.) .... **Protura**
— Antennae present (may be difficult to see) 3

3. Usually with forked spring (furcula - Fig. 11)on abdomen. Size small, 2-4mm. Always lacking apical abdominal cerci. If furcula absent, size and body shape are characteristic of order .. **Collembola**

Fig. 10. Protura

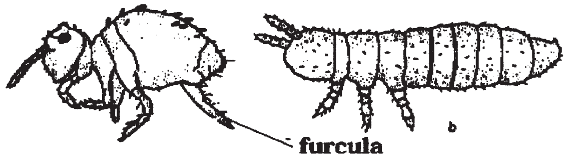

Fig. 11. Collembola

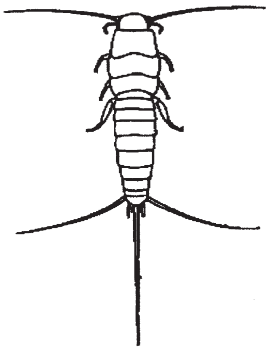

Fig. 13. Thysanura

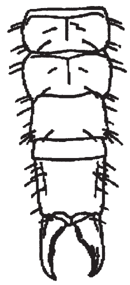

Fig. 12. Diplura

Fig. 14. Homoptera

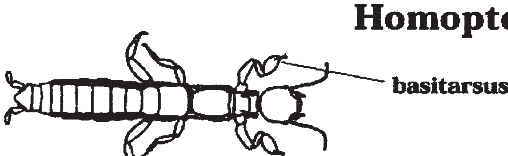

Fig. 15. Embiidina

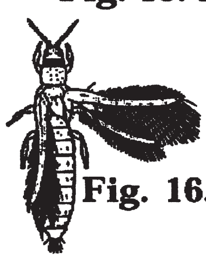

Fig. 16. Thysanoptera

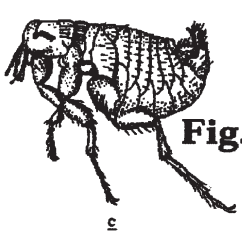

Fig. 17. Siphonaptera

— Furcula always absent. Body size larger, shape various 4

4. Apex of abdomen with long cerci (Fig. 13) and lacking ventral abdominal styliform appendages, or if ventral styliform appendages present, cerci are short 5
— Cerci short or lacking; abdominal styliform appendages always absent 6

5. Apex of abdomen with 3 filamentous cerci (silverfish) .... **Thysanura**
— Apex of abdomen with 2 cerci, either forceps-like (Fig. 12) or short and segmented .... **Diplura**

6. Large unsegmented forceps-like structures at apex of abdomen(earwigs) .... **Dermaptera**
— Cerci (when present) neither forceps-like nor unsegmented 7

7. Large insects, usually > 25mm in length; antennae frequently very long and slender 8
— Small insects, usually < 12mm in length 9

8. 4-segmented tarsi .... **Orthoptera**
— 5-segmented tarsi .... **Phasmida**

9. Tube-like structures (cornicles) (Fig. 14)protruding posteriorly from 4th to last abdominal segment; *OR* body covered with waxy filaments or a scale .... **Homoptera**
— Cornicles absent *AND* no scale or waxy filaments covering body 10

10. Abdomen constricted to narrow waist where it joins thorax (bees, wasps, ants, sawflies) .... **Hymenoptera**
— Abdomen not constricted into narrow waist 11

11. Front legs with enlarged first segment (Fig. 15) (basitarsus), which is modified for production of silk (webspinners) .... **Embiidina**
— First tarsal segment not enlarged 12

12. Mouthparts (rasping-sucking) contained in a short, cone-like beak; wings when present often with fringe of hairs (Fig. 16); size <3mm; abdomen often pointed at apex (thrips) .. **Thysanoptera**
— Mouthparts other than rasping-sucking; may be in form of elongate beak which extends ventrally and posteriorly beneath head; 13

13. Body flattened laterally, with numerous backward-projecting spines and bristles; legs long, with greatly enlarged coxae modified for jumping (fleas) (Fig. 17) .... **Siphonaptera**
— Body not flattened laterally; may have hairs or spines but these are not backwards projecting; if legs are modified for jumping, femora are enlarged 14

Fig. 18. Hemiptera

Fig. 19. Isoptera

Fig. 20. Mecoptera

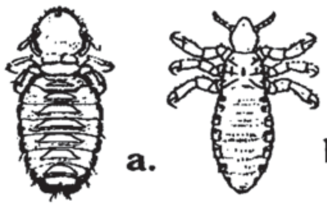

Fig. 21

Fig. 22. Ephemeroptera

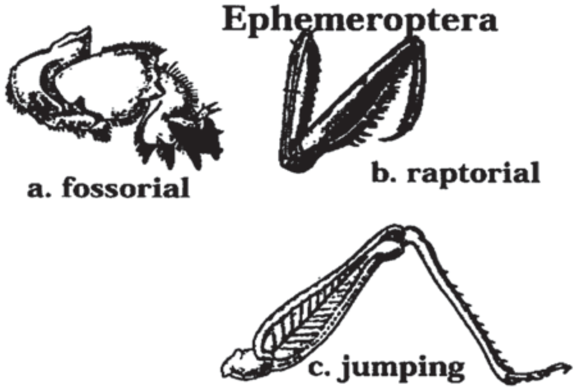

Fig. 23. Orthoptera leg types

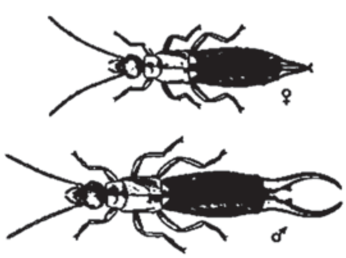

Fig. 24. Dermaptera

14. Mouthparts elongated into piercing-sucking beak 15
— Mouthparts not elongated into long piercing beak; head may be prolonged 16

15. Antennae hidden in grooves in head .... **Diptera**
— Antennae long and easily seen (Fig. 18)**Heteroptera**

16. Body covered with dense hair .... **Lepidoptera**
— Body lacking dense hair 17

17. Antennae moniliform (segments beadlike); short cerci present (Fig. 19)(termites) .... **Isoptera**
— Antennae not moniliform; cerci absent 18

18. Antennae long and slender 19
— Antennae short 20

19. Head prolonged and beak-like (Fig. 20); males of some species have scorpion-like abdomen (scorpionflies) .... **Mecoptera**
— Head not prolonged and beak-like .... **Psocoptera**

20. Tarsi with 4-5 segments .... **Diptera**
— Tarsi with 1-3 segment (lice) - **Phthiraptera** 21

21. Chewing mouthparts; head usually broader than long (Fig. 21a) .... **Mallophaga**
— Piercing-sucking mouthparts retracted into head; head usually longer than broad; legs greatly enlarged for grasping (body lice)(Fig. 21b) .... **Anoplura**

22. Abdomen with large unsegmented forceps-like cerci (Fig. 24) .... **Dermaptera**
— Cerci appearing segmented when present, not forceps-like, or absent 23

23. Cerci filamentous, longer than last 3 abdominal segments combined 24
— Cerci shorter than last 3 abdominal segments combined, not filamentous, or totally absent 28

24. Wings folded upright and parallel to body length; antennae setaceous (Fig. 22. mayflies) .... **Ephemeroptera**
— Wings various but not held upright above body; antennae elongate and filiform 25

25. Front pair of legs shaped differently than mid and hind pair, modified for digging (Fig. 23a) (fossorial) or grasping (Fig. 23b) (raptorial) .... **Orthoptera**
— Front pair of legs similiar to middle pair 26

26. Hind pairs of legs enlarged for jumping (Fig. 23c) .... **Orthoptera**
— Hind pair of legs similar to middle pair 27

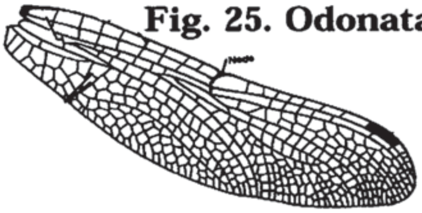

Fig. 25. Odonata wing

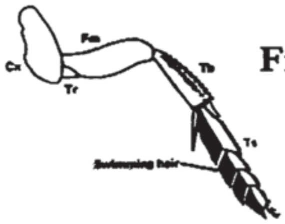

Fig. 26. Aquatic Hemiptera

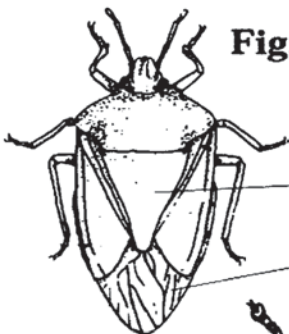

Fig. 27. Hemiptera

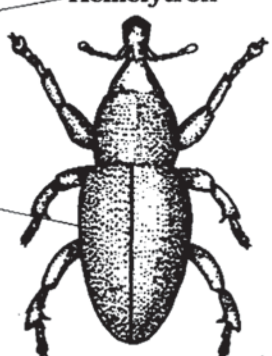

28. Coleoptera

Fig. 29. Orthoptera

Fig. 30. Lepidoptera

27. Tarsi 3-segmented; cerci long or short, not forceps-like; many segmented .... **Plecoptera**
— Tarsi variable (4-5 segments). Includes large, bulky insects, frequently with well developed wings. 31

28. Cerci present, shorter than last 3 abdominal segments combined 29
— Cerci absent (do not be confused by genitalia) 33

29. Small, delicate insects; wings transparent, uniform shape and size 30
— Body shape varied; wings in form of elytra, tegmina, or hemelytra 31

30. Front basitarsi (1st tarsomere) enlarged and dilated to form a webspinning organ .... **Embiidina**
— Front basitarsi not enlarged and dilated, appearing of normal proportions (termites) .... **Isoptera**

31. Tarsi 4-segmented .... **Orthoptera**
— Tarsi 5 segmented 32

32. Prothorax much longer than mesothorax; front legs modified for grasping .... **Mantodea**
— Prothorax not greatly lengthened; front legs not modified for grasping .... **Blattaria**

33. Large insects with 2 pairs of wings; wings usually transparent, each wing with an anterior node (Fig. 25)or notch (dragonflies, damselflies) .... **Odonata**
— Wings variable but lacking anterior node 34

34. One pair of wings; halteres present .... **Diptera**
— Two pairs of wings; halteres absent 35

35. Mouthparts in the form of a piercing-sucking, elongate beak which is mostly held beneath and behind the head; palpi absent 36
— Mouthparts other than above; palpi present 38

36. Hind leg without tarsal claws; adapted for swimming (Fig. 26) .... **Heteroptera**
— Hind leg with tarsal claws 37

37. Beak arises from anterior part of head; forewings usually as hemelytra (Fig. 27) .... **Hemiptera**
— Beak appears to originate from between front pair of legs; forewings of uniform texture .... **Homoptera**

38. Rasping-sucking mouthparts in form of cone-like beak; wings fringed with long hairs .... **Thysanoptera**
— Not as above 39

39. Front pair of wings hardened, of different texture than rear flight wings 40

14. Mouthparts elongated into piercing-sucking beak 15
— Mouthparts not elongated into long piercing beak; head may be prolonged 16

15. Antennae hidden in grooves in head .... **Diptera**
— Antennae long and easily seen (Fig. 18)**Heteroptera**

16. Body covered with dense hair ....**Lepidoptera**
— Body lacking dense hair 17

17. Antennae moniliform (segments beadlike); short cerci present (Fig. 19)(termites) .... **Isoptera**
— Antennae not moniliform; cerci absent 18

18. Antennae long and slender 19
— Antennae short 20

19. Head prolonged and beak-like (Fig. 20); males of some species have scorpion-like abdomen (scorpionflies) ....**Mecoptera**
— Head not prolonged and beak-like .... **Psocoptera**

20. Tarsi with 4-5 segments .... **Diptera**
— Tarsi with 1-3 segment (lice) - **Phthiraptera** 21

21. Chewing mouthparts; head usually broader than long (Fig. 21a) .... **Mallophaga**
— Piercing-sucking mouthparts retracted into head; head usually longer than broad; legs greatly enlarged for grasping (body lice)(Fig. 21b) .... **Anoplura**

22. Abdomen with large unsegmented forceps-like cerci (Fig. 24) .... **Dermaptera**
— Cerci appearing segmented when present, not forceps-like, or absent 23

23. Cerci filamentous, longer than last 3 abdominal segments combined 24
— Cerci shorter than last 3 abdominal segments combined, not filamentous, or totally absent 28

24. Wings folded upright and parallel to body length; antennae setaceous (Fig. 22. mayflies) .... **Ephemeroptera**
— Wings various but not held upright above body; antennae elongate and filiform 25

25. Front pair of legs shaped differently than mid and hind pair, modified for digging (Fig. 23a) (fossorial) or grasping (Fig. 23b) (raptorial) .... **Orthoptera**
— Front pair of legs similiar to middle pair 26

26. Hind pairs of legs enlarged for jumping (Fig. 23c) .... **Orthoptera**
— Hind pair of legs similar to middle pair 27

Fig. 31. Neuroptera, including Megaloptera

Fig. 32. Hymenoptera

Fig. 33. Psocoptera

— Front wings not thickened or hardened to form cover for flight wings 41

40. Front pair of wings thickened and usually hard, without crossveins, meeting along midline (meson) of the body to form elytra (Fig. 28); many forms with elytra shortened, exposing one or more abdominal segment from above (beetles); hind legs usually not modified for jumping .... **Coleoptera**

— Front pair of wings with obvious crossveins and veins (Fig. 29, tegmen), overlapping one another at least partially; hind legs often enlarged for jumping (grasshoppers, crickets, Katydids) .... **Orthoptera**

41. Front basitarsi (1st segment) enlarged to form silk-producing glands (Fig. 15) (webspinners) .... **Embiidina**

— Front basitarsi not any more enlarged than remaining segments 42

42. All wings equal in size; (termites) .... **Isoptera**

— Hind wings usually smaller than front pair of wings; 43

43. Mouthparts in the form of a coiled siphon (Fig. 30); wings and body usually covered with scales (butterflies and moths) .... **Lepidoptera**

— Mouthparts not in the form of a coiled siphon; body scales absent or few in number, restricted to wings and wing veins 44

44. Many crossveins in wings (Fig. 31), particularly at anterior edge; if few crossveins, wings covered with waxy coating and insect very small .... **Neuroptera**

— Few crossveins in wings; body and wings lacking waxy coating 45

45. Mouth reduced, vestigial; only palpi obvious; hairs often present on wings (caddisflies) .... **Trichoptera**

— Mouthparts not reduced or vestigial; chewing or chewing-lapping types 46

46. Chewing mouthparts elongated into a beaklike structure. Some males with scorpion-like abdomen (scorpion flies) .... **Mecoptera**

— Chewing mouthparts not elongated into beak; or with chewing-lapping mouthparts 47

47. Tarsi 4- or 5-segmented; wings folded flat over body (Fig. 32) (bees, wasps, ants, sawflies) .... **Hymenoptera**

— Tarsi 2- or 3-segmented; wings folded roof-like over body (Fig. 33) (treelice, booklice) .... **Psocoptera**

may be in one cluster, wingless in another. Then within one of these clusters, some other character such as antenna length is used to segregate individuals further: those with wings and long antennae in one cluster, those with wings and short antennae in another. Extended far enough, this process can lead to species-level determinations. Keys usually require the user to make a choice between only two characters at a time: so-called "dichotomous keys." However, it is also possible to have keys where the user is asked to pick among several groups of characters simultaneously. The choices are usually numbered (e.g., 1 and 1′, 2 and 2′, etc.), and the user is referred to various sections of the key by number.

Keys tend to be of two general types: "phylogenetic keys" or "artificial keys." Phylogenetic keys group together taxa with the same evolutionary history. Sometimes it is hard to see their common relationships based on external morphology. Thus, it is commonplace to group together taxa that simply share similar morphologies, regardless of phylogeny, creating a so-called artificial key. A combination of both approaches also is feasible.

In almost all cases, keys begin with a large taxon (e.g., arthropods or insects), and work down to smaller and smaller groups. Often insect keys segregate orders, and then there are separate keys for each order that separate families, then other keys to distinguish among the genera in the families, and then finally keys to species, which sometimes are integrated with keys to the genera. A common, but incorrect, assumption is that order or family keys are easier to use than species keys. The opposite is true. Keys to larger taxa must accommodate a great deal of variation, and sometimes it is difficult to find unifying characteristics.

Keys are often based primarily or exclusively on text: written description of a contrasting character or characters is used to distinguish among specimens. Illustrated keys have a major advantage in that they graphically display the characters of interest. It is much easier to understand differences among contrasting characters when they are illustrated. It also helps to have the key graphically displayed in a flow-chart arrangement. This gives the user better opportunity to see at a glance where the key is headed, and to easily work backward if diagnosis proves difficult. A few pointers on use of keys follow:

- Do not attempt to skip through a key, or to take short-cuts. Start at the beginning and work through the key methodically.
- Read the descriptions *carefully*; a large percentage of errors are caused by careless reading, or by the user not understanding the meaning of the words. Terminology may differ between taxa, so if you are not familiar with a taxon it is advisable to look up the exact meaning of terms. Illustrations are immensely helpful.
- You will be asked to make a series of decisions, usually making the "best" choice among two options. Your specimen should fit one of the two choices; if not, perhaps you made an incorrect decision earlier in the key.
- If more than one character is provided for you to examine, the first character is usually the most important. The others are secondary, or apply only in part.
- It is helpful to examine more than one specimen. It may be difficult to see a key character on certain individuals, or there may be sexual differences in the degree of expression.
- When you arrive at a final destination, do not automatically accept it. Always seek a more complete description of the organism to ascertain that the specimen seems to match.

Examples of Keys

Accompanying this section are some examples of North American keys to the classes of adult arthropods, to the orders of insects normally found in insect collections, and to some small groups of insects that are a nuisance or of public health concern. They illustrate some of the common types of keys used by entomologists, and demonstrate the value of illustrations. Note, however, that these are simply examples, and that they treat the names of certain taxa differently than treated elsewhere in this encyclopedia. Included in the reference section are some additional widely used sources of keys to insect orders and families. Each book contains numerous citations to other keys. Unfortunately, in most cases the scope is primarily North America.

Idiobiont

Parasitoids that immobilize or paralyze their hosts after oviposition, preventing further development. The larvae of these parasitoids normally develop externally, as ectoparasitoids.

Idiostolidae

A family of bugs (order Hemiptera, suborder Pentamorpha).

► Bugs

Ihering, Hermann Von

Hermann von Ihering was born in Kiel, Germany, on October 9, 1850. At the age of 18, he accompanied his father to Vienna. In 1870, during the Franco-Prussian war, he enlisted in a regiment of musketeers, served as medical assistant, then studied medicine in Berlin and Göttingen and obtained medical degrees. In 1876, he obtained a Ph.D. degree in zoology. In 1880, he moved to Brazil, and in 1893 was appointed director of the Museu Paulista. His research interests were in zoogeography and in South American social insects. For example, he published on the foundation of new colonies and fungus-gardens by leaf-cutting ants. In 1924 he returned to Germany and was appointed honorary professor of paleontology at Universität Giessen and published (1927) "Die Geschichte des Atlantischen Ozeans." He died in Büdingen, Germany, on February 24, 1930. His son, Rodolpho (1883–1939), also was an entomologist.

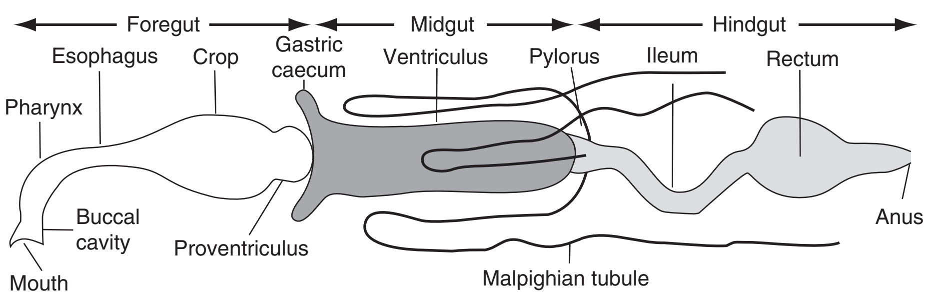
Ileum

The anterior portion of the hindgut, preceding the colon (if present) and rectum (Fig. 1).

► Alimentary System
► Alimentary Canal and Digestion



Ileum, Figure 1 **Generalized insect alimentary system (adapted from Chapman, The insects: structure and function).**

Imaginal Disc

A group of cells set off during embryonic development that are activated upon transformation to the adult stage, and develop into adult characters.

► Metamorphosis

Imago (pl. imagoes)

The adult or reproductive stage of an insect.

Immaculate

This describes objects lacking spot or dark markings.

Imma Moths (Lepidoptera: Immidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Imma moths, family Immidae, comprise 246 species, all tropical, and mostly Indo-Australian and South Pacific, mostly in the genus *Imma*; actual fauna likely exceeds 450 species. The family is the only family of the superfamily Immoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small to medium size (14–42) mm wingspan), with head smooth-scaled; haustellum naked; labial palpi upcurved and often prominent, with long second segment; maxillary palpi minute, 1–2-segmented. Forewings often somewhat rounded on the termens (Fig. 2). Maculation varies, but mostly shades of brown or gray, with various markings or bands, or more colorful; sometimes with translucent hindwings. Adults are diurnal, but some may be crepuscular. Larvae are leaf feeders, but only three species have biological data. Host plants are in Myrtaceae, Podocarpaceae, and Violaceae.

Immature

The feeding stage of insects after birth but before adulthood, including both larvae and nymphs.

Immidae

A family of moths (order Lepidoptera) also known as imma moths.

► Imma Moths

► Butterflies and Moths

Immigrant

An organism that was accidentally introduced. An immigrant is an organism that is not native to an area (it is adventive), and has arrived as the result of hitch-hiking (traveling) or by its own means of dispersal (usually by flight or rafting). Immigrants are often called "invaders" or "invasives," though their invasive properties vary considerably once they have arrived.

► Invasive Species

Immiscible

Liquids that cannot mix to form a homogeneous solution.

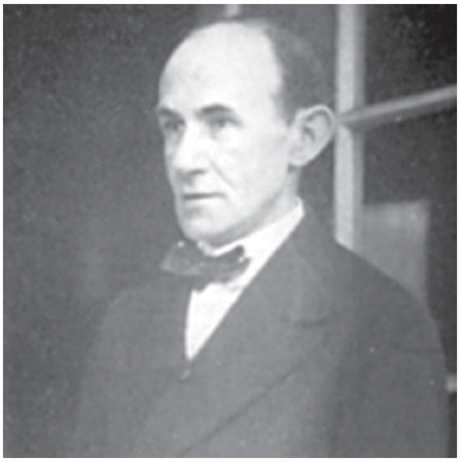
Immigration

Entry of organisms into a population from elsewhere (contrast with emigration).

► Invasive Insects

Imms, Augustus Daniel

Augustus Imms was born on August 24, 1880. He was educated at the University of Birmingham and then obtained a B.Sc. from London University. Next, he entered Cambridge University, from which he obtained a B.A. degree, and then a D.Sc. in 1907. In 1907 he became the first professor of biology in the University of Allahabad and later forest entomologist to the Indian government. He returned to England in 1913, and was appointed reader in agricultural entomology in the University of Manchester. He



Imms, Augustus Daniel, Figure 3 **Augustus Imms.**

worked at Rothamsted Experimental Station from 1918. In 1931, he was appointed head of the new Entomology Department of Cambridge University, where he remained until his retirement in 1945. Some of his research was on termites, and he wrote a book (1925) "Social behavior in insects." At Manchester and then at Cambridge, his teaching responsibilities were important. Two of his books, (1925) "A general textbook of entomology," and (1947) "Insect natural history" were aimed at students. The first of these, through its numerous editions, has been the primary textbook of entomology used in Britain and British Commonwealth countries by generations of students. He was elected a fellow of The Royal Society in 1929. In 1936–1937, he served as president of the Royal Entomological Society of London. He died on April 3, 1949 (Fig. 3).

Immunity

Immune response is defined as that response made by the immune system when invaded by foreign substances or by microorganisms. Invertebrate organisms, including insects, possess immune capability, but it is dissimilar to vertebrate immunity. Vertebrate immune response can be anticipatory, meaning that once a vertebrate animal acquires an infection, it is unlikely to develop this same infection again. This is due to the fact that protein molecules called antibodies or immunoglobulins, which are highly specific for the immunostimulatory molecules produced by the agent that caused the initial infection, can be rapidly generated by memory cells. Memory cells are lymphocytes (white blood cells) that do not actively engage in making a response to a foreign antigen during the primary challenge, but which react readily upon re-exposure of the animal to the same antigen.

Invertebrates lack the lymphocytes necessary to produce the antibodies needed for immunological memory and subsequent anticipatory immune response. It has been suggested that invertebrates do not require such complex immune defense mechanisms. For instance, the invertebrate body plan is less complicated than that of vertebrates. Insects are r-strategists and have a much higher reproductive potential than vertebrate species. Even if a large percentage of an invertebrate population is killed by disease, there are still enough surviving individuals for repopulation. Additionally, the life span of most invertebrates is relatively short, so that the production of immunological memory is not necessary and may even be excessive. The invertebrate intrahemocoelic cellular and humoral defense mechanisms form the innate or natural immune system, an immediate defense response that acts on microbes that breach the highly resistant insect cuticle.

Imported Cabbageworm *Pieris (Artogeia) rapae* (L.) (Lepidoptera: Pieridae)

This is one of the most abundant white butterflies in the temperate areas of the world. It feeds on cruciferous plants, including vegetable crops such as cabbage.

► Crucifer Pests and Their Management
► Cabbageworm

Import Permit

An official document that authorizes importation of a commodity in accordance with specified phytosanitary requirements.

► Regulatory Entomology

Incense-Cedar Wood Wasps

Members of the family Anaxyelidae (order Hymenoptera).

► Wasps, Ants, Bees and Sawflies

Incidence

(of a disease) The number of new cases of a particular disease within a given period of time, in a population being studied.

Incipient Species

Consistent variation from the "normal" in appearance, physiology or behavior in a species that might lead to reproductive isolation and speciation.

Inclusion Body

A polyhedral structure which, in insect viruses, normally contains virions. They are also called polyhedral inclusion bodies (PIBs). Inclusion bodies are the product of occluded viruses.

Incomplete Metamorphosis

A type of metamorphosis characterized by slight changes in body form during the developmental period, and the presence of the egg, nymphal and adult stages. The pupal stage is lacking. This is also known as simple metamorphosis or hemimetabolous development. Some of the aquatic insects displaying incomplete development (Odonata, Ephemeroptera, Plecoptera) differ in the degree of difference between the mature and immature stages, and so are sometimes said to have gradual metamorphosis or paurometabolous development.

► Metamorphosis
► Complete Metamorphosis
► Gradual Metamorphosis

Incubation Period

The period in which the embryo develops within the egg before hatching (eclosion). In epidemiology, however, it refers to the period between when organisms are infected with a disease, and the appearance of the disease.

Incurvariidae

A family of moths (order Lepidoptera). They commonly are known as leafcutter moths.

► Leafcutter Moths
► Butterflies and Moths

Index of Similarity

The ratio of the number of species found in each of two communities to the total number of species that are found in both.

Indian Meal Moth *Plodia interpunctella* Guenée (Lepidoptera: Pyralidae)

This grain-feeding insect attacks stored grain products throughout the world.

► Stored Grain and Flour Insects

Indicator Species

A species that can be used as an assessment or indicator of the general condition of a habitat, community or ecosystem. This is also called a sentinel species.

Indifferent Species

Species that occur in may different types of communities, and thus are not useful for characterizing a community.

Indigenous

Normally found within the region, at least within recorded history.

► Invasive Insects

Indirect Flight Muscles

Muscles that power wing movement by changing the shape of the elastic thorax. Among the indirect muscles are the dorsal longitudinal muscles that arch the tergum and depress the wings, and the dorsoventral and oblique dorsal muscles that flatten the tergum and elevate the wings.

Indirect Pests

Pests that inflict damage by attacking a portion of the plant that is not harvested (often the roots, stems, or foliage), and weaken the plant, reducing overall yield.

Induced Food Preference

A tendency of insects to prefer food that they have fed upon previously, even though capable of eating other foods.

Induction

In insect ecology, the display of induced food preference. In insect pathology, the activation of an occult pathogen, leading to progressive infection and disease.

Industrial Melanism

The predominance of darker forms of some Lepidoptera resulting from natural selection (reduced predation) in areas with severe air pollution. A form of crypsis.

Infection

The introduction or entry of a pathogenic microorganism into a susceptible host, resulting in the presence of the microorganism within the body of the host, whether or not this causes detectable pathologic effects.

Infectivity

The quality of being infective; the ability to produce infection.

Infestation

The presence of a number of pests in a field, on plants, or in the soil.

Inflorescence

The flowering part of a plant. The flower.

Innate Capacity for Increase

(r_{max}) A measure of the rate of increase of a population under controlled conditions. Normally this is the maximum rate of reproduction possible under laboratory conditions without the effects of naturally occurring mortality due to disease, predation, etc.

Innate Immunity

D. G. Boucias, J. C. Pendland
University of Florida, Gainesville, FL, USA

Innate immune systems, although lacking the highly evolved antibody-producing mechanisms, are complex and involve gene families involved in signal detection, signal transduction, signal modulation, and stimulus response. For example, recent transcriptional profiling has revealed that over 500 genes are altered in *Drosophila* challenged by septic injury. The pathways and component gene products associated with the innate immune response observed initially in *Drosophila* have homologues in other insects (*Apis*, *Anopheles*) that have been subjected to genome-wide sequencing efforts. Interestingly, the innate immune pathways, excluding the insect phenoloxidase melanization and encapsulation components, are remarkably similar to those found in the innate systems of mammals. For example, immune response in insects depends upon several different activities that interact to form a well-coordinated immune system. These different activities include cellular defense reactions such as phagocytosis, nodulation, and encapsulation, as well as proteolytic cascades including, most notably, the prophenoloxidase (melanization) cascade and the coagulation cascade, which has actually been better described in other invertebrates, e.g., the horseshoe crab (*Limulus*). Insects produce an array of antimicrobial substances, which are usually low molecular weight, cationic peptides. The vertebrate innate system, likewise, consists of a complex of cellular defense reactions (phagocytosis, granuloma formation) and activities associated with the so-called complement proteolytic cascade systems and with various antimicrobial factors.

The immunocytes that function in the innate response include the neutrophils and macrophages found in vertebrates, and the granulocytes and plasmatocytes that occur in insects. Several other types of immunocompetent hemocytes have been described in some insect species (e.g., lamellocytes from *Drosophila*) and non-insect invertebrates. These cells are generally analogous with respect to phagocytic activities and even have similar morphological characteristics. Invertebrate hemocytes, like the leukocytes, often contain numerous granules, which can be sites of synthesis and/or storage of substances needed in the killing and digestion of ingested microorganisms, for enzymes used in cascade reactions, and for sequestering humoral antimicrobial peptides or AMPs. However, even though the invertebrates lack true lymphocytes, their immunocytes are more comparable to the lymphocyte-like natural killer cells (NKCs) found in vertebrates than to the neutrophils and macrophages. NKCs are cytotoxic cells that kill certain kinds of tumor cells and virus-infected cells. NKCs do not need the same types of receptors (e.g., immunoglobulin receptors) used by other types of lymphocytes (B and T lymphocytes) in order to carry out their activities. Instead, they have a more primitive recognition system that identifies self and then reacts against any material that is nonself. NKCs have been found in some invertebrates and thus may represent a vertebrate remnant of invertebrate immunocytes that operate by self-recognition. Some of the receptors that function in this type of response are carbohydrate-type binding molecules, termed lectins, which are common in both invertebrates and vertebrates. The NKC lectins constitute a unique superfamily of integral membrane proteins that inhibit as well as activate cell function.

After nonself material has been recognized, it can become attached to the receptors on the membranes of immunocompetent blood cells and then eliminated from circulation via phagocytosis. Phagocytosis (from the Greek *phagein* meaning to eat) is a process that is carried out not only by the immune reactive cells in higher animals, but also by organisms such as protozoans (e.g., *Amoeba proteus*), which ingest foreign material for nutritional purposes as well as for self-defense. With respect to immune activities, nonself particles that become attached to phagocytic immunocytes are endocytosed. These particles are taken into the host cell usually by way of membrane-bound phagosomes; and are killed by mechanisms such as enzymatic degradation or by the effects of toxic reactive oxygen and/or nitrogen intermediates. Not all microorganisms are susceptible to the destructive processes that occur within the phagolysosomes; some survive and replicate as intracellular parasites. Intracellular parasitism blood cells provide infective propagules an effective means to avoid further encounters with immune system activities and to be disseminated throughout the host.

Phagocytic hemocytes can function individually, or they can be recruited to sites of infection where, in insects, they may aggregate around the invading microorganisms to form nodules and/or capsules; these structures are comparable to the granulomas, i.e., aggregates of leukocytes, found in vertebrate systems. Recruitment molecules that stimulate the movement of blood cells to infection sites have been identified in both vertebrates and invertebrates. The chemokines, including the chemotactic cytokines and cytokine-type signaling molecules are present in some invertebrates. In insects, molecules belonging to the eicosanoid group of signaling moieties have been reported to function in the nodulation process; eicosanoids include the well-known prostaglandins described in vertebrates.

Pattern-Recognition Receptors of Nonself

The recognition and attachment events that initiate cellular defense response in innate systems are regulated by humoral and by membrane-bound molecules (receptors) that discriminate self versus nonself by a process known as pattern recognition. Pattern-recognition proteins (PRPs) are able to distinguish the highly conserved characteristics (pathogen recognition molecular patterns, PAMPS) that are unique to pathogens and are not usually found on the cells of other types of organisms, including self. These patterns can be displayed on microbial surfaces in the form of peptidoglycan molecules in the case of bacteria, or as mannose, galactose, or β-1,3-glucan residues in the case of fungi. Such components, since they commonly occur on surfaces of a variety of different microorganisms, enable complementary pattern recognition molecules to identify a broad spectrum of potential pathogens. Many insect pathogens produce modified surface that either lacks or camouflages PAMPs thus mimicking self surface epitopes.

In vertebrates, pattern recognition molecules serve as a primary defense line during the lag time required for antibody production to take place. They are acute phase reactants and are rapidly induced upon challenge. Lectins constitute a widespread group of pattern recognition molecules in vertebrates and in invertebrates. In both systems, the occurrence of C-type (i.e., calcium-dependent) lectins has been especially well documented. In vertebrates, this lectin group is best exemplified by the mammalian serum mannose-binding protein (MBP) and the macrophage mannose receptor. The C-type lectins in invertebrates, including insects, have sequences similar to those of the vertebrate lectins such as MBP. Lectins and other types of pattern recognition molecules serve as opsonins, so that the microorganisms that they coat become better targets for immunoreactive blood cells (see cell defense systems). Pattern recognition molecules bound to their respective ligands, often in an opsonic capacity, activate other components (the complement pathways in vertebrates) in the innate system.

Non-lectin pattern recognition molecules that bind to peptidoglycans, and β-1,3-glucans play multifunctional roles in both cellular and humoral defense responses. For example, the peptidoglycan recognition proteins (PGRPs) described initially as extracellular sensor of bacterial infection is now recognized as a family of PRPs. In *Drosophila*, two isoforms exist, the short version that functions as a co-receptor in the recognition of diaminopimelic acid-type peptidoglycans and the long version that functions at an intracellular level in defense of potential intracellular bacterial pathogens. A second subgroup, the catalytic PGRPs produced by the midgut cleave glycans off the peptidoglycan structure reducing their immunostimulatory ability thus preventing diet borne innocuous peptidoglycan from initiating an immune response. Another subgroup would include the secreted PGRPs that degrade peptidoglycan structure and either directly destroys the bacterial invader or clears bacterial cell wall debris from the insect. A second group of non-lectin pattern recognition molecules would be the gram-negative binding proteins (GNBPs). Certain GNBPs interact with PGRPS in the activation of the Toll in response to gram positive bacteria. These GNBPs may contain glucanase-like domain can detect fungal β-1,3-glucans and/or effect the agglutination of fungal cells (Table 1).

Signaling Pathways

At present, there are several major signaling pathways used to activate the host cellular response to microbial infection. The NF-κB pathways Toll and Imd activate the transcription of antimicrobial peptides (AMPs). Mutations in these pathways increase the susceptiblilty of insects to infection. The insect Toll, described initially in *Drosophila*, is activated when a cocktail of PGRPs and GNBPs interact with lysine-type peptidoglycan (gram positive bacteria) or β-1,3-glucans. The resulting complex induces serine proteases that cleaves and activates membrane-bound Spaetzle. This active protein binds to the transmembrane receptor Toll, triggering an intracellular serine kinase cascade. This leads to the phosphorylation and degradation of the inhibitor κB protein Cactus. Removal of Cactus activates of the NF-κB proteins DIF and Dorsal that are translocated into the nucleus to activate the transcription of the insect AMPs and prophenoloxidase activators. The meso-diaminopimelic acid peptidoglycans associated with gram-negative bacteria and with *Bacillus* spp. elicit the Imd pathway. Different membrane-bound PGRPs recognizing monomeric and polymeric peptidoglycan fragments stimulate the Imd pathway, activating a protease cascade that activates the

Innate Immunity, Table 1 Granular contents of vertebrate and invertebrate immunocytes[a]

Vertebrate cells		Invertebrate cells
Neutrophils	**Macrophages**	
Primary (azurophilic granules)		
Myeloperoxidase	Collagenase	Acid phosphatase
Acid phosphatase	Elastase	Esterase
Glucosaminidase	Plasminogen activator	β-glucuronidase
5′-Nucleotidase	Arginase	Lysozyme
α-Mannosidase	Tissue procoagulant	Cationic peptides
Arylsulfatase	Lysozyme	Lectins and hemagglutinins
α-Fucosidase	Complement proteins	Prophenoloxidases and associated
Esterase	Interferons	Factors (e.g., proPO activating enzyme, 76 kDa adhesion protein from crayfish)
Cathepsin	Interleukins	Coagulation factors
Elastase	Tumor necrosis factors (TNF)	LPS – binding protein
Histonase	Growth factors	β-1, 3 glucan-binding protein
Phospholipase A	Apolipoprotein E	(Silkworm)
Cationic proteins	Platelet activating factor	Acid mucopolysaccharides
Defensins	Oxygen metabolites	TNF, ACTH (adenocorticotropin)[b]
Glycosaminoglycans	Nitric oxide	ECM components[c]
Chondroitin sulfate	Fibronectin	
Heparin sulfate		
Lysozyme		
Secondary and tertiary granules		
Alkaline phosphatase		
Histaminase		
Collagenase		
Vitamin B_{12}-binding protein		
Laminin receptor		
C3bi receptor		
FMLP		
Lactoferrin		
Cytochrome b245		
Flavoproteins		
Lysozyme		
Tetranectin		
Gelatinase		

[a]Represents only a partial list of granule contents
[b]Localized in hemocytes, but not definitively in granules of *Calliphora* (fly) (See Franchini et al. (1996))
[c]Indicated by cross-reactivity of monoclonal antibodies to both basement membranes and hemocyte granules, e.g., in beet armyworm and other insects

NF-κB protein Relish that up-regulates transcription of AMPs and melanization components.

In addition to the Toll and Imd pathways, various insects possess components of the Jun N-terminal Kinase (JNK) pathway and JAK/STAT signal pathways. The JNK, an important pathway in the morphogenesis of imaginal discs, plays an important role in wound healing and in cell program death or apoptosis. The JAK/STAT or Hopscotch (Hop) signaling pathway, initially associated with embryonic segmentation, has been associated with immune response of both *Anopheles* and *Drosophila*. The Hop pathway in the fat body is triggered by the hemocyte produced cytokine Upd3, a 65 kDa glycoprotein. The Upd3 binds to the transmembrane receptor dome that stimulates Hop to phosphorylate the transcriptional activator the STAT 92E protein. The Hop pathway controls the expression of both TEP1 and the Turandot (Tot) proteins in fat body. In mosquitoes, the TEP1 is believed to act as an opsonin promoting phagocytosis of nonself. Removal of TEP by RNAi reduced phagocytosis of bacteria in mosquitoes. The Tot proteins, although not antimicrobial, appear to be involved in protection and repair of damaged tissues. In *Drosophila*, this pathway has been implicated in lamellocyte differentiation and hemocyte proliferation, events important to both phagocytosis and encapsulation.

Antimicrobial Response

Since the early 1900s, insects have been reported to respond to microbial challenge and to produce soluble components having potent antibacterial activity. In the late 1950s, heat-stable antibacterial components were detected in several lepidopteran hosts that had been challenged with microbial antigens. This research demonstrated that the tolerance of these immunized insects to a second bacterial challenge was correlated with the titer of the heat-stable antibacterial component. Pioneering work by H. Boman and associates at Stockholm University during the late 1970s to early 1980s using the diapausing pupae of the giant silkworm (*Hylaphora cecropia*) as a model provided details on the biochemistry of insect humoral response. Hemocoelic challenge with non-pathogenic viable bacteria induced these pupae to produce antibacterial activity within 10 h post-injection. These diapausing pupae, having an intrinsic low metabolic activity, allowed Boman's team to selectively radiolabel the induced antimicrobial components. Using various biochemical methods, the major antibacterial components produced by *H. cecropia* pupae have been isolated and characterized.

In several respects, the insect humoral response has been compared to the acute phase response of vertebrates. Wounding or septic injury induces many insects to rapidly synthesize a complex of antimicrobial proteins/peptides that may act on a range of bacteria and/or fungi. Hultmark describes eight classes of AMPs including lysozyme, defensins, cercropins, diptercins, attacins, drosocins, Metchnikowins, and drosomycins. The synthesis of these antimicrobial components, detected in various host tissues within hours after being induced, protects the host animal against rapidly dividing microbes. It should be noted that insects produce a family of AMPs that are regulated by multiple overlapping pathways. In many insects, the levels of antimicrobial activity are maintained at inhibitory levels for several days. The majority of antimicrobial proteins found in insects are small peptides (about 10 kDa) that act in a stoichiometric fashion on the microbial membranes.

Lysozyme

The lysozymes from the wax moth *Galleria mellonella* and silkworm *Bombyx mori* represent the first antibacterial proteins to be purified from insects. Insect lysozyme, unlike other antimicrobial proteins, acts catalytically and digests the cell walls of certain gram positive bacteria. In several cases, lysozyme acts as a synergist with the smaller cationic peptides. The outer membrane of gram negative bacteria usually serves as an effective barrier against lysozyme attack. This enzyme digests the glucosidic bond between *N*-acetylglucosamine and *N*-acetylmuramic acid of the peptidoglycan layer. Additionally, certain insect lysozymes possess potent chitinolytic activity. Lysozyme synthesized in various tissues may possess a multifunctional role in different insects. In certain cyclorrhaphous flies, this enzyme is produced constitutively by the midgut tissue and assists in the digestion of ingested bacteria. The insect midgut lysozymes are active at an acidic pH, possess a high chitinolytic activity, and are functionally similar to the stomach lysozymes of vertebrates.

These enzymes are relatively small (about 15 kDa), heat stable, basic proteins and are very easy to detect and extract from insect tissues. Tissue homogenates may be acidified, heat-treated (boiled for 2 min), and centrifuged to remove large molecular weight proteins. The lysozyme may be readily extracted from the supernatants using cation exchange chromatography. During purification, lysozyme activity may be assayed against a cell wall preparation of the gram positive *Micrococcus lysodeiktus*. Lysozyme digests the cell wall, causing a decrease in the turbidity of the substrate that may be measured spectrophotometrically at 570 nm. Lysozyme may be detected in both normal and immunized insects. Many insects produce multiple forms of lysozyme that possess distinct isoelectric points and pH optima. The lysozyme genes of *D. melanogaster* exist as a multiple gene family, lack introns, and are not induced by bacterial challenge. In other insects, low levels of lysozyme are detected as a normal component of the hemolymph. The hemolymph lysozyme of *Manduca sexta* larvae has been reported to have played a key role in initiating and sustaining the humoral defense response. This enzyme digests the bacterial cell wall and releases peptidoglycan fragments which act as elicitors of the humoral response. The fat body is triggered by these elicitors (inducers) to synthesize and to secrete high titers (mg/ml) of both lysozyme and other antibacterial peptides into the insect hemolymph.

Antibiotic Peptides

The antibiotic peptide group, containing members with 50 amino acids (aa) or less, may be divided into the linear peptides and the cyclic peptides that contain one or more disulfide bridges. The hydrophobic domains allow these peptides to interact with the lipid bilayer of microbial membranes. Secondly, the majority of antibiotic peptides contain multiple arginine and/or lysine residues that confer a basic net charge to these cationic peptides. These peptides act stoichiometrically, inserting into and disrupting the microbial cell membrane. Although capable of killing many different species of prokaryotes, many antibiotic peptides have little or no effect on eukaryotic cells. In part, this specificity reflects the preferential binding of these cationic peptides to the anionic phospholipids contained within outer layers of bacterial cells. The presence of high levels of cholesterol in eukaryotic cell membranes has been reported to neutralize the effects of certain amphipathic peptides. In most insects, the synthesis of these peptides is induced when certain microbial elicitors (e.g., lipopolysaccharides, mannans, peptidoglycans) bind to cell membrane receptor domains. Induction results in the synthesis of a family of these antibiotic peptides that act in concert against a spectrum of potentially pathogenic microorganisms.

Many of the methods used to detect and to isolate insect antimicrobial peptides were established by H. Boman (University of Stockholm). His research group found that *H. cecropia* pupae and *Drosophila* larvae challenged with either live or killed bacteria or preparations of bacterial wall components generate a potent humoral response. Large insects such as lepidopteran larvae may be injected directly with a bacterial suspension, whereas smaller insects such as fruit fly larvae may be pricked with pins coated with elicitor preparations. At various time intervals post-challenge, either hemolymph or whole insects can be sampled for subsequent processing. Typically, hemolymph or tissue is homogenized in an acidified buffer containing appropriate protease inhibitors. These mixtures may then be heat-treated and centrifuged to precipitate large molecular proteins. The relative levels of antimicrobial activity may be monitored using growth inhibition assays. Target microbes, placed in broth or incorporated in solid media, are assayed against test suspensions. For example, to measure activity against gram negative bacteria, the *E. coli* K12 strain D-31 is used routinely as the detector organism. Bacteria are incorporated into solid media and test suspensions applied to wells cut in the agar surface. The diameters of the resulting inhibition zones are measured and compared to those produced by commercially available synthetic antibacterial peptides. Alternatively, detector bacteria may be placed in broth and amended with various dilutions of the test preparations. Growth inhibition, measured spectrophotometrically as a reduction in turbidity, may be used to calculate the minimum inhibitory concentration (MIC). It should be noted that certain insect antibacterial peptides/proteins may act in a synergistic fashion. For instance, the cell membrane-disrupting action of many peptides is known to increase the activity of lysozyme against gram negative bacteria. Therefore, the high antimicrobial activity detected in crude preparations may be dramatically reduced as the cofactors are subjected to chromatographic fractionation.

Linear Peptides (Cecropins)

The cecropins, initially described in the early 1980s from fruit flies and silkmoths, have since been detected in various vertebrates. These antibiotics consist of a linear chain of 35–37 amino acids organized into three regions: a strongly basic N-terminus, a long hydrophobic stretch at the C-terminus, and a middle hinge region containing proline and/or glycine. Structurally, these peptides form two α-helices connected by the middle hinge region. Various insect cecropins isolated from lepidopteran and dipteran host insects have been sequenced and their cDNA cloned. Structurally distinct forms of cecropins, produced by the same or different insects, possess distinct antibiotic activities against different bacteria. Cecropins are usually highly active against gram negative bacteria, active against selected gram positive bacteria, and inactive against most eukaryotic cells. In addition to insects, cecropins have been detected in vertebrates, e.g., cecropin P1 in porcine intestine. Unlike the insect cecropins, the P1 molecule contains an amphipathic α-helical structure through the entire sequence.

The cecropins secreted from insect cells recognize and bind to target microbial cells. The incubation of liposomes, comprised of acidic phospholipids, with sarcotoxin resulted in a dose-dependent release of entrapped glucose molecules demonstrating that cationic peptides can bind to acidic phospholipids and permeabilize the lipid layer. Amending liposome preparations with cholesterol repressed the cecropin activity. Further studies suggested that at a high dosage, cecropins aggregated on the bacterial membrane to produce ion channels. Cecropins at physiologically active levels bind to the outer membrane as monomers and then diffuse into the wall to reach the target inner membrane. As monomers, the active cecropins possessing a 12–15 aa α-helix have an estimated length of 20 Å, which is too short to span the 30 Å membrane lipid bilayer. Rather than producing ion channels, cecropins apparently cause a rapid lysis of bacterial cells acting in a detergent-like fashion to disrupt the bacterial membrane.

In addition to cecropins, animals produce a number of other linear antibiotic peptides with amphipathic α-helical conformations. For example, the honey bee *Apis mellifera* synthesizes a venom peptide, mellitin (26 aa), that possesses α-helical structures at both C- and N-termini. Mellitin is one of the most powerful cell lytic agents and is active against both prokaryotic and eukaryotic cells. This peptide is constitutively produced by the secretory cells of the venom duct as promellitin (70 aa) which is later activated by proteolytic cleavage. Hybrid molecules containing the

N-terminal sequences of mellitin and cecropin A have been synthesized and found to possess enhanced antibacterial activities. In addition to honey bees, several adult dipterans have been reported to constitutively secrete cecropin-type antibiotics from their reproductive organs. The ceratotoxins, 3 kDa antibacterial peptides, are specifically synthesized by the female accessory gland of the medfly *Ceratitis capitata*. These peptides, like mellitin, possess potent activity against gram negative and gram positive bacteria and possess a strong hemolytic response. Although related structurally to cecropins, ceratotoxin synthesis is stimulated by mating and not by septic wounding. The ceratotoxin gene codes for a 71 aa proceratotoxin which is activated by a dipeptidase. It has been proposed that this peptide, detected on the egg surface, protects the developing embryo from microbial attack. A second sex-specific antibiotic peptide, the 3 kDa andropin, has been found to be synthesized in the male ejaculatory duct of *D. melanogaster*. Andropin synthesis, unaffected by bacterial challenge, is induced by mating and is believed to inhibit bacterial infections in the reproductive tract.

Disulfide-Linked Peptides

These peptides, unlike the linear peptides, possess a β-sheet structure and contain one or more intramolecular disulfide bonds. The defensins are presently the most diverse and best-studied disulfide-linked antibiotic peptides. Pioneering research on defensins was conducted by immunologists studying the cationic peptides associated with the azurophilic granules of vertebrate neutrophils. Insect defensins, initially described in the dipterans *Phormia terranovae* and *Sarcophaga peregrina* are structurally similar to the defensins isolated from vertebrate phagocytic cells. The insect defensins contain about 40 aa residues, including six cysteines which produce the characteristic three intramolecular disulfide bridges. Insects in the orders Diptera, Hymenoptera, Coleoptera, Odonata, Trichoptera, and Hemiptera have been reported to produce defensins. Members within the order Lepidoptera, characterized by possessing inducible lysozyme genes, have not been found to produce defensins. Structurally, insect defensins possess an N-terminal flexible loop, a central amphipathic α-helix, and a C-terminal anti-parallel β-sheet. The *S. peregrina* defensin, termed sapecin, was isolated from the culture media of embryonic cell lines of *S. perigrina*. This peptide, constitutively produced by the cell line, inhibits gram positive bacteria more effectively than gram negative bacteria. Sapecin has a high affinity to cardiolipin, a major phospholipid of certain gram positive bacteria. Gram negative bacteria contain less cardiolipin and possess the outer LPS layer believed to serve as a barrier for certain cationic antibacterial substances. The second well-characterized insect defensin group was isolated from *P. terranovae* larvae which had been challenged by pricking insects with needles coated with the gram negative *Enterobacter cloaca*. Analysis of the *P. terranovae* defensins A and B demonstrated that their structures, which differ by a single amino acid, are highly homologous to the well-characterized vertebrate defensins. Various other defensin molecules have been detected in many other insects, including mosquitoes, honey bees, and hemipterans. In all cases, the insect defensins possessing a well-defined α-helix may be readily distinguished from the vertebrate defensins, which consist of only β-sheets. The vertebrate and insect defensins have been reported to form voltage-dependent ion channels in bacterial membranes. Vertebrate defensins are known to sequentially permeabilize the outer and inner bacterial membranes. Vertebrate defensins, existing as dimers, bind to the membranes via electrostatic interactions and produce a barrel stave aggregate, forming an ion channel. The *P. terranovae* defensin, like the vertebrate defensin, induces the formation of ion channels in assayed bacterial membranes. These channels, also produced by defensin treatment of liposomes, can be opened and closed by manipulation of the membrane potential.

Proline-Rich Peptides

These small (2 kDa), linear peptides contain high levels of proline residues. The first insect proline-rich antibacterial peptide, drosocin, was isolated from bacterially challenged *D. melanogaster*. Drosocin is *O*-glycosylated and possesses an *N*-acetylgalactosamine-galactose derivative on the threonine residue. Synthetic drosocin, lacking the sugar residue, possessed reduced antibacterial activity against target gram negative bacteria. Metchnikowin, also described from *Drosophila*, is a 26 kDa proline-rich inducible peptide that targets gram positive rather than gram negative bacteria and is also antifungal. Metchnikowin is expressed in fat body, and there is some sequence similarity to another proline-rich peptide, abaecin, from honey bees. Additional *O*-glycosylated proline-rich peptides have been detected in the hemipteran *Pyrrhocoris apterus*. This peptide, termed pyrrhocoricin, is highly active against selected gram negative bacteria. Unlike the previously discussed cationic peptides that are hydrophobic, the presence of the polar sugar residue confers a hydrophilic property to these proline-rich peptides. In general, the glycosylated antibiotic peptides act more slowly than the hydrophobic peptides. Sequence analysis has shown that pyrrhocoricins are somewhat homologous to the N-terminus of the glycine-rich peptides (see following section). The apidaecins, major components of the honey bee antibacterial repertoire, are small, non-glycosylated, proline-rich peptides.

Glycine-Rich Peptides

Various inducible proteins such as attacins (20 kDa) and sarcotoxins (24 kDa), and peptides such as coleoptericins (8 kDa), diptericins (9 kDa), and hymenoptaecins (10 kDa) can be included within this heterogeneous group. All of these antibiotic peptides/proteins contain a high percentage of glycine residues (12–22%). The attacins, named for the saturnid tribe *attacini*, were first isolated from *H. cecropia*. A total of six attacins, four cationic and two anionic isoforms, have been characterized in the hemolymph extracted from bacterially challenged *Cecropia* pupae. The different attacin isoforms are produced by differential post-translational modifications of two parental proattacin sequences. Attacins, unlike the smaller cationic peptides, are bacteriostatic and possess only limited activity against selected gram negative bacteria that are actively growing. Southern blot hybridizations of the radiolabeled attacin probe and digested *B. mori* genomic DNA suggest that *B. mori*, like *H. cecropia*, contains a multi-gene attacin family. Sequence analysis of the *B. mori* gene demonstrated extensive homology to the *Cecropia* attacins, and an attacin from *Trichoplusia ni* also shows significant homology to these peptides at both the nucleotide and peptide levels. In addition, the *B. mori* gene exhibits sequence similarity to the sarcotoxin II family. The sarcotoxins II (A-D), isolated from challenged *Sarcophaga peregrina* larvae, are large (24 kDa) glycine-rich peptides. The glycine-rich domain of sarcotoxins extends over 60 residues from the C-amidated terminus. *Sarcophaga peregrina* larvae may also be induced to synthesize a glycine-rich 8 kDa diptericin.

Diptericins were detected initially in bacteria-challenged *P. terranovae* and were characterized as cationic antibacterial peptides possessing an N-terminal proline-rich region and a C-terminal glycine-rich region. Some consider diptericins as chimeric molecules containing components of both the proline-rich and glycine-rich antibacterial peptides. The *P. terranovae* diptericin A possesses potent bactericidal activity against smooth strains of selected gram negative bacteria. Detailed chemical analysis of various isoforms of diptericin A demonstrated that this peptide is *O*-glycosylated at threonine residues located at both the proline-rich and glycine-rich domains. Septic wounding of larvae, pupae, and adult fruit flies induced the synthesis of diptericin transcripts within 2 h post-inoculation. In addition, both early pupae and adult stages displayed low levels of constitutive expression. Recently, a 133 residue glycine-rich peptide has been characterized from *P. apterus*, termed hemiptericin, which displays some homology to the glycine-rich domain of diptericin and is active against certain gram negative bacteria.

In addition to the glycine-rich antibacterial peptides, several members within this heterogenous group possess potent antifungal activity. The cationic antifungal peptide AFP is constitutively produced by *S. peregrina* larva. This peptide, possessing 67 amino acids, contains high levels of glycine (31%), histidine (20%), and glutamine (18%) residues. Bioassays have demonstrated that this peptide binds to the yeast *Candida albicans* through electrostatic interaction and disturbs the osmotic integrity of treated cells. Peptides related to AFP have been isolated from several coleopteran hosts. The peptide tenecin 3, extracted from the naïve meal worm *Tenebrio molitor*, possesses 78 aa of which 80% are glycine, histidine, and glutamine residues. Tenecin 3 at concentrations of 10 µg/ml inhibits the growth of the dimorphic vertebrate mycopathogens *Candida albicans* and *Cryptococcus neoformans*. A third antifungal peptide, referred to as drosomycin, has been detected in wounded, septic *Drosophila*. Unlike tenecin 3 and AFP, drosomycin is cysteine-rich and does not contain high levels of glycine, histidine, and glutamine. Structural characterization of drosomycin has demonstrated significant homology to the cysteine-rich plant antifungal peptides found in seeds of the Brassicaceae.

Genetics and Biosynthesis of Antibacterial Peptides and Proteins

Transcription of the antibacterial genes is induced by treating insect cells or whole insects with various elicitors such as bacterial LPS, phorbol myristate acetate (PMA), live and killed bacterial cells, etc. Sequencing regions upstream of the open reading frames of antibacterial genes has revealed the presence of cis-regulatory sequences resembling the κβ-binding motif that serves as the binding site for the transcription activators (see signal pathways). The κβ -binding motif has been found to be associated with genes coding for acute phase proteins, cytokinins, immunoreceptors, transcription factors, and in genes of certain DNA viruses.

The insect antibiotic protein and peptides are products of m-RNA transcripts translated on the insect ribosome. In most cases, the translation products are preproproteins and require additional processing for both secretion and activation events. Many preproproteins consist of three domains: a signal sequence, prosequence, and mature peptide. Within a particular peptide group extensive homology exists in the primary and secondary structure of the mature peptides. However, the N-terminal signal sequence may vary extensively among peptides extracted from different insect hosts. The signal sequence, usually comprised of ~20 aa, guides the translation product into the endoplasmic reticulum for further processing and transport to either intracellular or exocellular locations. The antibiotic peptides may undergo various post-translational modifications within the insect cell. The cecropins and certain glycine-rich peptides undergo a C-terminal amidation. Various defensins such as drosocin, pyrrohocoricin, and certain diptericins undergo *O*-glycosylation in the endoplasmic reticulum. These peptides are decorated with sugar moieties covalently linked to defined threonine residues. The basic and acid preproattacins may be proteolytically cleaved at a terminal tetrapeptide site of the mature peptide and/or have an N-terminal pyroglutamate residue formed. The result of these post-translational modifications is the production of six isoforms of attacins. Activation of the antimicrobial peptides involves proteolytic removal of the prosequence. For example, the preprocecropins contain 62–64 aa of which the signal peptide comprises the initial 22 aa of the N- terminus. The adjacent proline or alanine dipeptide (prosequence) is selectively removed by a dipeptidylaminopeptidase. Similarly, the 29 aa prosequence of the attacins is removed in the Golgi compartment by a dipeptidase recognizing the arg-arg motif.

In conclusion, the humoral antimicrobial peptides and proteins produced in insects play a significant role in their defense against invading pathogens, especially during the early phases of infection. Similarly, in vertebrates, such components often serve as acute phase molecules that function to protect an organism prior to activation of the more complex adaptive (antibody) response. These vertebrate antimicrobial proteins (e.g., lysozymes) and peptides (defensins) are structurally similar to those in invertebrates, so that the invertebrate homologues most likely represent evolutionary prototypes. Evidence that *H. cecropia* antibacterial genes have κβ-binding site transcription activators further confirms that innate immunity in higher animals is directly related to the defense response mechanisms displayed in more primitive organisms (Table 2).

Cellular Defense Systems

The major cellular defense systems in insects involve specific classes of mobile hemocytes found in the hemocoel. Morphological heterogeneity within a population of these cells due to variations in age or physiological state has led workers to assign more than 70 different names to the blood cells collected from insects. Insect hemocytes can be placed into six different categories: prohemocytes (stem cells), granulocytes, plasmatocytes, spherulocytes, adipohemocytes, and oenocytoids. The morphology of these cells varies considerably among the orders of insects and even among the different genera, and morphological changes also occur as the cells

Innate Immunity, Table 2 Different groups of antimicrobial peptides and proteins produced by various insect and vertebrate hosts

Peptide group	General structure	Host animal	Target microbe
Linear peptide without cysteine			
Cercropins A, B bacteria (35–39 aa)	Two α helical domains connected with hinge c-amidated	Lepidoptera, pig small intestine	Diptera gram negative
Magainins (23 aa)	Amphipathic α helix	Frog skin	Gram positive and negative bacteria, fungi, protozoa
Ceratotoxin	Helical	*Ceratitis capitata* females	Bacteria
Andropins (32 aa)	Two helices	*Drosophilia* males	Bacteria
Linear peptides and proteins with high proportion of a amino acid(s)			
Apidaecins (18 aa)	Proline, arginine rich	Honeybees	Gram negative bacteria
Drosocin (19 aa)	Proline rich, glycosylated	*Drosophila*	Gram negative bacteria
Bac (43, 59 aa)	Proline, arginine rich	Bovine neutrophils	Gram negative bacteria, antiviral
PRPs (39 aa)	Proline, arginine rich	Pig intestine	Gram negative bacteria
Acid attacin (20 kDa)	Glycine rich protein two G-domains	*H. cecropia*	Gram negative bacteria
Sarcotoxin IIA (24 kDa)	Glycine-rich protein C-animated, two g-and one P-domain	Fleshfly *Sarcophaga*	Gram negative bacteria
Diptericin (9 kDa)	Glycine and proline C-amidated, one G and one P-domain	Fleshfly *Phormia*	Gram negative bacteria
Peptides with A single disulfide bond			

Innate Immunity, Table 2 Different groups of antimicrobial peptides and proteins produced by various insect and vertebrate hosts (Continued)

Peptide group	General structure	Host animal	Target microbe
Bactenecin (12 aa)	4 Arginine residues	Bovine neutrophils	Bacteria (neuronal cells)
Brevinin (34 aa)		Frog skin	Bacteria
Peptides with two or more disulfide bonds			
α-Defensins	3 Disulfide bridges, pore formers	Vertebrate phagocytic and mucosal cells	Bacteria, fungi
β-Defensins (38–42 aa)	3 Disulfide bonds	Bovine neutrophils	Bacteria
Insect defensins	3 Disulfide bonds inducible peptides	Species within six insect orders	Gram positive bacteria
Protegrins (16–18 aa)	2 Disulfide bonds	Pigs leukocytes	Bacteria
Tachyplesins (17–18 aa)	2 Disulfide bonds	Granules of horseshoe crab hemocytes	Bacteria
Androctonin (25 aa)	2 Disulfide bonds	Scorpion hemolymph	Bacteria, fungi
Buthin (34 aa)	3 Disulfide bonds	Scorpion hemolymph	Bacteria

For additional data see Boman, 1995

mature. There are a number of synonyms for granulocytes, including coagulocytes, cystocytes and amoebocytes, among others. In *Drosophila*, plasmatocytes involved in encapsulation have been named lamellocytes, and the crystal cells in these insects may be the equivalent of the oenocytoids described in other genera. Markers (e.g., lectins, monoclonal antibodies) for specific cell surface ligands have been used to distinguish different types of hemocytes in some insects.

It is generally agreed that hemocytes from the granulocyte (GR) and plasmatocyte (PL) classes perform most of the cell defense activities. In some insects, the GRs are the predominant immunocompetent cells, whereas in others, the PLs carry out most of the immunological activities. The number of immunocompetent cells can fluctuate, most notably during morphogenesis and aging of insects. As in the case of the mobile phagocytes (polymorphs and macrophages) in vertebrates, the GRs, PLs, and other types of insect hemocytes associate with various tissues either as loose aggregates of cells or as distinct, well-defined organs. These reservoirs of sessile hemocytes function as phagocytic organs and/or as hemopoietic organs, i.e., as sites for the formation of new blood cells.

The granulocyte is the most common type of blood cell found among arthropods and is considered to be the primitive cell form from which other classes of hemocytes evolved. As suggested by their name, these cells are distinguished by the presence of numerous cytoplasmic granules. Insect granulocytes are generally spherical or oval and vary in size. The granules also differ in size and in shape and can be electron-dense or electron-lucent. Numerous ribosomes and polysomes, Golgi bodies, endoplasmic reticulum, lysosomes, and microtubules also are found in the GR cytoplasm. The nucleus varies in size and is usually centrally located. The plasmatocytes are polymorphic and are round, amoeboid, spindle, or leaf-shaped. The cytoplasm may contain electron-dense granules and, as in the GRs, is rich in organelles, ribosomes, and microtubules.

The Phagocytic Process

Phagocytosis consists of several discrete steps which include chemotaxis, activation of receptors on the phagocyte plasma membrane, attachment of the microorganism to the membrane receptors, and engulfment by extensions of the phagocyte (pseudopodia) so that the microbe becomes encased in a vacuole, i.e., a phagosome. Events which follow the formation of the phagosome usually result in the killing and digestion of invading microorganisms. Chemotaxis in invertebrates in several respects parallel those pathways operating in the vertebrate system. For example, hemocytes from some invertebrates (e.g., the oyster or the clam) are attracted only to live bacterial (*E. coli*) cells, thus demonstrating that migration of the blood cells is induced by chemo-attractants that are secreted by the microbial cells. Mollusc hemocytes have been found to migrate to *N*-formylmethionyl peptides, the bacterial metabolites that are chemotactic for vertebrate neutrophils. Among this group of peptides, formyl-methionyl-leucyl-phenylalanine (fMLF) is the strongest attractant for neutrophils. It also affects migration of the clam hemocytes and is chemokinetic, thus affecting speed and/or turning maneuvers for randomly moving *Mytilus edulis* (mollusk) hemocytes. As in vertebrates, microorganisms other than bacteria have been observed to be chemotactic for invertebrate hemocytes. Invertebrate phagocytes are comparable to those of vertebrates in that they require a functional cytoskeleton in order to be mobile. Toxic fungal metabolites, such as cyclic peptides, are known to inhibit chemotactic and chemokinetic response.

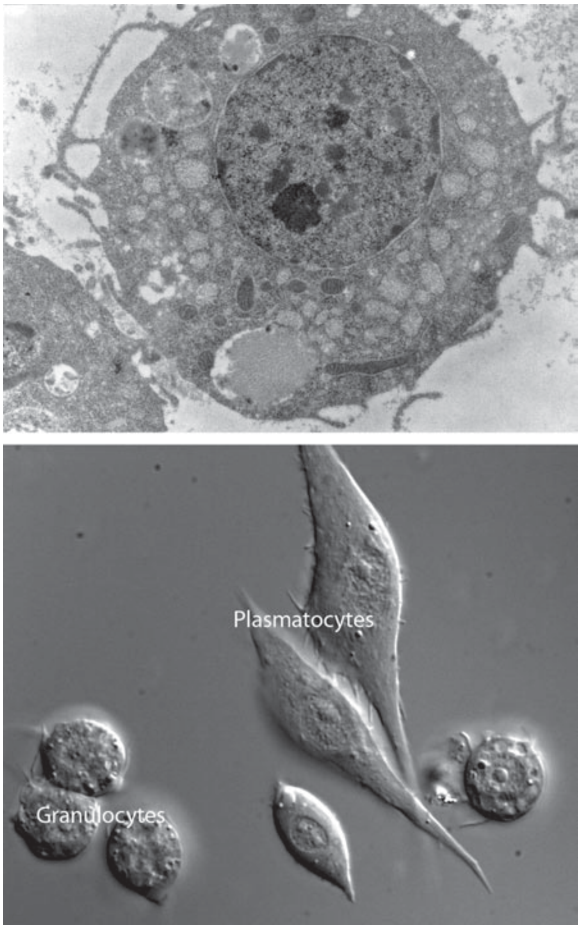
In insects and other invertebrates, the aggregation of hemocytes around infectious propagules (i.e., nodulation, encapsulation), as in the generation of granulomas in vertebrates, requires intervention by chemotactic factors. The cytokines and neuropeptides and the activities of eicasonoid-type signaling molecules are likely involved in the nodulation and phenoloxidase cascade in some insects. There are chemo-attractants released during activation of the cascade that facilitate hemocyte recruitment. Prophenoloxidase and phenoloxidase form a complex with the IL-1-like molecules in *Manduca*. When phenoloxidase is deposited on foreign material subsequent to activation of the ProPO cascade, the IL-1 molecules become localized and, as a result, other chemo-attractants as well as hemocytes are directed to an infection site.

Cell Surface Receptors and Ligands

The attachment step in the phagocytic process involves the binding of microbial cells to phagocytic cell surfaces. Divalent cations are required for phagocytosis and may be involved in the initiation of binding via electrostatic forces as well as in the receptor-mediated consolidation of attachment which follows. Lectin-mediated attachment, which involves the interaction between microbial surface oligosaccharides and receptors with lectin or lectin-like properties is often calcium-dependent. Phagocytosis resulting from lectin-carbohydrate attachment mechanisms is termed lectinophagocytosis. This process does not require opsonization of microorganisms prior to attachment to phagocyte surfaces. Opsonization involves the coating of foreign particles by host serum components (e.g., humoral lectins, immunoglobulins, or complement) so that they become better targets for phagocytic cells. Opsonin-mediated phagocytosis is called opsonophagocytosis, and this process, since it often requires the presence of IgG or complement, is probably more advanced in evolutionary terms than non-opsonin-mediated mechanisms such as lectinophagocytosis.

In invertebrates, the physicochemical aspects of attachment have been characterized quite extensively, often with respect to surface charges on foreign particles that are targeted for encapsulation by insect hemocytes. However, very little is known about the specific plasma membrane receptors that mediate microbial attachment to invertebrate phagocytes, especially as compared to the information available on vertebrate leukocyte receptor biology. The binding patterns of monoclonal antibodies produced against insect hemocytes suggest that certain epitope binding sites function in recognition of and attachment to microorganisms. In the waxmoth *Galleria mellonella*, monoclonal antibodies bound to a 90 kDa protein antigen on granulocytes reduced the phagocytic ability of these hemocytes. A number of studies have utilized both exogenous (plant) and purified endogenous lectins with different sugar specificities to probe the surface distribution of specific carbohydrate residues on invertebrate hemocytes. These lectin binding sites represent glycosolated protein and lipoprotein receptor molecules that function during non-opsonin-mediated lectinophagocytosis or during opsonophagocytosis of microbes coated with exogenous lectins. In some insects, hemocyte lectin binding patterns correlate to the immune capabilities of these cells. For example, binding patterns of wheat germ agglutinin (WGA)-FITC conjugates to *Aedes* or *Drosophila* hemocytes coincide with immunocompetence, but it is not known if the WGA-binding epitopes are the same as those that recognize and attach to surface components on parasitic organisms. In other insects, lectin binding sites visualized on hemocyte surfaces appear to represent functional microbial recognition and attachment sites. For example, a galactose-specific lectin purified from *Spodoptera exigua* (beet armyworm) hemolymph specifically labels a plasma membrane component(s) only on granulocyte-type hemocytes. Granulocytes, in turn, are the only hemocytes involved in recognition, attachment, and phagocytosis of certain fungal cells. Most importantly, these fungal cells must be opsonized with the lectin in order to elicit cellular response. Granulocytes from *S. exigua* also are labeled by some exogenous plant lectins, and these too enhance binding if used to coat selected target particles (Fig. 4).

Lectins are integral components of the invertebrate hemocyte membranes. These lectins function as pattern recognition molecules during



Innate Immunity, Figure 4 Granulocytes: (*above*) Transmission electron micrograph of a granulocyte. The cell contains a centrally located nucleus and is characterized by the presence of a number of morphologically diverse granules. (*below*) Differential interference contrast micrograph of insect hemolymph showing round granulocytes and spindle-shaped plasmatocytes containing an elongate nucleus and numerous mitochondria.

non-opsonin-mediated phagocytosis and thus are comparable to mannose receptors and to integrin receptors that have lectin domains in vertebrates. There are integral hemocyte membrane receptors that cannot be classified as lectins which mediate phagocytic activities in invertebrates. These include adhesion molecules comparable to the integrins which, in vertebrates, have dual functions in cell-cell adhesion and in nonself recognition. In *Drosophila*, a 68 kDa membrane protein (croquemort) expressed in embryonic macrophages is a member of the CD36 type superfamily of membrane receptors which, in vertebrates, serves in both cell adhesion and in nonself recognition.

A second membrane receptor expressed in embryonic hemocytes from *Drosophila* is a scavenger-type molecule referred to as DSR-C1 (*Drosophila* scavenger receptor, class C). Class A and B scavenger receptors (SR-A and SR-B) have been identified in vertebrate systems. Mammalian SR-A is macrophage-specific and binds to a wide variety of polyanionic ligands. DSR-C1 has similar binding specificities, but its protein sequence differs from the SR-A and SR-B sequences. The insect receptor is a multidomain protein having the polyspecificity necessary for the self versus nonself discrimination mechanisms that operate during innate immune response in both vertebrates and invertebrates. Scavenger receptors therefore function in the recognition and phagocytosis of a variety of different microorganisms as well as in the clearance of damaged or dead self tissues and cells, and as adhesion molecules during development, where they interact with other cells or with ECM-type components.

Immunoglobulin-like Molecules and Humoral Lectins in Insects

Pathogens invading invertebrate organisms often require opsonization before they can be recognized by specific receptors on phagocytic cells. In insects, there are several different classes of molecules which are opsonic. These include humoral lectins, lectin-like agglutinin molecules, and products of the prophenoloxidase (proPO) cascade system. The multifunctional proPO cascade is comparable to the vertebrate complement system in a number of ways. Both systems generate opsonic intermediates that assist in the initial recognition and attachment phases of phagocytosis.

The insect humoral as well as those from other invertebrates function in ways not necessarily related to host defense. These include activities associated with metamorphosis, such as the scavenging and removal of cells and tissue fragments during molting and at pupation. In addition, they aid in regulating tissue growth and differentiation, act as cell-to-cell adhesion molecules, and as transport or storage molecules for sugars. With respect to immune defense, invertebrate humoral lectins can function as opsonins and as agglutinins, causing the formation of clumps of microbial cells (e.g., bacteria) or parasites (trypanosomes), both of which can be more easily phagocytosed or encapsulated than individual cells. A lectin (M13) from *Manduca* initiates hemocyte coagulation. Since coagulation and the proPO cascade are interactive processes, humoral lectins and proPO components must also be interactive, functioning interdependently rather than as separate entities in the immune defense system. It has been reported that insect lectins have binding sites other than those for their specific carbohydrates, and that these alternative sites are involved in the activation of the proPO cascade. For example, several lectins from *Blaberus discoidalis* (cockroach) serum have been observed to activate the proPO system, even in the presence of carbohydrates for which they have a known affinity. Thus, insect lectins may activate proPO in much the same manner that MBP stimulates the complement system in mammals. In addition, the *B. discoidalis* lectins may regulate the proPO cascade by affecting serine protease and/or protease inhibitor activities along the chain. The initial regulatory step involves the binding of the lectin(s) to specific glycoprotein receptors on hemocyte membranes. Evidence from earlier studies already has shown that these (i.e., sugar residues specific for the *B. discoidalis* lectins) are displayed on the hemocyte membranes. The relationship between the proPO system and humoral lectins is probably less complicated in some other insects. For example, it is reported that hemagglutinin(s) in the hemocoels of *Anopheles quadrimaculatus* binds to carbohydrates on the surfaces of *Brugia malayi* filarial parasites. The coated filarial parasites are then recognized as nonself, resulting in activation of the proPO cascade. The nonself display is due to the bound hemagglutinin moieties presenting a configuration different from the unbound, endogenous form.

Hemolin has been isolated from the hemolymph of the moth *Hyalophora cecropia* and the tobacco hornworm *Manduca sexta*. It is a 48 kDa protein made up of four C2-type Ig domains; C2 domains are present in many cell adhesion molecules and may best represent the prototypical Ig domains. Hemolin is closely related to the other insect IgSF molecules, i.e., amalgam, fasciclin II, and to the neural cell adhesion protein neuroglian, with which it shares approximately 38% homology. Hemolin is present in low levels in naïve insects, and these levels increase significantly upon challenge with gram negative or gram positive bacteria or with bacterial cell wall components. The protein is encoded by a single gene and is synthesized in the fat body and hemocytes. Induction is rapid, with increases in levels of hemolin mRNA appearing in the fat body within 1 h after injection of bacteria. Thus far, hemolin is the only invertebrate IgSF member found that can be up-regulated and released upon infection. Hemolin has been observed to bind to fat body, Malpighian tubules, and hemocyte surfaces; thus, it may serve to recruit hemocytes to these tissues much like the cell adhesion molecules that regulate leukocyte adhesion to endothelial cells and ECM components during inflammation in vertebrates (e.g., selectins).

With respect to its role in the insect immune system, hemolin binds to hemocyte membranes, thus preventing hemocyte aggregation and adhesion of these cells to other surfaces. Hemolin may trigger the release of sessile immunocompetent hemocytes into the hemocoel during infection and/or prevent excessive formation of hemocytes into nodules so that these aggregates do not become large enough to deplete the supply of circulating hemocytes or to interfere with circulation. In addition, hemolin binds to bacterial (e.g., *E. coli*) surfaces; this association is mediated by a specific molecule on the microbial surface. Hemolin is not bactericidal, but functions as an opsonin so that when it coats the bacteria, it makes them better targets for hemocytes participating in cellular immune response. Opsonization is, of course, a major function of antibody-type IgSF members in vertebrates. Hemolin stimulates the phagocytosis via a pathway that involves protein kinase C activation and protein tyrosine phosphorylation, which indicates that its role in phagocytosis is as a signal transduction molecule. This function may be a result of the structural relatedness of hemolin to the IgSF cell adhesion factors, which can also participate in intracellular signaling processes. So far, no variability has been observed in the invertebrate IgSF members. In vertebrates, sequence variability resulting from the rearrangement of genes coding for antibodies is a hallmark of adaptive immunity.

Among the insects, the most thoroughly described humoral lectin is *Sarcophaga* lectin from the larvae of the fleshfly *Sarcophaga peregrina*. This lectin has dual functions, operating both in immune defense and developmental processes. As mentioned above, the *Sarcophaga* lectin is a C-type lectin, specific for galactose. The native molecule (190 kDa) consists of two α and two β subunits, with molecular weights of 32 and 30 kDa, respectively. Synthesis occurs in the fat body, and both subunits are derived from the same gene. Lectin secretion into the hemolymph occurs upon injury to the body wall, indicating that protein synthesis is induced under conditions that stimulate defense activities. Other insect lectins share similarities with the well-characterized *Sarcophaga* lectin system. For example, a lectin from pupal hemolymph of the Chinese oak silk moth *Antheraea pernyi* also has dual functions, serving both in developmental and in immune defense capacities.

Fungal cell wall β-1,3 glucans and bacterial LPS are involved in activating the expression of lectin genes as well as the previously discussed AMPs. The promoter regions of the several insect opsonin genes (lectins, hemolin) have NF-κβ-like binding sequences. Many insect lectins have multiple binding specificities and thus have the potential to opsonize the surfaces of cells from a broad range of microorganisms, as compared to lectins with limited specificity. As opsonins, humoral lectins and agglutinins from insects are somewhat comparable to vertebrate immunoglobulins. Although the lectins may not be synthesized in the blood cells, as in the case of Ig production in B lymphocytes, they can be synthesized at other sites such as fat body, then sequestered from the hemolymph into the hemocytes and stored in granules. Alternatively, it has been reported that some lectins, such as those from *Bombyx* and *Leucophaea* are synthesized in the hemocytes. In any event, when the lectins are released from the hemocytes, they serve as opsonins, binding to carbohydrate moieties on either microbial cell surfaces or hemocyte plasma membranes.

The galactose-specific lectin from the larval beet army worm *Spodoptera exigua* is synthesized in the fat body and, as evidenced by immunocytochemical localization, is stored in the granular hemocytes. This lectin can be visualized on the granulocyte surface, and there is strong evidence suggesting that it is closely associated with cytoskeletal elements (e.g., actin) in the granulocytes either directly as a plasma membrane receptor or indirectly if bound to another membrane receptor as an opsonin. The cytoskeleton is an essential part of the phagocytic process. As a hemocyte opsonin or a receptor, the beet armyworm lectin remains evenly distributed over the granuloctye surface at cold temperatures or in the presence of cytoskeletal inhibitors such as cytochalasin. However, at normal temperatures, the membrane lectin is highly mobile and aggregates, via cytoskeletal activity, at coated pits, where it is rapidly endocytosed. This lectin is a microbial opsonin binding to galactose residues on the surfaces of some microorganisms and mediating their attachment to granulocytes at significantly higher rates than those of non-opsonized target cells.

In addition to the beet armyworm lectin, several other humoral lectins from insects, including those from *Melanoplus differentialis* (grasshopper), *Locusta migratoria*, and *Periplaneta*, have been shown to have opsonic properties. The 30 kDa lectin from *Periplaneta americana* recognizes 2-keto-3-deoxyoctonate in bacterial LPS. This protein, as well as the 28 kDa LPS-binding protein from this insect, participates in the clearing of bacteria from abdominal cavities. It is speculated that a peptidoglycan-binding protein from *Bombyx* serves as an opsonin for gram positive bacteria. The attachment of such opsonized cells to specific receptors on immunocompetent hemocytes likely stimulates the proPO cascade. Thus, LPS and β-1,3 glucan-binding molecules, some of which may be lectin or lectin-like proteins, could constitute a functional link between the humoral opsonins and the proPO cascade. For example, a β-1,3 glucan-specific lectin on *Galleria mellonella* (wax moth) plasmatocyte membranes may trigger proPO activities as it binds to soluble β-1,3 glucans in the hemolymph or to these components on fungal cell wall surfaces. It is important to mention that the proPO pathway, no matter how it is activated, can generate additional opsonins, which allows for further recognition of nonself material. In addition to producing opsonins, the proPO system plays a major role in a number of other invertebrate immune defense activities.

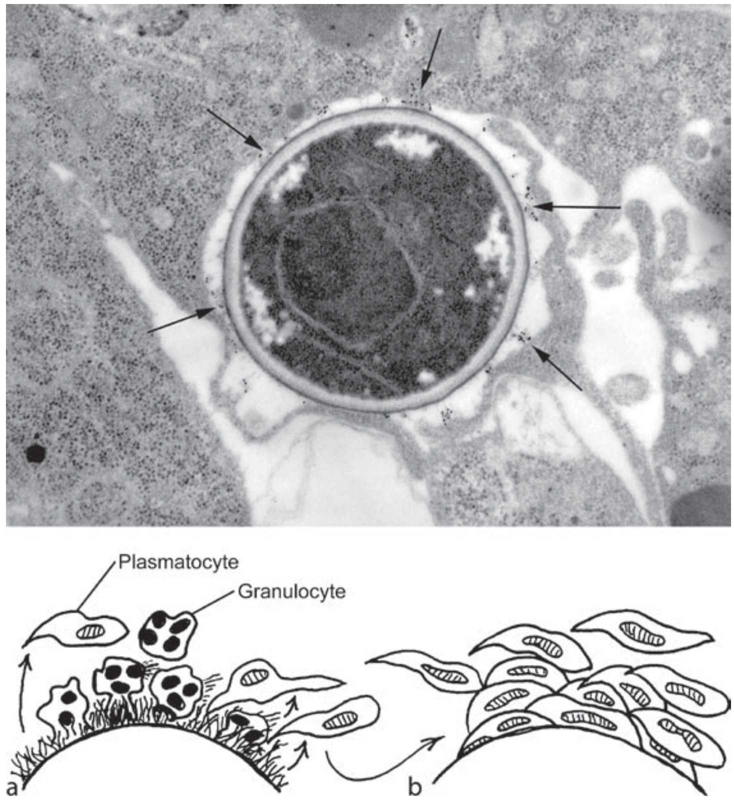
Prophenoloxidase (proPo) Cascade Systems

Phenoloxidases, the enzymes involved in production of melanin pigments, are widespread among microorganisms, plants, and animals. In arthropods, melanin is formed during hardening and darkening of the cuticle and in response to cuticular wounding and invasion of foreign matter into the hemocoel. Phenoloxidases occur as inactive precursors, termed the prophenoloxidases. Prophenoloxidases are activated by a proteolytic cascade system referred to as the proPO-system. Activation of the cascade produces melanin and stimulates cellular defense activities including hemocyte attachment, spreading and degranulation, phagocytosis, nodule formation and encapsulation, and hemocyte locomotion. The cascade is activated by microbial cell wall components such as bacterial LPS and peptidoglycans as well as the fungal β-1,3-glucans. Insect hemolymph prophenoloxidases share many similarities. The cDNA clone for *Manduca* proPO encodes for a 80 kDa polypeptide, and *Bombyx* and *Galleria* proPOs also have subunits in this molecular weight range. The amino acid compositions of the proPOs from the latter two insects are very similar, and a monospecific antibody against the *Galleria* protein cross-reacts with *Manduca* proPO. The proPO from *Bombyx* has been localized in the oenocytoids and plasmatocytes, but not in granulocytes. The cDNAs of this enzyme lack signal peptide sequences, thus indicating that mature proPO is stored in hemocytes. Prophenoloxidase is synthesized in hemocytes, and then released into the hemolymph when insects are challenged (e.g., bled).

Proteins that bind to the microbial cell wall elicitors of proPO have been isolated from the plasma of both insects and crustaceans. A 62 kDa and a 90 kDa β-1,3-glucan binding proteins (BGBP) have been isolated from *B. mori* and from *B. craniifer* plasma, respectively, The silkworm BGBP has been localized in granules, of both granulocytes and spherulocytes, but not in other hemocyte types, fat body, or integument BGBPs appear to be highly specific for glucans with β-1,3-glycosidic linkages; they do not bind to other carbohydrates such as mannans and cellulose. BGBPs from both insects and crustaceans enhance β-1,3-glucan activation of the proPO system. In insects, it has been suggested that the serine protease enzymes are activated when β-1,3-glucans bind to BGBPs due to conformational changes in the BGBPs. It also has been proposed that the BGBP-β-1,3-glucan complexes bind to specific receptors on granulocyte (e.g., *B. mori*) membranes, causing degranulation and release of more BGBP stored in the granules. This newly released protein then concentrates around invading fungal cells and triggers the proPO cascade in the hemolymph. When the cascade is triggered, other molecules, including opsonins and chemokinetic factors, are produced and stimulate additional defense-related activities such as phagocytosis and encapsulation (Fig. 5).

ProPO systems are normally triggered when specific elicitor molecules are present. However, if extensive lysis of hemocytes containing proPO components occurs, there are inhibitory molecules in the plasma that prevent the cascade process. These include protease inhibitors such as the trypsin inhibitors found in the hemolymph of some insects. Significantly, both the proPO cascade in insects are analogous to the vertebrate complement pathways not only with respect to the protease inhibitory functions but in other ways as well. These systems activated lectins or lectin-like molecules binding to microbial cell wall components and involve the limited proteolytic activities of serine-type proteases that are regulated by enzyme inhibitors.

Although the complement-like activities generated during the proPO cascade contribute significantly to immune defense in invertebrates, the melanin produced as an end-product of the cascade is also important. Phenoloxidase, the enzyme which catalyzes the synthesis of melanin, self-aggregates and associates with other plasma macromolecules (e.g., proteins) and with surface molecules on foreign particles such as microbial cell wall polysaccharides. Phenoloxidase oxidizes phenolic substrates (e.g., tyrosine) to generate intermediate quinones which then form the melanins. Thus, when phenoloxidase is deposited on microbial surfaces it can produce melanotic capsules capable of physically restraining growth and movement of the microorganisms and of isolating them from host tissues. In addition, both the quinones and melanin can be toxic to microorganisms. Studies also have shown that the phenoloxidase-activated melanization reaction in *Heliothis virescens* (tobacco budworm) larval hemolymph is the basis for the antiviral activity observed in this serum. The hemolymph has no antiviral activity when phenoloxidase activity is inhibited by the addition of phenylthiourea, which acts by combining with copper in the enzyme.



Innate Immunity, Figure 5 **Phagocytosis and encapsulation: (*above*) Transmission electron micrograph showing phagocytic uptake of a blastospore of the fungus *Paecilomyces farinosus* by granulocytes. The fungal cells were first opsonized with the galactose-specific lectin purified from the insect; this coating was then visualized by labeling with a lectin-specific monoclonal antibody followed by an anti-IgG-gold secondary antibody (see *arrows*). The lectin-antibody complex becomes detached from the fungal surface and is endocytosed by the phagocytic hemocyte via a coated pit mechanism. (*below*) Diagrammatic representation of the formation of a cellular capsule around a pathogen invading a host insect. When the pathogen enters the insect hemocoel, the granulocytes discharge their contents onto its surface. The discharged contents include factors that recruit other cells such as plasmatocytes to the microbe, and these cells may then aggregate to form the capsule. The hemocytes deposited directly on the surface of the pathogen become tightly appressed, whereas the more distal cells are loosely aggregated and can even separate from the capsule.**

Cellular Encapsulation

Cellular encapsulation occurs in arthropods when a foreign object is too large to be phagocytosed and thus becomes surrounded by one or more layers of hemocytes. This process is less specific than humoral encapsulation in that it is provoked by a wider variety of organic and inorganic substances. Tissue grafts, parasitoid eggs, various bacteria, fungi, protozoans, nematodes, filarial worms, glass, nylon, plastic resins, gold colloids, and paraffin, among other things, have been reported to elicit cellular encapsulation. Initially, it was believed that elicitation of cellular encapsulation in insects depends upon physicochemical properties, especially the charge on the surfaces of foreign objects. Therefore, since the basement membranes of insect (self) tissues do not stimulate hemocyte response and are negatively charged, it was generally accepted that only positively charged foreign objects would be interpreted as nonself and encapsulated. However, in some insects encapsulation of negatively charged particles does occur. For example, even though *Schistocera* (locust) hemocytes do not respond to negatively charged Sepharose beads, *Periplaneta* (cockroach) hemocytes encapsulate these beads as well as those with positively charged and neutral surfaces. In the soybean looper *Pseudoplusia includens* larvae, both negatively charged and positively charged particles are encapsulated. The rate of encapsulation of negatively charged Sephadex beads is slower than that for positively charged Dowex beads but, after 24 h, most beads from both of these types are encapsulated. Interestingly, in this insect only a small percentage of DEAE Sepharose beads, which are positively charged, are encapsulated even after 24 h. Thus, although physicochemical properties do mediate the rapid response of hemocytes to some particles (the Dowex beads), other particles (e.g., the negatively charged Sephadex beads) may require surface modification for hemocyte recognition.

The humoral encapsulation promotion factors that coat foreign objects are homologous to certain basement membrane (ECM) proteins. Sepharose beads coated with Arginine-Glycine-Aspartate (RGD) peptide fragments are encapsulated within 3 h after injection into *Pseudoplusia* larvae, whereas those coated with RGE (E = glutamic acid, the negative control) are not encapsulated until 24 h later. In addition, encapsulation of the RGD beads is inhibited only by soluble RGD. RGD-containing proteins, present in vertebrate ECM components such as laminin, serve as cell recognition adhesion sites for integrin-type receptors on membranes of cells that bind to the ECM. It is likely that capsule formation by plasmatocytes in *Pseudoplusia* is an RGD-dependent cell adhesion mechanism. ECM-like RGD-containing proteins may be released from granular hemocytes and coat foreign particles that are recognized by integrin-like receptors on the plasmatocyte membranes. Results from several studies show that ECM-type proteins are synthesized in and released from insect hemocytes. Monoclonal antibodies to hemocyte antigens in *Periplaneta* cross-react with basement membranes (ECM) of tissues lining the hemocoel and, in *Locusta*, the same antibodies that bind to basement membranes also bind to hemocyte components.

In *Pseudoplusia*, the integrin-like receptors of plasmatocytes that bind to RGD fragments on foreign particles are likely to be in an activated state, in contrast to the inactivated receptors on hemocytes from non-challenged larvae. Switching between active and inactive states explains why hemocytes do not bind to RGD molecules displayed on the basement membranes lining the hemocoel. Insect hemocytes adhere to damaged areas on basement membranes or to abnormally developing tissues, thus indicating that trauma such as wounding activates the RGD receptors, or that changes in the self-arrangement of matrix components allows hemocytes to bind by an alternative receptor mechanism. Interestingly, completed cellular capsules in some insects have an outer coating that is similar to basement membranes in ultrastructure and in staining properties. Coated capsules from one insect (*Periplaneta*), when washed and transferred to hemocoels of allogeneic or xenogeneic (*Schistocerca*) recipients, will not elicit further encapsulation, demonstrating that once a capsule is completely formed, it is interpreted as self and is no longer subject to defense processes.

Capsule formation requires the active recruitment of encapsulating hemocytes to foreign objects. In vertebrates, recruitment of phagocytes (e.g., macrophages) and the formation of granulomas around parasitic organisms are regulated by the cytokines released by the activated T-cells. There are probably similar substances that are responsible for elicitation of hemocytes during capsule formation in invertebrates. These factors attract additional granulocytes and/or other types of hemocytes (plasmatocytes, lamellocytes), which interact with surface components on the nonself and with each other to form capsules. As mentioned earlier, components of the proPO system could function as signaling molecules to promote encapsulation. Recently, a 400 kDa complex consisting in part of prophenoloxidase, phenoloxidase, and an interleukin 1 (cytokine-like signal molecule) was isolated from *Manduca* hemolymph. Likewise, proPO cascade factors such as the 76 kDa protein (peroxinectin) from crayfish and the 90 kDa protein from *Blaberus*, when released from granular cells upon activation, play roles in signaling. These components, as well as other cascade molecules, may also be opsonic, coating foreign particles so that recruited hemocytes can recognize and bind to them. In some insects the initial recognition, opsonization, and recruitment processes appear to be a passive phase of encapsulation. This initial phase proceeds even during metabolic inhibition, whereas a second phase, the consolidation of hemocytes around target objects, is active and cannot take place under inhibitory conditions (e.g., low temperatures). In addition, the phases in capsule formation can be morphologically as well as physiologically distinct from one another. For example, in the hemocoel of *Anopheles* mosquitoes, humoral encapsulation of microfilariae begins as early as 10 min after a blood meal, followed by cellular encapsulation within 2 h. After 24–48 h, the melanized humoral capsules become surrounded by a single layer of two or three plasmatocytes; these completed capsules isolate and destroy the microfilariae. The formation of a melanized humoral capsule before initiation of the cellular encapsulation phase confirms that components of the proPO system deposited on foreign particles serve as hemocytic recruitment and/or adhesion factors during organization of the cellular layer(s).

In many insects the encapsulation response results in the production of a multilayered structure. In addition, the total encapsulation process may not always occur in well-defined non-cellular and cellular phases. For example, in *Galleria mellonella* larvae implanted with nerve tissue from *Schistocerca*, granulocytes making contact with the transplants immediately discharge their contents onto the nonself surfaces. After 20 min, plasmatocytes, elicited by the material from the lysed granulocytes, attach to the transplants at sites of lysis. The plasmatocytes then form a multilayered sheath. Alternatively, *Periplaneta* challenged with tissue implants, produces a capsule composed of three distinct regions of granulocyte. The inner cellular region next to the debris layer (lysed granulocytes) exhibits up to seven layers of necrotic hemocytes which, in the completed capsule, forms a continuous syncytium-like giant cell mass with no delineating plasma membranes. The second region of the cellular capsule consists of 10–12 layers of flattened, necrotic cells which are not as compressed as those in the first layer and which have intact plasma membranes. Cells near the periphery of this region show less degradation than cells nearer to the transplant. The third and outer region of the capsule consists of three or four layers of loosely aggregated, normal hemocytes. There is little melanization of capsule products in this system. Likewise, in beetle (*Diabrotica*) larvae, capsules are composed of three layers of hemocytes overlaying an inner layer of material from cells that have lysed onto the target (e.g., nematode) surfaces. Unlike the encapsulation process in *Periplaneta*, however, this layer becomes melanized, then is covered by a layer of necrotic, pigmented hemocytes. The middle layer consists of extremely flattened hemocytes, and the third, outer region is composed of a layer of loosely attached hemocytes. Syncytia do not form in these capsules.

Cellular capsule formation varies depending upon the host insect and the nature of the foreign object to be encapsulated. It is suggested that the surfaces eliciting capsule formation stimulate hemocytes to different degrees, and that the degree of stimulation can determine the number of cells recruited to a target surface and the thickness of the resulting capsule. Also, factors (e.g., cytokine-type molecules) which regulate the activities of the elicitors (other cytokines) released during hemocytic stimulation serve to control the number of recruited cells. A hemocyte aggregation inhibitor protein (HAIP) from *Manduca* hemolymph modulate the adhesive properties of hemocytes and thus act as regulatory factors during encapsulation. Capsule formation is a physically self-limiting process. When the innermost layers of the capsule containing the recruitment factors become covered by other layers of hemocytes, the factors no longer diffuse to the outer regions of the capsule to recruit more cells. This stimulus gradient from the center to the periphery of the capsule results in a loose aggregation of the hemocytes in the outer region. Some of these cells detach from the capsule surface and return to circulation in the hemolymph.

The association between melanization and encapsulation varies. If melanization occurs, it begins during the early phases of capsule formation, as described above in *Anopheles* and *Diabrotica*. Melanization begins on the surface of the foreign object where hemocyte lysis products are deposited, and it sometimes expands from this inner region to the middle and outer capsule layers. Cross-linking of proteins occurs during melanization, and these interactions can function to strengthen and harden the capsule. It is believed that in some *Drosophila* larvae, darkening of capsules around parasitoid eggs is due to hemocyte necrosis rather than to melanin deposits in the outer layers. Melanization occurs only during the early stages of capsule formation, i.e., during opsonization of the egg surface and activation and recruitment of hemocytes. The toxic effects (e.g., synthesis of free radicals) of melanin production on the egg surface kill the parasitoid embryo and cause necrosis of the insect hemocytes.

There are instances in which phenoloxidase activity and melanization are not involved in encapsulation as illustrated in *Drosophila melanogaster*. The prophenoloxidases necessary for melanin formation are released onto the parasitoid (*Leptopilina boulardi*) egg surfaces from crystal cells that are hemocytes with paracrystalline inclusions containing the prophenoloxidases. Mutant *D. melanogaster* larvae possessing disfunctional crystal cells utilize lamellocytes to recognize and encapsidate nonself. Unlike the capsules in normal larvae, those in the mutants do not darken or harden. Lamellocytes have sticky surfaces and can mediate cell-to-cell adhesion without the input of the opsonic components of the proPO system. In other experiments designed to evaluate the role of prophenoloxidases during encapsulation, it was found that *S. gregaria* hemocytes, which normally fail to encapsulate uncoated, negatively charged beads, still do not respond to these particles even if they are precoated with a lysate known to contain activated phenoloxidase. In summary, a central, well-defined role for proPO cascade and melanization reactions in the immune encapsulation process in insects has not yet been characterized (Table 3).

Nodulation

Nodulation is a defense reaction in arthropods that occurs in response to the invasion of the hemocoel by large numbers of particles that cannot be removed by phagocytosis alone. Nodules can form around various types of abiotic and biotic materials, including ink and dye particles, red blood cells, bacteria, fungi, and protozoans. In addition, soluble molecules such as endotoxins from bacterial cell walls and β-1,3-glucans from fungal walls can stimulate nodule production. Nodulation, which involves the trapping and isolation of foreign particles within hemocytic aggregates, may be compared to granuloma or giant cell formation by macrophages in vertebrate systems. Nodules and cellular capsules can form simultaneously in an insect and are often difficult to distinguish from one another.

A detailed study of the nodulation process has been carried out in *Galleria mellonella* and *Pieris brassicae* larvae challenged with various bacteria. In *G. mellonella*, the process takes place in two phases. The first phase begins 1 min after injection. Granulocytes contact bacteria and degranulate so that both the cells and other reactive hemocytes become trapped in a mass of coagulum. These aggregates then attach to

Innate Immunity, Table 3 Selected insect hemolymph lectins[a] and lectin-like hemagglutinins

Source insect	Carbohydrate specificity	Probable function(s), if proposed
Anopheles quadrimaculatus[b]	Gluconic acid, galacturonic acid, glucosamine, mannosamine, NeuNAc*	Bind to carbohydrates on sheaths of microfilarial parasites, resulting in activation of proPO cascade
Antheraea pernyi	Gal, GalNAc	Immune defense, development and morphogenesis
Anticarsia gemmatalis	Gal, Lac, fucose, NeuNAc	Immune defense
Blaberus discoidalis[b]	Glc, man, GlcNAc, β-1, 3-glucan	proPO activation
Bombyx mori (Hemocytin, C-type lectin)	D-man, GalNAc, D-maltose	Immune defense, LPS binding, metamorphosis, scavenging, coagulation
Extatasoma tiaratum	Gal, Lac, α-MeGal, GalNAc, raffinose	Opsonin
Hyalphora cecropia[b]	Gal, GalNAc	
Hyphantria cunea	Gal	LPS binding C-type lectin
Leptinotarsa decemlineata	Heparin, mucin, hexosamines	
Leucophaea maderae[b]		
Locusta migratoria	α-Gal pyranosides, fucose	Opsonin
Manduca sexta (immunolectin-2)	Gal	LPS binding C-type lectin
Melanoplus differentialis	Gal, Glc	Opsonin
Periplanta americana (30 kDa lectin)	2-keto-3-deoxyoctonate	Opsonin, proPO activation
Rhodnius prolixus[b]	GalNAc, Gal, α-MeMan	Immune defense
Sarcophaga peregrina	Gal, Lac	Metamorphosis, scavenging, opsonin, activation of immune defense
Schistocerca gregaria	Sucrose, fetuin, l-Rhamnose	Immune defense
Spodoptera exigua	Gal, Lac	Opsonin

[a]Represents a partial list of insect humoral lectins
[b]Indicates the presence of multiple lectins or hemagglutinins
*Carbohydrate abbreviations: GalNAc = N-acetyl-D-galatosamine; NeuNAc = N-acetyl neuraminic acid; GlcNac = N-acetyl-D-glucosamine; Gal = galactose; Lac = lactose; Glc = glucose; man = mannose; α-MeGal = α-methyl galactose; α-MeMan = α-methyl mannose

various tissues such as fat body or Malpighian tubules. By 1 h post-injection melanization begins within the aggregates, and the mass of cells becomes compacted. At 1–6 h, the second phase begins with the attachment of plasmatocytes to the melanized aggregate. Plasmatocytes form a multicellular sheath with an inner region of flattened, degenerating cells, a middle region of extremely flattened cells with well-defined cell junctions (desmosomes) and numerous microtubules, and an outer region of recently attached plasmatocytes. Thus, after 24 h, the bacteria are surrounded by a central area of melanized, necrotic hemocytes enclosed in a plasmatocyte sheath. In other insects, such as the beetle *Tenebrio molitor*, attaching plasmatocytes contain bacteria.

The extent of nodule formation varies depending upon the insect and/or the nature of the foreign substance introduced into the hemocoel. In both *Schistocerca gregaria* and *Periplaneta americana*, large nodules (>100 μm in diameter) form in response to the presence of fungal spores, whereas medium to small (<40 μm) nodules form in the presence of soluble molecules such as LPS. Nodulation is not always effective in eliminating potentially pathogenic organisms and in preventing infection. In *G. mellonella*, nodules are formed around pathogenic *Bacillus cereus*. However, *B. cereus* overcomes this defense mechanism either by the active escape of vegetative cells (e.g., by digestion of nodule components) or by the germination of endospores, which allows the bacteria to break out of the nodule. Hyphae of some entomopathogenic fungi, which often elicit nodulation, can elongate, break free from the hemocyte aggregates, and establish successful infections. Pathogenic microbes may not elicit nodule formation in host insects. For example, nodule production does not occur in *G. mellonella* or *P. brassicae* injected with pathogenic *Staphylococcus aureus* bacteria or in *Lymantria dispar* (gypsy moth) larvae challenged with highly virulent *Xenorhabdus luminescens* bacteria; however, nodules do form in this insect in response to the non-pathogenic bacteria (*Bacillus subtilis*). Likewise, there is rapid nodule development around non-pathogenic *Candida albicans* yeast cells injected into *Spodoptera exigua* (beet armyworm) larvae, but yeast-like hyphal bodies of the fungal pathogen *Nomuraea rileyi* do not elicit any immune response. *Trypanosoma cruzi*, which is not pathogenic to the vector reduviid *Rhodnius prolixus*, is rapidly cleared from this insect via nodule formation, but hemocyte aggregation is delayed in response to pathogenic *T. rangeli* cells.

The destruction of microorganisms trapped in nodules may be due to the toxins (e.g., quinones) generated during melanization. Activities of the proPO cascade preceding melanin production appear to be closely linked to nodule formation. For example, it has been shown that in locusts, soluble LPS which can elicit a high degree of nodulation also induces greater levels of phenoloxidase activity in whole blood homogenates than does LPS from a different bacterium which elicits little or no nodule formation. In addition, it has been suggested that in *Ceratitis capitata* (medfly) larvae, nodulation in response to the introduction of *E. coli* results from binding of a hemocyte protein to the bacteria, forming complexes which cross-link to hemocytes via quinone intermediates. ProPO components also may be involved in recruitment of hemocytes to nodule forming sites, as during hemocytic recruitment in the cellular encapsulation process (see previous section). During nodulation in *G. mellonella*, active recruitment of hemocytes most likely occurs during the second stage when the plasmatocytes aggregate to form the outer sheath. Plasmatocytes require stimulation by chemotactic factors that may be released by granulocytes in order to be attracted to the central region of the nodule. In addition to the proPO components mentioned above, chemotactic factors may include cytokine-type molecules as well as biogenic amines and eicosanoids.

Biogenic amines and eicosanoids are known to mediate immune response in mammals. Amines (neurohormones), which in mammals elevate cAMP levels, have been found in insect hemolymph, and amine-sensitive receptors have been identified in some insect hemocytes. Two amines, octopamine and 5-hydroxytriptamine (5-HT), have been shown to increase the survival of cockroaches (*P. americana*) challenged with *S. aureus* by enhancing phagocytic and nodulation activities. Eicosanoids are autocrine signaling molecules which enable cells to send signals to other identical cells or to themselves. They function in cell-to-cell communication during development and, in mature mammals, function in platelet aggregation as well as pain and inflammatory response mechanisms. Eicosanoids are fatty acid derivatives found in all mammalian tissues, and recently they have been identified in some insects (e.g., *M. sexta*). They are synthesized from precursors, mainly arachidonic acid, that are cleaved from plasma membrane phospholipids by phospholipases, such as the PLA_2 identified from *Manduca* hemocytes and *Bombyx* fat body. Phospholipases, including PLA_2, have been found in various pathogens (bacteria, protozoans, fungi), where they may function as virulence factors since they have the potential to damage host cells and tissuues. In mammals, eicosanoids are continuously synthesized, released from the cell, and then broken down by enzymes in the extracellular fluid. There are four major classes of eicosanoids synthesized via one of two specific biosynthetic pathways. In insects, it has been found that nodule formation in response to bacterial infection is strongly reduced in larvae when eicosanoid synthesis is inhibited. Such inhibition can be effected by injecting test insects with the phospholipase A_2 inhibitor dexamethasone or with specific cyclooxygenase or lipoxygenase inhibitors. Therefore, since nodulation is affected by inhibiting eicosanoid production at various stages along its biosynthetic pathway, it is likely that several different kinds of these signaling molecules are involved in the numerous steps leading to complete nodule formation.

Clotting

Although the active recruitment of cells may not be necessary during the first stage of nodulation in *G. mellonella*, another mechanism within the immune defense system, clotting, is important at this time. The formation of sticky coagulum upon activation of the granulocytes (degranulation) traps foreign particles. Clotting is important in wound sealing in insects and in other invertebrates. As mentioned earlier (see proPO section) clotting or coagulation can result from a cascade-type reaction, as described in detail for the mechanism that occurs in *Limulus*. However, a cascade system has not yet been fully described in insects.

Clotting in insects has been characterized as pattern II-type coagulation. In this process, long strings form between the hemocytes and develop into a dense mesh which traps hemocytes and insoluble hemolymph components. The long strings develop from material extruded from granules in the hemocytes. True clots are composed of a hemocyte-derived component and a plasma coagulogen, which cross-links with the hemocyte coagulogen. Evidence for the involvement of two factors in clot formation comes from studies on *Locusta migratoria* and *Leucophaea maderae* (cockroach) showing that plasma without hemocytes will not clot. Although the material from the hemocytes can gel in the absence of the plasma coagulogen, this gel differs from a clot formed by both coagulogens. The hemocyte gel is dissolved with urea and a reducing agent (DTT), whereas the clot resists this treatment.

The most likely plasma coagulogen is lipophorin, which functions in adsorption and transport of lipids as well as in clotting. Lipophorins, major components in hemolymph, are lipoproteins consisting of 30–50% lipid and 1–4% carbohydrate. The carbohydrates, usually mannose and glucosamine, are associated with the apoprotein portion of the molecule, which in turn consists of two subunits of about 250 and 80 kDa. Lipophorins from different insect orders are similar. They are synthesized in the fat body along with other hemolymph proteins. The hemocyte coagulogen is present in granules of granular-type hemocytes (granulocytes, plasmatocytes, coagulocytes). The gel formed by this coagulogen is not only sensitive to DTT, but also to proteolytic enzymes. Therefore, it must consist of at least a protein backbone with disulfide bridges and, since most hemocyte granules contain carbohydrates, it could be a glycoprotein. The hemocyte coagulogen ages within 30 min of its release from the cells and loses its clotting ability very rapidly.

In order to form a true clot, the two coagulogens must interact. They may form separate networks that interweave, but it is more likely that they form an intermolecular connection since true clots are insoluble in DTT. Antibodies to the hemocyte coagulogen inhibit binding of the gel to the plasma coagulogen. The mechanism of an intermolecular interaction in clot formation requires divalent cations (Ca^{++}), since chelating agents inhibit clotting. This strongly implies that the cross-linking of the coagulogens involves the catalytic activities of Ca^{++}-dependent enzymes (e.g., transglutaminase). It is known also that hydroxylamine inhibits clotting of the two *Leucophaea* factors, thus suggesting that as in vertebrate and crustacean systems, amino groups participate in cross-linking. In other words, interaction may occur via cross-links between free amino groups of the plasma coagulogen molecule and the hemocyte coagulogen. The acceptor residue on the hemocyte coagulogen may be similar to vertebrate fibrin or to some type of collagen moiety. In addition, it is possible that the role of lipids on the plasma coagulogen molecule (i.e., lipophorin) is to interact with hydrophobic entities of the hemocyte coagulogen molecule, thus establishing affinity between the two factors.

Many components function in the insect clotting system, but most have not been identified or well-characterized. One protein from *Manduca* hemolymph, scolexin, which appears to be involved in coagulation, has been described in detail. Scolexin is an immune protein with lectin-like properties that is induced by bacterial challenge but is not bactericidal. It concentrates in the coagulum in nodules that form around injected bacteria and thus is assumed to play a role in clotting. Scolexin is synthesized, in part, in the epidermis. It is structured from two 36 kDa subunits that have the same N-terminus. The subunits form two different charge isomers, scolexins 1 and 2, and scolexin 2 is glycosylated. The protein is larval-specific, and its synthesis declines during the fifth instar.

Phagocytosis of Nonself

For over 30 years, the most widely accepted mechanism of phagocytosis in vertebrates has been the zipper mechanism. In this model, phagocytosis of one foreign particle does not initiate the nonspecific uptake of other particles in the vicinity of the phagocyte. Instead, particles become specifically bound via their surface ligands to receptors on the phagocyte plasma membrane. Thus, as long as the entire particle is covered with the appropriate ligand (e.g., an opsonin), the receptors on the phagocyte pseudopodia sequentially bind or zipper to the ligand molecules until the entire particle is engulfed. If the target is unevenly covered with ligand moieties, then pseudopodial extension around it stops at the surface region lacking these moieties. This zipper mechanism model represents the phagocytic process that occurs when opsonized fungal cells are taken up by *S. exigua* hemocytes in monolayer experiments. The purified lectin from larval hemolymph, the ligand, bound to the walls of the fungal cells, can be visualized by TEM using gold particles. The lectin-gold conjugate binds to galactose residues in a fibrous coat on the fungal surface, then the granulocyte receptor attaches to this lectin complex. These complexes are sequestered from the pseudopodia into coated pits located along the granulocyte plasma membrane. The coated pits then form into vesicles and move via cytoskeletal activity into the cytoplasm. Actin is heavily concentrated in the pseudopodia and is likely to function not only in the formation of these structures, but also in the sequestering of the lectin complexes to the coated pits. Microtubules are more prevalent in the non-extended areas of the phagocyte and are often associated with coated pits and vesicles and sometimes with endocytosed fungal cells. In a successful phagocytic event, the pseudopodia fuse at their tips so that they completely encircle the target particle. This results in the formation of a vacuole, the phagolysosome.

The *S. exigua* phagocytic process is comparable to the zipper model that was proposed as a result of studies on vertebrates using lymphocytes coated with IgG (ligand) molecules. The lymphocytes capped the IgG, which was labeled with peroxidase, onto one small region of the plasma membrane, leaving the rest of the cell surface void of ligand molecules. Thus, the pseudopodia of the phagocytes (macrophages) could not completely surround the target lymphocytes since the IgG was not distributed evenly. The macrophage attached to the lymphocyte only at the small area where the ligand was capped. Likewise, in the insect system, fungal cells unevenly coated with the lectin are not completely engulfed by the granulocyte pseudopodia. As in the case with vertebrate cells, the coated pits and vesicles on *S. exigua* granulocytes become filled with the ligand complex, i.e., the lectin-gold complex and fibrous fungal cell wall material that has detached during sequestering.

After complete engulfment of pathogenic microorganisms by host phagocytes, the phagosome goes through a maturation process. In vertebrates, and undoubtedly in invertebrates as well, this process involves an inward (endocytosis) and outward (exocytosis) movement of various components to and from the phagosome. Maturation of phagosomes is a modification of the endocytic system that functions during pinocytosis of soluble molecules and small particles.

Receptor-mediated endocytosis has been described best in vertebrates using LDL (low density lipoprotein) as the internalized ligand. This trafficking system can be used as a model to explain the movement and processing of the *S. exigua* lectin-cell wall complex that detaches from the fungal surface and enters the granulocytes in coated pits and vesicles. These structures are so named because they are coated with clathrin, a protein that forms basket-like lattices that function in vesicle budding. Clathrin is shed from the coated vesicles before they fuse with the early endosomes. Early endosomes are acidic and separate the ligand-receptor complexes so that the receptors can be recycled back to the plasma membrane and the ligand can be carried to lysosomes. Late endosomes, which constitute an intermediate step in the trafficking process, are more acidic than early endosomes and contain lysosomal hydrolases which have been transported from the Golgi apparatus. Late endosomes actually mature into lysosomes as they reach a more acidic pH due to further fusion with Golgi-derived vesicles containing a battery of acid hydrolases.

The processing of large particles in phagosomes consists of a pathway similar to that of LDL. Phagosomal components move into the early endosomes, and molecules from the endosomes and primary lysosomes move into phagosomes. This transport of materials both into and out of the phagosome results in the formation of a phagolysosome able to fuse with secondary lysosomes (acidic late endosomes). In some cases, primary lysosomes can be identified with specific granules observed in some immunocytes, such as vertebrate neutrophils and invertebrate granulocytes. Acid hydrolases have been localized in granules in some invertebrate immunocytes, but lysosomal functions are limited to a certain group(s) of these structures. The endolysosomal pathway proposed for granular cells in this organism is very similar to the vertebrate model except that the early endosomal or prelysosomal stage may be represented by multivesicular bodies (MVBs), which also are common in some insect (*S. exigua*, *G. mellonella*) phagocytes. Granules containing acid hydrolases (primary lysosomes) also fuse with MVBs, which then mature into late MVBs capable of fusing with Golgi vesicles containing more hydrolases. Granules also can fuse with the plasma membrane to release lysozymes into the serum.

Killing of Engulfed Microorganisms

Killing of the microorganisms trapped in phagolysosomes often results from the activities of the acid hydrolases introduced into the vacuole by fusion with endosomes, granules, and Golgi vesicles. These enzymes also are necessary to digest the microbial cells even if they must be killed by another mechanism. For example, in order to kill gram positive bacteria, lysozyme hydrolyses the cross-links of peptidoglycan molecules. However, gram negative bacteria are more resistant to this enzyme because they have an additional LPS component on the outer surface. Therefore, killing these cells may require an alternative mechanism. Killing of pathogens via enzymatic activity is grouped among the oxygen-independent killing mechanisms. The acidification of the phagolysosome may be severe enough to kill some pathogens. This drop in pH occurs not only because of the presence of acid hydrolases, but also because of the production of protons by microorganisms and the active transport of hydrogen ions. Other oxygen-independent killing systems can include deprivation of iron necessary for bacterial growth. Vertebrate neutrophil granules release lactoferrin, which absorbs iron and therefore kills some bacteria. A vitamin B_{12}-binding protein also can be released from some granules, and the cationic peptides such as defensins described in relation to humoral immunity in insects are common in vertebrates as well. Defensins, in fact, may constitute up to 50% of the protein in vertebrate neutrophil granules. Serine proteases, found in both vertebrates and invertebrates, can kill a variety of different pathogens, and enzymes such as gelatinases, elastases, and collagenases also exhibit defensive activities. In addition, bacterial permeability-increasing proteins, some of which may be cationic peptides, function in all types of host organisms.

Oxygen-dependent killing mechanisms have been described for both vertebrate neutrophils and insect hemocytes. Toxic reactive oxygen intermediates (ROIs), including superoxide anions and H_2O_2, are produced during phagocytosis via a respiratory burst pathway that is stimulated by substances such as LPS, β-1,3-glucans and cytokines. In addition, the granule protein lactoferrin can be involved in limiting the formation of hydroxyl radicals that occurs in the presence of iron (Fe^{3+}). A reduction in hydroxyl radicals is believed to allow the killing of microbial cells without the concurrent destruction of host tissues. Superoxide anion generation has been detected in several invertebrates, including some insects. Relatively little is known about oxygen-dependent microbial killing mechanisms in insects. Superoxide anions have been detected in several lepidopterans (*T. ni*, *B. mori*, *Pseudaletia separata*), and there is evidence that lipophorin is involved in production of these molecules. The presence of superoxide in *P. separata* and *B. mori* hemolymph is due to the result of a process involving at least two factors. These factors have been purified from *B. mori* sera and include a low molecular weight (<5 kDa) moiety (LMF) and a high molecular weight (>100 kDa) component (HMF) which has been identified as lipophorin. A mixture of these two purified components caused a reduction of NBT which would be inhibited specifically by superoxide dismutase. It is speculated that the LMF is a substrate discharging electrons and that the lipophorin (HMF) acts as an enzyme, mediating the transfer of electrons to O_2 to form O_2^-. Reactive nitrogen intermediates (RNIs) such as nitric oxide (NO) also act as a signaling/messenger molecule and/or as a toxic antimicrobial agent. Nitric oxide synthetase (NOS) has been detected in *B. mori* fat body and Malpighian tubules, but not in hemocytes. The fat body NOS is induced by LPS, whereas Malpighian enzyme levels correlate to the life cycle and may be hormonally regulated. The expression of Malpighian NOS at the late stage of the fifth instar occurs in synchrony with increases in the activity of the *B. mori* lectin, hemocytin. Thus, both components could be significantly involved in metamorphosis and/or defense reactions.

The residual molecules produced during killing and degradation of microorganisms in phagolysosomes are usually discharged from the cells. For example, in *S. exigua*, the gold particles linked to the opsonizing lectin on blastospore cell walls cannot be degraded and are subsequently observed outside of the granulocytes several hours after the initiation of phagocytosis. In another experiment using *B. mori* hemocytes *in vitro*, it was found that LPS is released into the medium shortly after the phagocytosis of *E. coli* cells. It is assumed that the bacteria taken up by the granular cells are digested in the phagolysosomes and that the LPS residue is then excreted. More importantly, the increased levels of LPS, and perhaps other molecules released as a result of phagocytosis and degradation, strongly induce gene expression of cecropin B. This is reminiscent of the antigen-presentation process in vertebrates which serves to induce further immune response.

Microbial Evasion of Cellular Immune Response

The strategies used by various microorganisms to overcome host defense mechanisms have been described throughout the textbook. Such strategies are notable because they are included among the basic concepts of pathogenicity, and the ability of a microorganism to bypass immune response contributes to or represents the major determinant that confers pathogenicity. Cellular immune response can be avoided, depending upon the microorganism, at any of the steps along the phagocytic pathway (chemotaxis → phagolysosomal killing). Inhibition of immunocyte chemotaxis can result from the effects of bacterial (e.g., streptolysins, *Clostridium perfringens*) toxins or fungal (cytochalasins, destruxins) toxins. Other inhibitors act by interfering with the chemotaxins that stimulate phagocyte migration.

The basic physicochemical properties of both the host and pathogen cell surfaces affect defense responses during the attachment step of phagocytosis. The nature and magnitude of the surface charge on a microorganism, for example, often determines whether or not immunocyte attachment occurs (see Encapsulation section). A more specific evasion strategy is molecular mimicry, in which the parasite produces surface molecules that mimic those on host cell surfaces. The pathogen is perceived as self rather than nonself so that phagocytes do not respond. Hyphal bodies of the hyphomycete *Nomuraea rileyi* avoid *S. exigua* granulocyte attachment via molecular mimicry. Mimicry also may be a result of molecular disguise, in which the mimicking molecules expressed by the pathogen are actually encoded by genes acquired at some time from the host. For example, *Metarhizium anisopliae*, the hyphal bodies produce a collagenous coat that masks the antigenic surface epitopes. This strategy could prove to be relatively widespread once more information from molecular studies on insect pathogens becomes more available.

Another evasion method is antigenic variation. This is well-described among the trypanosomes infecting vertebrate hosts, although it is not the only evasion strategy used by this organism. In this case, the parasites display variant surface glycoproteins (VSGs). There is a sequential variation in surface coats so that even though the initial group of infecting parasites is eliminated by antibody response, parasites with variants produced later with new antigen are not recognized. Although invertebrates do not have antigen/antibody systems (adaptive immune response), variations in pathogen cell surface epitopes during the infection process occur and affect evasion of host defense. For example, *Beauveria bassiana* blastospores are phagocytosed rapidly by *S. exigua* hemocytes due to binding of the insect lectin to galactose on the fungal cell walls. However, the blastospores are not killed in the granulocytes; they survive and replicate as intracellular pathogens. When they emerge from the phagocytes, they possess little or no cell wall material and therefore have no lectin binding sites. These cells are not recognized and rapidly shift to an invasive hyphal form. In addition to a lack of lectin binding sites, it is possible that the emerging blastospores further evade granulocyte response via mimicry, since antibodies against *S. exigua* hemocytes strongly cross-react with fungal surface epitopes. Protoplasts from some Entomophthorales, like the intracellularly produced *B. bassiana* blastospores, also are able to evade insect immune response. In contrast, their walled forms elicit strong defense activities. This is due to the presence of cell wall β-1,3-glucans that stimulate the phenoloxidase cascade. Likewise, the nature of microbial cell surface components determines the effectiveness of vertebrate complement pathways.

Invertebrate phagocytes, especially those of insects, react rapidly to fungal hyphae, while showing little or no response to blastospore or yeast-like forms. This is probably due to the presence of hyphal β-1,3-glucans that activate proPO components in the same manner as for the Entomophthorales. In invertebrates, production of specific defense molecules such as the mollusk defense molecule can be down-regulated or suppressed by parasite activities. Such inhibition can occur before the microbe is engulfed and/or within the phagosome. Some yeasts are known to resist phagolysosomal digestion in vertebrate cells, and within these specialized environments, they can produce novel proteins. Some of the proteins include heat shock proteins that could interfere with the activities of host proteins (e.g., enzymes) by controlling their conformation. In addition, the levels of host-degradative components could be down-regulated in the presence of the pathogen. Such mechanisms may be involved in the *B. bassiana* – *S. exigua* system, thus enabling the blastospores to survive as intracellular parasites within the host granulocytes.

The ability of *B. bassiana* hyphae as well as hyphae from other fungi to overcome the rapid nodulation or encapsulation response elicited in many insects is due to a different mechanism than that used by the intracellularly parasitic blastospores. The hyphal cells must overcome the toxins (e.g., melanin) resulting from proPO activation and must have the mechanical strength to grow out from host cell aggregates that form the nodules or capsules. The size of these aggregates may be self-limiting (see Encapsulation) or may simply depend on the number of available hemocytes. Parasites other than fungi can escape from nodules (e.g., the microsporidian *Vairimorpha plodiae* infecting *G. mellonella* larvae). This response is advantageous to the pathogen because the nodules circulate in the hemolymph and spread the infection throughout the insect.

Returning to microbial survival strategies within the phagosome, some of the specific mechanisms by which intracellular pathogens can evade host oxygen-dependent killing have already been described. More generally, intracellular bacteria can produce catalase and/or superoxide dismutase to detoxify H_2O_2 and O_2^-, respectively. Little information is available as to how invertebrate pathogens can escape phagolysosomal activities. It is likely that similar mechanisms are used by both types of organisms. For example, *Bacillus cereus* can evade cockroach (*Leucophaea maderae*) cellular immune response by producing cytolytic phospholipase C to disrupt hemocyte membranes. In addition, molecules such as the annexins that are likely involved in membrane fusions along the endocytic pathway have been identified from invertebrates, including the insect *Drosophila*.

Summary

It is obvious that even though the immune system in insects lacks the intricate adaptive component present in the vertebrate system, it is nevertheless a complex mechanism. Insect defense against microorganisms can involve an array of different molecules, many of which must interact with each other in order to be functional. Many aspects of invertebrate immunity are not well understood, especially in comparison to vertebrate systems. For example, in insects little is known about coagulation and whether or not it is a multi-step cascade process as reported for other invertebrates. The possible function of lectins in insect defense is also not well defined and insect resistance to viral pathogens is just beginning to be characterized. There is no doubt that further research is needed in this field. It is essential to understand host-pathogen interactions for the purpose of developing bioinsecticides, as well as for defining the steps leading to the evolution of immunity in higher animals.

Inocelliid Snakeflies

Some members of the family Inocelliidae (order Raphidioptera).

► Snakeflies

Inocelliidae

A family of insects in the order Raphidioptera. They commonly are known as inocelliid snakeflies.

► Snakeflies

Inoculative Biological Control

Release of a biological control agent into an area where it does not occur, with the intent of establishing the population.

► Classical Biological Control

Inoculum

A small number of pests or pathogens that can lead to a greater abundance, and subsequent damage.

Inorganic

Not containing the element carbon. Usually derived from naturally occurring minerals.

Inorganic Insecticide

A category of insecticides that lack carbon, being instead of mineral origin. Typically they are crystalline, and applied as dusts or baits. Examples include cryolite, diatomaceous earth, borate, silica, and sodium fluoride. These materials vary from moderately toxic to quite toxic, and tend to be quite persistent. Their use is fairly restricted.

► Insecticides

Inornate

In ticks, this refers to the absence of a color pattern on the scutum.

Inquilines and Cleptoparasites

ANDREI SOURAKOV
University of Florida, Gainesville, FL, USA

Inquilines are arthropods that live in structures created by other arthropods, such as galls, burrows or nests. Generally, they are considered to do so without interfering in an important way with their hosts, or they may scavenge for a living without significantly harming their hosts. In some cases, especially in the case of social insects, inquilines may be parasitic and consume their host's food resources. When insects steal food and pillage nests of other species they are usually called cleptoparasites. Social insects such as ants and termites typically have many inquiline inhabitants of their nests, but it is not always apparent whether or not the inquilines are cleptoparasites. Many inquilines (particularly ants) are very closely related to their host organism.

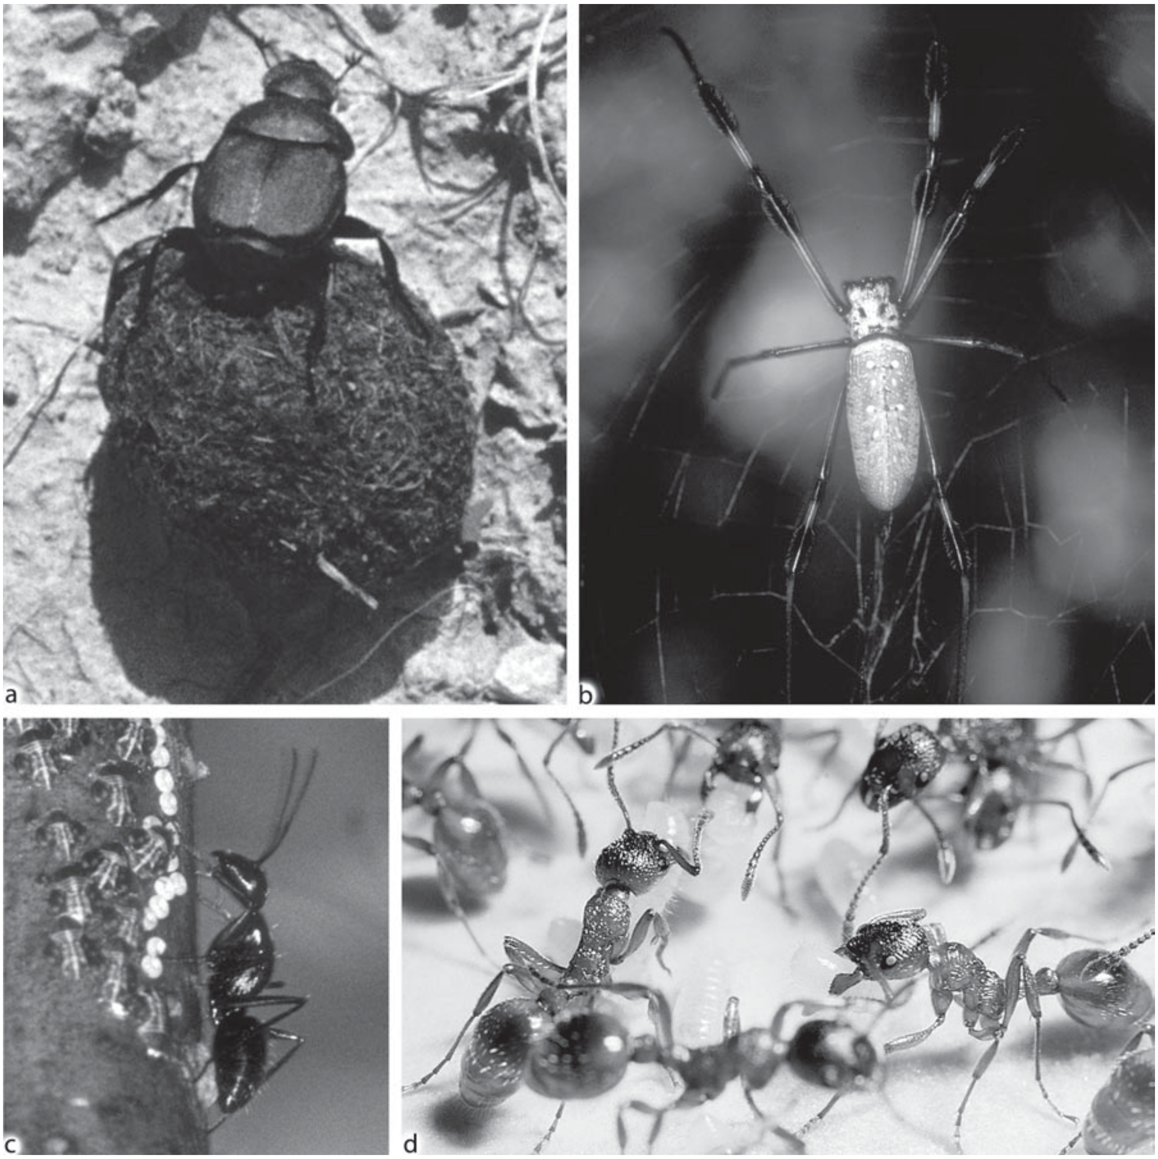
Scarab beetles are known for rolling balls of dung, which they bury deep underground in burrows, and which serve as a food resource for their immatures (grubs). When they roll their dung balls, small flies (various families) are attracted. These flies show remarkable dependence on the scarabs in their life cycle. The adult flies are attracted to a scarab beetle's burrow, lay their eggs in the dung ball, and escape before the beetle seals the hole. The fly larvae share the provisions with the grubs, but do not negatively affect the host. Without the new generation of dung beetles developing successfully, newly developed flies would not be able to dig their way out of the sealed burrows. In this case, the host does not suffer from the activities of the inquiline (Fig. 6).

Some spiders simply hide in or near the predators' homes and steal or snack on their prey without directly harming the predators. For example, a minute droplet spider, *Argyrodes* sp., lives in webs of the large golden orb weaver spider, *Nephila* sp. It hides until the much larger *Nephila* has subdued a prey, and then sneaks up and shares the meal. *Argyrodes* relies on speed for defense, as well as its ability to travel through the web without moving it.

Among other insects that steal food from spiders are milichiid flies that often sip blood from stinkbugs caught in the spider webs. Scorpionflies have been observed to feed on sphinx moth caterpillars that fell victim to spiders. Some mirids also inhabit the webs of a subsocial spider *Anelosimus studiosus* (Hentz) in Florida, where they scavenge on dead insects. Recently it was discovered that the same spider gives a home to caterpillars of the pyralid moth *Tallula watsoni* Barnes and McDunnough, which are never found outside of spider webs. Spiders do not attack the caterpillars, probably because these caterpillars have developed some sort of chemical camouflage as well as the ability to remain motionless and not set off the vibration of the web. In Florida, the caterpillars simply feed on the vegetation that happens to be incorporated into the spider web, but in the Neotropics there is a noctuid moth caterpillar (*Neopalthis madates* Druce) that scavenges on the dead insects caught in the webs.

Inquiline associates of ants are especially well studied, and display varying levels of host exploitation. In the Neotropics, predacious silverfish and wasps follow raiding army ants, looking for easy prey. There are also species that infiltrate the ants' nests and eat their brood or food. Pausid beetles produce secretion in their huge balloon-like antennae. The ants bite into the balloons and suck up this nectar while the beetles consume their brood. Blue butterflies (Lycaenidae), induce ants to feed and care for their young by secreting pheromones that mimic those produced by the ant brood; the ants actually carry the caterpillars into their own nests. The caterpillars also produce a sweet, nutritious fluid much liked by the ants. In exchange, they benefit from frost and fire-proof housing in the ant nests and are protected from predators and parasitoids. Like pausid beetles, they also frequently feed on the ant larvae.

Commonly known as cuckoo wasps, the hymenopteran family Chrysididae is a very large group of over 3,000 described species. They often have sculptured metallic bodies, so they are also known as jewel wasps, gold wasps, or emerald wasps. They are typically associated with solitary bee and wasp species. Cuckoo wasps lay their eggs into the nest of these other hymenopterans, sometimes puncturing the mud wall of the nest with the ovipositor, or chewing a hole in it to gain access. After ovipositing in the cell of its host, cuckoo wasps seal the hole, and leave its offspring to kill the host wasp larva and to complete its development on a stockpile of food meant for raising the host's offspring. Some cuckoo wasps enter the nest of its host at the moment when the provisions are brought in, laying their eggs on the food (various paralyzed insects or spiders) in plain site of the host.



Inquilines and Cleptoparasites, Figure 6 **Some examples of inquilinines and cleptoparasites: (a) Dung balls created by dung beetles as a larval food substrate often provide food for other insects. (b) A tiny droplet spider *Argyrodes* sp., lives in webs of the large golden orb weaver spider, *Nephila* sp. It hides until the big *Nephila* has subdued a prey and then sneaks up and shares the meal. *Argyrodes* relies on speed for defense as well as its ability to move in the web without moving it. (c) An ant guarding lycaenid eggs. (d) Many species of ants host caterpillars of Blue butterflies in their colonies. Larvae of the European lycaenid, *Maculinea arion*, are carried by *Myrmica rubra* ants into the nest, where it feeds on ants' brood in exchange for sweet secretions.**

The cuckoo wasps can roll up like an armadillo into an impenetrable ball, which saves them from possible attack by the host. Some cuckoo wasps do not accept the "loot" until they have won it in a contest. Larvae of the cuckoo wasp *Praestochrysis lusca* Fabricius, for example, do not touch the stockpiled food of their hosts unless a battle with the host larva occurs. If the combat (the outcome of which is never certain) does not take place, the cuckoo wasp larva starves to death – apparently the battle with the host larva triggers feeding behavior.

The sarcophagid fly *Miltogramma germari* Meigen depends on *Bembex* digger wasps to obtain a suitable host (a paralyzed caterpillar) and also a suitable habitat. The sarcophagid stalks the *Bembex* while it digs a hole in the ground – the site for a nest where the caterpillar will be buried together with the *Bembex*'s egg. While the wasp digs, there are numerous opportunities for the fly to lay its own eggs on the caterpillar, but it waits until the very last moment. Only as the wasp disappears into the hole dragging the caterpillar along does the fly deposit live larvae on the edge of the hole. The wasp emerges from the hole and covers the entrance with dirt; the fly larvae are the first to fall in. The hole is sealed and so is the fate of the wasp's offspring – the fly larvae will feed on the caterpillar, consuming the wasp egg in the process. Obviously, this is a case of parasitism; the host wasp suffers and the fly benefits.

Insecta

The class of organisms containing insects. It is sometimes called Hexapoda, though Hexapoda is more often is considered to be a superclass containing class Insecta and class Entognatha. Insecta is one of the most important classes within the phylum Arthropoda, and the largest class of animals. Estimates of insect diversity range from 1.4 million to over 5 million species, but less than 1 million have been described.

► Classification
► Phylum
► Orders

Insect Growth Regulator

A hormone-like substance (hormone analog) naturally produced by plants, or produced synthetically by chemists, that affects the normal growth of insects.

► Ecdysone Agonists
► Ecdysteroids
► Juvenile Hormone
► Insecticides

Insecticide

A pesticide applied to manage insect populations.

► Insecticides
► Acaricides
► Miticides

Insecticide Application: The Dose Transfer Process

TIMOTHY EBERT, ROGER DOWNER
The Ohio State University, Wooster, OH, USA

In the broadest sense, the application of pesticides involves the transfer of a toxicant from the manufacturer to the target organism. This is the dose transfer process, which can be broken down into several major events. However, difficulties at any step can result in a loss of biological activity, excessive environmental contamination or both.

The dose transfer process is a roadmap for the events that take place in delivering a toxicant to a target organism. In field agriculture, a small quantity of toxicant must be spread over a large area (acres or hectares). On a smaller scale, the same process is used for home garden and turf application. However, many steps in the dose transfer process are reduced when traps are used (e.g., cockroach and ant control in houses), or when the toxicant is used as a barrier (e.g., treated lumber for insect and fungus control). Each step in the dose transfer process is unique for each toxicant, its formulation, its intended use and the environment where it will be used. A general outline of the steps in the dose transfer process that emphasizes their interrelatedness is presented here. While most applicable to water-dispersed toxicants applied to field crops via atomization through a small orifice, the discussion could be applied to most pest control activities with some judicious modification (Fig. 7).

The act of formulation is the addition of chemicals other than the toxicant or diluent to the overall sprayed product. These chemicals are collectively called "adjuvants." The manufacturer of the toxicant, distributors of the toxicant, and persons involved in applying the toxicant determine the formulation that is applied to the field. While the applicator is not usually thought of as a formulation chemist, he is altering the physicochemical properties of the toxicant-diluent mixture when adjuvants are added. Usually the objectives of adding adjuvants are: (i) consumer usability; (ii) dispersal in diluent; (iii) retention by foliage; (iv) reduced redistribution through the drift of small droplets in the air, or the washing off of the toxicant from rainfall; (v) improved biological activity, including improved pick-up of the toxicant by the insects and redistribution to the chemically active site in the insects; and (vi) correction of existing problems like the presence of specific ions in the water used for the diluent.

This description of the dose transfer process focuses on the application of toxicants with water as a diluent. The second most common diluent is oil. As oil is different from water, the following discussion may not always apply to applications with oil as the diluent.

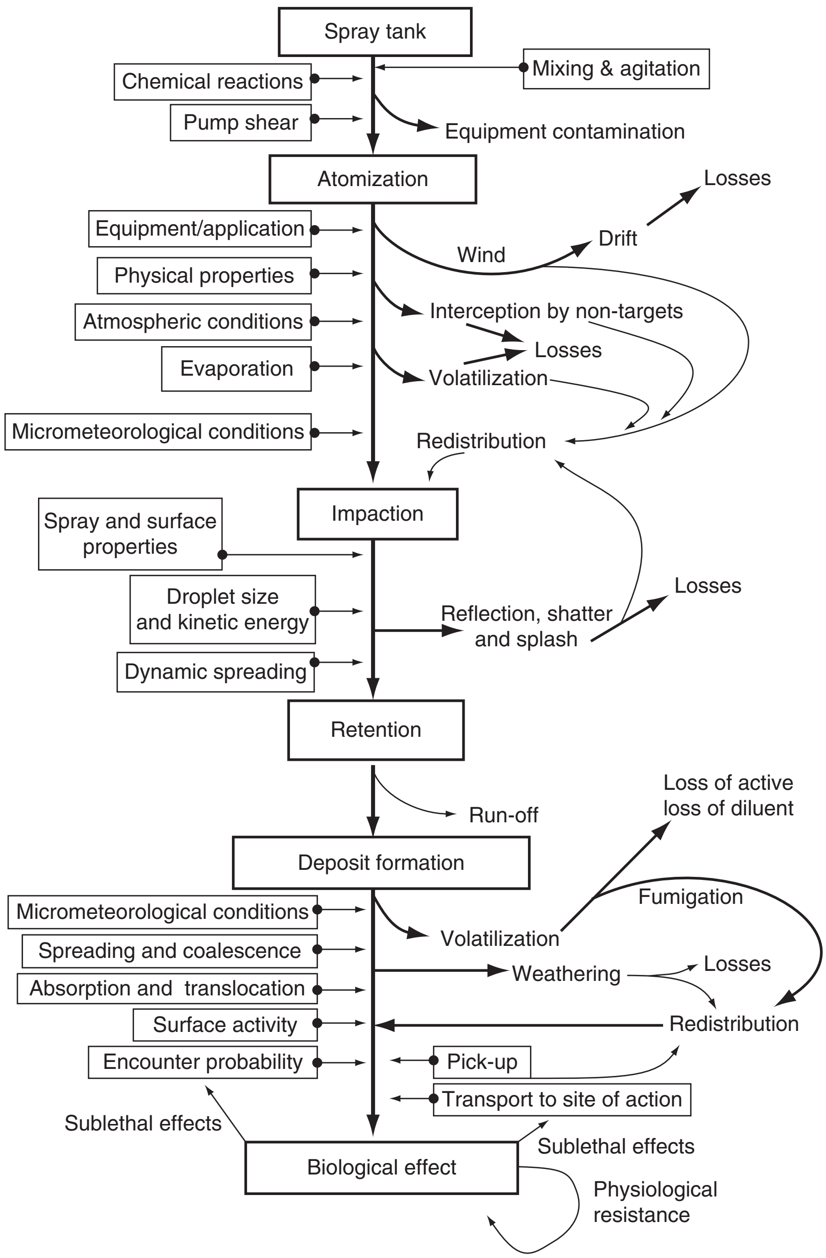
Consumer Usability

Consumer usability does not fit in the dose transfer process because it is strictly a human use and safety issue. A colorless, odorless toxicant can be made less hazardous by including an odiferous adjuvant (= stenching agent) in the formulation. Other issues include ease of removal from the container, or increase the shelf life of the product. While addressing these issues may result in formulation changes that affect toxicant efficacy, the goal is not related to the manipulation of toxicant functioning. Therefore, consumer usability is not listed as part of the dose transfer process.

Spray Tank

Dispersal is first affected by the chemistry of the different formulation components interacting with each other and the diluent. Water is a common diluent for high volume applications (100 gallons per acre). Many pesticides are hydrophobic (repel water). Therefore, additional chemicals are needed to keep the toxicant suspended in the diluent. This is done with chemicals that promote the formation of an emulsion (emulsifiers), or that promote the formation of a suspension (antiflocculating agents). These approaches lead to the formation of two important classes of pesticide formulation: "Emulsifiable Concentrates (EC)" and' suspension Concentrates (SC)'.

Following the addition of chemicals (toxicant(s), formulation components and adjuvants) to the spray tank, the initial goal is to distribute these chemicals uniformly throughout the diluent. This can be achieved through agitation of the carrier liquid and the addition of dispersing agents. However, vigorous agitation is not always



Insecticide Application: The Dose Transfer Process, Figure 7 Flow diagram representing application of liquid pesticide.

a guarantee of proper mixing. Interactions between the types of agitation (e.g., paddle mixing, recirculating pumps) and the shape of the spray tank can leave areas of relative calm where formulation components or toxicants can separate or settle out of solution. Where agitation is provided by recirculation through a centrifugal pump, the heat and friction from the pump may promote chemical reactions that alter the expected behavior of the atomized spray. An example of this would be the addition of long chain polymers for drift control. The mechanical action of the pump breaks the long chains, thereby reducing their effect on the atomization properties of the liquid. Dispersing agents that can be added include emulsifiers (surfactants used to mix oil and water), buffers (solubility is sometimes pH dependent), and anti-flocculants (keeping small particles suspended in water).

Atomization

In some way, the toxicant must be distributed over the target area. While other methods are used (e.g., dusting, painting), a common approach is to atomize a liquid containing the toxicant and distribute the resulting droplets over the target area. This can be done in several ways, among them are: (i) hydraulically forcing fluid through a small orifice (hydraulic sprayers); (ii) use a high speed air stream (mist blowers); (iii) placing liquid on a rapidly spinning disk or cage (Controlled Droplet Applicators [CDA] like spinning disks and rotary cage atomizers); (iv) using a hot and rapidly moving air stream (thermal foggers); (v) electrohydrodynamically (Figs. 12 and 13). The general process whereby the bulk liquid is broken up into millions of small droplets is similar for all these application strategies.

In hydraulic sprayers, the most common approach to atomization, a liquid is forced through a small orifice under pressure. At pressures close to atmospheric pressure, the liquid flows out of the orifice as a stream because surface tension forces exceed the energy from internal and external sources. Increasing pressure will increase the internal turbulence in fluid flow and increase the velocity of the liquid exiting the orifice relative to the surrounding air. Low-pressure application pressures are 15–40 psi. At some point below these pressures, sufficient energy is imparted to the liquid stream to cause it to disintegrate into small droplets, and increasing pressure results in smaller droplet sizes. Most hydraulic atomizers exhibit three modes of liquid sheet disintegration: rim disintegration, perforated sheet disintegration, and wavy-sheet disintegration. Rim disintegration is droplet formation from a thickened rim at the leading edge of the liquid sheet (usually occurring in high viscosity and high surface tension liquids). Perforated sheet disintegration takes place in holes that develop in the sheet. Wavy sheet disintegration takes place due to oscillations that tear off droplets at the leading edge of the sheet (Fig. 14). In all three cases, ligaments form and disintegrate to produce droplets. However, droplets produced from rim disintegration tend to be larger. Wavy sheet disintegration produces a highly variable range of droplet sizes. Thus, the relative contribution of the different modes of liquid sheet disintegration will determine the size range of droplets produced and the abundance of droplets of a particular size within this range. Droplet sizes within the spray cloud are determined by the thickness of the liquid sheet from which the droplet originates, with larger droplets being produced by thicker sheets. The droplet size range in the spray cloud is also dependent on the velocity of the sheet relative to the surrounding air, and the liquid properties of the atomized fluid (e.g., viscosity, surface tension). Other processes involving high pressures can also atomize a fluid. However, all of them ultimately rely on the Rayleigh mechanism, so named because Lord Rayleigh postulated the breakup of a liquid stream first by ligament formation, then by ligament disintegration into droplets.

The large droplets produced by primary atomization may undergo further disintegration. In still air, the surface tension of the liquid will create spherical droplets because a sphere minimizes the strain within the droplet. It also minimizes the surface area exposed to the air. However, the velocity of the droplets creates air turbulence, and the process of atomization produces a vacuum that also creates turbulence. Also, the droplet is elongated while attached to the ligament, and relaxation of this deformation following detachment from the ligament produces additional stresses. If these forces exceed the surface tension, the droplet will disintegrate by one of three processes described by the shape of the parent droplet prior to breakup: lenticular deformation, cigar-shaped deformation, or bulgy deformation. The breakup of droplets is termed secondary atomization.

Droplet diameters range in size from under 1 μm (1/1,000 mm) to over 1 mm depending on the process used to form them. For field application of pesticides with a low-pressure (15–40 psi) hydraulic nozzle, a typical droplet size range is from 50 to 1,000 μm in diameter. Some high-pressure (2,500 psi) hydraulic sprayers used in greenhouses have a droplet size range of 1–300 μm in diameter. These ranges would be typical for water, but small quantities of adjuvants (e.g., surfactants or polymers) can change these ranges significantly'. Surfactants' are *sur*face *act*ive *agents*.

Measurement

The output of atomization devices needs to be measured to maintain proper functioning of the equipment and to develop new methods for improving the pesticide application process. Methods of evaluating the output from nozzles can be categorized as quantitative and qualitative. Quantitative measures are most useful for equipment maintenance. These approaches include measuring the output of individual nozzles with a bucket to check for plugged or damaged nozzles. At a finer resolution, smaller containers, or a sheet of corrugated roofing material could be used to measure the fluid deposited over a specific area. This approach would also detect plugged nozzles, but would also detect proper alignment of the nozzles along the boom. While these measures improve the uniformity of toxicant distribution over a field by aiding in equipment calibration, they are not designed to provide sufficient detail for evaluating coverage of individual plants (or leaves) within that field.

Devices for measuring atomization characteristics of nozzles are categorized as mechanical, electrical and optical. Furthermore, the techniques are grouped as intrusive and non-intrusive. An example of an intrusive mechanical approach would be to use several vials placed in different parts of the spray cloud. One then measures the liquid collected per vial over some time interval, much like what is done for equipment evaluation. This provides some measure of uniformity across the spray cloud for individual nozzles, and can also be used to measure output from several interacting nozzles. However, describing the spray cloud in terms of droplet sizes, numbers and velocities provides a better picture of the output of a specific nozzle. The factors to consider when selecting a technique for measuring spray cloud parameters include the effects of spatial sampling versus temporal sampling (factors like equipment cost are not considered here). Spatial sampling describes the droplets that pass through a specific volume in an instant in time. Methods for spatial sampling include high-speed photography and laser holography. Temporal sampling measures droplet sizes that pass through a specific volume over some time interval. Methods for temporal sampling include collection techniques and optical instruments. One collection technique is droplet freezing by injecting liquid nitrogen into the spray cloud. Balls of ice drop into a collection pan and are subsequently sieved. The mass collected in each sieve is divided by the average diameter between the next largest sieve and the current sieve and the numbers of droplets collected can then be estimated. These types of collection techniques are not usually used for assessing agricultural sprays. Spatial drop size data may be converted to temporal data by multiplying the size-specific droplet velocities by the droplet sizes. Temporal sampling has been suggested as the most appropriate method for agricultural uses. Optical instruments for sampling spray clouds include the Malvern particle sizer and the Phase Doppler Particle Analyzer (PDPA). The Malvern is a nonintrusive technique for measuring droplet sizes. The device is based upon a Fraunhofer diffraction of a laser beam. The PDPA is another nonintrusive approach based on work by Bachalo. However, it measures droplet velocity, and then estimates the numbers and sizes of droplets that passed through the probe volume while it was measuring other droplets. The PDPA uses a beam splitter to create two in-phase beams of coherent light. The point where these beams cross is the area that is measured. Droplet sizes are based on the interference fringe pattern as detected by three successive independent sensors. Droplet size is estimated based on the phase shift of droplets as each sensor detects their fringe pattern.

Characterization

Characterizing the spray cloud is done with descriptive statistics and mathematical models for which parameters are estimated based on measurements. At present, the most common model is the Rosin-Rammler droplet size distribution function that was based upon work done by these authors for describing particle sizes in powders, or a modified version of this model based on work by Rizk and Lefebvre. The advantage of using a model is that droplets that were not measured (for whatever reason) can be included in the calculation of descriptive statistics. However, regardless of the approach used, the data need to be summarized for comparative purposes and to provide concise inputs for studying the effects of atomization on retention and biological effect. Variables include droplet surface area, droplet diameters, droplet volumes and droplet velocities. These variables can then be described using the mean, median, or mode. Additionally, some description of the dispersion of the data around these values is often useful. These measurements can apply to the entire cloud, but typically scans are made along one axis of the spray cloud. For a flat fan nozzle, the z-axis is parallel to the flow out of the orifice with the origin at the center of the orifice; the x-axis is perpendicular to the z-axis and oriented along the major axis if droplet dispersion in the x-y plane forms an ellipse. This can be broken down further by taking point measurements at discrete intervals throughout the x-y plane at one or more points along the z-axis. However, it is not clear how these measures of spray quality can be used to predict toxicant retention on plant surfaces, or ultimately, the biological effects of the application.

Post-atomization

Following atomization, droplets must travel through the atmosphere to arrive at their target. Two forces act to alter droplet sizes arriving at the plant surface: evaporation and friction with the atmosphere. Evaporation changes the droplet size, and for any evaporation rate, the change will be greater in smaller droplets than in larger droplets; i.e., the smaller droplets will get smaller more quickly than will the larger droplets. In some cases, the aqueous component may completely evaporate, leaving only non-volatile formulation components. Friction with the atmosphere is important because smaller droplets loose velocity more quickly than larger droplets, and the terminal velocity of smaller droplets is much lower than for larger droplets. Consequently, small droplets do not travel as far nor penetrate as deeply into the crop canopy. However, small droplets can be entrained in the air turbulence formed by the wake of a passing larger droplet (Table 4).

In the application of pesticides, one cause of toxicant loss is the drift of small droplets away from the field. Drift may occur when the wind speed “up” (away from the crop canopy) exceeds the terminal velocity of the droplet. Under such conditions, the droplet will not fall onto the crop, and any lateral wind has the potential to move the droplet outside the field boundaries. Given sufficient wind, even the largest droplets will become susceptible to drift. While drift is a loss of toxicant out of the field, some wind-generated turbulence can aid deposition by moving drift-prone droplets into the plant canopy.

In application, a common height above the crop canopy is 18 inches (0.46 μm). Thus, a 10 μm diameter droplet will probably evaporate before the droplet reaches the canopy if the air is still, and as droplet size decreases, the droplet becomes more susceptible to drift because it will take it longer to travel the remaining distance to the target surface. Thus, some wind is beneficial because the small droplets are moved into the plant canopy, which prevents these droplets from becoming driftable.

Insecticide Application: The Dose Transfer Process, Table 4 **Terminal velocities of droplets of water falling through still air**

Droplet diameter (μm)	Droplet volume (μl)	Terminal velocity (m/s) [mph]	Extinction time (s)[1]	Time to fall 18″ (0.46 m) in s
10	5.24×10^{-7}	0.003 [0.007]	0.568	152.4
50	6.54×10^{-5}	0.072 [0.161]	14.205	6.4
100	0.00052	0.253 [0.566]	56.818	1.8
500	0.06545	2.051 [4.588]	1420.455	0.2
1000	0.52360	3.869 [8.655]	5681.818	0.1

[1]Extinction time is estimated based on 20°C ambient temperature, 80% relative humidity, and a temperature difference of 2.2°C between wet and dry bulb thermometers

It should be noted that atomized droplets are not in still air, and are often traveling faster than their terminal velocities near the nozzle. Droplets then slow down to their terminal velocity due to friction. Also, because the bulk liquid is, on average, traveling into the crop canopy, there is considerable air movement into the crop canopy, especially with high volume (934.6–9346 l per hectare = 100–1,000 U.S. gallons per acre) application strategies. Thus, the values in the table should not be used too literally. While it might be nice to provide more accurate values, such calculations are difficult (may be impossible) due to the number of variables that must be accounted for both in terms of the physico-chemical nature of the sprayed liquid and the external environment.

Many adjuvants added to tank mixtures modify one or more atomization parameters. Such adjuvants include anti-evaporants, spreaders and drift reduction agents. Anti-evaporants retard water loss, thereby increasing the life expectancy of droplets. Anti-evaporants have the greatest effect on smaller droplets. Anti-evaporants may retard water loss by forming a film, or they may be hygroscopic. Spreaders are surfactants. By lowering surface tension, the liquid has less cohesion and breaks apart more readily. Drift-reduction agents are usually polymers. The addition of a polymer increases the viscosity of the liquid, thereby increasing droplet size and reducing the proportion of smaller droplets in the spray cloud. The addition of surfactants and drift control agents may also change the atomization characteristics of the liquid.

Much of the above discussion on atomization is based on the atomization of pure water, or water and a water-soluble formulation. Additional problems arise when the toxicant is dissolved in oil (as in emulsifiable concentrate [EC] formulations) or is left as discrete particles that are suspended in water (as in suspension concentrate [SC] formulations). As an example, consider the SC formulation. During atomization, droplets with diameters less than the particle size of the formulation cannot have any toxicant (assuming the toxicant is completely insoluble, or nonfunctional if particles are damaged as is the case with the application of an insect pathogen). On the other hand, particles will carry some water with them and some particles will group together to form larger droplets. Consequently, the presence of particles will decrease the numbers of droplets with diameters less than the particle size of the formulation. The distribution function for the numbers of particles based on the size of the droplets will determine the toxicant distribution over the treated surface, and this distribution will influence the biological effect.

Following atomization, the droplets must travel to the plant canopy. They have a velocity vector along the z-axis, and a radial component away from the z-axis is also present in most droplets. Furthermore, the traveling speed of the nozzle over the crop canopy will add a velocity vector that is almost parallel to the y-axis (the exact orientation being determined by the orientation of the nozzle axes on the spray boom). Turbulence from wind passing over the crop canopy and turbulence from the spray boom moving over the field will change the velocity vector of droplets before they impact the plant surface.

The air flow at the plant surface is essentially stationary. The depth of this stationary layer is determined by leaf surface topology. Wind velocity increases gradually until it reaches the current wind speed above the crop. The transition zone between the stationary air and the current wind speed is termed a boundary layer. The boundary layer has no specific dimensions except those defined by the researcher. The direction of air flow in the boundary layer changes from the current wind direction to become almost parallel to the leaf surface (laminar boundary layer). The depth of the laminar boundary layer increases with distance from the leading edge of the leaf. However, temperature gradients, leaf topology and turbulent air flow within the crop limit the size of the laminar boundary layer.

Air flow above the crop canopy is usually turbulent due to interactions between the air mass above the crop and the irregularities within the crop. Furthermore, heating of the ground and crop surface creates convective cells that also contribute to air turbulence above the crop. If temperature gradients are small and the surface is fairly regular (same species, same height, etc…), then the average velocity will increase logarithmically with the height above the canopy until it reaches the wind speed. The depth of the boundary layer above the crop where the air velocity is increasing to the wind speed is a function of the distance traveled over the crop. This is similar to what happens at the leaf-air interface, but the mathematical relationships differ considerably.

The air flow over the crop and over surfaces in the crop canopy are important because droplets must pass through these layers before they impact the plant surface. Droplets that eventually impact a leaf surface must pass through a turbulent layer of air above and within the crop canopy, and then pass through a boundary layer close to the leaf surface where the air movement is laminar and parallel to the leaf surface. Small droplets (usually less than 100 μm diameter) may be carried in the air currents in the laminar boundary layer unless they have sufficient energy to penetrate this layer. These droplets may then deposit on the underside of the leaf if the turbulence at the leeward edge is sufficient, or they are carried somewhere else. Droplets with insufficient energy to reach the crop may end up drifting to other locations and may become health or environmental hazards. Even if such hazards are not present, such losses represent lost revenue to the farmer because the toxicant is no longer in a location for effective management of pest problems in the field.

Impaction and Retention

Three physical properties of liquids that are important in relating atomization characteristics to retention on plant surfaces are: (i) equilibrium surface tension; (ii) dynamic surface tension; (iii) viscosity. Equilibrium surface tension is caused by the cohesive molecular attraction between molecules in the liquid, and molecules at the surface that have one or more sides exposed to the air. Liquids minimize this exposure by keeping the surface area to a minimum, which means that droplets in air will form spheres. Molecules at the surface tend to be more tightly packed and are arranged more regularly than those in the bulk liquid. Equilibrium surface tension is the energy required to expand the surface area of a liquid at rest. When a liquid is moving, the molecules at the surface are less ordered and more similar to the molecules in the bulk liquid. For water, it takes about 40 milliseconds for the surface film to become stable. This period of adjustment is characterized by declining surface tension. Because the surface tension is constantly changing during this period, it is termed dynamic surface tension. Viscosity is a function of the cohesive forces between molecules, but it also depends on molecular shape. Viscosity is a mea-sure of how readily molecules pass one another. High viscosity may be due to high cohesion between molecules, or because molecules become entangled with one another.

Once the spray cloud reaches the plant canopy, the foliage acts as a filter that removes droplets from the air column. The leaves and stems fill an area through which the droplets will pass aided or hindered by their original velocity following atomization, gravity, friction with the atmosphere, and air turbulence. As foliage density increases, the degree of penetration into the canopy will decrease. Furthermore, spray deposits will be greater on surfaces directly facing the nozzle. Usually this is the upper (adaxial) leaf surface, though bent leaves and the flexing of leaves due to air turbulence may result in specific examples where the abaxial surface receives more toxicant. As a general rule, larger droplets will penetrate the plant canopy more effectively than smaller droplets, but smaller droplets have a greater potential to deposit on the bottoms of leaves. The reason is that small droplets are entrained in the laminar air flow around the leaf and are subsequently deposited on the abaxial surface by the turbulent air flow at the edges of the leaf. This results in a common abaxial leaf surface deposit pattern of more droplets occurring at the edge relative to more central abaxial leaf areas.

Impaction occurs when the droplet has penetrated the boundary layers around the leaf and hits the leaf surface. Droplet deformation occurs upon impact with any surface (leaf, leaf hairs, stems, soil, etc.). Droplets spread upon impact, where the degree of spread is a function of the energy of impact balancing with the cohesive forces within the droplet. If the energy of impact is too great, the droplet will shatter into several smaller droplets. If the droplet does not shatter, it will deform into a torus. Dynamic surface tension will pull the torus back into a sphere and the droplet will rebound if it has not adhered to the plant surface. The impact of a droplet upon a surface, its deformation and subsequent rebound (if that occurs) takes about 1 millisecond.

A plant surface consists of several elements important to the retention of droplets. The physical topology of the leaf is defined by the shape of the leaf, folding or bending of the leaf surface, leaf hairs, stomata, the presence of specialized tissues like veins or glands and the shape of the individual cells within these tissues and how they fit together. Leaf shape determines how far air currents travel from the windward to the leeward sides of the leaf. Leaf hairs may increase retention of droplets, but may also prevent droplets from touching the leaf cuticle. Stomata provide a direct route through which insecticides may enter, but only if the surface tension is low enough to reduce the contact angle below the wall angle of the stomata. While this may be desirable for systemic insecticides, it may reduce the biologically available dose for other insecticides. Veins provide channels that may reduce the liquid carrying capacity of the leaf by providing routes along which liquid flows. The spaces between cells also are recessed relative to the intracellular areas. Liquid often becomes trapped in these areas, thereby promoting retention (Figs. 8-10).

The physico-chemical property of the plant cuticle also plays a role in retention. Plant cuticles are a thin continuous covering that may be from less than 0.1 to 10 μm thick depending on the species and the location on the plant. The outermost two layers are an epicuticular wax layer that blends into the cuticular wax layer. These layers are attached to the cell wall by a matrix of cutin (a cross-linked polymer of hydroxylated fatty acids) and carbohydrate fibers. Below the cell wall is the cell membrane. The physical characteristics of the epicuticular waxes provide the first barrier to retention. The physical structure of this layer is often crystalline, as plates, tubes, rods, or other shapes. These shapes rise above the cuticular waxes and repel water by their physical structure. The epicuticular waxes are mostly composed of long

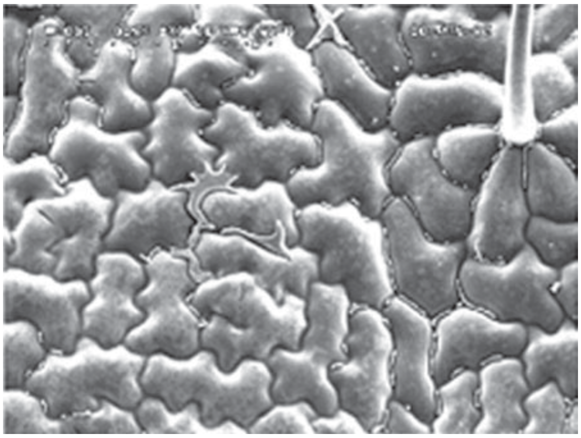
chain (often C_{26} or C_{28}), even numbered, primary alcohols, acetates, aldehydes and fatty acids. Additionally, this layer has odd-numbered (usually C_{29} or C_{31}) alkanes. Additional components are present, though in lesser amounts, and the exact composition is species-specific as modified based on abiotic conditions (e.g., temperature, humidity, light). Thus, the problem for pesticides is to stick to the plant surface. However, contact insecticides cannot stick too well to the plant surface because they must adhere to the insect cuticle. Systemic insecticides also present a special problem because they must pass through these cuticular layers and then be transported in the phloem/xylem. Penetration rates through the cuticle will be dependent on the molecular size of the toxicant, and the path length through the cuticle. Because the cuticle is partly composed of cutin and other long chain organic molecules, toxicants must move around these molecules to penetrate the cuticle. Therefore, the path length is greater than the liner thickness of the cuticle.

Given the physical and chemical composition of the cuticle, the impacting droplet will remain on the surface if the kinetic energy of the droplet is less than the adhesive forces keeping it on the plant surface. If the droplet has wetted the plant surface upon impaction, some portion of the droplet will remain. Droplets with considerable kinetic energy that have adhered to the plant surface may shatter, giving rise to one or more smaller droplets. Droplets that hit a pre-wetted surface may also provide enough energy to produce one or more smaller droplets. These droplets may impact other plant surfaces, or be lost from the crop. The likelihood that droplets will rebound from a surface or shatter upon impact can be modified with the appropriate selection of stickers, polymers and surfactants. The selection of product must balance drift, impaction and retention. While these products will influence the final distribution of the toxicant, the toxicant distribution will also influence the biological effect of the application. However, in many cases, there is a period of time between the retention of the liquid on the plant surface and the time when the insect encounters the toxicant. During this time, several dynamic events take place that influence toxicant distribution as encountered by the target (or non-target) insect.



Insecticide Application: The Dose Transfer Process, Figure 11 **Roundup Ultra sprayed on the adaxial surface of a cotton leaf. The deposit has filled in the gaps between cells (Courtesy of Molecular and Cellular Imaging Center, The Ohio State University).**

Redistribution and Deposit Formation

Once the liquid spray has settled on the leaf, the deposit finishes spreading over the leaf. The maximum spread is related to the viscosity, surface tension and chemistry of the liquid along with the chemical and physical structure of the plant surface. However, the rate of spread will be inversely proportional to time. Thus, in some cases, droplets will not achieve their maximum dimensions because they do not achieve equilibrium before evaporation reduces the liquid volume. Alternatively, some sprays will contain lipophylic components that may continue to spread through the cuticular wax layers until a steady state has been reached. While it is easy to see an oil spread on waxy plant surfaces, the spread of the lipophylic components is not necessarily representative of the spread of the toxicant (Fig. 11).

Droplet size interacts with evaporation to change concentrations within the droplet. Small droplets with a dilute surfactant solution may have insufficient surfactant to wet the leaf surface. Such droplets will evaporate, and the final microscopic piece of formulation and toxicant will be easily dislodged from the surface. Larger droplets of the same solution will maintain a large contact angle with the plant surface until the surfactant concentration reduces surface tension to the point where the surface is wetted.

Under some conditions, the leaf surface could be viewed as a thin layer chromatography plate, and the formulation components as solvents for the toxicant. If the toxicant is nearly insoluble in the formulation, then most of the toxicant will remain wherever it was deposited following atomization. However, if the toxicant is soluble, it will flow over the cuticle with the bulk liquid, and then be carried some distance further as the solvent moves through the cuticular waxes.

The final shape of the deposit after spreading and evaporation have finished is highly variable, and subject to the physico-chemical parameters already discussed. On a flat leaf surface, droplets can form deposits that look like atolls (a ring of small islands located near the outer edges of the droplet), archipelagoes (irregular islands randomly located within the boundaries of the old droplet), mountains (a hill where the formulation components went out of solution, usually near the center of the old droplet), solid films that may or may not cover underlying features of the cuticle, and various other shapes.

Degradation

During these processes, and throughout the life of the toxicant, the toxicant will degrade. Degradation is a combination of a large number of forces that can be classified as chemical or physical. The two most common chemical actions are hydrolysis and photolysis. Hydrolysis is the addition of water to the toxicant molecule. This usually splits the toxicant into two inactive molecules. Photolysis is the action of sunlight hitting the toxicant and breaking it. Within the plant (for systemic toxicants), and within the insect, enzymatic degradation will become more important, but the toxicant has not yet entered the insect or the plant. Physical degradation of the deposit is an abiotic process whereby the toxicant is physically removed from the plant surface. Rain is a common source of physical degradation, but heavy dew or fog can also act in the same manner. For water-soluble toxicants, dew can also redistribute the toxicant over the leaf by rewetting deposits. Wind and wind-blown sand can provide mechanical abrasion to remove surface deposits. While not commonly considered, gutation (exudation of water from leaves due to water pressure from the roots) could also provide sufficient leaf surface water to redistribute toxicants.

The physical forces in toxicant degradation can also act to redistribute the toxicant within the plant canopy. For example, rain may pick up some portion of the toxicant on a leaf surface and move it to the leaf axil, or along the stem. Water that does not fall off the plant will then evaporate creating a new deposit.

Toxicant Acquisition and Biological Result

Following deposition on the plant (or other) surface, the toxicant must be acquired by the insect in sufficient amounts to produce the desired result. Complicating factors include growth of the insect because the lethal dose is determined in part by insect biomass.

Consider a caterpillar feeding on a leaf treated with sufficient toxicant to kill the larva if the larva consumes the entire deposit. If the toxicant is spread uniformly over the entire leaf surface (as might happen if sufficient surfactant is added), then the larva must consume the entire leaf before acquiring a lethal dose. During this time, the larva is exposed to sub-lethal doses, and exposure to sub-lethal doses is one factor that can lead to insecticide failure. Furthermore, the entire leaf has been eaten, so the level of plant damage is high. One solution is to increase the dose of toxicant, but for every doubling of the dose, the savings is only half of the leaf eaten by the larva at the next lower dose; i.e., double the dose from the previous example, save half the leaf, quadruple the dose save three-quarters of the leaf, and so forth. An alternate solution is to concentrate the toxicant into a single deposit. In this case, the larva will (on average) eat only half the leaf. However, in this case there is no benefit to increasing the dose unless there is an accompanying increase in the size of the deposit. This is because the biological response is driven entirely by the probability that the larva will encounter the dose. The benefit is that for a minimal dose, more of the plant is saved and there is no exposure to sub-lethal doses. Obviously, "real" applications produce deposit structures somewhere between these two extremes.

Deposit structure is defined as the distribution of toxicant over a surface. It can be relatively uniform, absolutely uniform, or heterogeneous. Relative uniformity is scale specific, i.e., uniform at 1 cm or greater scales; for example, the ink distribution in a picture in the newspaper. Absolute uniformity is scale independent (at least down to the sub-micrometer level); for example, the distribution of silicon over a computer microchip. Thus, absolute uniformity implies relative uniformity, but the reverse is not true. This is important in application technology because one measure of uniformity is coverage, where the goal of some applications is 100% coverage. 100% coverage may be uniform over a hectare or a whole plant, but is seldom uniform over every leaf on that plant. Absolute uniformity thus implies 100% coverage, but the reverse is not true. Other ways of viewing absolute uniformity is that all toxicant molecules have the greatest possible distance between them over the treated area. Deposit structure can also be heterogeneous. While there are many texts describing heterogeneity in different fields of research, there is no currently accepted measure for heterogeneity in pesticide application.

Two examples will suffice to demonstrate how insect behavior interacts with heterogeneous deposit structures to influence the biological result:

1. If the deposit applied to the leaf surface is sufficient to kill the larva, and the deposit is large enough so that it takes two bites for the larva to ingest the entire deposit, then the way in which the larva feeds will determine the survival time of the larva and the amount of damage to the leaf. At the extremes, a larva could start in one place and feed until all the food was consumed (called "chompers"), or a larva could take one bite, move, take another bite, move, and so forth (called "nibblers"). With chompers, the larva is most likely to consume the entire deposit once it has encountered it. Thus, on average, the larva will eat just slightly more than half the leaf before it dies. With nibblers, it is unlikely that the larva will eat the second part of the deposit in the bite following acquisition of the first part. Depending on how the larva moves, it may eat half the leaf before encountering the deposit for the first time, and then eat half of the remaining leaf before encountering the deposit again. Thus, the feeding behavior of individuals interacts with heterogeneous toxicant distributions to influence the biological result.
2. If three lethal doses of toxicant are applied as three deposits and three larvae are allowed to feed on the leaf, the result is dependent on whether feeding is sequential or simultaneous. If feeding is sequential, then the first larva will eat 1/2*1/3 of the leaf, the second will eat 1/2*((1–1/2*1/3)/2), and the third will eat half of what is left – thus, 37/48ths (a bit over 3/4) of the leaf will be eaten. If all three larvae feed sequentially, then each larva will feed on its 1/3 of the leaf and consume half of that before encountering a deposit – thus, half the leaf will be eaten. Of course, there are many assumptions necessary to make this simple model work. A few of these are: larvae do not interact, larvae are not cannibalistic, deposits are far apart, larvae die upon consuming the deposit, contact with a deposit does not elicit a behavioral response in the larvae, and the toxicant is only acquired through feeding. Obviously, few larvae interact with toxicants in this way. However, modeling more complex systems can be done by judicious modification to the simplified model.

This approach identifies expected results based on one (or a few) larvae interacting with very well defined deposits. However, many toxicants do not behave in this way (consider a toxicant which acts through inhalation). Furthermore, it requires a careful set of experiments to identify "lethal dose" and care must be taken because the definition of "lethal dose" will change based on how the insect encounters the toxicant. If the toxicant is uniformly distributed, the lethal dose may be quite high because the insect has time to metabolize the toxicant and it can grow. If the toxicant is concentrated, the effect of metabolism is minimized, but the insect will have a variable length of time to grow depending on how long it takes before the toxicant is encountered. An alternative approach is to model the system based only on the characteristics of the droplets used to create deposits on the leaf surface.

In an atomized spray, the total quantity of toxicant applied to a leaf is related to the number of droplets that are retained by the leaf, the diameter of those droplets (volume = 4/3 π (droplet radius)^3), and the concentration of toxicant within each droplet. In an ideal world, all droplets can be considered to have the same toxicant concentration (uneven tank mixing and evaporation rates may change this under actual conditions, but that adds additional complications). Clearly in this

Insecticide Application: The Dose Transfer Process, Figure 12 **The DRAMM Coldfogger sprayer for greenhouse pest management. The sprayer delivers a fine mist under high pressure.**

system, if the toxicant load on the leaf remains constant, then a change in toxicant concentration must be compensated for by changes in droplet number, droplet size, or both factors. While still a novel approach, recent experiments suggest that the optimal distribution of toxicant is a balancing act between these factors. Thus, smaller droplets increase efficacy up to a point. This point is reached when the accompanying increases in droplet number provide excessive uniformity, or when accompanying increases in concentration no longer have any effect. Increases in concentration may not have an effect if they do not result in additional toxicant transferred to the target, or (especially with herbicides) the toxicant produces localized damage that restricts further acquisition of toxicant. Likewise, increases in concentration (as with ULV application relative to high volume applications) will improve efficacy until accompanying changes in droplet size or droplet number change the encounter probabilities and thereby

reduce toxicant efficacy. By extension, reducing the numbers of droplets will increase toxicity up to the point where reductions in efficacy from suboptimal values of droplet size and toxicant concentration overcome further benefits from using fewer droplets (Fig. 13).

The four variables (dose, droplet number, droplet size and toxicant concentration) define much of the dispersion of toxicant over a leaf surface. If the method of application ensures that the number, size and location of droplets impacting the leaf is random (and toxicant concentration is uniform), then this would be sufficient to define the toxicant distribution over the leaf. However, the distribution of droplet sizes is not uniform within the spray pattern in the x-y plane. Also, large droplets create a wake that can capture smaller droplets. Further, droplet spread, evaporation, and the coalescence of droplets are not independent of droplet size (Fig. 14). It is, therefore, possible that the models predicting toxicant effects would be improved by including some measure of dispersion. Defining the proper measure of dispersion is still being researched.

This discussion may make the dose transfer process appear like a very ordered set of linear steps that result in a biological result. However, the process is not entirely linear. A droplet that shatters on impact may hit the ground and be lost, or it may impact the underside of another leaf. If the target insect typically lives on abaxial leaf surfaces, this may improve efficacy. A deposit may be encountered by a non-target insect and moved to another part of the leaf where it may be more (or less) effective. If the deposit contained insufficient toxicant to kill the insect, it could produce a behavioral change in the insect. This behavioral change would then influence the probability of further contact. Also, while it is important to understand how toxicant distributions influence the fate of individual targets, the effect this has on populations should not be ignored. For example, if sublethal doses are common for the population, expect the population to become less susceptible to the toxicant. Sensitive individuals are selected against, and resistant individuals survive to breed the next generation.

This discussion on the dose transfer process is focused on insects and insecticides. However, much of it is important to other pesticides. Most of the material about deposition on surfaces came from research on herbicides, but will also apply to fungicides. The description of the biological effect is specific to insecticides, but with judicious modification, will also apply to some herbicides and systemic fungicides. Because the driving force in many systemic products is a function of the area of contact between the toxicant and the plant surface along with the concentration gradient of the toxicant, there is clearly a tradeoff between increasing the contact area (larger droplets and higher application volume) and increasing the toxicant concentration in the spray tank to achieve a greater concentration gradient. While it is possible to have both of these factors increase by increasing the quantity of toxicant applied, such an approach is environmentally unfriendly and not an economically viable option for farmers.

The importance of insect behavior should not be underestimated. Behavior reflects toxin apparency, mode of action, and insect response to sublethal doses. The interaction between these behavioral responses and heterogeneously distributed toxins and physiological mechanisms of tolerance may influence the evolution of insecticide resistance.

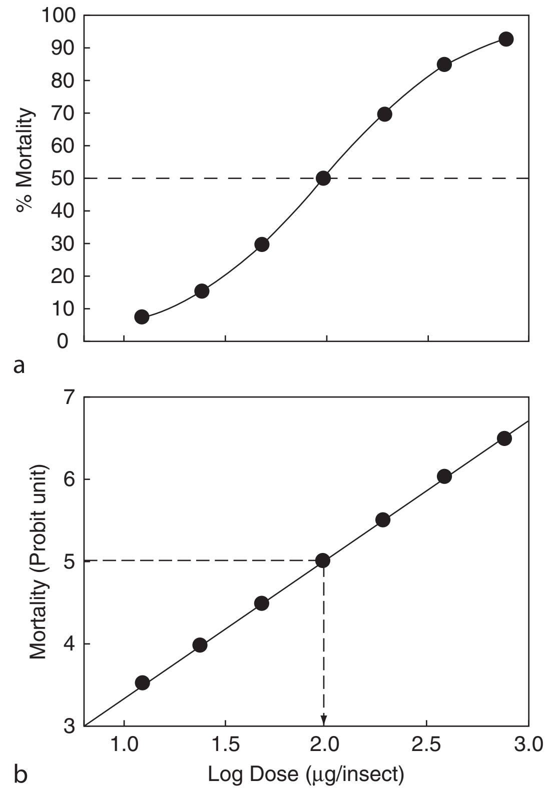
Insecticide Bioassay

KUN YAN ZHU
Kansas State University, Manhattan, KS, USA

Insecticide bioassay refers to any quantitative procedure used to determine the relationship between the amount (i.e., dose or concentration) of an insecticide administered and the magnitude of response in a living organism. If the toxic effect (e.g., death) indeed results from the action of an insecticide, there must be a positive correlation between an appropriate range of the insecticide dose administered and the magnitude of the effect. Such a relationship is known as the dose-response relationship and is fundamentally important in insecticide bioassay (Fig. 15).

Insecticide bioassay with insects or other arthropods often is used to estimate the median lethal dose (LD_{50}) or concentration (LC_{50}) and its associated 95% confidence intervals (95% CI) from a dose-response model. The LD_{50} or LC_{50} is the dose or concentration of an insecticide required to kill 50% of a given population or strain under the specified conditions. These statistics are adopted as the benchmarks to express the toxicity level of an insecticide because the medians tend to be more consistent and to have narrower confidence intervals than lower or higher percentiles in dose-response models.

Insecticide bioassay also may be used to estimate the median lethal time (LT_{50}) which is the time required to kill 50% of a test population or strain with a fixed dose or concentration of an insecticide. For insecticides with a knockdown activity, such as many pyrethroid insecticides, the median knockdown dose (KD_{50}) or concentration (KC_{50}), or median knockdown time (KT_{50}) may be determined by a bioassay. In some instances, the toxicity of an insecticide is measured as sublethal effects (e.g., effects on growth, reproduction, etc.) instead of mortality or knockdown. In such



Insecticide Bioassay, Figure 15 **Two graphic representations of the dose-response relationship. a) When the extent of any particular response (e.g., % mortality) is plotted against log dose, a characteristic S-shaped curve is obtained.**
(b) When % mortality in the y axis is converted to probit units, the dose-response relationship becomes linear. In the log-probit analysis, the antilogarithm of the log dose corresponding to the probit unit of 5, which represents 50% mortality, is the LD_{50} value for the insecticide tested.

cases, the term median effective dose (ED_{50}) or concentration (EC_{50}) may be used to express the toxicity level of the insecticide.

A number of standard techniques are available for insecticide bioassay. The most commonly used techniques include topical application, residual or surface contact, immersion, and feeding bioassays. For example, the LD_{50} or LC_{50} value for an insecticide can be estimated by exposing insects to several different doses (or concentrations) of the insecticide for a certain length of time under specified conditions. Insects treated with the insecticide solvent often are used as a control. Insect mortality data are then recorded and subjected to an appropriate statistical analysis (Table 5).

Based on the concepts of the dose-response relationship, the dose-response data can be analyzed for the LD_{50}, LC_{50} or other toxicity parameters. For example, in the log-probit analysis for the LD_{50}, the doses of an insecticide are transformed into the logarithm scale and the % mortality at each given dose into the probit unit. The transformation of the % mortality data into probit unit allows the conversion of a typical S-shaped curve into a straight line. The antilogarithm of the log dose corresponding to the probit of 5 (i.e., 50% mortality) is taken as the LD_{50}. All the calculations for the LD_{50} value and its associated statistics (e.g., 95% confidence intervals, Chi-square, etc.) can be simultaneously performed using a computer program.

Representative Procedure of Insecticide Residual Contact Bioassay For Aphids (from Gao and Zhu, 2000).

- Pre-determine the insecticide concentration range that results in appropriately 10 and 90% mortality for the lowest and highest concentrations, respectively.
- Prepare at least five concentrations of the insecticide in an appropriate solvent (e.g., acetone).
- Label four 8-ml glass vials for each concentration and the control with the name and concentration of the insecticide.
- Pipet 0.25-ml aliquots of the solvent (for control) and each insecticide solution into each set of vials, beginning with the lowest concentration.
- Load the dosed vials onto a rotator and rotate the vials in a fume hood for 3 min or until acetone is completely evaporated.
- Place 20 apterous adult aphids in each vial with a fine brush and loosely cover the vial with a cap.
- Assess aphid mortality after they are maintained at an appropriate temperature (e.g., 25°C) for a specific time period (e.g., 24 h) in a growth chamber.
- Calculate the LC_{50} value and its related statistical parameters using the log-probit analysis procedure.

Insecticide Bioassay, Table 5 **Insecticide bioassay techniques commonly used for insects**

Technique	Description of Technique	Data Expected
Topical application	Individual insects are directly treated with a known dose of an insecticide via a microapplicator or microsyringe	LD_{50}, KD_{50}, ED_{50}, LT_{50}, or KT_{50}
Residual contact	Groups of insects or individual insects are exposed to a dry residue of an insecticide on natural (e.g., leaf) or artificial (e.g., glass) substrates	LC_{50}, KC_{50}, EC_{50}, LT_{50}, or KT_{50}
Immersion	Groups of insects or individual insects are dipped in insecticide solutions of known concentration	LC_{50}, KC_{50}, EC_{50}, LT_{50}, or KT_{50}
Feeding	Groups of insects or individual insects are reared on a diet containing an insecticide of known concentration	LC_{50}, KC_{50}, EC_{50}, LT_{50}, or KT_{50}

Because the toxicity of an insecticide is related to the size of the organism exposed, the body weight units (milligram, gram, kilogram, etc.) of the test organism should be taken into consideration when the toxicity level is expressed. For example, the oral LD_{50} value of parathion for rats is 2 mg of parathion per kilogram of the rat's body weight (i.e., $LD_{50} = 2$ mg/kg). For insects, researchers sometimes use slightly different units for LD_{50}. One of the commonly used units is μg/insect. In this case, the toxicity level of an insecticide is expressed based on the unit of an insect rather than the unit of the insect body weight. Because substantial differences exist among different ages, developmental stages, and genders of an organism due to their different body size and metabolic capability, the age and developmental stage of the test organism must be clearly specified. In addition, the purity of the insecticide, the solvent used to prepare the insecticide solution, the method and time of insecticide exposure, and the temperature and sometimes humidity must also be specified in an insecticide bioassay.

Insecticide Formulation

KUN YAN ZHU
Kansas State University, Manhattan, KS, USA

An insecticidal chemical synthesized by a manufacturer or laboratory prior to its further processing is known as technical grade compound. Technical grade insecticides often have high purity (e.g., greater than 95%). The essential component of a technical grade insecticide is the active ingredient (A.I.) that exerts toxic actions on an organism. However, technical grade insecticides are seldom used directly for pest control because their chemical and physical properties often are not suitable for commercial use. Therefore, technical grade insecticides should be brought into more appropriate forms (i.e., formulations) for their application, either as sprays, powders, granules, fumigants, baits, seed dressings, or other types of formulations.

The process of insecticide formulation involves the use of various methods to improve the properties of an insecticidal compound for storage, handling, application, efficacy, or safety. Typically, insecticides are formulated by mixing the active ingredients and auxiliary materials. Most auxiliary materials (Table 6) are inert; they serve strictly as carriers for active ingredients and have no direct effect on pests. However, other auxiliary materials, including synergists, surfactants (wetting agents, spreaders, emulsifiers, and dispersing agents), foam suppressants, and stickers, have important properties and functions. These auxiliary materials are commonly known as formulation adjuvants.

Main purposes of insecticide formulation

- Minimization of hazards to human s, animals, non-target organisms, and environment
- Maintenance of chemical and physical stability of formulations during storage, application and post-application periods (e.g., stability to heat, oxidation, water-hydrolysis, sunlight, and various forms of chemical deterioration)

- Application of a relatively small amount of the A.I. uniformly on a target to achieve the desired biological effect (efficacy) at the lowest cost
- Application of insecticides with ease and with readily available equipment
- Enhancement of the compatibility of the insecticide with other pesticides

The active ingredients of most insecticides are not very soluble in water, but are fairly soluble in lipophilic organic solvents such as petroleum and xylene. If an insecticide active ingredient is dissolved in an organic solvent and then diluted with water, the organic layer will quickly separate out from the water. This problem can be solved by adding an emulsifier, which is a surface active agent, to the insecticide solution in a formulation process. The emulsifier will allow the insecticide to form a stable emulsion of small globules on mixture with water in the spray tank. Thus, the insecticide emulsion can be sprayed easily onto the crop. Generally, the term formulation is reserved for commercial preparations of insecticide before they are sold. Final dilution of a formulated insecticide is not considered the process of formulation (Table 6).

Formulated insecticides are the final physical state that may be sold under the formulator's designated brand names. Because one insecticide active ingredient may be formulated into several different formulations for different applications, the same active ingredient may have several different formulations under different brand names. In 1997, approximately 20,700 formulations, representing 891 registered active ingredients of pesticides (insecticides, herbicides, fungicides, and others), were sold in the United States.

Many different types of insecticide formulations are currently available (Table 7). Choosing the most appropriate formulation for a particular pest management project is critical to effective and safe uses of insecticides. The most important question to ask in choosing an insecticide formulation is whether or not the product is labeled for the insect and crop or circumstance for which application is intended. In the United States, the State Agricultural Experiment Stations and Cooperative Extension Services are excellent sources for recommending the most appropriate insecticides and formulations for particular pest management problems.

Common factors to be considered in choosing an insecticide formulation (from Higley et al., 1989)

- Pesticide regulation: Whether or not the product is labeled for the insect pest and crop or circumstance for which application is intended.
- Type of environment: Some formulations may be more suitable for certain environmental settings (agricultural, urban, aquatic, etc.).
- Plant, animal, or surface to be protected: Some formulations may be phytotoxic, absorbed by the animal, or may pit and mar surfaces.
- Availability and suitability of application machinery: Some formulations require constant agitation or specialized equipment.

Insecticide Formulation, Table 6 Types of commonly used insecticide formulation adjuvants

Adjuvant	Properties and function
Surfactants	Affect properties that depend on surface tension, namely dispersability, emulsifiability, wetting and spreading of liquids
Spray modifiers	Modify the spray solution in the tank on the way to the target or on the target itself, such as spreaders and stickers that enable active ingredients to be retained on treated surfaces for a longer period
Utility modifiers	Widen the range of conditions under which a given pesticide formulation is useful, such as buffering agents and antifoam agents
Synergists	Are relatively nontoxic themselves, but capable of enhancing the toxicity of an active ingredient when mixed or used sequentially

Insecticide Formulation, Table 7 Common insecticide formulations and their characteristics

Formulation	Characteristics
Aerosol (A)	An active ingredient is dissolved in an oil solvent (or liquid carbon dioxide) and propellant. The insecticide is applied as a gas-propelled spray through a fine opening into closed or confined areas
Bait (B)	An active ingredient is mixed with an edible or attractive substance
Dust (D)	An active ingredient is mixed with a dry inert diluent (e.g., talc, clay). The formulated insecticide can be suspended easily in air
Emulsifiable concentrate (EC)	An active ingredient is dissolved in an oil-based solvent (toluene) and mixed with an emulsifying agent which permits the formulation to mix with water to form an emulsion
Flowable (F or L)	An active ingredient is wet-milled with a clay diluent and water to produce a gel-like material that can be measured as a liquid and mixed with water to form a suspension for spraying
Fumigant (F)	A volatile liquid or solid insecticide acts as a poisonous gas that is used in confined areas
Granular (G)	A liquid insecticide is applied to coarse particles (20–80 mesh) of a porous inorganic material such as clay or organic material such as macerated walnut shells or oat bran
Microencapsulation	An insecticide (either liquid or dry) is encapsulated in permeable microscopic spheres or capsules to permit the release of the insecticide at a slow or consistent rate
Soluble powder (SP)	An active ingredient is mixed with a finely-ground inert solid. The formulated insecticide can be dissolved completely in water or other liquid to form a true solution
Solution (S)	A concentrated liquid insecticide formulation may be used directly or mixed with water to form a true solution
Ultra low volume (ULV)	An insecticide concentrate can be sprayed undiluted at 0.6–4.7 l per hectare as finely dispersed droplets
Wettable powder (WP or W)	An active ingredient is mixed with an appropriate inert solid (e.g., talc, diatomaceous earth) and a wetting agent which permits the powder to mix with water to form a suspension

- Hazard of drift or run-off: Some formulations have greater hazard of drift or run-off than others. Proximity to sensitive areas and the likelihood of wind or rain should be considered.
- Safety to applicator and non-target animals: Insecticide exposure to an applicator and non-target animals can be significantly reduced by choosing an appropriate formulation.
- Habits or growth patterns of the pest: Some formulations may be more suitable to control pests in certain habits or at certain developmental stages.
- Cost: The price, efficacy and application of different formulations of the same insecticide may affect overall cost.

Insecticide Resistance

KUN YAN ZHU
Kansas State University, Manhattan, KS, USA

Insecticide resistance refers to the insecticide-selected inheritable ability of an insect or other arthropod population to withstand the exposure to a dose of an insecticide that would kill the majority of a normal (susceptible) population of the same species. Insects and other arthropods acquire resistance to natural, synthetic or bioengineered insecticides through various genetic alterations. Insecticide resistance is known to occur in target species for virtually all insecticide classes.

In contrast to resistance, insecticide tolerance is a natural tendency and is not a result of forced change in the genetic makeup of a population. Therefore, tolerance is often known as natural resistance. Many factors can lead to tolerance to insecticides in an insect. For example, old larvae of many lepidopteran insects are more tolerant to many insecticides than young larvae of the same species due to substantial differences in body size, cuticle thickness, and detoxification ability. Such differences should be identified as tolerance or natural resistance rather than true insecticide resistance.

Insecticide resistance was first found in the San Jose scale, *Quadraspidiotus perniciosus* (Comstock) to lime sulfur in 1908 in the state of Washington. There were only a few reported cases of insecticide and acaricide resistance before the introduction and widespread use of synthetic pesticides in the late 1940s. Currently, however, at least 540 insect and other arthropod species have been documented to have strains or populations resistant to one or more insecticides or acaricides. Insecticide resistance has become the limiting factor in managing many agriculturally and medically important pests worldwide.

Possible consequences of developing insecticide resistance in agricultural pests (based on Forgash, 1984)

- Loss of many formerly efficacious insecticides
- Significant losses and even complete failures of crops due to the increased difficulties in pest management
- Increase in production costs because of the need for higher dosages and more frequent applications of insecticides, or for new insecticides that are often more expensive
- Secondary pest outbreaks or pest resurgence because of the ecological disruption of the density relationships between the pest and beneficial species
- Increase the hazards of added insecticide burdens to non-targets and the environment
- Socioeconomic disruptions in agricultural communities because of the change of cultivation to escape from resistance scenarios

Development of insecticide resistance in insect populations can be explained by the selection principle of evolution. The alleles (genes) that can confer resistance to insecticides probably already exist in a given population due to polymorphism or gene mutation. When an insecticide is applied, the susceptible individuals are killed, leaving behind only those with the resistance alleles. Resistant individuals continue to reproduce and pass their resistance traits to the next generation. Thus, as more generations are exposed to the same insecticide, a larger proportion of the population becomes resistant to the insecticide. Eventually, the whole population may become resistant to the insecticide. Although the selection pressure of insecticides is a key factor leading to the development of resistance in an organism, many other factors also can influence the development and stability of insecticide resistance.

Major factors affecting development and stability of insecticide resistance

- Availability of resistance-conferring allele(s) in a given population
- Degree of dominance of the resistance-conferring allele(s)
- Degree of selection pressure by an insecticide within the population
- Persistence of the insecticides
- Relationship of an insecticide to earlier used insecticides (e.g., chemical nature, mode of action, etc.)
- Number of generations per year for the organism
- Mode of reproduction (sexual vs. asexual, fecundity, etc.)
- Population size
- Mobility of the organism (e.g., migration)

Both the chemistry of insecticides and the biology of arthropods are very diverse, but the number of mechanisms conferring insecticide resistance is relatively small. All known mechanisms can be generally classified into five types including behavioral avoidance, reduced penetration, sequestration, metabolic detoxification, and reduced sensitivity of target sites. Some mechanisms may be more common and important than others in conferring insecticide resistance in a given arthropod species.

Known mechanisms of insecticide resistance in arthropods

- Behavioral avoidance of exposure to insecticides in an organism (less well studied)
- Reduced penetration of insecticides through insect cuticle
- Sequestration of insecticide molecules by binding proteins or enzymes (e.g., esterases)
- Increased metabolic detoxification by various enzymes: Cytochrome P450 polysubstrate monooxygenases, carboxylesterases (e.g., malathion-specific carboxylesterases), phosphotriesterases, glutathione *S*-transferases
- Reduced sensitivity of insecticide target-sites: Acetylcholinesterase for organophosphates and carbamates, voltage-gated sodium channels for DDT and pyrethroids, γγ -aminobutyric acid (GABA) receptors for cyclodienes, binding receptors for the *Bacillus thuringiensis* toxins

An insecticide resistant population may show cross-resistance to several closely related insecticides (e.g., organophosphates) because of a common detoxification pathway or a change in susceptibility to common biochemical or physiological lesions. A resistant population also may show multiple-resistance to several unrelated insecticides with different modes of action and different detoxification pathways. Multiple-resistance often is caused by multiple resistance mechanisms and results from selection with different insecticides.

Because the development of insecticide resistance is a natural response of a pest population to selection by insecticides, resistance will remain an ongoing dilemma as long as insecticides are used in pest management programs. On the other hand, the use of insecticides will continue to be an indispensable component of pest management systems for the foreseeable future. Therefore, resistance management is a critical issue in any pest management program involving the use of either conventional chemical insecticides or transgenic plants containing toxin genes from other organisms such as the bacterium *Bacillus thuringiensis* (Bt). Every effort should be made to promote the long-term effectiveness of both currently available and newly developed insecticides.

Insecticides

STEVEN M. VALLES
USDA-ARS, Center for Medical, Agricultural, and Veterinary Entomology, Gainesville, FL, USA

Pesticides, chemical substances used to kill pests, may be more specifically categorized by the group of organisms they are designed to control. For example, herbicides are used to kill plants, rodenticides are used to kill rodents, and insecticides are used to kill insects. Herbicides are the leading type of pesticide, in terms of both user expenditures and volumes used. Annual pesticide use expenditures in the United States totaled $11.3 billion in 1995 with agriculture accounting for more than two thirds. About 1 billion pounds of active ingredient of pesticides are used annually in the USA. These chemicals are steeped in controversy. They are disparaged by environmentalists and lauded by many in the agricultural and public health communities. Despite how you may feel personally about pesticides, their use has undeniably improved the quality of life of human beings by increasing agricultural yields to levels that have maintained pace with an exponential human growth rate and improved public health by reducing or eliminating insect disease vectors. The following sections provide a brief overview of pesticide characteristics such as classification, mode of action, relative toxicity, and use. For more specific information on pesticides, the reader is referred to several authoritative references cited at the end of this article.

Definitions

Knowledge of a small number of definitions will be beneficial in understanding a discussion on pesticides and their characteristics. Most of these definitions can be found in the Federal Insecticide Fungicide and Rodenticide Act (FIFRA) which was first passed in 1947 (7 U.S.C. s/s 136 et seq. [http://www.epa.gov/pesticides/fifra.htm]) and later revised to the Federal Environmental Pesticide Control Act (FEPCA) in 1972. The primary focus of FIFRA was to provide federal control of pesticide distribution, sale, and use. The environmental protection agency (EPA) was given authority under FIFRA to study the consequences of pesticide usage and to require users to register when purchasing pesticides. The law also requires users to take exams for certification as pesticide applicators. All pesticides used in the U.S. must be licensed by the EPA (equivalent agencies in other countries regulate pesticide use). The Food and Drug Administration (FDA) is responsible for enforcing pesticide tolerances for humans. Listed below are some important terms necessary for the discussion of pesticides. An extended dictionary of terms can be found at the URL http://pmep.cce.cornell.edu/facts-slides-self/dictionary.html.

Pesticide

Any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest; any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant.

Pest

Any insect, rodent, nematode, fungus, weed, or any other form of terrestrial or aquatic plant or animal life or virus, bacteria, or other micro-organism (except viruses, bacteria, or other micro-organisms on or in living man or other living animals) which the Administrator declares to be a pest under section 25(c).

Active Ingredient

In the case of a pesticide other than a plant regulator, defoliant, or desiccant, or nitrogen stabilizer, an ingredient which will prevent, destroy, repel, or mitigate any pest; in the case of a plant regulator, an ingredient which, through physiological action, will accelerate or retard the rate of growth or rate of maturation or otherwise alter the behavior of ornamental or crop plants or the product thereof; in the case of a defoliant, an ingredient which will cause the leaves or foliage to drop from a plant; in the case of a desiccant, an ingredient which will artificially accelerate the drying of plant tissue; and in the case of a nitrogen stabilizer, an ingredient which will prevent or hinder the process of nitrification, denitrification, ammonia volatilization, or urease production through action affecting soil bacteria.

MSDS (Material Safety Data Sheet)

Data sheet required to accompany all restricted use pesticides. Contains information on toxicity, reactivity and fire hazards, emergency information, health information, personal protection information and waste disposal instructions.

Lethal Dose Value

The LD value is associated with a subscripted numeral (e.g., LD_{50}). This is the quantity of active ingredient (expressed as milligrams of active ingredient per kilogram of body weight [mg/kg]) required to kill a specified proportion of a sample population. For example, the oral LD_{50} of malathion in the rat is 5,500 mg/kg. Therefore, at a dose of 5,500 mg/kg, malathion would be expected to kill 50% of the same species of rats by oral treatment. This value provides a method for comparing toxicities among and between species and for developing acceptable minimal exposure levels for humans.

Exposure Type

The method used to expose an organism to an active ingredient, including oral, inhalation and dermal. In addition, the exposure method may be conducted by acute treatment (one large single dose), subacute (several small doses over time), or chronic (small consistent doses over the course of an organism's lifetime).

Formulation

A mixture of active and inert ingredients that make a pesticide available for practical use.

Restricted Use Pesticide

A pesticide that can only be applied by EPA-certified applicators because of their inherent toxicity or potential hazard to the environment.

Mode of Action

The biochemical and/or physiological methods by which a toxicant functions.

Insecticide Toxicity Categories

FIFRA required that the toxicity of every insecticide appear on its label. A classification system was developed that placed an insecticide in one of four categories based on toxicity. Category I insecticides have an oral LD_{50} of up to 50 mg/kg and are labeled with the hazard indicator "Danger-Poison." Category II insecticides have an oral LD_{50} between 50 and 500 mg/kg and are labeled with the hazard indicator "Warning." Category III insecticides have an oral LD_{50} between 500 and 5,000 mg/kg and are labeled with the hazard indicator "Caution." Category IV insecticides have an oral LD_{50} greater than 5,000 mg/kg and are labeled with the hazard indicator "Caution."

Pesticide Nomenclature

There are currently about 875 active ingredients registered for use in the USA as federally restricted pesticides. Literally thousands of formulations are manufactured from these basic chemicals for use in urban, agricultural and other specialized environments. To avoid confusion among the different forms of pesticides, a standardized method of nomenclature has been established. There are four names a pesticide can be assigned: the manufacturer's identification number, the common name, the formulation name, and the chemical name. Hydramethylnon will be used to illustrate these different names. When the manufacturer assesses an active ingredient for activity as a pesticide, it is assigned an identification number for obvious reasons. Using our example, hydramethylnon was assigned the number AC 217,300 (AC is for American Cyanamid). Once the manufacturer is satisfied with the performance of an experimental pesticide, a common name is assigned to the active ingredient by the professional society most closely associated with the chemical's use. AC 217,300 was developed as an insecticide, therefore, the Entomological Society of America assigned the common name hydramethylnon to the active ingredient. Formulation manufacturers are now able to use hydramethylnon to produce a number of formulations for use, perhaps, in different areas and against different insect pests. The formulated products are identified by trade names. Several examples of trade names for formulated hydramethylnon include Amdro (fire ant bait), Combat (cockroach bait), and Maxforce (cockroach bait). The final name is the chemical name which is assigned according to IUPAC (International Union of Pure and Applied Chemists) rules. The chemical name for hydramethylnon is tetrahydro-5,5-dimethyl-2(1H)-pyrimidinoine (3-(4-(trifluoromethyl)phenyl)-1-(2-(4-(trifluoromethyl)phenyl)ethenyl)-propenylidene) hydrazone.

Formulations

A formulated insecticide is a mixture of active and inert ingredients that permit practical use of an insecticide. The active ingredient alone is rarely used in its raw form. Formulation processing improves active ingredient properties of storage, handling, application, effectiveness, and safety. Most restricted use insecticide formulations must be diluted before being used. Conversely, most general use insecticides (those applied without specialized training) are diluted and ready to apply. For example, Raid Ant and Roach spray is sold in a ready to use form. Insecticide formulations are listed, described and general characteristics provided below. Traditionally, each formulation type is abbreviated (shown in parentheses). In agriculture and urban settings, most insecticides (more than 75%) are applied as water-based sprays. However, it must be realized that most insecticide active ingredients are not water soluble; therefore, to apply as a water spray, surfactants must be added to facilitate dispersion in water. Obviously the goal of insecticide formulating is to make the product more efficacious against the target pest. An array of chemicals, called adjuvants, may be included in an insecticide formulation to achieve this goal. Surfactants are adjuvants that disperse an insoluble insecticide in water. These may be anionic (e.g., sodium lauryl sulfate), cationic (e.g., lauryl trimethyl ammonium chloride), or nonionic (e.g., glycol monolaurate). In addition, surfactants lower the surface tension of water which provides more coverage by aqueous solutions on leaf surfaces. Synergists are also important adjuvants added to insecticide formulations. Alone, synergists are non-toxic, but when mixed with certain insecticides greatly increase their toxicity. Synergists achieve this by inhibiting the metabolic enzymes that detoxify the insecticide. Synergists are most widely used in combination with pyrethrins and pyrethroids, especially in the urban environment. The most common synergists are methylene dioxyphenyl compounds (e.g., piperonyl butoxide and sesamex). Other adjuvants include foam suppressants, penetrants, and pH buffers.

Emulsifiable Concentrates (EC)

Concentrated oil solutions of the technical grade material containing an emulsifier (surfactant). The emulsifier is a detergent-like material that surrounds the hydrophobic insecticide active ingredient creating microscopically small oil droplets in water to form an emulsion. The appearance of a prepared EC is milky. The toxicant content in an EC generally ranges from 25% to 50% w/v. Because ECs contain organic solvents they may burn foliage. ECs are applied as liquid sprays.

Water-Miscible Liquids (Includes Water-Soluble Concentrates [WSC], Liquids [L], Soluble Concentrates [SC], and Solutions [S])

The technical material is provided in a water or alcohol base that is diluted in water. The active ingredients are generally water or alcohol miscible. These formulations are applied similarly to ECs. Most of these formulations are restricted use. These formulations are applied as liquid sprays.

Water-Soluble Powders (SP)

The technical material is water soluble and provided as a powder or solid. A small amount of surfactant may be added to facilitate mixing. These can be very toxic to handle because the active ingredient is not diluted in any way. Thus, they are often manufactured in water soluble bags that are simply dropped into a spray tank with water. After dissolution, the insecticide is ready to be sprayed. SPs are applied as liquid sprays.

Wettable Powders (WP)

In WPs the technical material is adsorbed onto a dust particle. In addition, wetting agents are added to facilitate dispersal. The powder is added to water and sprayed as a suspension of particles in water. This formulation requires constant agitation to keep the particles suspended. It is generally packaged at a concentration of 50–75% active ingredient. WPs are abrasive to spray equipment and do not burn foliage because they do not contain an organic solvent as ECs do. WPs are applied as liquid sprays.

Oil Solutions

Oil solutions are most often the ready-to-use household and garden insecticide sprays. The active ingredient is dissolved in some type of oil or organic solvent. Oils may be further diluted in kerosene or diesel fuel. Oil solutions are applied as liquid sprays.

Flowables (F)

This formulation was created for insecticides that were not soluble in water or oil. Therefore, the technical material is wet-milled with a clay diluent and water, leaving the pesticide-diluent mixture finely-ground but wet. This thick and creamy "pudding" mixes well with water and can be sprayed. However, constant agitation is required as with the WPs. Flowables are applied as liquid sprays.

Ultralow-Volume (ULV)

Technical material dissolved in a very low volume of solvent. Applied without dilution by special aerial or ground equipment that limits the volume applied (0.5 pints to 0.5 gallons per acre). ULVs are applied as a liquid spray.

Dusts (D)

An active ingredient with an inert clay diluent (such as pyrophyllite). Dusts are distinguished from granulars by size. Dusts will pass through a 60 mesh screen. Drift is a major disadvantage of using dusts. Dusts are applied as a dry formulation.

Granular (G)

Small pellets formed from inert clays sprayed with a toxicant-containing solution to give the desired content. Granulars range from 2% to 25% active ingredient. Granulars are applied as a dry formulation.

Aerosols

A common formulation used by homeowners. Aerosols are comprised of technical material solubilized in a volatile, petroleum solvent which has been pressurized (by a propellant gas). When the petroleum solvent is atomized, it evaporates quickly, leaving micro droplets of toxicant suspended in the air. Little to no residual activity is provided by aerosols. Aerosols are a liquid formulation.

Fumigants

The active ingredient of a fumigant either sublimates or boils at standard temperature and pressure. For example, moth balls and moth crystals, naphthalene and paradichlorobenzene, respectively, are solids that sublimate slowly at room temperature. Other fumigants have extremely low boiling points and are kept as liquids under high pressure. Pressurized fumigants are primarily used for drywood termite control, nematode control, and stored product insect control. Fumigants are applied as a gas.

Baits

This formulation has seen renewed interest in recent years because they use a very small quantity of insecticide and specifically target the pest of interest. Baits are comprised of an active ingredient incorporated into a food matrix that is palatable to the target insect pest.

Controlled-Release (CR)

This formulation is based on the incorporation of a volatile insecticide into a (usually) polymer matrix. By several mechanisms, including degradation or diffusion, a steady release of insecticide occurs. Controlled release formulations may be liquids or solids that are released as a gas.

Insecticides

Insecticides can be classified or grouped by their chemical structure, mode of entry into the insect, toxicity, or mode of action. The most common method of classification employed by insecticide toxicologists is chemical structure. By this method, insecticides with a similar chemical framework or motif are grouped together. As this is the most widely accepted method of discussing insecticides, it will be employed here. Pesticides have been used since at least 1,200 B.C.; however, the following discussion will focus on modern synthetic organic insecticides debuting after World War II. Some mention of botanical insecticides will also be included as these plant-derived chemicals often serve as models for synthetic organic insecticides. The characteristics, mode of action, toxicity, uses, examples and peculiarities of each insecticide chemical class will be described.

Organochlorines

Dichlorodiphenyltrichloroethane (DDT) Group

Examples of this group include DDT, DDD, TDE, Dicofol, and Methoxychlor. These insecticides are effective against a wide range of insect pests, most notably the mosquito. In fact, Paul MÜller won the Nobel prize in 1948 for discovering the insecticidal properties of DDT. These insecticides are environmentally persistent (DDT has a half life of 10 years), have a low vapor pressure, low water solubility, moderate stability to sunlight and low mammalian toxicity (toxicity category II to III). They are also lipophilic and metabolically stable which results in bioaccumulation (Fig. 16).

Interestingly, these insecticides exhibit a negative temperature coefficient of toxicity. In other words, they become more toxic at lower temperatures. DDT was banned from use in the United States in 1973. The target site for this group is the voltage-gated sodium channel, a neuron protein involved in the propagation of nerve impulses. It is believed that these chemicals act as a wedge that hold the channels in the open position thus preventing repolarization and resulting in constant stimulation of the nerve.

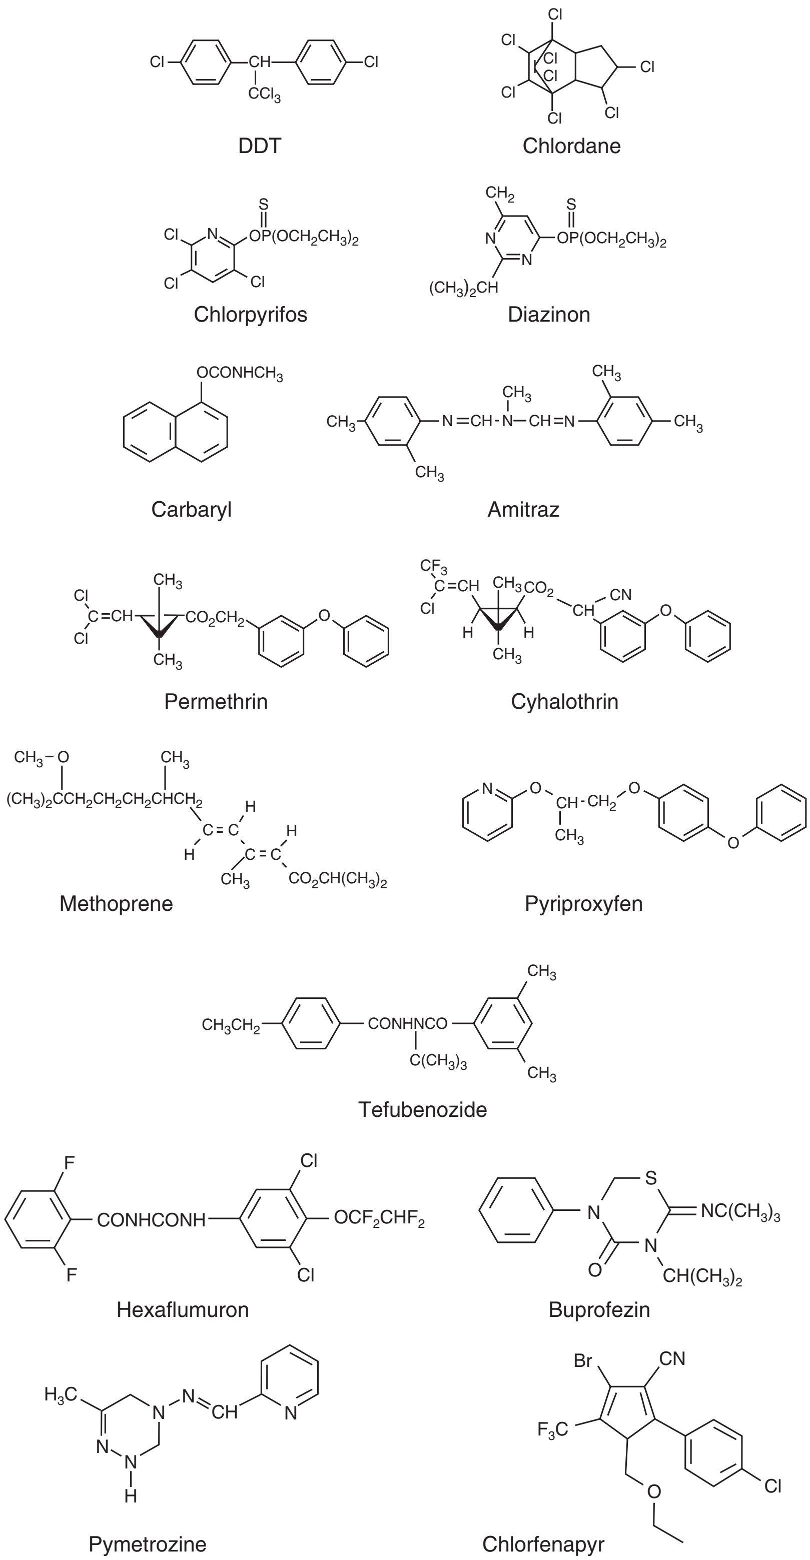
Chlorinated Cyclics

Examples of this group include Lindane, Aldrin, Dieldrin, Endrin, Isodrin, Chlordane, Mirex, Heptachlor, Chlordecone, and Endosulfan. These insecticides were used widely in urban settings, most notably for termite (Chlordane, Aldrin, Heptachlor) and imported fire ant (Mirex) control. Also, because they were stable in soil and against ultraviolet light, they were used against soil inhabiting insects in agriculture. Most of these insecticides were banned from agricultural use in the USA between 1975 and 1980. Mirex was banned for use in the USA in 1977 and chlordane in 1988. This group is persistent, lipophilic and has a low vapor pressure (10^{-6}–10^{-7} mmHg). Lindane is still available for use in the USA on avocados, pecans, Christmas trees, commercial ornamentals, structural treatments, and dog dusts. Many of these insecticides are metabolically activated (i.e., are made more toxic *in vivo*) by an epoxidation reaction catalyzed by cytochromes P450. The mode of action of cyclodienes was only recently elucidated. These insecticides are gamma-aminobutyric acid (GABA) receptor antagonists. Although environmentally persistent, acute toxicity of organochlorines is generally low to moderate (toxicity category II–III).

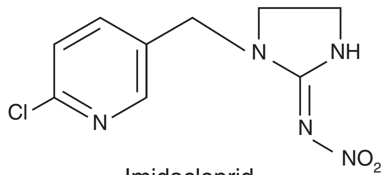
Organophosphates

Derived from phosphoric acid, this is the most toxic group of insecticides (toxicity category I to II). This large group of insecticides replaced the organochlorines and includes Malathion, Parathion, Dimethoate, Dicrotophos, Disulfoton, Monocrotophos, Trichlorfon, TEPP, Acephate, Methamidophos, Diazinon, Azinphosmethyl, and Chlorpyrifos among others. Organophosphates are unstable, susceptible to hydrolytic and oxidative detoxification, moderately to considerably water soluble and have a vapor pressure in the range of 10^{-3}–10^{-5} mmHg. The insecticidal activity of organophosphates was discovered in Germany during World War II while studying the nerve gases Sarin, Soman, and Tabun, which are also phosphoric acid derivatives. Organophosphate insecticides are anticholinesterases. They bind, with tenacious affinity, to acetylcholinesterase (AChE), a crucial enzyme found in the synaptic cleft between neurons or neuromuscular junctions. AChE normally hydrolyses the neurotransmitter acetylcholine released from the presynaptic neuron. However, organophosphate insecticides inhibit this enzyme preventing normal hydrolysis of acetylcholine and resulting in constant post-synaptic depolarization (stimulation). Many orga-nophosphate insecticides are activated (made more toxic) *in vivo*. Phosphorothioate (P = S) is oxidized to an oxon (P = O) form by cytochromes P450 making the insecticide bind even more tightly to acetylcholinesterase.

Although organophosphorus insecticides are all derived from phosphoric acid, there are 6 different subclasses depending on the molecular composition about the phosphate nucleus.



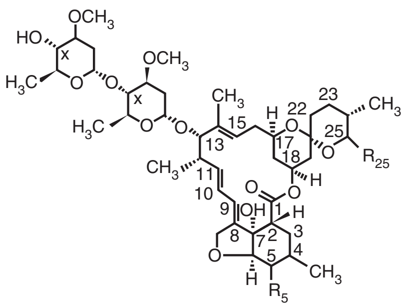
Insecticides, Figure 16 **Representative molecular structures of each insecticide class.**



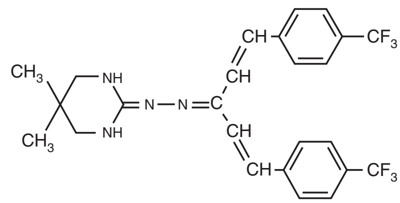
Imidacloprid

$F_3C-CF_2-CF_2-CF_2-CF_2-CF_2-CF_2-CF_2-S(=O)_2-NH-CH_2-CH_3$

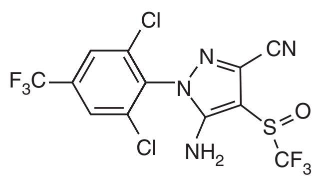
Sulfuramid



Avermectin (base structure)



Hydramethylnon



Fipronil

Insecticides, Figure 16 (Continued).

These subclasses include phosphate, phosphonate, phosphorothioate, phosphorothiolate, phosphorodithioate, and phosphoramidate. Organophosphate insecticides have seen wide use in agricultural, silvicultural, and urban insect control. However, because of their acute toxicity, much of this insecticide class is being banned from use, especially in the urban environment.

Carbamates

Introduced by the Geigy Chemical Company in 1951, carbamates are derivatives of carbamic acid (CO_2NH_3). As with the organophosphates, these insecticides are also anticholinesterases. They are biodegradable, moderately volatile (vapor pressure between 10^{-4} and 10^{-6} mmHg), moderately soluble in water, and susceptible to hydrolysis. Some of the more common carbamates include Propoxur, Bendiocarb, Carbaryl, Methomyl, Carbofuran, Aldicarb, and Thiodicarb. These insecticides exhibit toxicities that range from class I (e.g., Methomyl) to III. Carbaryl, introduced in 1956, has been used more than any other carbamate because of its low mammalian toxicity (Oral LD_{50} 307 mg/kg) and broad spectrum of insect control.

Formamidines

This is a small group of pesticides with insecticidal, acaracidal and ovacidal activities. The only formamidine currently in use in the USA is Amitraz. Chlordimeform was found to be carcinogenic and banned from use in the USA in 1988. Formamidine insecticides are octopaminergic agonists, so they interfere the normal activity of biogenic amines.

Because octopamine is an important neurotransmitter, formamadine interference results in behavior modification. For example, it causes loss of appetite and feeding, alters mating behavior, and detachment of ticks from the host. They also have been shown to synergize pyrethroid insecticide toxicity by modifying binding cooperativity in neural proteins. Toxicity category ranges from II to III.

Pyrethroids

Pyrethroids are synthetic chemicals modeled after the botanical insecticide pyrethrum, an organic extract of *Chrysanthemum cinerariaefolium* (Compositae) flower heads. The active principle of pyrethrum is pyrethrins, esters formed by the combination of acid (mono- and di-chrysanthemic acids) and alcohol (pyrethrelone, cinerolone, and jasmolone) components. Although pyrethrins exhibit good insecticidal activity, they were very labile. Therefore, synthetic versions were produced to improve their stability. Pyrethroids may be further categorized based into Type I and Type II groups. These refer to the types of neurological tremors produced and is loosely associated with the presence of a cyano (-CN) moiety at the alpha carbon position. Pyrethroids are widely used broad spectrum insecticides including Permethrin, Resme-thrin, Tetramethrin, Allethrin, Bifenthrin, Cypermethrin, Fenvalerate, Deltamethrin, Tralomethrin, Fluvalinate, Fenpropathrin, Cyhalothrin, and Esfenvalerate. Pyrethroids exhibit stereoisomerism (geometric, enantiomeric), low water solubility and vapor pressure (10^{-6} to 10^{-7} mmHg), negative temperature coefficient of toxicity (the alpha-cyano pyrethroids may exhibit a slightly negative or positive temperature coefficient of toxicity) and stability without persistence (bioaccumulation). They are susceptible to hydrolysis. Pyrethroids represent one of the first steps toward a precision targeting approach to pest control because they are more toxic to insects than mammals. This moderate level of specificity has resulted in extensive use of pye-throid insecticides. Unfortunately, pyrethroids are extremely toxic to fish, so care must be exercised when applications take place near water. Pyrethroids target the voltage-gated sodium channel of the nervous system and result in uncontrolled nerve excitation, as do the DDT insecticides. However, the specific binding site on the voltage-gated sodium channel is different from the DDT group.

Insect Growth Regulators

This group is comprised of a diverse group of chemical compounds with varying molecular structures. However, they are grouped together here because they all affect insect growth in some manner. Note that these chemicals are comparatively new tools used in insect control. Interestingly, these chemicals illustrate the evolution of insect control methods which are becoming more specific for the target species which reduces environmental impact and improves efficacy.

Juvenoids

Compounds that mimic the juvenile hormone of insects include Methoprene and Hydroprene. These juvenoids keep the insect in its immature form which prevents the production of future generations and often results in death from conflicting hormonal messages during ecdysis to the adult stage. Fenoxycarb (a carbamic acid derivative without anticholinesterase activity) and Pyriproxyfen also are juvenoids, however, unlike Methoprene and Hydroprene do not resemble the structure of juvenile hormone. All of these compounds act as juvenile hormone agonists (mimics).

Ecdysone Agonists

These chemicals mimic the action of the insect hormone ecdysone and thus induce premature molting. Rohm and Haas have developed several ecdysone agonists including Tebufenozide and RH-5849. These are substituted dibenzoyl hydrazine compounds.

Chitin Synthesis Inhibitors (CSI)

The final group of insect growth regulators include the chitin synthesis inhibitors. These include benzoylphenyl ureas (Diflubenzuron, Chlorflurazuron, Teflubenzuron, Hexaflumuron, and Novaluron) and buprofezin. These CSIs inhibit chitin formation thereby causing abnormal cuticular formation and abortive molting. Benzoylphenyl ureas have become important components of subterranean termite control in the US. They also have found utility in veterinary and agricultural areas.

Pyridine Azomethines

The only example of this new insecticide group is Pymetrozine (GCA 215,994). Pymetrozine is anticipated to be an important component of IPM programs against sucking insect pests because it exhibits a high degree of selectivity, low mammalian toxicity, and safety to birds, fish and nontarget arthropods. The target site for this insecticide is not currently known; however, it causes an immediate and irreversible cessation of feeding after exposure. The mode of action is due to a blockage of stylet penetration.

Chloronicotinyls

This group was initially developed during the 1970s (heterocyclic nitromethylenes), but recent chemical optimizations have resulted in the highly active insecticide, Imidacloprid. Other modifications resulting in insecticidal chloronicotinyls include Nitenpyram and Acetamiprid. The group has broad applicability as many insect species are susceptible. Imidicloprid is translocated making it ideal for use against sucking insects. It has also been shown to be quite effective as a termiticide. Imidicloprid has been shown to displace alpha-bungarotoxin, a specific ligand of the nicotinic acetylcholine receptor (nAChR) which demonstrates that it acts directly on this receptor. Indeed, electrophysiological experiments have shown that Imidacloprid depolarizes the cell membranes of insect cholinergic motor neurons. Furthermore, Imidacloprid does activate vertebrate nAChRs, however, the effect is more than 1,000-fold weaker than the action on insects. Therefore, it appears as if Imidacloprid is insect selective.

Inhibitors of Cellular Respiration

A number of relatively new insecticide classes that target cellular respiration are available. These insecticides exhibit a novel mode of action by inhibiting oxidative phosphorylation through several mechanisms. Many are proinsecticides (i.e., they require metabolic activation for toxicity).

Pyrroles

The inspiration for development of this group originated in dioxapyrrolomycin, a fermentation product of *Streptomyces fumanus* isolated in 1985 by American Cyanamid's Medical Research Division. Unfortunately, the mammalian toxicity of this compound was quite high which precluded its use in the insecticide market. However, after extensive chemical manipulation based on a fundamental understanding of oxidative phosphorylation, an insecticidal chemical was produced with acceptable vertebrate toxicity. CL 303,630 (Chlorfenapyr) was the result. This insecticide uncouples oxidative phosphorylation by disrupting the proton gradient across the inner mitochrondrial membrane impairing ATP production. Interestingly, Chlorfenapyr is a proinsecticide requiring oxidative N-dealkylation for toxicity. Chlorfenapyr is active against a wide array of insects and is being marketed for use in agricultural and urban environments.

Amidinohydrazones

This insecticide class is represented by Hydramethylnon. Hydramethylnon is primarily used in baits (e.g., against fire ants, pest ants, and cockroaches). It is an extremely effective insecticide with low mammalian toxicity (toxicity category III). This insecticide is a potent inhibitor of electron transport, specifically ubiquinone cytochrome c reductase (complex III). Interestingly, Hydramethylnon has been used against the German cockroach, *Blattella germanica*, for nearly two decades, however, no resistance has been observed to date.

Halogenated Alkyl Sulphonamides

Represented by a single insecticide, Sulfluramid, this compound acts as a protonophore disrupting the proton gradient generated by the electron transport system, thus inhibiting ATP production via oxidative phosphorylation. As is Chlorfenapyr, Sulfluramid is a proinsecticide that requires oxidative *N*-dealkylation for toxicity. It is primarily used in ant and cockroach baits.

Sulfluryl Fluoride

Sulfluryl fluoride is a fumigant used primarily for the treatment of drywood termites. This is not an organic insecticide, however, it is included here because of its importance in termite control. Known by the trade name Vikane, sulfluryl fluoride disrupts substrate level and oxidative phosphorylation by inhibiting aconitase in the tricarboxylic acid cycle and enolase in the glycolytic cycle.

Additional Inhibitors of Cellular Respiration

Several additional insecticidal compounds that inhibit cellular respiration have been identified and investigated. However, they are in varying stages of development and not currently available for use in the US. These include: (i) Diafenthiruon, a thiourea that is activated *in vivo* to its carbodiimide product which blocks the coupling site and mitochondrial F_0/F_1 ATPase activity; and (ii) Fenazaquin, a quinazoline that uncouples oxidative phosphorylation by inhibiting complex I of the electron transport chain. The only other insecticide known to inhibit complex I is Rotenone, a botanical insecticide.

Avermectins

Avermectins are a series of homologous macrocyclic lactone natural products (termed A_{1a}, A_{1b}, A_{2a}, A_{2b}, B_{1a}, B_{1b}, B_{2a}, and B_{2b}) derived from the soil microorganism *Streptomyces avermitilis*. The B_{1a} and B_{1b} homologues are very potent against mites and certain insect species. These compounds act as chloride channel agonists (GABAergic channels) as do the cyclodienes. Primarily used as an acaracide, avermectins have also been used in fire ant baits and against several leafminers.

Phenylpyrazoles

Represented by Fipronil, the phenylpyrazoles are also GABA-gated chloride channel antagonists. Other phenylpyrazoles exhibit herbicidal activity. Based on synergist data from some insect species (e.g., German cockroach), fipronil may be activated *in vivo*. This insecticide is effective against a wide array of insects and appears to be an extremely effective termiticide.

Miscellaneous/Botanicals

Insecticidal chemicals derived from plants (botanicals) also serve as an important source of insecticides. Numerous botanicals are available with diverse modes of action which are discussed elsewhere in this reference. Although botanical insecticides are "natural," often they are extremely toxic and should be handled with great care.

Other insecticides used currently include *Bacillus thuringiensis* (Bt), the active component of which (delta-endotoxin) is now heterologously expressed in numerous crop plants, inorganic insecticides (e.g., boric acid, cryolite [Na_3AlF_6]), fumigants (e.g., para-dichlorobenzene, methyl bromide), and soaps. Many of these additional insecticides are described elsewhere in this reference or can be found in the following references.

Toxicity

Insecticide toxicity is dependent upon the class, formulation, mode of action and mode of entry of a chemical into an organism, and may be assessed or quantified in many different ways. For example, an insecticide's toxicity can be measured based on its carcinogenicity, dermal effects, inhalation effects, reproductive effects, acute toxicity, subchronic and chronic effects and genetic effects. Each group of insecticides will exhibit unique characteristics, and although the toxicity will vary considerably among and between insecticide groups, they must all be handled with great care (Table 10).

Insecticide Toxicity

KUN YAN ZHU
Kansas State University, Manhattan, KS, USA

Toxicity refers to the innate capacity of a chemical to be poisonous to living organisms. Virtually every known chemical has the potential to produce toxic effects (e.g., injury or death) if the chemical is administered to an organism at a sufficient dose. If a chemical indeed exerts its toxicity on an organism, there must be two key features associated with the toxicity as determined by an appropriate bioassay. First, there is an observable and well-defined end effect resulting directly from the action of a toxic chemical. For example, the death of insects exposed to an insecticide is an observable and well-defined end effect. Secondly, the toxic effect must be dose-dependent. Within an appropriate dose range, the toxic effect must be positively correlated with the dose. Such a relationship, commonly known as the dose-response relationship, is the most fundamental and important feature of toxicity.

Insecticide toxicity can be either acute or chronic. Acute toxicity refers to injury or death after a short and often intense exposure of an organism to an insecticide. In laboratory toxicity testing, the duration of an acute exposure to an insecticide generally ranges from several to 48 h. For example, a single dose or exposure of an insecticide to insects and other arthropods for 24 h is most commonly used to evaluate the acute toxicity of the insecticide. In contrast, chronic toxicity refers to adverse effects after prolonged or repeated exposures of an organism to low doses of an insecticide. Chronic toxicity is commonly determined beyond 96 h, and usually after several weeks to several months of exposure. In vertebrates, for example, observable end effects for chronic toxicity of an insecticide may include development of tumors or cancer, reproductive problems, damage to the nervous system, damage or degeneration of internal organs such as the liver, allergic sensitization, etc.

Acute toxicity of an insecticide is commonly expressed as the median lethal dose (LD_{50}), concentration (LC_{50}) or time (LT_{50}). The LD_{50}, LC_{50}, and LT_{50} refer to the dose, concentration, or time, respectively, required to kill 50% of the population of the test organism under stated conditions. In the cases in which the rate of knockdown of the test organism is a more important criterion than the rate of killing for the toxicity of an insecticide, the median knockdown dose (KD_{50}), concentration (KC_{50}), or time (KT_{50}) is used. In some instances, the toxicity of an insecticide is measured as developmental and reproductive toxicity, mutagenicity and other effects rather than the mortality or knockdown caused by the insecticide. In such cases, the median effective dose (ED_{50}) or concentration (EC_{50}) is commonly used.

Because the toxicity of an insecticide is related to the developmental stage, body size, gender and species of the organism exposed, the species (and strain), developmental stage, and sex of the test organism are often specified and the body weight units (milligram, gram, kilogram, etc.) used to express the toxicity level of an insecticide. For example, the LD_{50} value of cypermethrin for third-instar larvae of the fall armyworm (*Spodoptera frugiperda*) is 0.46 μg/g determined by a 48-h topical bioassay. That is, if the larvae are topically applied with cypermethrin at the dose of 0.46 μg/g of the larval body weight, 50% of test larvae will die in 48 h. Obviously, the smaller the LD_{50} value is, the greater the toxicity is for an

Insecticide Toxicity, Table 8 Representative toxicities of two pyrethroid insecticides to larval and adult fall armyworm (*Spodoptera frugiperda*) and black cutworm (*Agrotis ipsilon*) (Lepidoptera: Noctuidae)

Insect	Stage/sex	Cypermethrin LD_{50} (95% CI), µg/g	Permethrin LD_{50} (95% CI), µg/g
Fall armyworm	Third instar	0.46 (0.33–0.59)	0.71 (0.58–0.87)
	Male	0.95 (0.75–1.19)	1.20 (0.92–1.54)
	Female	1.28 (0.63–1.72)	1.85 (1.46–2.27)
Black cutworm	Third instar	0.48 (0.26–0.64)	0.35 (0.05–0.62)
	Male	2.26 (1.83–2.82)	2.52 (2.01–3.18)
	Female	1.74 (1.37–2.23)	0.99 (0.81–1.20)

Data adapted from Usmani and Knowles (2001). The Ld_{50} values were determined based on 48-h topical bioassays

Insecticide Toxicity, Table 9 Classification of toxicity and examples of insecticide toxicity to rats (from Tomlin, 2000)

Toxicity class (LD_{50} range, mg/kg)	Name of insecticide	Oral LD_{50} (mg/kg)
Supertoxic (<5)	Parathion	2
Extremely toxic (5–50)	Carbofuran	8
Very toxic (50–500)	Chlorpyrifos	135–163
Moderately toxic (500–5,000)	Malathion	1,375–2,800
Slightly toxic (5,000–15,000)	Fenoxycarb	>10,000
Practically non-toxic (>15,000)	Methoprene	>34,600

insecticide, or the more susceptible the insect is to an insecticide. Researchers sometimes use slightly different LD_{50} units for insects. One of the commonly used units is 1/4g/insect, which is expressed based on the unit of an insect rather than the unit of the insect body weight (Table 8).

Based on the LD_{50}, LC_{50} or other toxicity values determined using a standard animal species such as rats, insecticides can be classified into six categories from supertoxic to practically non-toxic. Although there are considerable differences in response to an insecticide among different animal species, toxicity data determined using a vertebrate species (e.g., rats, mice and rabbits) generally serve as good references for other vertebrates such as humans. Therefore, the mammalian toxicity data can be very useful in helping establish the guidelines for safe handling, storage, and application of insecticides (Table 9).

Insectivore

An animal that feeds on insects. An entomophage.

Insectivorous Plants

J. HOWARD FRANK
University of Florida, Gainesville, FL, USA

For all the popular enthusiasm for insectivorous (carnivorous) plants and the general assumption that insects are the victims, there is little knowledge of the victims. This article provides a brief background to distribution, diversity, and trapping methods of insectivorous plants, and it attempts to associate the entomological knowledge for each genus. Lack of entomological information below under the name of any plant genus simply means that the author found none, or at least none obtained from the field. (The ability of these plants to digest insects such as fruit flies provided to them in cultivation tells little about their diet in nature.) Carnivorous fungi are not discussed in this article.

In general, plants absorb nitrogen and phosphorus from the soil through their roots. Insectivorous plants, however, absorb nitrogen and phosphorus from their animal prey through their leaves specially modified as traps. Thus, at simplest, insectivorous plants trap animals and absorb nutrients from the trapped prey.

However, some botanists have codified this process and they claim that to be insectivorous, a plant should have:

- A method of attracting animal prey
- A method of trapping animal prey
- A method of killing animal prey
- A method of digesting animal prey and taking up nitrogen (and phosphorus)

Not all insectivorous plants listed as such by botanists pass all these tests. In particular, many have not yet been shown to secrete digestive enzymes or take up nitrogen through their leaves. Conversely, the account below shows that some plants obtain nutrients from trapped prey by variant mechanisms. The principal types of traps used by plants to capture insects are discussed elsewhere (see Carnivorous Plants).

Nepenthaceae: *Nepenthes*

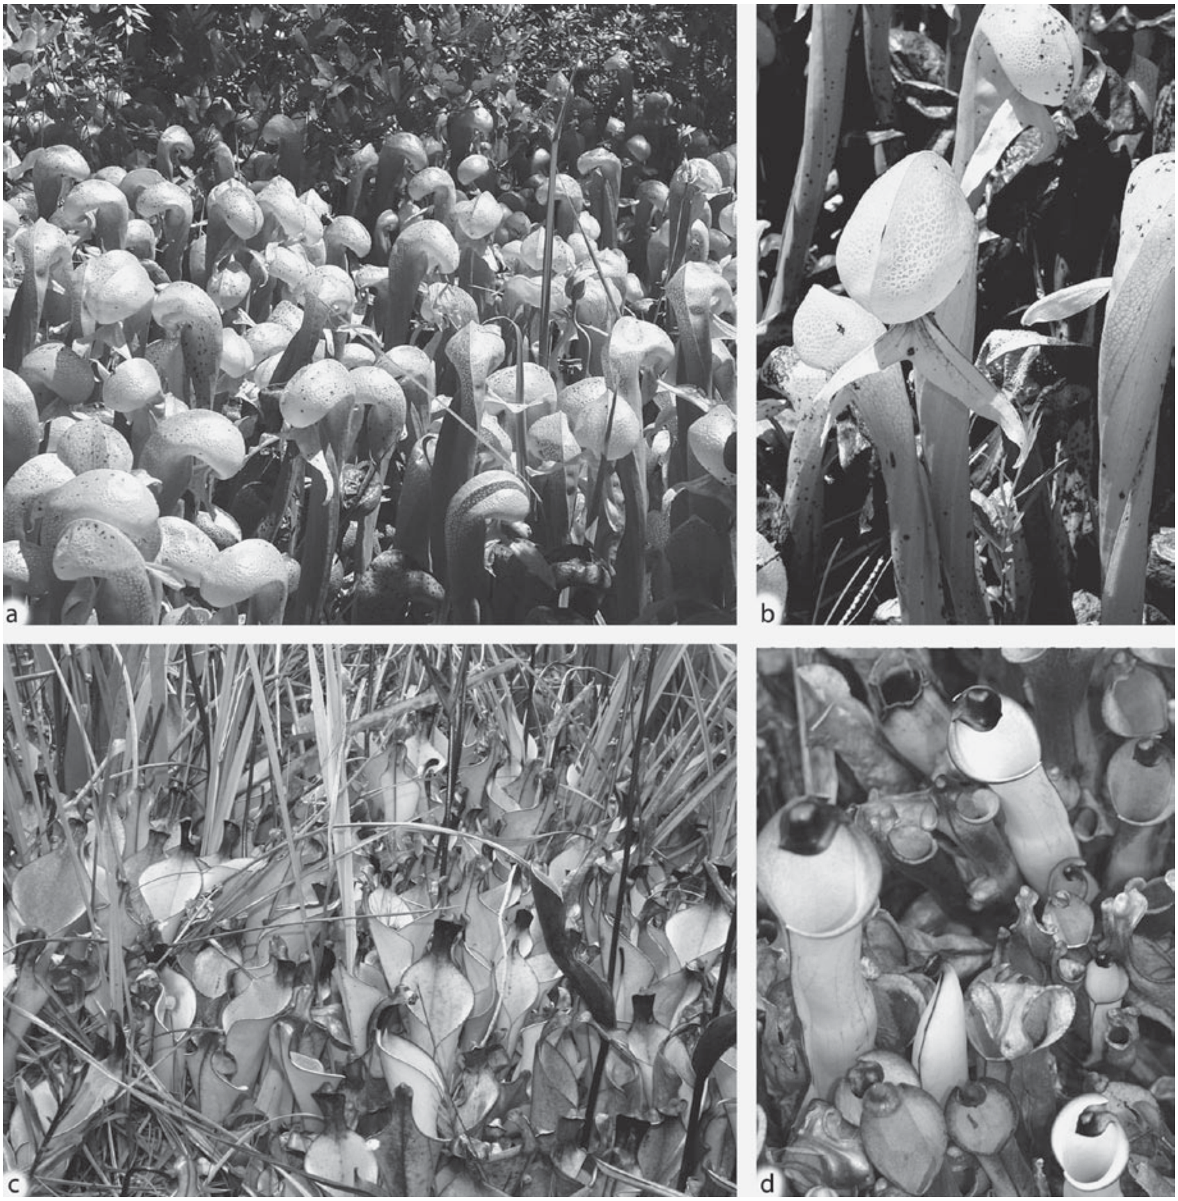
Ninety species of *Nepenthes* are known from northern Australia, New Guinea, Indonesia, Southeast Asia, Sri Lanka., the Seychelles, and Madagascar. They exist from sea level to 3,500 m depending upon species, in humid habitats, for the most part in full tropical sun. Each plant when young and short-stemmed develops a rosette of leaves, all of which form round-bottomed, cup-shaped pitchers resting on the ground. In some species the plant then grows as a climbing vine and develops aerial pitchers with slender, curved bases. The pitchers are modified leaf-tips, each with a cap which may or may not be large enough to exclude some rainfall. They are green or suffused with red and vary in shape between species, the largest capable of holding 1,000 ml of liquid in *N. rajah* Hook f. The rim (peristome) of the pitcher has radial ridges of overlapping epidermal cells and is wettable by rain or nectar so that adhesive pads of insect tarsal claws "hydroplane" on it whereas insect claws slip due to surface topography. Nectaries of the pitcher (the plant has others) are on the underside of the lid and between the teeth of the peristome at its inner edge. Insects attracted to the nectar may slip over the peristome into the pitcher. The upper walls of the pitcher are very smooth and slippery due to a waxy coating. In the depths of the pitcher is a zone of absorptive cells producing phosphatase and (in some species) protease. The pitcher is generally part-filled with fluid which is partially the product of secretory cells and partially water. Ants are well-represented among the prey. (Although most *Nepenthes* grow in full sun, *N. ampullaria* Jack grows in forests and obtains up to 35% of its nitrogen from trapped leaf litter rather than from prey. It has evolved to use leaf litter in parallel to epiphytic bromeliads.) Cleptobionts (which steal the trapped prey) are represented by spiders, sarcophagid and calliphorid flies, a mycetophilid fly, and the necrophagous caterpillar of *Eublemma radda* Swinhoe (Lepidoptera: Noctuidae).

Pollination may be by nocturnal insects but these remain unstudied. *Nepenthes* pitchers provide phytotelmata for a wide array of insects including larvae of mosquitoes and midges which have been reasonably well-studied in a few localities. Larvae of the leafminer *Phyllocnistis nepenthae* Hering (Lepidoptera: Gracillariidae) are attacked by a parasitoid, *Coprodiplosis syringopais* Hering (Diptera: Cecidomyiidae), in Sumatra.

Sarraceniaceae: *Darlingtonia*, *Heliamphora*, and *Sarracenia*

Darlingtonia is represented by a single species, *D. californica* Torrey, native to northwestern California and southwestern Oregon (Fig. 17). Its typical habitats are cool and moist with fresh water and have 0–40% shade from other plants. It reproduces asexually by means of woody stolons, and sexually by means of a flower borne on a tall scape. Immature plants produce small tubular leaves, but mature plants produce leaves shaped like pitchers. The pitchers are green, mottled above with red and variously suffused with red. Each pitcher is hooded, and distal to its opening hangs an appendage shaped like a fishtail. In the hood of the pitcher are transparent cells forming a window (fenestration). The dome of the hood with its fishtail appendage has earned the plant the name of cobra lily for a fancied resemblance to the erect head of a cobra with tongue represented by the fishtail appendage. The pitcher may grow to about 1 m in height and it widens with height. Inside it, at the upper levels are downward-pointing hairs, but the surface below is smooth. Glands on the reverse of the fishtail appendage secrete a sweet-smelling nectar which attracts various flying insects to the vicinity of the opening to the pitcher. Similar glands also are present around the opening, on a structure that has been termed a nectar roll. Insects that then move to leave by following the light shining through the fenestration hit against the hood of the pitcher and fall within it to the liquid contained inside, where they drown. All attempts to demonstrate production of digestive enzymes have failed. Nevertheless, bacterial decomposition of trapped prey occurs within the pitchers. The prey is said to consist of various flies, wasps, and beetles. The pitchers provide phytotelmata within which various invertebrates, notably the immature stages of *Metriocnemus edwardsi* Jones (Diptera: Chironomidae), develop.

Heliamphora is currently represented by 15 species, and perhaps more will be discovered, all of them native to the Guiana Highlands. This geologically ancient area is the sandstone mesas of southern French Guiana, Suriname, Guyana, Venezuela, the far north of Brazil, and adjacent areas of lower altitude. Roraima, on the border of Guyana and Venezuela is an example, and Auyán tepui in Venezuela is another (tepui, plural tepuis, is an Amerindian word adopted into Spanish meaning mesa or flat-topped mountain). They grow on top of these high tepuis at 1,800–2,800 m, and some in surrounding areas at altitudes as low as 600 m. Their typical habitat is a cool seepage bog with high humidity. The plants develop along a branching rhizome (as does *Darlingtonia*), all the leaves form pitchers, and the flower is borne on a scape 20–50 cm tall. Hybridization occurs readily as in *Sarracenia* (below). Most grow in full sunlight, although some (at lower altitudes) grow among other vegetation and may tolerate up to about 20% shade. Each plant forms a rosette of 3–10 leaves. Leaves of young plants are tubular (as in *Darlingtonia*) and up to about 12 cm long. Leaves of mature plants are upright and cylindrical and may reach 1.5 m in height, although some have been reported to reach a height of 4 m. Pitchers are not necessarily plain green, but may be variously suffused with red, or even may be deep dark red, almost black. Each pitcher (unlike other pitcher plants) has a vertical slit to drain off excess water so that it does not become overly full. Each pitcher of most species has a small apical growth ("nectar spoon") having nectar glands. The inner surface of the pitcher is waxy and,



Insectivorous Plants, Figure 17 **Examples of insectivorous plants in the family Sarraceniaceae: (a, b) *Darlingtonia californica*; (c, d) *Heliamphora heterodoxa* (photos by Bruce Holst, Marie Selby Botanical Gardens).**

in most species, has downward-pointing hairs. The method of prey digestion is not understood. Pitchers at least of some species serve also as phytotelmata, having a fauna including larvae of some mosquito species.

Sarracenia is represented by eight to ten species. They are distributed in an arc from eastern Texas via northern Florida to North Carolina. But one of them, *S. purpurea* L., has a wider distribution, occurring also in the northern USA from Lake Superior eastward, and even more widely in Canada, from northeastern British Columbia to Newfoundland. There also are many hybrids. The typical habitat is acidic freshwater bogs in full sun. As in *Darlingtonia* and *Heliamphora*, a branching rhizome produces first a

15–70 cm tall flower scape and then a rosette of leaves. Four species produce simple leaves, but they and all others produce pitcher-shaped leaves, and each mature pitcher has a lid that excludes rain. The lid is in the same position as the nectar spoon of *Heliamphora*. Leaves of newly germinated plants are more or less simple tubes. Pitchers are not necessarily plain green, but may be variously mottled with yellow, red or white. Dependent upon species, the pitchers may be tall, widening with height, or pipe-shaped and horizontal in *S. psittacina* Michaux, in all instances exceeded in height by the flower scape. Nectar glands are concentrated around the rim of the opening, or form a trail leading ground-dwelling insects such as ants to climb the pitcher, and also inside the pitcher beneath the lid. In *S. minor* Walter and *S. purpurea* L., however, the pitcher is hooded, and areoles in the hood function like the window of the hood of *Darlingtonia*, to misdirect exiting insects. The upper part of the interior of the pitcher is smooth and slippery, but below are downward-pointing hairs, and below that are embedded digestive glands. Phosphatase and protease are secreted by *S. purpurea* L., but the enzymes of other species are little-studied. Prey lists have been compiled for *S. purpurea* in Ontario and North Carolina, for *S. flava* L. in North Carolina, and to some extent for *S. rubra*, all showing that ants are a major prey item. Ants also form a major prey item for *S. minor* in Florida. Larvae of *Exyra* spp. (Lepidoptera: Noctuidae) feed on the leaves, with those of *E. semicrocea* (Guenée) reported as making two thirds of the pitchers of *S. minor* non-functional in Florida. An aphid, *Macrosiphum jeanae* Robinson, was reported as feeding on *S. purpurea* in Manitoba, but not yet detected elsewhere. One species, *S. purpurea*, is perhaps the best-studied phytotelm plant anywhere and harbors larvae of *Wyeomyia smithi* (Coquillett) (Diptera: Culicidae), *Metriocnemus knabi* Coquillett (Diptera: Chironomidae) and other arthropods. Sarcophagid larvae of the genera *Fletcherimyia* and *Sarcophaga* inhabit pitchers of *S. purpurea* and some other species and perhaps concentrate their feeding as cleptobionts on the prey trapped by the pitchers. Pollination of *Sarracenia* flowers by wild bees, Halictidae and Melittidae for the smaller-flowered species, and queens of *Bombus* spp. (Apidae) for the larger-flowered species, has been noted.

Cephalotaceae: *Cephalotus*

Cephalotus has only one species, *C. follicularis* Labillardière, which dwells in peaty swamps in southwestern Australia. It has leaves of two forms: normal leaves and pitchers. Each pitcher (much as in *Nepenthes*, and about 3–5 cm long) is fitted with a lid, and a group of them sits on the ground surface around the base of the tall flower scape. The peristome resembles that of *Nepenthes*. Within each pitcher are down-pointing spines which prevent trapped insects (mainly ants) from escaping. It produces a phosphatase. Larvae of a fly, *Badisis ambulans* McAlpine (Diptera: Micropezidae), live within the pitchers, feed on the plant's prey, and leave the pitcher to pupate.

Bromeliaceae: *Brocchinia* and *Catopsis*

First detection of an insectivorous bromeliad (*Catopsis berteroniana* Schult. (f.) Mez) was by University of Florida entomology graduate student Durland Fish, outlined in his 1976 dissertation. Three years later, the observations and hypothesis were explained again by botanist D.B. Ward and Durland Fish in a book on Florida's rare and endangered plants. The hypothesis was that a white ultraviolet-reflecting powder produced by the green or yellow-green leaves camouflages the plants from insect vision (they are not distinguishable from open sky), causing insects to crash into them. Insects hitting the plants may then tumble into the tank (a rosette of leaves forms a water-impounding tank) and are unable to escape because of the coating of slippery white powder. The insects eventually drown and are decomposed by autolysis. The normal method of water and nitrogen uptake by epiphytic bromeliads of the subfamily Tillandsioideae is through foliar trichomes which may be especially aggregated on the surfaces near the leaf bases (within the water-impounding axils of those species that form tanks). This plant grows in some places on telephone lines, clearly dependent for nutrients on minerals absorbed through its leaves and with roots serving only as holdfasts. Therefore, these plants do not need digestive enzymes to avail themselves of the nitrogen provided by the corpses of drowned insects. Yet the carnivory of *C. berteroniana* has been criticized irrationally on grounds that "digestive enzymes have not been demonstrated." That *C. berteroniana* does indeed trap insects was confirmed experimentally by J. H. Frank and G. F. O'Meara, published in 1984. Clearly, *C. berteroniana* is insectivorous because it traps insect prey and obtains nutrients from them by autolysis and uptake through trichomes.

In 1984 came designation as insectivorous of the South American *Brocchinia reducta* Baker, and later of the very similar *B. hechtioides* Mez. Both of these plants grow in the southern uplands of Venezuela and Guyana with adjacent extreme northern Brazil. Their trapping of insects, however, has not yet been confirmed experimentally. Like *C. berteroniana*, they produce a slippery white powder from yellow-green leaves which was stated to attract insect prey. This explanation is questionable because ultraviolet light is an attractant for some nocturnal insects, but ultraviolet lamps do not attract insects in daylight hours, and the white powder of *Brocchinia* and *Catopsis* must reflect ultraviolet only when it is present (during daylight). *Brocchinia* belongs to the subfamily Pitcairnioideae, in which plants are terrestrial, their roots absorb nutrients, and their propensity to absorb nutrients through their leaves is slight. Thus, to be insectivorous, *B. reducta* must (unlike *C. berteroniana*) not only be demonstrated to secrete digestive enzymes but also be able to take up the nutrients through its leaves.

Additional phenomena in Bromeliaceae bear investigation. For example, unopened flower pods of a species of *Vriesea* in Venezuela secrete a copious mucilage that traps tiny flying insects. This species is illustrated and named as *V. platynema* Gaudichaud in a book about Venezuelan bromeliads, but Elton Leme (Rio de Janeiro) has suggested that it does not belong to that species and probably is *V. oleosa* Leme.

Byblidaceae: *Byblis*

Byblis, with six species, is the only included genus in this family. The species are distributed in Western Australia and Northern Australia, with one, *B. liniflora* (Salisb.) extending also to New Guinea. They have bilaterally symmetrical flowers, and mucilage-secretory cells on the leaves. Only some of them, *B. filifolia* (Planchon) and *B. gigantea* (Lindl.), are believed to secrete phosphatases. They have a remarkable relationship with *Setocoris bybliphilus* China and Carvalho (Hemiptera: Miridae) in that these long-legged, agile bugs roam the leaf surfaces of the plant sucking body fluids from trapped insects. The plants are believed to benefit nutritionally from the excreta of the bugs.

Roridulaceae: *Roridula*

Roridula has two shrubby species in Cape Province of South Africa, *R. dentata* L. and *R. gorgonias* Planchon. They have stalked glands secreting a sticky resin, and they produce a phosphatase. With *R. dentata* is associated a mirid bug, *Pameridea marlothi* Poppius, and with *R. gorgonias* is associated *P. roridulae* Reuter. These bugs roam the plant surfaces sucking the body fluids of the trapped prey just as do *Setocoris* spp. on *Byblis* and *Drosera* in Australia. Urea in the excreta of the bugs is absorbed by the plant.

Dioncophyllaceae: *Triphyophyllum*

Triphyophyllum peltatum (Hutchinson and Dalziel) Airy Shaw is a climbing vine (liana) native to moist West African forests. It produces leaves of three types, one type borne on short shoots, having a reduced lamina, and appearing almost cylindrical. Such leaves are produced before the height of the rainy season, perhaps when suitable prey insects are most abundant. The entire surface of this type of leaf bears large, stalked glands producing mucilage and involved with trapping and digestion of prey. Phosphatase and protease have been detected. The Coleoptera, Isoptera, Hymenoptera, and Diptera trapped may be mainly species with crepuscular or nocturnal activity. The plant has been termed a "part-time carnivore" because the trapping leaves persist only briefly.

Drosophyllaceae: *Drosophyllum*

Drosophyllum has a single species, *D. lusitanicum* (L.) Link, in southern Portugal, extreme southern Spain and adjacent northern Morocco. It is a shrub, growing up to 1.6 m tall and has elongate leaves, each with a deep furrow on the upper side. Leaves have sessile digestive glands and stalked mucilage-secreting glands. They secrete a phosphatase and a protease.

Droseraceae: *Aldrovanda*, *Dionaea*, and *Drosera*

Drosera (sundew) has 152 species distributed in tropical and temperate regions throughout the world (Fig. 18). Many species are confined to freshwater bogs, but some species occupy drier soils. Its flowers are borne on a tall flower spike. The upper surface of each leaf is covered with stalked glands that function as tentacles, those toward the margin of the leaf being longest. The tentacles secrete a sticky mucilage. When a prey insect lands on the leaf surface, it becomes stuck in the mucilage, tentacles wrap toward it, and (at least in species with broader leaves) the closest leaf edge rolls upward. Proteases and phosphatases have been detected and they digest the prey. As in *Byblis*, two Australian species of *Setocoris* are associated in the same way with *Drosera*. They are *S. droserae* (China) and *S. russelli* (China). Larvae of the plume moth *Buckleria parvula* (Barnes and Lindsey), which feeds on several *Drosera* spp. in Florida, are attacked by a parasitoid, *Cotesia* sp. (Hymenoptera: Braconidae). The food pyramid thus has a wasp at its top, a caterpillar at the next level below, an insectivorous plant below that, the insect prey of the plant below that, and the food of the prey insects at a still lower level, so has at least five steps, matching those of *Phyllocnistis nepenthae* in *Nepenthes*.

Dionaea muscipula J. Ellis (Venus flytrap) is the only species of this genus and is native to freshwater bogs in the coastal plains of the Carolinas of the USA. It has an even taller flower spike than does *Drosera*, but a very different trapping mechanism. Leaf margins are provided with spines which mesh together when the leaves fold along their central vein. The leaves are triggered to fold by contact of insects with leaf hairs, and they fold rapidly in about 0.5 s to enclose any insect resting on the abaxial surface. Each leaf can fold and unfold about seven times during its life, but the mechanism is not yet fully understood. All leaves are of the same form. Leaves produce a phosphatase and a protease to digest the prey (Fig. 19).

Aldrovanda vesiculosa L. is the only known species of this genus, and is widely distributed in the Old World including Australia. It is an aquatic plant, floating just below the water surface of freshwater pools and having short flower scapes. A slender stem bears whorls of eight leaves, each leaf broadening to its apex and culminating in four or six long spines and a snap-trap operating rather like those of *Dionaea*. A phosphatase has been detected. The whorls of leaves resulted in its being named waterwheel plant.

Insectivorous Plants, Figure 18 **Examples of insectivorous plants in the family Droseraceae: (a) *Drosera intermedia*; (b) *Drosera capensis* (photos credits: (a) Jay Hupp; (b) Lyle Buss, both University of Florida).**

Lentibulariaceae: *Genlisea*, *Pinguicula*, and *Utricularia*

Genlisea has 20 species, known from Africa, Madagascar, and South America. Some of its species have been shown to secrete digestive enzymes. The plants are aquatic and lack roots. The emersed foliage leaves have chlorophyll, but the submersed leaves lack chlorophyll and appear like threadlike leaves except that they bear bladders (utricles, 1–4 mm long) proximal to the deeply forked apices of these submersed leaves. Distal to the utricle, each submersed leaf is a hollow tube which divides to form two helical ducts. A phosphatase is secreted. Protozoa are the prey. The flower is borne on a tall scape.

Pinguicula (butterwort) has 79 species, known from Asia, Europe, North America, and South America. The plants are terrestrial but in wet (freshwater) locations, typically in full sun. A rosette of yellow-green leaves grows from a short stem, the leaves lying flat on the ground and looking and feeling soft and greasy due to secretion of mucilage. Flowers are borne on tall scapes. The leaves form sticky traps for numerous small insects. When a prey item is trapped, the closest leaf edge curls partially upward as if to protect the catch. A phosphatase and a protease are secreted.

Utricularia (bladderwort) has about 220 species known from temperate and tropical areas throughout the world. Plants once attributed to the genera *Biovularia* and *Polypompholyx* are now considered to belong to *Utricularia*. Phosphatases are produced by at least 27 species. The habitat of some is in wet mosses, and two are epiphytic, one of these seemingly restricted to the tanks of bromeliads. Most are aquatic in freshwater ponds and, lacking roots, they float. Their trapping mechanisms are tiny bladders (utricles), ranging from 0.5 to 10 mm depending upon species. Bladders arise from the stolons as well as the leaves of the plant. Trigger hairs in many but not

Insectivorous Plants, Figure 19 **Example of insectivorous plant in the family Droseraceae: (a, b) *Dionaea muscipula* (note tall flower spike in "a") (photos credits: (a) Lyle buss; (b) Jay Hupp, both University of Florida).**

all species of *Utricularia* trip the inwardly opening door of the trap. The hinged door opens rapidly, accompanied by a dilation of the thin wall of the bladder to produce negative water pressure and suck in the victim with inflowing water. Traps that are sprung without catching prey may be reset within 15 min. Otherwise, digestion of the prey proceeds. A phosphatase and a protease are secreted. The size of the bladders obviously limits the size of the prey, which may typically be minute Anomopoda (Crustacea), but some trap tiny aquatic insect larvae including those of mosquitoes. Experimental evidence from Canada has revealed reduced numbers of mosquito larvae in ponds with *Utricularia* than in ponds without. Even tiny anuran tadpoles have been trapped within bladders of some species, such as young tadpoles of *Bufo marinus* L. in Australia. The flower is borne on a tall scape (Fig. 20).

Conclusion

All insects die somewhere, and recycled nutrients from their bodies are generally available for uptake by plants. Some insect bodies are recycled in the form of excreta of their predators. So, insectivorous plants have evolved to gain an improved supply of these nutrients. They have done it by trapping insects and other small animals and, in some way, by being able to absorb the nutrients from the bodies of their prey.

Most insectivorous plants are dicotyledons, but one monocotyledonous plant family (Bromeliaceae) has two genera (*Brocchinia* and *Catopsis*) each with one or two insectivorous species among others that are not insectivorous. Those few species are the exceptions among the bromeliads, a family of about 2,500 known species. Their diet in their nutrient-poor habitats is supplemented by insectivorory.

Insectivorous Plants, Figure 20 **Example of insectivorous plant in the family Lentibulariaceae: (a) *Utricularia quelchii*; (b) *Utricularia jamesoniana* (photos by Bruce Holst, Marie Selby Botanical Gardens).**

Insectivorous Plants, Figure 21 **Other insectivorous plants: (a)** ***Catopsis berteroniana*** **(family Bromeliaceae) (photo by Howard Frank); (b)** ***Pinguicula lutea*** **(family Lentibulariaceae) (photo by Jay Hupp); (c)** ***Nepenthes*** **sp. (family Nepenthaceae) (photo by Diane Davidson).**

Dicotyledons provide most of the approximately 500 known species of insectivorous plants. All species of most of the families named above are insectivorous, and those that have not been demonstrated as such are assumed to be so, rightly or wrongly. Many of these plants secrete digestive enzymes but, in some, no digestive enzymes have been demonstrated. Nor has a method of nutrient uptake through the leaves been demonstrated in all of them. However, some (*Byblis*, *Roridula*) can absorb nutrients from the excreta of cleptiobiont bugs, and some (*Darlingtonia*, some *Sarracenia*) can wait until trapped insects and the pitchers that contain

Insectivorous Plants, Figure 22 **Examples of insectivorous plants in the family Sarraceniaceae: (a, b) *Sarracenia* hybrid; (c) *Sarracenia rubra*; (d) *Sarracenia leucophylla*; (e) *Sarracenia flava* (photo credits: (a, b) Lyle Buss; (c, d, e) Jay Hupp).**

Insectivorous Plants, Table 11 Cleptobionts are animals that steal the animal prey trapped by insectivorous (carnivorous) plants. Note that many other insect species living in insectivorous plants that form phytotelmata may participate at some level in consumption of trapped prey or their breakdown products. Those listed here are viewed as primary cleptobionts specialized to their host plants and specialized to consuming the trapped prey

Cleptobiont	Plant	Geographical area
Aranea: Thomisidae		
Misumenops nepenthicola	*Nepenthes* spp.	Indonesia, Malaysia
Misumenops thienemanni	*Nepenthes tobaica*	Sumatra (Indonesia)
Diptera: Mycetophilidae		
Xenoplatyura beaveri	*Nepenthes ampullaria*	Malaysia
Diptera: Micropezidae		
Badisis ambulans	*Cephalotus follicularis*	Australia
Diptera: Calliphoridae		
Nepenthomyia malayana	*Nepenthes ampullaria*	Penang (Malaysia)
Wilhelmina nepenthicola	*Nepenthes ampullaria, N. rafflesiana*	Borneo, Sumatra
Diptera: Sarcophagidae		
Fletcherimyia abdita	*Sarracenia* spp.	Southern USA
Fletcherimyia celarata	*Sarracenia leucophylla*	Southern USA
Fletcherimyia fletcheri	*Sarracenia purpurea*	Canada, northeastern USA
Fletherimyia folkertsi	*Sarracenia rosea*	Alabama, Florida (USA)
Fletcherimyia jonesi	*Sarracenia flava, S. minor*	Southern USA
Fletcherimyia oreophilae	*Sarracenia oreophila*	Alabama (USA)
Fletcherimyia papei	*Sarracenia rubra*	Southern USA
Sarcophaga papuensis	*Nepenthes mirabilis*	Queensland (Australia)
Sarcophaga sarraceniae	*Sarracenia* spp.	Southern USA northward to eastern Canada
Sarcophaga urceola	*Nepenthes albomarginata*	Penang (Malaysia)
Hemiptera: Miridae		
Pameridea marlothi	*Roridula dentata*	Southern South Africa
Pameridea roridulae	*Roridula gorgonias*	Southern South Africa
Setocoris bybliphilus	*Byblis spp.*	Australia
Setocoris droserae	*Drosera* spp.	Australia
Setocoris russelli	*Drosera* spp.	Australia
Lepidoptera: Noctuidae		
Eublemma radda	*Nepenthes* spp.	Borneo, etc.

them decompose and return nutrients to the soil surrounding the plants; the same objective is reached by all these mechanisms.

Insects have the following relationships with insectivorous plants:

- Pollinators. Flowers of insectivorous plants (except *Nepenthes*, *Byblis* and *Roridula*, and except *Aldrovanda*, which does not trap winged insects) seem to be borne on tall flower stalks that are well away from the trapping mechanism,

Insectivorous Plants, Table 12 Phytophages are animals that eat insectivorous plants. Listed below are only specialist phytophages, those that are believed to eat nothing but the plant specified

Phytophage	Plant	Geographical area
Hemiptera: Aphididae		
Aphis droserae Takahashi	*Drosera* sp.	China, Taiwan
Macrosiphum jeanae Robinson	*Sarracenia purpurea*	Manitoba (Canada)
Lepidoptera: Gracillariidae		
Phyllocnistis nepenthae Hering	*Nepenthes* sp.	Sumatra (Indonesia)
Lepidoptera: Noctuidae		
Exyra fax (Grote) [= *rolandiana* (Grote)]	*Sarracenia purpurea*	Central to eastern Canada, eastern USA
Exyra ridingsii (Riley)	*Sarracenia flava*	Southeastern USA
Exyra semicrocea (Guenée)	*Sarracenia* spp.	Southeastern USA
Lepidoptera: Pterophoridae		
Buckleria brasilia Gielis	*Drosera* spp.	Brazil
Buckleria paludum (Zeller) [= *paludicola* Fletcher]	*Drosera* spp.	Palearctic and southern Asia
Buckleria parvula (Barnes and Lindsey)	*Drosera* spp.	Florida, Alabama (USA)

as if to shield insect pollinators from becoming prey. Pollinators of *Sarracenia* species are various bees, with *Bombus* spp. queens pollinating the larger plants. Almost nothing is known of pollination in other insectivorous plants, and the dearth of observations of pollinating insects has even led to suggestions that spiders may pollinate *Darlingtonia* (Fig. 21).

- Prey. Extensive lists of prey trapped by *Sarracenia flava*, *S. purpurea*, *S. rubra* (Fig. 22), *Nepenthes mirabilis* and *N. reinwardtiana* have been published. From these it can be seen that insects trapped seem to represent much of the diversity of the prey. Ants are well-represented among the prey. Information on prey of *Drosera* suggests that the bulk of their prey is nematocerous Diptera, but in some localities and times Collembola may outrank Diptera.
- Cleptobionts (Table 11). These are insects and other organisms that obtain their food directly from the trapped prey of insectivorous plants. In those insectivorous plants that also are phytotelmata, such as pitcher plants, the breakdown of trapped prey is the basic food resource of a web of denizens, includin0.g insects (see Phytotelmata).
- Phytophages (Table 12). These are insects, and perhaps other organisms, that specialize in feeding on insectivorous plants. Other species may eat insectivorous plants as part of their diet.

Insectoverdin

This is a common green pigment of insects produced by a mixture of blue and yellow compounds. The blue is usually mesobiliverdin, and the yellow is a carotenoid. The normal green coloration of insects results from a blending of blue and yellow pigments, and variance in green coloration observed in some species may be due to lack or excess of the blue or yellow pigments.

Insects as Aphrodisiacs

DEIRDRE A. PRISCHMANN
USDA, Agricultural Research Service, Brookings, SD, USA

Throughout history, humans have used insects and their products as aphrodisiacs to produce physiological effects, real or imagined. Insects were used in various ways, including entomophagy, external applications of insect preparations, and as symbolic charms. Spanish fly, or the chemical cantharidin produced by meloids, is the most famous insect aphrodisiac, yet many insect species (or their products) in several orders have been used as sexual aids.

People around the world have consumed insects in hopes of curing sexual maladies and influencing their sexuality. Some of the supposed benefits were pleasure enhancement, genital enlargement, increasing attractiveness, love, sexual desire, fertility, semen quantity/quality, penile turgidity and erections, soothing scrotal irritation, and prevention of amenorrhea, groin buboes, male weakness, impotence, nocturnal emissions, and premature ejaculation. Insects in multiple orders were consumed in hopes of attaining these benefits, including: Blattodea, Coleoptera, Hemiptera, Hymenoptera, Isoptera, Lepidoptera, Mantodae, Neuroptera, Odonata, and Orthoptera. The underlying reason(s) for associating a given insect with a particular amorous effect is often unclear, but can relate to its behavior, chemical composition, or physical attributes. One example of the latter is the belief that eating queen termites enhances human reproduction, because these insects are prolific egg producers.

Insect products were also applied externally in an attempt to cure ailments or alter genitalia. Ash from hornets' or wasps' nests was mixed with water or wine and applied to the penis for sexual stimulation, erectile dysfunction, and plentiful sperm production. People would also topically apply formic acid or dried ants in oil, which caused dermal irritation and thus sexual arousal. The "*Kama Sutra of Vitsayayana*," a classic in erotic literature, talks at length about aphrodisiacs, including how men could cause permanent lingam (penis) enlargement by undergoing a 10-day process that involved rubbing oil and bristles from specific arboreal insects on their phalluses.

Other insects have a symbolic role, including cicadas and butterflies, which are associated with love charms and represent love and marital satisfaction due to their singing and beauty. Egyptians used a ritual involving scarabs bound with colored threads to gain sexual mastery, while Europeans analyzed ladybird beetles' flight paths to discover potential lovers.

One of the most widely used aphrodisiacs is honey, either pure, mixed with other ingredients, or as mead. One common practice was ingesting various honey mixtures with numerous ingredient variations, including almonds, pine pollen, onion seeds, plant juices, fruit, radishes, resins, frankincense, oil, spices (pepper, saffron), drugs (cannabis, opium) and animal products (lizards, bird eggs, ass or camel milk, and dove blood). Other practices involved applying the honey directly to the body, either for sexual excitation or submissiveness, or genital enlargement for both men and women. To increase penis size, a man would rub honey and ginger or spit a mixture of chewed cubeb berries (Piperaceae: *Piper cubeba* L.), honey, and pepper onto the distal end of his member.

But perhaps the most famous insect aphrodisiac is Spanish fly. The name "Spanish fly" (in older literature, "Spanish flies" or "cantharides") is a misnomer. It refers to blister beetles and/or cantharidin, a crystalline substance synthesized solely by meloids, including *Lytta vesicatoria* L. (Coleoptera: Meloidae), a species commonly found in Spain. Meloids biosynthesize and sequester cantharidin, which they subsequently use to deter predators (Figs. 23 and 24).

Historically, Spanish fly was prescribed for a multitude of human and animal medical conditions, and despite its toxicity, has been employed in diverse amorous exploits over the centuries, including sexual coercion, orgies, and sexual blackmail. Spanish fly was ingested in several forms, including pills, desserts (cookies, laced candies, chocolates, and cakes), sweetmeats, liquor epispasticus, folklore remedies, and live and roasted blister beetles. Concoctions of Spanish fly were often mixed with other ingredients, including honey, spices (cloves, cubeb peppers, nutmeg, cinnamon and saffron), nuts or seeds (acorns, almonds, and sesame seeds), butter, and cannabis (Table 13).

Cantharidin was first isolated in 1812 from *Lytta vesicatoria*, and despite its reputation as a medical wonder and putative sexual stimulant, Spanish fly is highly toxic and can be deadly. Contemporary examples of cantharidin poisoning abound, both intentional and accidental. The latter commonly involve ignorance of the inherent danger of ingesting Spanish fly or blister beetles, although poisonings are not always fatal. Applied topically, cantharidin is a strong irritant that readily enters and affects the epidermis, causing redness, intense burning, and blisters. Ingestion results in mucous membrane corrosion, blisters and hemorrhage, epithelial cell alterations, dysphagia, nausea, dysuria, bladder lesions, hematuria, severe colic, intestinal inflammation and pain, and vaginal and rectal bleeding. Multiple organs and physiological systems can be affected, including the skin, heart, kidneys, intestines, liver, spleen, lungs, genitals and central nervous system. Extremely serious conditions include renal failure, intravascular coagulation, internal hemorrhage, seizures, spontaneous abortion, pulmonary collapse, myocardial degeneration, cardiac disturbance, coma and death.

Insects as Aphrodisiacs, Figure 23 **Photograph of "Spanish Flies, Cantharis." Crude drug form, donated to the Smithsonian Institution in 1881 by Schieffelin and Co. National Museum of American History object catalog #50,590; Smithsonian photo negative #74–1947.**

Insects as Aphrodisiacs, Figure 24 **Mating *Meloe niger* Kirby (Coleoptera: Meloidae). (Picture by R. Akre, Washington State University.)**

Given the long list of adverse effects associated with cantharidin, why did people believe Spanish fly was an aphrodisiac? Because cantharidin irritates the urogenital tract, tingling and burning sensations are felt in the genitalia, and due to blood vessel dilation, the penis and labia engorge with blood. Because it made people more aware of their genitals, it was thought to build erotic passion and cause sexual excitement. Occasionally Spanish fly caused persistent erections, although this condition, termed priapism, usually is not associated with sexual pleasure, can require surgical correction, and if left untreated can damage the organ's vascular tissues.

Due to their history, diversity, and varied biological activities, insect aphrodisiacs (notably cantharidin) have appealed to humans on several levels. They encompass a plethora of materials, concoctions, techniques, and ideas, with effects ranging from innocuous to deadly. However, although insect aphrodisiacs have outstanding reputations, these claims have not been validated, while the harmful effects of Spanish fly, or cantharidin, have been well documented.

Insight Learning

This form of learning requires reasoning, which involves analyzing past experiences from which deductions are made. This level of learning is

Insects as Aphrodisiacs, Table 13 Historical uses of insects for sexual purposes

Insect Order/Family	Region Used/ Consumed	Historical Sexual Use
Blattodea (cockroaches)	China	Enhance fertility, prevent sterility
Coleoptera (beetles)		
Buprestidae (metallic wood-boring beetles)	China	Increase sexual desire and attractiveness, invoke love
Carabidae (ground beetles)	China	Invoke love between couples
Coccinellidae (ladybird beetles)	Europe	Discover mate(s)
Dytiscidae (predaceous diving beetles)	Malay, Singapore	Aphrodisiac
Elateridae (click beetles)	China	Increase sexual desire and attractiveness, invoke love
Meloidae (blister beetles)	Worldwide	Aphrodisiac, sexual stimulant, used in orgies, sexual blackmail, cure impotence, persistent erections
Scarabaeidae (scarab beetles)	Egypt	Obtain sexual prowess
Tenebrionidae (darkling beetles)	Malaysia	Aphrodisiac
Hemiptera (true bugs)		
Belostomatidae (giant water bugs)	Malay, Singapore	Aphrodisiac
Cimicidae (bedbugs)	Morocco	Love potion
Pentatomidae (stink bugs)	China	Erection stimulator
Reduviidae (assassin bugs)	Mexico	Aphrodisiac
Cicadidae (cicadas)	China	Symbol of love and bliss, increase semen production and fertility, aphrodisiac, impotence cure
Coccidae (scales)	China	Sexual malady cure
Hymenoptera (bees, wasps, etc.)		
Apidae (bees: honey, mead, royal jelly)	Worldwide	Aphrodisiac, increase sexual vigor, become more attractive, increase female subjugation, enlarge male and female genitalia, benefit sperm (male potency), increase sexual pleasure, premature ejaculation, confer fertility
Formicidae (ants)	Italy	Sexual stimulant, love potion
Vespidae (wasps, hornets)	China	Increase sexual stimulation and vigor, impotence cure, increase sperm count
Isoptera (termites)	India	Aphrodisiac, rejuvenation
Lepidoptera (moths, butterflies)	North America, China	Love charm, symbol of love and bliss
Bombycidae (silkworms)	China	Stimulate erections, prevent ejaculation, enhance semen, extend intercourse, ease scrotal itching, benefit women
Sphingidae (hawk moths)	China	Aphrodisiac, cause large erections, increase male fertility and semen

Insects as Aphrodisiacs, Table 13 **Historical uses of insects for sexual purposes (Continued)**

Insect Order/Family	Region Used/ Consumed	Historical Sexual Use
Mantidae (mantids)	China	Prevent premature ejaculation, nocturnal emission and impotence
Neuroptera (lacewings, etc.)

Inspection

From a regulatory perspective, this is the official visual examination of plants, plant products, or other regulated articles to determine if pests are present, and/or to determine compliance with phytosanitary regulations. The individual who performs the inspection according to standard regulatory procedures is the inspector.

► Regulatory Entomology

Instar

The insect (larva or nymph) between molts. Instars are referred to by number: the first instar is the stage between after hatching and before the first molt, the second instar occurs after the first larval (nymphal) molt but before the second, etc. Technically, the pupal stage (if present) is an instar, though it is not numbered like the others, and is simply referred to as the pupa. This term often is confused with 'stadium,' a term restricted to the time interval of an instar.

► Stadium, Metamorphosis

Instinct

Behavior performed without the benefit of previous experience or learning from other members of the species. Unlearned stereotypic behavior.

Integrated Pest Management (IPM)

JOHN ALL
University of Georgia, Athens, GA, USA

Integrated pest management (IPM) refers to coordinated systems for managing pest populations that use preventive and suppressive control tactics, which are unified by surveillance to assess hazard for injury and to determine whether curative action is needed. Technically, IPM programs can be developed for any pest, including insects and mites, plant pathogens, weeds, vertebrate pests, etc., and IPM programs on specific commodities can involve complexes of several types of pests. The nature of IPM is perceived differently among individuals that are dependant on or are affected by pest control technologies, including pest control professionals, growers, environmentalists, government officials, and the general public. Conceptually, many people believe that IPM avoids reliance on pesticides and promotes preventive control tactics that restrain pest populations, but are not detrimental to non-target animals or the environment. In many practical circumstances, however, IPM programs must rely heavily on judicious use and management of pesticides, especially in circumstances where tolerance of pests or injury is low. Most people would agree that IPM involves strategic blending of multiple pest control procedures. IPM programs are highly specialized and adapted to individual needs on many commodities that have various fixed and variable constraints on the type of control tactic that can be used at a particular time. Regulatory controls (pesticide laws, government subsidies, etc.) and societal concerns (non-acceptance of pest presence or damage and anxiety about effect on health of pesticide residues and transgenic insecticidal crops) have tremendous effect on decisions for IPM tactics that are used on certain commodities. Strategic planning for IPM is based on knowing details of pest biology and cumulative risk for injury to a commodity, and an awareness of the costs and effectiveness of control methods that can be practically applied in a coordinated management program.

IPM includes both prevention and suppression philosophies of pest management. The objective of prevention is to restrain pest populations from producing appreciable injury to commodities, whereas the goal of suppression is to exterminate pest infestations. There are many preventive control methods that can be used in IPM programs. Use of pesticides or some form of direct physical destruction (e.g., burning, freezing, or crushing) are methods used for suppression of pest infestations that threaten immediate and severe damage to a commodity. Surveillance of pests or having knowledge based on past histories that a high probability exists for pest infestations is a central element of IPM. Surveillance involves accurate identification and effective sampling or scouting of pests and observing symptoms of injury on a commodity. The information from pest monitoring is used to determine when action thresholds (pest populations or injury levels that equal or exceed the cost of pest suppression) requiring remediation have been reached.

Preventive control tactics used in IPM programs include:

Cultural Control

The use of any commodity production or use method with some consideration for IPM. Cultural control practices either avoid developing high hazard environments for pest problems or produce conditions that are detrimental to pests. There are numerous cultural control practices used in IPM programs, examples include sanitation of infested materials, selecting pest tolerant or resistant crops or cultivars (including pesticidal transgenic plants), manipulating planting and harvesting dates to avoid pest populations, etc.

Biological Control

The manipulation of natural enemies (parasitoids, predators, and pathogens) to control pests. The manipulation of biological control agents for IPM is done either naturally by manipulating commodity environments to conserve or enhance existing populations of natural enemies or it is accomplished artificially by rearing or mass-producing natural enemies for introduction or application in pest environments.

Mechanical Control

The direct application of lethal physical forces to pests including heating, freezing, suffocation, irradiation, crushing, chopping, etc., or the use of devices or packaging that prevent access of pests to commodities.

Chemical Control with Enticements or Deterrents

The use of attractants, feeding stimulants, repellents, and antifeedants to manipulate pest behavior for control.

Chemical Control with Pesticides

The use of formulated substances that kill pests by physiological intoxication or by inducing lethal pathogenic infections.

Regulatory Control

Participation by IPM personnel in governmental programs that govern pest management activities such as quarantine and area wide eradication projects and by abiding by laws created to protect or indemnify individuals that are impacted by IPM actions. Regulatory control also includes following use requirements prescribed by manufacturers of pesticides and transgenic crops.

The design and implementation of IPM programs using preventive or suppressive strategies requires an awareness of resident pest hazard on a commodity, which is influenced by numerous factors that may fluctuate in diverse locations at different times. Pest hazard can be high, normal, or low, and knowledge of all three possible conditions is important in making IPM decisions. For example, a preventive control tactic that lowers pest hazard by direct lethal impact, such as fall tillage in cornfields for burial of pest-infested debris, is considered a cultural control tactic for IPM. On the other hand, having knowledge that late planting of the crop has high hazard for pest problems is also a form of cultural control, because alternative tactics such as early planting can be considered as a preventive tactic. Pest hazard of a commodity involves both its vulnerability to pests and its loss in value from injury. Vulnerability involves susceptibility of the commodity and the prevalence and aggressiveness of pests for producing injury. Commodity value relationships influence pest hazard by dictating the amount of injury the commodity can bear under pest presence before real value is lost and how much can be spent for IPM. Value relationships include costs of production, commodity unit value, and economic tolerance of the commodity for the presence of pests or injury. Commodity value relationships with pests are used to develop action (economic) thresholds. In IPM practice, much of preventive control is initially based on assessment of hazard for pest problems on a commodity and surveillance is used to determine when suppression is warranted.

Integument

The outer covering or cuticle of an insect, plus the epidermal cells that secrete the cuticle. The integument functions in locomotion, feeding, excretion, protection from desiccation, breathing, and many other important functions. Many of the characteristics that make insects unique among animals are attributable to the integument.

► Cuticle
► Epidermis
► Integument: Structure and Function

Integument: Structure and Function

JAMES L. NATION
University of Florida, Gainesville, FL, USA

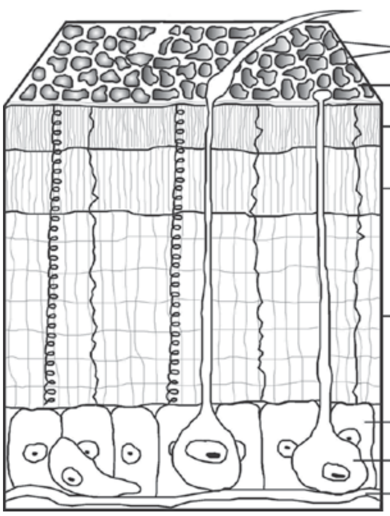
The integument is composed of the cuticle and the underlying epidermal cells that secrete the cuticle. The cuticle serves as the exoskeleton of the insect, the site for muscle attachment, the first line of defense from fungi, bacteria, predators and parasites, and environmental chemicals, including pesticides. The integument functions in locomotion, breathing and respiration, feeding, excretion, protection from desiccation, behavior, osmoregulation, water control, and as a food reserve. The many roles played by the integumentary covering of insects are in part reflected in the complexity of its structure and chemistry, and in the special ways it is adapted to function in the ecology of its owner.

Despite many species-specific features, there are certain common features in the integument. There is always a single layer of epidermal cells lying immediately beneath the cuticle. These cells secrete the new cuticle at molting, and in some insects at least, continue to secrete cuticle even in the adult. In all insects there is a thin layer of cuticle with special properties called the epicuticle at the surface of the insect, and beneath this there is additional cuticle that can sometimes be divided into several layers depending primarily upon the degree of sclerotization or cross-linking of the molecules of protein and chitin.

The cuticular part of the integument is composed of several layers, including epicuticle, exocuticle, endocuticle, and an epidermal cell layer. There is always an epicuticle layer and the epidermal cell layer, but the exocuticle and endocuticle may be greatly reduced or absent in particular parts of the cuticle of the same or different insects. Often there are additional cuticle layers within one or more of the three principal layers as evidenced by electron density in cross sections viewed in the transmission electron microscope. The epidermal cells secrete the overlying cuticle, the lipids (waxes), cement, and often many additional chemical components that occur on or in the cuticle layers. When a new cuticle is secreted at molting, the cuticle below the epicuticle layer is first called procuticle, because it is not sclerotized into the distinct layers noted above. Such sclerotization occurs, however, soon after the cuticle is secreted (Fig. 25).

Epicuticle

Epicuticle is the outermost part of the integument in contact with the environment. Because it is so thin (from 1 to 4 μm in thickness), the detailed chemical structure of the epicuticle has been difficult to discern, but it is known to contain



Integument: Structure and Function, Figure 25 A generalized diagram of the layers of the cuticle.

sclerotized proteins impregnated with lipoproteins, lipids, waxes, cement, and minor amounts of various minerals and other chemical components. It does not contain chitin, a major structural carbohydrate in other parts of the cuticle. The proteins and some of the lipids appear to be covalently linked, and the proteins are tanned or sclerotized by phenolic compounds and their oxidized products, quinones. Sclerotization gives the epicuticle strength, hardness, and low water permeability. Reduced permeability to water is also provided by lipids and the cement layer on the surface.

Because the epicuticle bears the surface sculpturing of insects, its gross appearance is highly variable in different species. It does, however, contain one common layer in all insects, the cuticulin layer. Cuticulin is a very thin layer of protein about 0.0075 μm thick, which is the typical thickness of an animal cell membrane. It is impregnated with lipids, some of which may be covalently bound to proteins as lipoproteins. Cuticulin is the first layer of new cuticle to be secreted in preparation for a molt, and new procuticle is secreted beneath it. There may be additional layers in the epicuticle, such as an inner cuticulin layer similar in composition to cuticulin. If present it is usually thicker than the cuticulin layer and may be up to 1 μm thick. In some insects numerous layers interior to cuticulin can be differentiated as layers of greater or less electron density with transmission electron microscopy.

Cement, often described as a shellac-like substance at the air interface of the cuticle, is secreted by specialized epidermal cells called dermal glands and transported to the surface of the epicuticle. A traditional view is that the cement layer is the outermost layer on the cuticle, with a lipid layer just beneath the cement. Probably in some insects this view is valid, but in the caterpillar *Calpodes ethlius* the cement layer is not continuous, but is broken by patches of lipids, called “wax blooms,” at the surface. It seems likely in many insects that a mosaic patchwork of cement and lipid exists at the surface of the epicuticle. Other insects are known that have much or even all the body covered with lipid at the surface. Despite the thin nature of the epicuticle, it nevertheless is extremely important to surface pattern and features, to permeability of the cuticle, and it represents a limitation on expansion of the cuticle in immature insects, necessitating molting during growth.

Exocuticle

The exocuticle, containing chitin and protein, lies just beneath the epicuticle. It is highly sclerotized and is therefore hard and rigid. Lamellae or layers within the exocuticle may refract light in such a way to produce structural colors in some insects. Many of the iridescent greens and blues of insects are structural colors due to refracted light rather than to pigments. The thickness of the exocuticle is variable and species specific. Adult insects generally have a thicker and more sclerotized exocuticle than larval insects. In particular, the thorax in flying insects has heavily sclerotized exocuticle to support the strong flight muscles. Many larvae have a soft flexible cuticle with little or no exocuticle. Exceptions exist; there are larval insects with hard sclerotized exocuticle, and soft-bodied adults with little or no exocuticle.

The greater the degree of sclerotization, the harder the cuticle. The content of chitin does not control hardness of the cuticle, but sclerotization does. Because of the sclerotization, little or none of the exocuticle is digested by molting fluid, and it is shed, along with the epicuticle, at molting.

Mesocuticle

Some insects have a layer of less highly sclerotized cuticle between the exo- and endocuticle called mesocuticle. It also contains chitin and protein. Mesocuticle is distinguished on the basis of the degree of sclerotization and by its red staining reaction with acid fuchsin in Mallory’s triple stain.

Endocuticle

The endocuticle is soft, flexible cuticle containing both chitin and proteins. It has little sclerotization, which is why it is soft and flexible. Stabilization of the proteins and chitin in the endocuticle occurs through some covalent bonds, hydrogen bonds, and probably occasional quinone cross-links. Generally soft-bodied insects have relatively thick endocuticle, which remains flexible and soft, and thin or no exocuticle. There is, however, always an epicuticle layer at the body surface of soft-bodied insects.

Pore Canals and Wax Channels

Pore canals are passageways from 0.1 μm to 0.15 μm diameter extending from the epidermal cells through the endo- and exocuticle. Larger canals are often flattened, ribbon-like, and may be twisted or straight. The pore canals transport lipids and cement, and sometimes additional chemical components. Formation of the pore canals has not been entirely resolved. Some research has suggested that the passageways are the result of cytoplasmic extensions of the epidermal cells present during cuticle secretion. Usually after a new cuticle has been secreted, the cell extensions are withdrawn leaving the open canals. Some workers who have studied cuticle formation do not accept this mode of formation because cell extensions are not always evident even during new cuticle secretion, but no competing alternative idea has been advanced. The pore canals can be very numerous; for example, as many as $1.2 \times 10^6/mm^2$ in some cockroaches, or as few as $15{,}000/mm^2$ (about 50–70 per epidermal cell) in a sarcophagid (a flesh fly) larva.

Pore canals terminate at the junction of the epicuticle; they do not penetrate epicuticle. There are, however, passageways through the epicuticle called wax channels (about 0.006 μm–0.013 μm in diameter) that are 10–20 times smaller than pore canals. Wax channels stain with osmium tetroxide, a stain for unsaturated lipids, and this is taken as evidence that the channels continue the transport of lipids, and probably other materials, to the surface. There is no evidence of a 1:1 correspondence of pore canals to wax channels at the junction of the exo- and epicuticle. Chemicals passing up through the pore canals probably diffuse out of the pore canals laterally to some extent all along their length, and also at the epicuticular interface, and thus impregnate the entire cuticle. Some of the lipids find their way to the surface of the insect, where they provide waterproofing, and perhaps other ecological and behavioral functions.

Epidermal Cells

The cells underlying the cuticle are arranged in a single layer. They usually are called simply the epidermal cells, but sometimes referred to as the cuticular epithelium and the hypodermis. All epidermal cells probably secrete chitin and proteins, and some may secrete lipids, although the cells that secrete lipids have not been easy to always identify. Cement may be secreted by specially modified glandular epidermal cells. There frequently are specialized glandular cells in the cell layer, either in small groups or as scattered isolated glandular cells, that secrete special products. For example, the sex pheromone in most female Lepidoptera is secreted by a small patch of tall, columnar epidermal cells located beneath the cuticle of the ventral intersegmental membrane in the 8–9th segment of the abdomen.

Epidermal cells are separated from the circulating hemolymph by a basement membrane or basal lamina, a layer of poorly defined chemical composition, but with pores large enough to permit larger hemolymph proteins and other molecules to pass from the hemolymph into the epidermal cells. Small tracer particles of gold or ferritin pass from the hemolymph through the basement membrane, but larger particles are stopped on the hemolymph side. Hemidesmosomes hold the basement membrane to the epidermal cells. The origin of the basement membrane is not defined for most insects; some evidence supports secretion by hemocytes, while the desmosomal attachments to epidermal cells suggest that the epidermal cells themselves secrete it. Tracheae, tracheoles and nerves pass through the basement membrane to reach the epidermal cells.

The basal membrane of epidermal cells may be smooth or may contain many and deep infoldings, depending upon function and stage in which the insect exists. The basal cell membrane may change in appearance, and undoubtedly in function, as the insect develops, and there are marked changes in preparation for and during a molt.

In the intermolt period epidermal cells typically have a regular polygonal outline and form a sheet of cells beneath the cuticle. Contiguous epidermal cells often are held together by various types of junctional contacts. The same types of cell-to-cell contacts occur in many other cells as well. The junctional contacts not only hold cells together, but help prevent movement of molecules that might otherwise squeeze between adjacent cells. The cell-to-cell contacts help reduce outward loss of water and inward penetration of chemicals the insect might encounter in the environment. Septate desmosomes are close together and numerous, like stitches, between the lateral faces of cells, particularly toward the apical (cuticular) surface, and likely play an important role in preventing inward and outward movement of materials between the cells. Gap junctions also occur in this region. Depending upon cell function and physiological condition of the insect, there may be sinuses with varying width from time to time between adjacent cells, with cells being held together mainly at basal and apical surfaces. Cationic ferritin does not penetrate these spaces.

Under the influence of hormones, and in preparation for a molt, epidermal cells generally change shape to become more columnar. They begin to divide by mitosis, and move or expand into new space, and sometimes new shapes, that will become the body outline of the next instar as they secrete the new cuticle.

Epidermal cells secrete cuticle at the apical face, and a typical cell has a series of ridges or knobby projections on its apical face where the fibers of chitin are secreted. These projections have been called plasma membrane plaques. They may be involved in transport of precursors for chitin synthesis and/or assembly of chitin fibers. At the initiation of new cuticle synthesis prior to molting, cuticulin, the first new cuticular layer secreted, begins to form on these knobby plaques. There also may be long microvilli on the apical face which may transfer lipids to be passed to the cuticular surface.

Epidermal cells have extensive rough endoplasmic reticulum (RER) where protein synthesis occurs, and areas of smooth endoplasmic reticulum (SER) for lipid synthesis. Cell nuclei are often polyploid, with multiple nucleoli. During development, nucleoli enlarge and develop multiple lobes, when there is evidence of new synthesis of RNA and ribosomes. The Golgi complex is prominent in epidermal cells, and probably serves several functions including the following: (i) processing of secretory substances necessary to synthesize cuticle, (ii) production of material for the plasma membrane of the cell, (iii) packaging of cellular components in isolation envelopes for later autophagy, and (iv) processing and packaging of lysozymes needed for autophagy and heterophagy.

Epidermal cells are involved in wound repair, and can move from an area of undamaged cells into an area of damaged or destroyed cells. Cells at the leading edge spread over the wound until they cover it and establish contact with another epidermal cell. The population of cells in the peripheral zone around a wound is temporarily reduced as cells migrate toward the wound area, but cell divisions soon repopulate the area.

Oenocytes are large, prominent cells scattered among the epidermal cells, and also clustered at spiracles, near origin of larger tracheae, and scattered among fat body cells. Oenocytes present among the epidermal cells are considered a type of epidermal cell, but as noted, some are located outside the epidermal layer. Oenocytes are differentiated from epidermal tissues during embryogenesis, as well as later in development. These cells are usually large, polyploid, and always have extensive tubular smooth endoplasmic reticulum and well developed plasma membrane reticular system. Their function is not very clear, but their morphology suggests lipid secretion and lipid metabolism.

Cuticle is secreted as thin lamellae or sheets, like sheets of paper stacked on top of each other. The rods or crystallites of chitin are embedded in the protein matrix of a sheet and provide strengthening, in much the same way as that provided by steel rods (reinforcement bars, commonly called "rebar" in the construction industry) embedded in concrete columns and walls. Adjacent sheets of cuticle are stabilized by quinone tanning agents and by hydrogen bonds between chitin rods in adjacent cuticle sheets when the rods are near the surface of each sheet. It is still uncertain whether quinone tanning agents directly link chitin rods to protein.

In successive sheets of cuticle the chitin rods often are shifted slightly in orientation relative to the sheet above it (the older sheet), and this gives rise to bouligand helicoids in thin transmission electron micrographs sections. One structural model is that chitin rods are embedded parallel to each other in the protein matrix in a plane or sheet of cuticle only a few nm thick. In each successive sheet of cuticle the model suggests that rods are reoriented slightly through a small angle relative to rods in the plane lying above. The shift in orientation of the chitin rods produces a helicoid pattern when oblique sections are cut through the cuticle. When the rotation has passed through 180°, the result is a lamella of cuticle (Fig. 26).

Cross sections and freeze-fracture of insect cuticles often show a "plywood-like" arrangement. The "plywood" arrangement has been explained as a sandwich arrangement in which there is a very thin lamella of cuticle holding together two layers of cuticle of many sheets in which rods do not shift, but run parallel to each other through many successive sheets. Based upon the principle that manufactured plywood sheets are designed in this way for added strength, one can assume that similar strength is imparted to cuticle with this arrangement.

Intercalary Vein

An added or supplementary wing vein; it varies in appearance among different taxa.

► Wings of Insects

Intercropping

The culture of two (or more) crops simultaneously in the same field.

► Polyculture

Interference Competition

Competition for resources wherein one individual or species acquires greater access to necessary resources. The "winner" of the competition is not necessarily ensured adequate resources, only a greater probability of acquiring sufficient food. It also is known as contest competition.

Intergenic Region

The noncoding region between segments of DNA that code for genes (i.e., introns).

Internal Anatomy of Insects

JOHN L CAPINERA
University of Florida
Gainesville, FL, USA

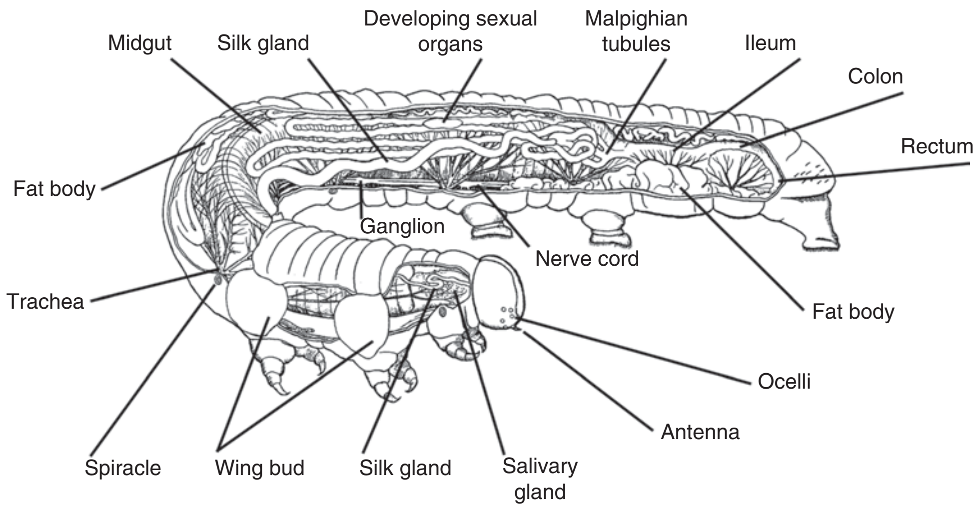
The insect body is a slightly to pronounced elongate, cylindrical structure. Its shape is determined by the integument and associated muscles. As is the case with the wide variation in external appearance among taxa, there is considerable variation in internal structure. The same basic systems are normally present in all insects, of course, but their expression varies with their behavior and ecology. Similarly, the systems found in the immature and adult stages may be quite similar in some insects or quite different in others, depending not only on the development of reproductive structures in adults but also on the feeding ecology on the insects. There are several important internal systems that together provide many of the unique characteristics that make an insect different from most other animals (Fig. 27).

Muscular System

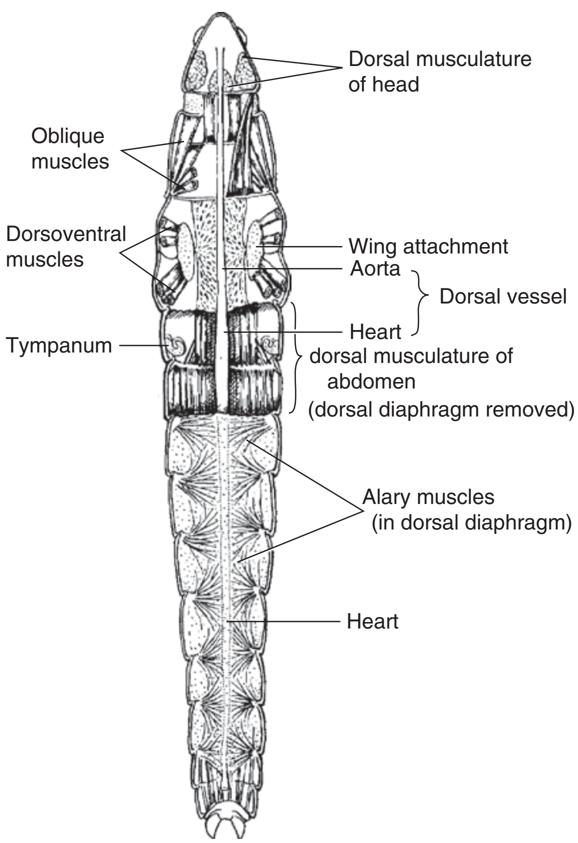
Muscles are found throughout the insect body, though they are most pronounced in the head (for ingestion) and thorax (for locomotion). The muscles are pale in color and striated, forming flat or strap-like bundles. The naming system of muscles is confusing, and tends to be named in some cases for the function they perform, but in other cases based on their point of attachment to the integument. Skeletal muscles tend to be segmented in concert with body segments, the most important of which are the cephalic, thoracic (including flight) and abdominal muscles. They are anchored to various points of the integument, including internal extensions of the integument. The cephalic muscles control the activities of the head, such as moving the head, moving the mouthparts, and moving the antennae. The thoracic muscles control the legs and wings. The wing muscles may act directly on the wing (so-called direct flight muscles) or indirectly (so-called indirect flight muscles. The indirect flight muscles are of two principal types: the dorsoventral and the longitudinal. The alternately deform the shape of the integument, which in turn provides energy to help power the wings. The indirect muscles usually are more important for flight. The abdominal muscles connect abdominal segments and serve to bend and contract the abdomen. In addition, there are visceral muscles associated with such organ systems as the gut, heart, and gonads. They may encircle the organs, or run longitudinally, but they are small muscles and not well tracheated (Fig. 28).

Fat Body

The fat or adipose tissue is found widely in the body, and consists principally of lipids, glycogen



Internal Anatomy of Insects, Figure 27 **Caterpillar with integument partially removed to expose the internal anatomy (modified from Essig 1942).**



Internal Anatomy of Insects, Figure 28 **Dorsal view of a grasshopper showing principal elements of the circulatory and muscular systems.**

and protein. It is not simply a storage area for energy, however, and sometimes assumes other functions. Usually it is whitish or yellowish in color, and forms irregular masses or lobes. It is especially pronounced in immature forms of insects.

Digestive System

The digestive system (also called alimentary system or alimentary canal) extends the length of the body from the mouth to the anus. In general, is consists of a straight tube, though there are various points where it may be dilated, convoluted, or branched.

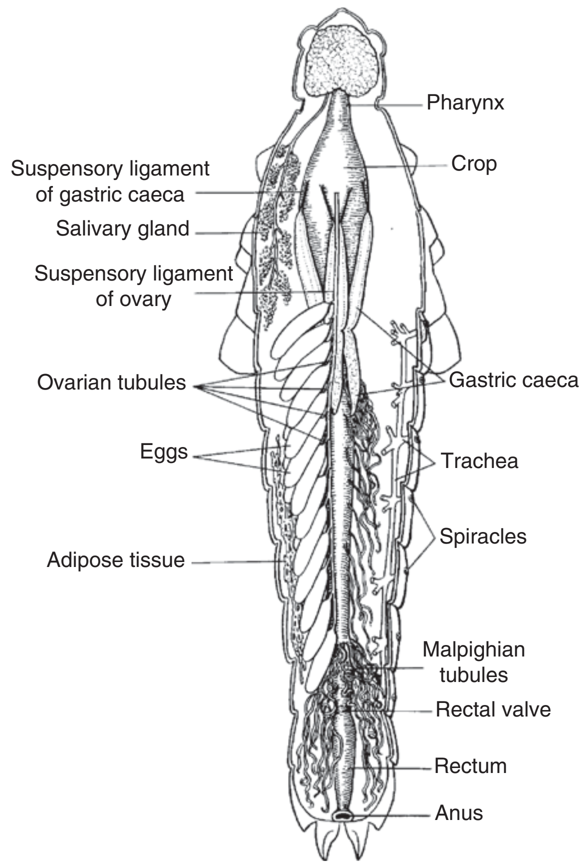
This system begins at the mouth or buccal cavity, and salivary glands often provide enzymes and lubricants at this point. Generally, the alimentary system is said to consist of three parts: the foregut, midgut, and hindgut. Sometimes the buccal cavity is considered to be part of the foregut. The foregut (also known as the stomodeum) also consists of the pharynx, esophagus, crop, proventriculus, and esophageal valve. This section serves mostly to transport, store, and sometimes filter the ingested food, which then enters the midgut (ventriculus). The midgut is the' stomach' of insects, and is the principal site of digestion. It may possess gastric caeca, bladder-like pouches that increase the surface area of the midgut. The posterior region, or hindgut, consists of an anterior portion of intestine, or ileum, followed by the posterior intestine, or colon. The anterior and posterior regions of the intestine are not always differentiated. The beginning of the hindgut is marked by the attachment of Malpighian tubules. The hindgut terminates with a chamber called a rectum, which regulates movement of waste materials into the anus (Fig. 29).

Circulatory System

The circulatory system of insects is usually but a single dorsal vessel. It extends from the posterior region forward to the head, and consists of two principal components, a pumping organ or heartposteriorly, and a large vessel for transport, or aorta anteriorly. The blood, or hemolymph, circulates freely in the spaces between the organs. However, diaphragms in various parts of the body also serve to direct the flow of blood, and blood flows through veins of the wings. In some insects, accessory pulsatory organs occur. These sac-like structures function independently of the heart, and assure that blood flows into the appendages.

Respiratory (Ventilatory) System

Exchange of gases in insects is accomplished through a system of trachea (large vessels) and tracheoles (small vessels). It is analagous to a system of arteries, veins, and capillaries, with air (rather than blood) provided to the organs, tissues and cells of the body. The trachea take on a silvery appearance when filled with air. The trachea open to the outside of the body through opening called

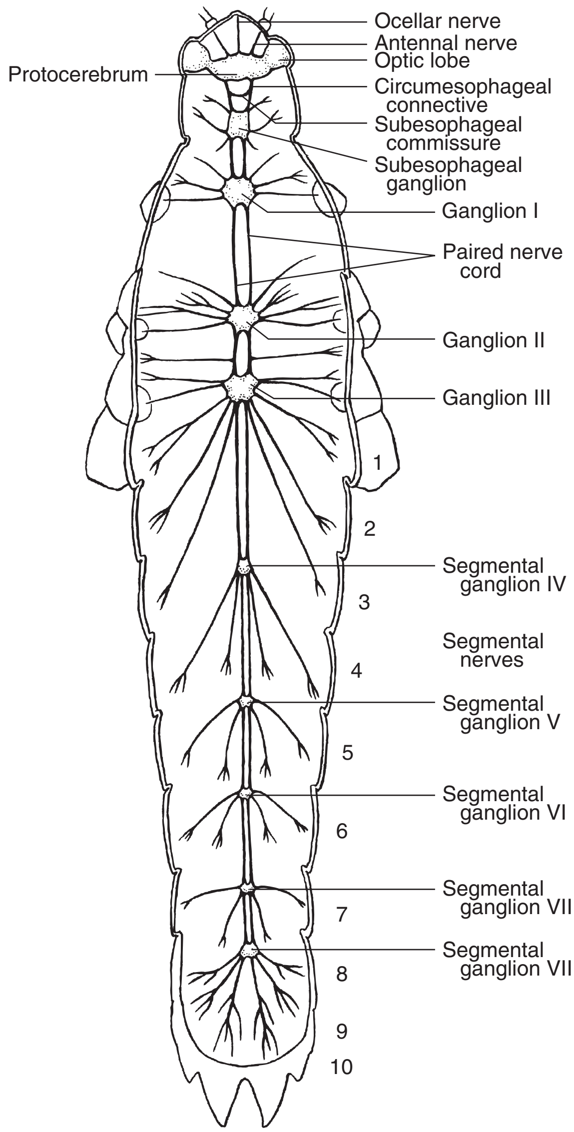


Internal Anatomy of Insects, Figure 29 Dorsal view of a grasshopper showing principal elements of the digestive, respiratory and female reproductive systems.

spiracles. The spiracles are arrayed laterally along the thorax and abdomen. Although traditionally considered to be a passive system, air sacs occur in many insects. Air sacs are dilations of the trachea, and constitute a significant air reservoir. Pressure on the air sacs helps to move air through the ventilatory system. In aquatic insects, the exchange of gases may occur in tracheal gills that occur in the normal positions of the spiracles, or from the sides of the body or associated with the rectum. Sometimes gas exchange is cutaneous.

Nervous System

The central nervous system of insects is located ventrally along the length of the body. It consists of a series of ganglia (often one per segment) that are connected by a double nerve cord. Nerves also radiate to all regions of the body, though each ganglion tends to serve principally the functions of the segment in which it is found. In the head, enlarged ganglia form the brain and subesophageal ganglion. The nerves connect to the sense organs, and though there are many types of sense organs in insects, the compound eyes and antennae are most important (Fig. 30).



Internal Anatomy of Insects, Figure 30 Dorsal view of a grasshopper showing principal elements of the nervous system.

Glandular Systems

There are many important secretions from various glands in the insect body. Exocrine glands release chemical to the outside, whereas endocrine glands release chemicals internally. Among the important exocrine glands are the salivary glands, silk glands, poison glands, odor glands, wax glands. Salivary glands are located in the head and thorax and empty into the region of the mouth. Sometimes the salivary glands are very large. Silk glands similarly can be quite large, depending on the silk production of the insects. Silk glands produce fibrous protein material, which is often used to construct cocoons. Normally, silk is released from the labium, but in some insects the tarsi or anus is involved. Poison glands sometimes produce secretions associated with setae, such as the venom found in caterpillars with stinging hairs or spines. Some secretions are sticky and aid in insect adhesion. Poison glands also may be found in association with the ovipositor or sting, and are modified accessory reproductive glands. Odor glands are quite variable. Those associated with glandular scales on wings of butterflies are quite small, whereas those associated with the osmeteria of swallowtail caterpillars, and the stink glands of stink bugs are larger. Many glands have a defensive function. Wax glands are found commonly in Hemiptera and bees. Wax secretion range from a powdery covering to large and complex body coverings.

Among the endocrine glands are the corpora allata, corpora cardiaca and the prothoracic glands. Corpora allata are small exocrine glands associated with the brain, and produce juvenile hormone. Corpora cardiaca are small organs associated with the brain that store and release prothoraciotropic hormone (PTTH) that activates the prothoracic glands. The prothoracic glands are found in the thorax of insects and secrete molting hormone (ecdysone) or a closely related ecdysteroid.

Reproductive System

The reproductive system of insects is quite variable among species, but unlike most other systems, also differs markedly between the sexes. The male reproductive system consists of paired tested composed of testicular follicles, paired vasa defferentia, a seminal vesicle, a media ejaculatory duct, and accessory glands that open into the genitalia. Sperm are produced in the testicular follicles, travel down the vas deferens to the seminal vesicle where they are stored, and then released, often is association with a secretion of the accessory glands. The female reproductive system consists of paired ovaries composed of ovarioles, paired oviducts, a common oviduct and vagina, accessory glands, spermatheca, sometimes a bursa copulatrix, and an ovipositor. The eggs are produced in the ovarioles, travel down a paired oviduct to the common oviduct, where they are may be fertilized by sperm that has been stored in the spermatheca.

► Tracheal System and Respiratory Gas Exchange

Interneurons

Nerves that are located entirely within the central nervous system and transmit messages to other interneurons or to motor neurons.

Interspecific Competition

Competition between members of different species. (contrast with intraspecific competition)

Interstitial

Situated between two segments.

Intertidal Dwarf Bugs

Members of the family Omaniidae (order Hemiptera).

► Bugs

Intima

The cuticular lining of the foregut, hindgut, and trachea (but not the midgut).

Intraspecific Competition

Competition between members of the same species. (contrast with interspecific competition)

Intrinsic Rate of Increase

(r) The maximum rate of population growth, estimated as the birth rate less the mortality rate. The net increase in population size.

Introduced

An organism that is native elsewhere, but was deliberately moved by people to the area specified. This term is often incorrectly applied to organisms that invaded.

► Invasive Insects

Introgression

The incorporation of genes of one species into the gene pool of another. If the ranges of two species overlap and fertile hybrids are produced, they will tend to backcross with the more abundant species.

Intron

A region of eukaryotic DNA coding for RNA that is later removed during RNA splicing. The final RNA product does not contain the intron segments.

Inundative Biological Control

The release of large numbers of a biological control agent relative to the target organism, with no expectation of permanent establishment.

Invader

An organism that has arrived in an area from elsewhere. Other terms for invader are nonindigenous, non native, and adventive.

Invasion Area

An area invaded by insects (usually locusts) during a period of outbreak, though this area typically does not support the invaders.

Invasive Species

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Invasion of new territories by insects and related organisms has always been a major source of pest problems. Indeed, in most areas of the world the principal pests are invaders from another area, usually another continent. This is not to say that invaders cannot be local or regional pests. For example, agricultural pests commonly move from native flora or weeds to crops, and can be considered invaders of the crop. Likewise, biting insects often disperse short distances from undisturbed natural areas to places inhabited by people or livestock. Sometimes highly dispersive pests fly thousands of kilometers each year to invade areas where they cannot survive the winter. However, this article focuses on nonindigenous (adventive, alien) invaders, which are considered to be pests that have moved a considerable distance, rather than locally, to permanently establish populations where they have not occurred previously.

Some Terminology

Terminology related to invasiveness is not always used consistently. Following is some clarification of terminology:

Invasive. Having a tendency to spread, or population increase resulting from immigration. Invading (adventive) organisms differ in their invasive potential, but have a tendency to be more invasive if they find a particularly suitable habitat or are free of the suppressive agents occurring in their home environment. However, naturally occurring (precinctive) organisms can also become invasive, as might occur when habitat is altered, making it more suitable for the precinctive organism.

Indigenous. An organism is present, occurs naturally, and evolved in this location. Indigenous = "native." The opposite of indigenous is "nonindigenous," and although "adventive" is a preferable term relative to nonindigenous, the latter is used widely because it is unambiguous.

Precinctive. An organism is indigenous/native, but only found in a certain area. It is also possible for an organism to be indigenous but not precinctive, as it may be found widely. The term "endemic" is sometimes used in place of precinctive, but it has other meanings so should not be used with respect to distribution.

Adventive. An organism that came from elsewhere. Adventive = not native, or nonindigenous, or alien. Adventive organisms may be introduced or immigrants.

Introduced. An organism not native to an area but that has arrived as a result of purposeful introduction. Introduced species sometimes are quite invasive and escape beyond the region or purpose of their release, so this must be guarded against.

Immigrant. "Accidentally introduced." An immigrant is an organism that is not native to an area (it is adventive), and has arrived as the result of hitchhiking (traveling) or by its own means of dispersal (usually by flight or rafting). Immigrants are often called "invaders" or "invasives," though their invasive properties vary considerably once they have arrived.

Why Invasive Species Are So Abundant

As mentioned previously, the major pests throughout the world often are nonindigenous species. When nonindigenous species invade new areas they sometimes cause great damage simply because they are new, and management procedures have not been formulated or communicated. Once effective techniques have been developed and implemented, the nonindigenous species may join the ranks of most indigenous pests as occasional problems. But in some cases, nonindigenous pests attain and maintain unusually high levels of abundance, relative to their place of origin, and continuously inflict considerable damage. In a few cases, such pests are abundant everywhere they invade, and *also* in their place of origin. The exact reason for the unusual abundance of nonindigenous species usually is not certain, but several explanations have been suggested, including:

Enemy Release

This is the explanation most often given to explain unusual abundance of invaders. In this scenario, the invader leaves behind its natural enemies, which may be parasitoids, predators, pathogens, and even vertebrates. The best evidence for this explanation being valid is the spectacular success of some classical biological control programs once natural enemies have been introduced into territory newly invaded by a pest. Likewise, the failure of some biological control programs to achieve success can be used to argue that the absence of such biotic agents are not the only reason invaders are so successful. However, biological control programs never achieve complete transplant of natural enemies. Only the seemingly most important natural enemies are introduced, leaving behind most of the nonspecific arthropod predators and vertebrate predators, and usually most of the insect pathogens. From this perspective, it is amazing that natural enemy relocation (classical biological control) works as well as it does.

Competitive Advantage

A nonindigenous invader would not necessarily be expected to out-compete indigenous species for resources, but it sometimes happens that indigenous species are displaced by invaders with higher rates of reproduction, better survival rates, or other fitness factors that lead to increases in their abundance. In other cases, not all niches are occupied, so in some instances it is exceedingly easy for invading species to take up residence without significant competition. For species that are serious pests nearly everywhere they occur, superior fitness is a logical explanation for their abundance.

Novelty

Invaders may be taxonomically unrelated or functionally distinct from indigenous species or, as mentioned previously, may occupy vacant niches. This may not only allow ready establishment due to limited competition, but may account for a dearth of natural enemies that might adopt the invader as a resource. It commonly requires several generations or years for indigenous parasitoids and pathogens to develop strains that can effectively kill new (nonindigenous) hosts. Thus, the novelty (newness) of the invader may account for initial success in the newly invaded environment.

Preadaptation

Invaders may be uniquely adapted for a particular resource or environment. Crop plants may be especially suitable for exploitation because crops usually are bred for horticultural attributes, but usually not antiherbivore traits. In fact, many efforts to improve horticultural characteristics weaken the natural antiherbivore defenses of plants. Even if the fitness of a host has not been diminished by artificial selection, once an insect parasite adapts to the host it has a very large resource base available to it. So long as the adapted herbivore is able to track its resource in time and space, it can readily exploit the host population. Evidence for the importance of preadaptation can be seen in the redistribution of crop pests around the world; the same important (well-adapted and damaging) species tend to follow the movement of crops to new environments. Preadaptation also applies to weather and climate, because insects perform better in certain environments than in others. Upon attaining the most favorable environment, their populations are most likely to display explosive growth.

Pathways of Dispersal

Natural dispersal of pests (dispersal without assistance of human activities) is frequent, and the natural range of most insects was established by natural dispersal long before humans were navigating the globe. Even remote locations such as the Hawaiian Islands and the Galapagos Islands had a modestly rich insect fauna before the arrival of humans. Rafting on floating debris, hitchhiking on birds, and direct flight are the likely modes of transport, of course, with rafting probably most important. However, since regular movement by humans to these remote locations began about 300 years ago, the fauna has changed considerably, and of course the pathways have changed through the use of ships and aircraft. Species richness in Hawaii has increased immensely with the addition of about 2,300 invaders to the approximately 3,750 indigenous species, and in the Galapagos by the addition of 295 nonindigenous species to the 1,550 indigenous species. At these island locations, nearly all of the increase in species richness is due to the inadvertent (but sometimes deliberate) movement of hitchhiking (traveling) arthropods. This is not to say that natural dispersal over such long distances is not possible. The relocation of large numbers of desert locusts, *Schistocerca gregaria* (Forskall), to the Caribbean and northern South America from Africa with the assistance of weather fronts in 1988 stands out as an example of how natural, long-distance transport remains possible. And although the dispersing *S. gregaria* did not establish successfully in the western hemisphere during this dispersal episode, the ancestors of the numerous *Schistocerca* species inhabiting the western hemisphere are believed to have originated from a similar episode thousands of years ago.

Human-assisted dispersal now is the principal means by which nonindigenous insects gain access to new territory. Sometimes relocation of nonindigenous species is deliberate. European honey bee, *Apis mellifera* L., for example, has likely been relocated to everywhere that humans exist, except for polar regions. Other examples of deliberate relocation include silkworm, *Bombyx mori* L., for silk production, and the many predators and parasites that attack plant pests of crops grown in greenhouses. Nowadays, these arthropod relocations are usually accompanied by appropriate regulatory oversight, and there is minimal risk of ecological and economic problems.

Accidental dispersal of insects is much more likely to result in problems. In earlier times, dispersal of nonindigenous insects was often associated with sailing ships, or more specifically, with disposal of ballast carried in sailing ships. The unloading of ships' ballast on the seashore of ports often resulted in inoculation with nonindigenous organisms. Ballast is weight needed to stabilize sailing ships so that they do not tip excessively.

The traditional ballast for sailing ship in the 1600s–1800s was stones, gravel, and rubble. Local ordinances in ports forbade the dumping of ballast in the water (where it would soon clog the harbor), so it was unloaded on the shore. Many arthropods, molluscs, and nonindigenous plants were introduced to port cities via ballast. Many spread from these sites of introduction, but often the only records are from these ballast heaps, and they did not disperse more broadly, eventually disappearing. Interestingly, ships traveling from Europe to North America often contained human passengers or refined goods, which did not constitute a great deal of weight, hence the need for ballast. However, on the return journey, the cargo consisted of heavy, raw materials such as lumber, hides, grains and tobacco, so ballast was not needed. This perhaps explains the overwhelming movement of pests from Europe to North America, and the relatively slight movement from North America to Europe. During this period of time, straw was often used for packing and for animal forage, serving to provide a convenient mode of inoculation of organisms associated with straw.

As sailing ships were replaced by steam-powered ships, the importance of ballast as a source of inocula was diminished because steam ships were less susceptible to tipping, and changes in technology allowed liquid ballast to be used. However, the proliferation of steamships in the late 1800s and early 1900s was coincidentally accompanied by a strong interest in botanical gardens, and the introduction of new plants for food and forage crops with the aim of improving agriculture. Travel by steam-powered ships was more reliable and often faster than by wind-powered vessels, so shipments of plants (and their hitchhiking arthropod pests) were more likely to arrive at their destination alive. Thus, accidental transport of insects increased rather than decreased.

This time period was also accompanied by the proliferation of canals and railroads. Thus, not only was it more likely for pests to traverse the world's oceans, but upon introduction to new territory the pests were quickly moved far inland from the ports by canal boats and railroad cars. Thus, the inland environments as well as the coastal environments were inoculated with nonindigenous organisms.

In the latter half of the 1900s, the movement of products by sea in sealed containers became dominant, and travel by air became commonplace not only for people, but for expensive and perishable goods such as flowers and fruit. This allowed short-lived organisms easier access to new environments. Also, the nature of ballast had changed, and liquid (seawater or riverwater) rather than solid ballast predominated. Thus, marine and freshwater invertebrates, algae, and perhaps vascular plants became important items of concern, and arthropods were less likely to be associated with ballast. However, arthropods remained important as contaminants of sea containers, perishable goods and other agricultural commodities, and of contaminants of handbags carried by the ever-increasing numbers of tourists. Infestation of wood used to construct shipping crates also became an issue as tree-infesting pests were moved around the world, and ants proved especially adept at entering shipping containers and being relocated with the ever-increasing international commerce. The table below shows some recent data on infestation frequency of commercial shipments arriving in the USA from Mexico, and demonstrates that most types of cargo shipments have the potential to be contaminated with insects (Table 14).

A less-important but notable method of introduction of invasive nonindigenous organisms is contamination of military equipment. Within the context of war, concern about contamination or equipment and material by pests is replaced by concerns about safety and success of the military operation. Thus, in the wake of major conflicts of the twentieth century there was some relocation of pests. But even during relatively peaceful times, movement of military equipment is a potentially important source of pest inoculum.

By way of example, the following table highlights some of the pathways of invasion of Japan by immigrant insects (Table 15).

Invasive Species, Table 14 Insect interceptions associated with transport of cargo from Mexico to the USA during the period 1997–2001 (adapted from Work et al. 2005. Biological Invasions 7: 323–332)

Type of Transport	Type of Cargo	Number Containers Inspected	Number Insect Interceptions
Maritime	Empty container	606	0
	Nonagricultural	883	0
	Nonrefrigerated containers	6459	125
	Refrigerated containers	2578	208
Air	Agricultural	4150	142
	Nonagricultural	1266	2
Land	Low-risk agriculture	4902	5
	Empty container	2407	0
	Nonagricultural	1019	0
	Agricultural	5093	77

Ecological and Taxonomic Patterns of Dispersal

In addition to the shift in the method of transport of nonindigenous organisms, the nature of the pests being relocated has also changed with time. In North America, many of the pests initially introduced were stored products pests. This was a period of relatively slow transport, however, when perishable goods did not survive the many months at sea necessary for long distance travel, so long-lasting stored grains and legume seed were disproportionately used as food for sailors and transported to support colonists who were struggling to establish new economies. As the rate of transport was enhanced, vegetable and fruit pests were moved around the globe, as such foodstuffs survived the weeks of transport from location to location. More recently, ornamental plants are being moved with greater frequency, and the pest complex has changed again. Often it is propagative materials that are being moved from low-labor cost areas to higher labor cost areas in an effort to reduce the overall labor costs associated with ornamental plant production. Also, cut flowers are commonly produced in relatively small areas favored by climate or labor costs, and then redistributed around the world. Homogenization of ornamental plant pests, especially greenhouse-grown plant pests, seems inevitable.

The taxonomic shift is as significant as the ecological changes among North American invaders. Early in the settlement of North America, beetles (Coleoptera) were the dominant invaders. By the late 1800s, however, Lepidoptera (moths) and Hemiptera/suborder Stenorrhyncha (aphids, whiteflies, scales, and mealybugs) assumed dominance. In the 1900s, Hymenoptera (principally ants) became quite important.

The continents of origin for arthropods successfully invading the USA (except for Alaska and Hawaii) are shown in (Fig. 30). Perhaps it is not surprising that the majority of immigrant arthropods originated in Europe, because early colonization of North America was by Europeans, there remain strong cultural and economic ties with Europe, and the climates and flora are similar. However, due to the proximity and presence of a land bridge between North and South America, we might expect a higher rate of invasion of North America from Central and South America. But the tropical fauna of Central and northern South America are not well adapted to temperate North America, and temperate South America has reversed seasons from North America, which likely impedes movement and establishment. This pattern is seen elsewhere in the world. For example, the acquisition by remote Australia of European fauna is likely due to similar circumstances.

In Japan, a similar but slightly different pattern of introduction emerged. There, the island nation was largely protected from invasive pests until about 1868 when the national isolation policy ceased. Immediately thereafter, new fruit tree varieties were imported, and scale insects and mealybugs were introduced along with nursery stock. Following the cessation of World War II in 1945, massive quantities of grain were imported to compensate for food shortages caused by the war. Not surprisingly, the grain insects that earlier had been moved around the world were finally introduced to Japan. Then, during the 1960s to the mid-1980s, a number of weevils were introduced that affected food crops, ornamental trees, and turf. Finally, at the close of the 20th century, Japan saw the accidental introduction of the many greenhouse pests that were being redistributed elsewhere in the world, including thrips, whiteflies, mealybugs, leaf miners, and aphids. Not surprisingly, the principal arthropods associated with nursery stock and other propagative materials were aphids, thrips, whiteflies and mites; the contaminants of cut flowers were aphids, thrips and mites; the contaminants of fruits and vegetables were fruit flies, weevils and leaf beetles; the contaminants of grain and other seeds were bean weevils and khapra beetles; and the contaminants of wood were bark beetles, longhorn beetles and other wood borers. The following table shows how the pests of greenhouses elsewhere in the world have also become the pests of Japanese greenhouses (Table 16).

In many respects, the accidental movement of molluscs (slugs and snails) is similar to that of arthropods. Homogenization of the world's mollusc fauna is occurring rapidly. In earlier times, deliberate introductions of snails (e.g., European land snails for escargot) for human consumption was unimpeded, but this has been largely curtailed. However, the aquarium trade has resulted in relocation of many snails as "pets" or as contaminants of aquatic plants, much to the detriment of aquatic communities in some areas. Also, in an effort to curtail the problems of snail damage to plants, some predatory snails have been moved to new locations. Examples include the rosy predator snail, *Euglandina rosea* (Férrusac), which has been introduced for control of giant African snail, *Achatina fulica* Bowdich, and likewise decollate snail, *Rumina decollata* (L.), for brown garden snail, *Helix aspera* Müller. Unfortunately, in some cases these imported predators have affected native snails as well as their intended targets. Similarly, in an effort to control aquatic weeds such as water lettuce, *Pistia stratiotes*, herbivorous snails have been released in some

tropical locations, only to have the snails serve as vectors of human schistosomes.

Despite these examples of deliberate and misguided relocations of molluscs, accidental relocation remains the principal means by which nonindigenous molluscs move around the world. The principal pathways of introduction are the same as for arthropods, the contamination of horticultural and agricultural products, soil, military equipment, and shipping containers. In the USA, plants for propagation and cut flowers are the principal source of detected mollusc entry, followed by crates of roofing and household tiles, attachment to sea containers, and finally by association with agricultural products.

Mollusc contamination is particularly threatening because many species are hermaphroditic, and capable of self-fertilization, which means that even introduction of a single individual can lead to successful inoculation. Even those that require sperm storage, however, often can store sperm for over a year, and snails are capable of surviving for months without moisture. Water ballast has significant potential to move snails between fresh water ports, a route not usually considered to be associated with invading arthropods.

Establishment and Spread

Accidental introduction is usually determined by human activities. Hand luggage is often cited as a pathway of introduction, and indeed, many travelers naïvely or deliberately bring fresh produce (mostly fruits and vegetables) into new areas, and sometimes these are infested with pests. Even smuggling of wildlife or pets is risky, because ticks and other parasites have been introduced with such unlikely hosts as tortoises and snakes. Although some pests probably are introduced in this manner (large fruit flies [Diptera: Tephritidae] are perhaps the most likely to accompany smuggled fruit and vegetables from tropical areas) the legal international shipment of propagative plant materials also is a principal route of entry for most pests, with contamination of wood crates or natural packing material also an increasing problem. The following table illustrates the frequency of infestation of baggage and cargo detected upon entering the USA during the period of 1984–2000, and demonstrates how commodities vary with respect to the occurrence of infestation (Table 17).

Certain patterns of introduction of immigrant insects, or potential introduction, usually emerge when the history of invasion is studied.

For example, 70% of the interceptions of immigrants in the USA are made at only three ports: Miami, New York, and Los Angeles. In Miami, the vast majority of detections originate in Central America, whereas in New York, Europe and China predominate as sources, and in Los Angeles most interceptions originate in China, Thailand and Central America. The table below shows the top sources of invading insect detections found on plant material intended for propagation that was imported in recent times. These data show that the sources of pests do not necessarily reflect trade with the "top" trading partners of the USA; rather, they reflect the unique circumstances of the plant propagation trade, and point out the need to fully understand the unique pathways of international trade (Table 18).

The increase in the "free trade" movement throughout most of the world in recent years has resulted in vast increases in material moving by truck, boats and aircraft. Only a small proportion of the material crossing international boundaries is inspected, and even then it is difficult to critically examine many commodities. In New Zealand, for example, 20% of sea containers are inspected, and in the period of 1999–2000, 24.8% of the containers were found to be contaminated and require quarantine action. Unfortunately, the incidence of contamination by pests has been increasing steadily since 1993–1994, when only 6.4% of the containers held pests. In contrast, only 1–2% of shipments to the USA are inspected, despite the fact that 10.4% of the aircraft arriving at Miami International Airport in 1998–1999 contained insects. Aircraft from Central American countries had a higher incidence of infestation, 23%. These

alarmingly high levels of infestation clearly indicate that insects are routinely transported in commercial cargo, and that inadequate efforts are being made to prevent such transport. Shippers and retailers of imported products often are unwilling or unable to curtail contamination, which is best handled by prevention before shipment, not inspection after shipment.

Establishment of pests in a new environment is related to several factors, including:

Frequency of Inoculation

Some pests are a greater hazard because they more frequently are transported to new environments. Pests that are more cryptic, that infest perishable produce which must be transported with little delay, or that infest material that is imported in high volume are more likely to be transported.

Climatic Suitability of the New Environment

Transport of insects between like climates is most likely to result in successful establishment of the immigrant. Thus, movement of insects between Europe and North America has a higher potential for successful inoculation of a new pest than transport between North America and South America, because in the former case the seasons are the same, whereas in the latter case the opposite seasons prevail. Related to this is the fact that benign climates are more likely suitable for insect invaders than are severe climates.

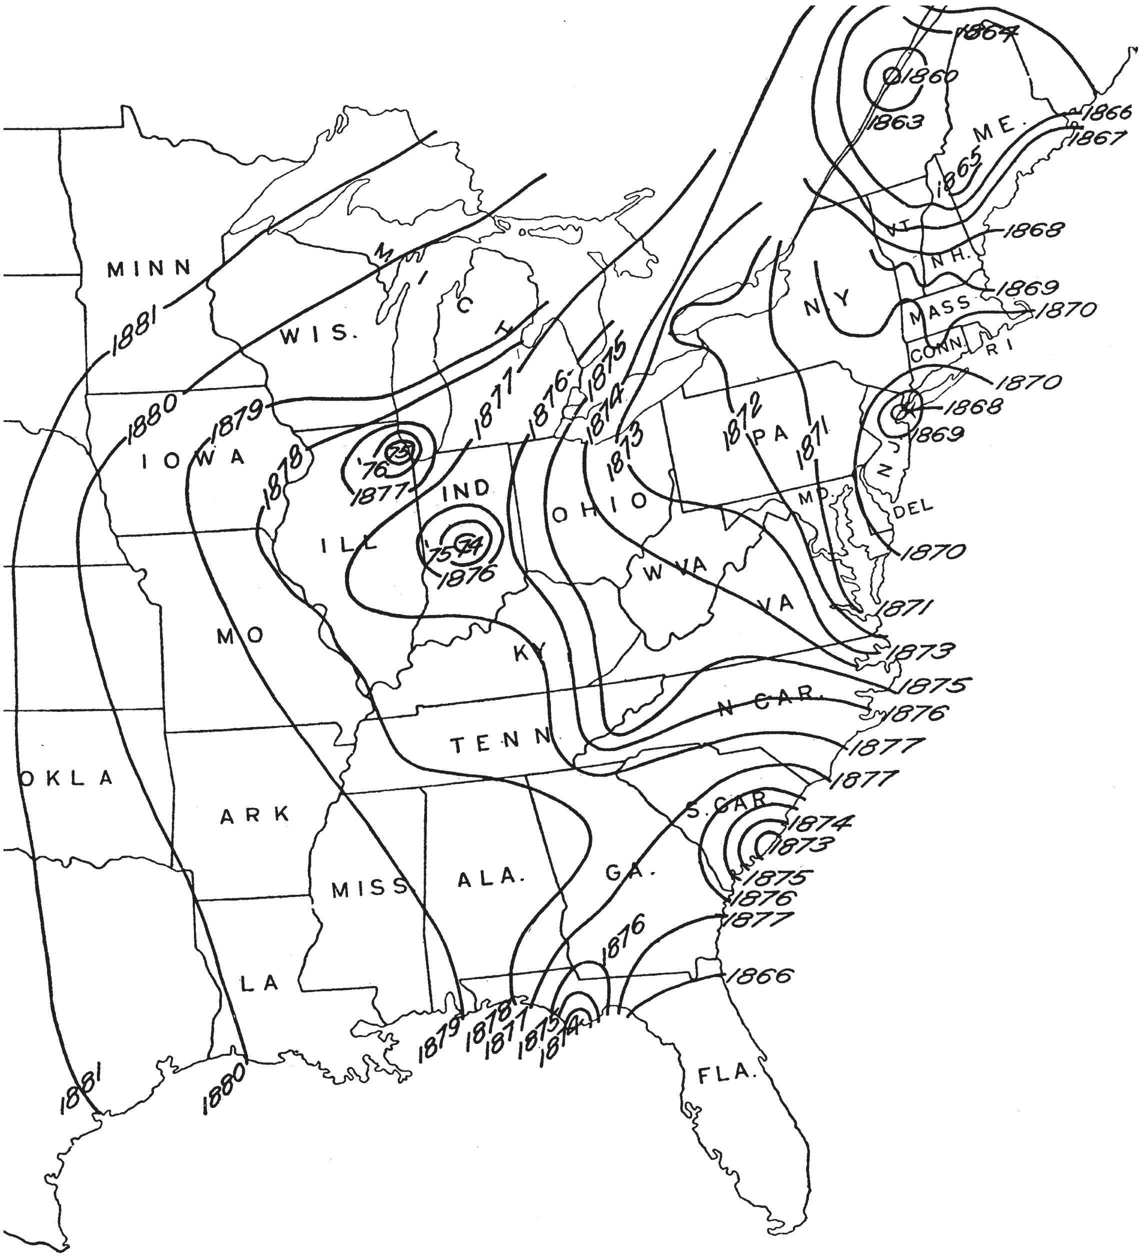
Biological Characteristics of the New Environment

The availability of suitable hosts is critical for successful establishment of invaders. Insects with a narrow host range are more at risk of not arriving in a location where a suitable host is present, but even insects with a broad host range have some hosts that are much more suitable for survival. In fact, insects that are preadapted (that have coevolved) have an extraordinarily high rate of success in tracking their host plants as they are moved around the world. The likelihood of an invading organism establishing successfully is positively related to the size of the area (e.g., number of hectares under cultivation) supporting a suitable host. Disturbed habitats, and habitats with few competing species, also are favorable for establishment of invaders.

Biological Characteristics of the Potential Invaders

Certain biological characteristics predispose insects to establish successfully. Invaders that are small enough to escape detection, that have good powers of flight, that reproduce parthenogenetically, that have a high rate of reproduction, and that are preadapted for the new environment (both host environment and weather) have an above average chance of establishment. The likelihood of establishment also increases when the invader arrives with a large founding population.

The actual pattern of invasion varies with the nature of the introduction, the environment into which the invader is introduced, and the biological characteristics of the invading organism. The accompanying map of the eastern USA (Fig. 31) shows the invasion of this area by imported cabbageworm/small white cabbage butterfly, *Pieris rapae* (L.) (Lepidoptera: Pieridae), and serves to illustrate several points about invaders. *Pieris rapae* was first found in North America at Montreal, Canada (top, right portion of the map), about 1860. After this primary invasion event, it spread by natural means in all directions, but in some cases it apparently was assisted in its dispersal by movement of material. Thus, in a secondary invasion event it was detected in the area of New York City in 1868, before it occurred in surrounding areas. Likewise, it was introduced to Charleston, South Carolina, about 1873 before the adjacent



Invasive Species, Figure 31 **The pattern of invasion of *Pieris rapae* in eastern North America following its introduction about 1860 (from F.H. Chittenden. 1916. *USDA Farmers' Bulletin* 766. 14 pp.).**

areas were infested, etc. It is not surprising that port cities would be points of introduction (including the inland, lake port of Chicago, Illinois, in 1875). The inoculation of central Indiana in 1874 before the surrounding areas were infested could be due to movement of infested produce to this area, an unusual weather event depositing winged adults, or an artifact of early detection.

Weather can play a significant role in assisting dispersal, but climate often sets boundaries on long-term establishment. In the case of *P. rapae*, the entire region has been infested with this adaptable species. In contrast, there are many examples where climate limits distribution of immigrant species in this same area, such as imported red fire ant, *Solenopsis invicta* Buren

(Hymenoptera: Formicidae), which occurs only in the southern region of USA, north to Tennessee, whereas Japanese beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae) occurs in the northern region of USA, south to Georgia. The occurrence of host plants limits the distribution of species with a narrow host range, but usually the plant host range exceeds that of the arthropod herbivore range.

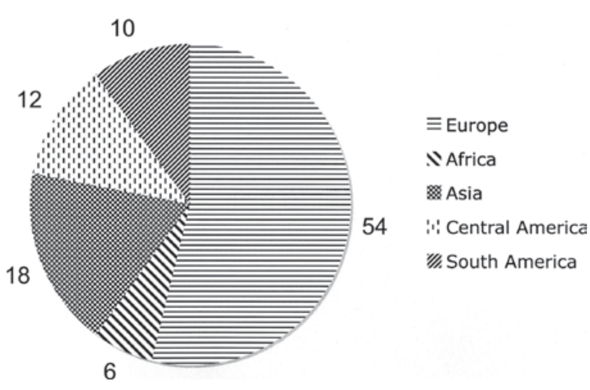
Latency

The period of time between the introduction of nonindigenous species and their detection has been called the latent period. It is usually impossible to pinpoint the exact time that an alien invader arrives, though sometimes it can be deduced with a degree of accuracy. One exception to this generalization is the accidental release of gypsy moth, *Lymantria dispar* L. in Medford, Massachusetts, in 1869. In this case the date was known precisely, but because the city administration did not care, nothing was done until this species became abundant and damaging 20 years later, in 1889. This might be viewed as a surprisingly long period for such a potentially damaging insect to be latent and unnoticed. However, it is not uncommon for gypsy moth to be at a low level of abundance for 10 or more years, only to suddenly increase in abundance, presumably due to some shift in weather.

In Japan, an analysis of the latent period showed a range of from 0.5 to 80 years of latency, and a mean of 11.8 years. However, the mean value is inordinately affected by a few "statistical outliers." In fact, most species (25 of the 35 species) had a much shorter period of latency, and of this group, the latent period was only 3.8 years. Extremely damaging species, and perhaps species that affect certain crops, are more likely to be detected earlier. Thus, because greenhouse crops tend to be high value and inspected regularly, we would expect pests of such crops to be noticed soon after invasion. On the other hand, tree pests that inflicted little damage might go undetected for a considerable period. Often, the likelihood of detection is a function of morphology or behavior; things that look strikingly different or behave differently are apt to be noticed (Fig. 32).

The latent period for detection of invaders is almost never known precisely, but in most cases it is a considerable period of time. Thus, there is a good possibility that new invaders will have time to establish and spread, making eradication difficult or impossible. Most countries make efforts to prevent establishment of potential invaders not only by inspection of incoming materials, but also by trapping at ports and other routes of entry. The period of latency makes it unlikely that immigrants will be detected in a timely manner.

Often there is a population outbreak displayed by immigrants following establishment and adaptation. The outbreak (and the lack of sizable populations during latency) is likely due to genetic shifts in the invading organisms as they adapt to new hosts and new weather, or as they await opportunity to arrive in an optimal environment. Once conditions are suitable, and especially if natural enemies of the pests have been left behind, populations can increase. Often they attain alarmingly high numbers, but then subside. Subsidence may be due to a shift of indigenous natural enemies to new hosts, a shift in the genetics of the host, induced resistance in the hosts, change in



Invasive Species, Figure 32 **The sources of arthropods establishing in the USA (modified from R. I. Sailer. 1978.).**

weather, or a change in the management practices of people in the affected area.

Impacts

The economic effects of nonindigenous arthropods are difficult to assess accurately. In the case of crops and livestock, it is possible to estimate the costs of pesticides used for their protection, and to add to this the loss experienced by the commodity even in the presence of pesticide use. However, such data are notoriously unreliable. Even more problematic are aesthetic costs (e.g., damage to the appearance of lawns and gardens) and environmental effects (e.g., water quality, habitat degradation, loss of wildlife). Sometimes the calculations used to generate such figures use imperfect methodology, though often out of necessity. For example, one might partition the total economic losses due to insects into the proportions caused by indigenous species and nonindigenous species. However, would one make that partition based on the proportions of indigenous and nonindigenous species in the pest species assemblage? This approach has been used, but it likely underestimates the impacts of nonindigenous species, which often account for disproportionately large amounts of damage. For example, of the total crop losses attributable to arthropods in Hawaii, Florida, and California, the proportions due to nonindigenous species are estimated to be 98, >90, and 67%, respectively, whereas the proportions of nonindigenous arthropod pests in these locations are only 34, 7.5 and 2%, respectively.

Some estimates of loss caused by nonindigenous pests in several countries are found in Table 19. For comparison purposes, losses are partitioned into "agricultural" losses to crops, pastures and forests, and into environmental losses to the nonagricultural environment. Also, arthropod-caused losses are contrasted with losses due to weeds, vertebrates, and plant pathogens. Although these data may be imperfect, they clearly demonstrate how costly nonindigenous pests are to societies throughout the world.

The redistribution of arthropods around the world has been occurring for many years, and in some respects is continuing unabated. The pattern of establishment of immigrant arthropods in Florida, USA, is shown in Fig. 33, and demonstrates the high degree of year-to-year variation in invasion (or detection). It also shows that there is not much of an increase, if any, in the rate of invasion. The same pattern is occurring in California, USA. On the other hand, there is growing concern about invasive pests throughout the world, so how can we reconcile the increase in concern with the apparent steady rates of invasion? There are several possible explanations, including:

High-Profile Pests

In recent years there have been some especially high-profile invasions that severely affected crop production in agricultural areas, but also some that affected inhabitants of cities and elsewhere, including the health of humans. Thus, more people have become aware of the problem.

Cumulative Effects

Although the rate of invasion may not be increasing, the number of immigrant species continues to increase, and the total impact grows ever larger. Although the impacts of some nonindigenous pests are neutralized by highly effective, low-cost methods such as biological control, in most cases they remain a problem requiring continued vigilance and economic cost (Fig. 34).

Increased Environmental Awareness

Over most of the globe, there is increasing concern about the quality of the natural environment. As human populations continue to grow, we see decreases in water quality, increases in soil erosion, more deforestation, depletion of

energy reserves, reduction in marine fish populations due to over-fishing, and global warming. Perhaps we have become more sensitive to the problem of invasive species because it is just another manifestation of natural resource mismanagement.

Risk Assessment and Quarantines

Quarantine procedures commonly eliminate the likelihood of pest relocation by banning the movement of potentially infested products or by requiring product treatment to eliminate the threat of pest movement. Though effective, this interferes with international commerce. Indeed, the risk of pest infestation has been used, at times, as a trade barrier to reduce competition covertly. Sociopolitical issues increasingly dictate that quarantines not be used to interfere with trade, necessitating better risk assessment, reducing the risk that pests will enter the stream of commerce, improving early pest detection, and developing more efficient pest elimination techniques.

Risk assessment necessitates determining which pests could be imported, the likelihood of importation, and the consequences of importation. Several systems have been designed for determining the probability that a pest will become invasive. The assessments are fundamentally qualitative, but by assigning ratings to a series of pest biological characteristics (e.g., reproductive potential, dispersal abilities, host preferences, etc.), characteristics of pest "opportunity" (e.g., likelihood that pests will hitchhike, likelihood that pests will evade detection), and consequences of introduction (e.g., economic or environmental impact), it is possible to categorize risk in an objective fashion. It appears that the best predictor of a pest's invasiveness and potential for damage is its record elsewhere, but particularly in similar climatic areas. Although there are no scientific principles that conclusively identify invasive potential, the opinions of experts who have first-hand knowledge are extremely valuable, even though "data" may be lacking.

Modern quarantine procedures often have several layers of defense designed to mitigate the threat of invasion. In addition to conducting a careful risk assessment, which can be used to identify the likely pathways of inoculation and provide focus for efforts to prevent introduction of pests, quarantine procedures may include:

Production Management Techniques

Commodities should be cultured in a manner that reduces the likelihood of infestation with pests of quarantine importance. This usually requires use of insecticides to eliminate pests, but also could include production of commodities in pest-free areas, use of pest-resistant hosts, etc.

Pre-border Clearance

Overseas inspection of commodities and certification of "pest-free" status as they are packaged for international shipment is sometimes an option, eliminating the need for inspection at the port of entry. The advantages of obtaining pre-clearance include the reduction in backlog at ports of entry and eliminating delay of entry (this can be very important for highly perishable commodities), and the elimination of the need to discard/destroy infested commodities after the expense of transport has been incurred.

Disinfestation

Commodities that are infested or might be infested can often be disinfested in transit by use of cold storage, heat treatment, or controlled atmospheres that will kill the pests without harming the commodities. Alternatively, chemical fumigation with insecticides can be used.

Border Treatments

Efficient detection is the most important quarantine protocol when commodities have arrived at an international (sometimes intranational) border. Detection of small or cryptic pests, or pests occurring at a low incidence, may be nearly impossible. Detection is enhanced by knowing which pests are likely to be hitchhiking, and the exact origin of the commodities. There can be significant differences in infestation rates among geographic regions, and times of the year when pests are likely to be hitchhiking. Even the practices of individual producers and shippers can influence the level of infestation. If pests are present, disinfestation with fumigants or other techniques may be mandated. If this is not possible, commodities may be returned to the country of origin, or destroyed.

Restricted Distribution of Commodities

In large countries with varying environmental conditions, the threat of nonindigenous pest introduction and establishment may be limited to only a portion of the area within its political boundaries. Thus, risk can be mitigated by restricting importation and distribution of commodities that might be infested to areas where the pest cannot survive.

Eradication

Inevitably, some pests are detected in a new location, and a reproducing population may be established by the time of detection. Again, efficient detection is the best defense against this occurring, but if it does occur, host destruction and chemical treatment with insecticides are the commonest approaches to eliminate the pests. For pests where sterility techniques (e.g., release of sterile males for some tephritid fruit flies) or effective trapping (e.g., oriental fruit fly, *Bactrocera dorsalis* [Hendel]) exist, these approaches may be more effective. However, alternatives to insecticides and host destruction usually exist only for pests that have been well studied.

Risk Mitigation for Avocado: An Example

An excellent example of risk mitigation involves the quarantine protocol allowing importation of avocados from Mexico to the USA. Avocados in Mexico are infested with fruit flies not found in USA, so for many years the importation of this fruit was prohibited. The quarantine protocol developed for Mexican avocados consists of several mitigation procedures, including:

Field Survey

Growing areas must demonstrate absence of flies.

Trapping

Traps in production and packing areas must remain fly-free.

Sanitation

Fallen and over-ripe fruit must be collected and destroyed to minimize fly breeding.

Host Resistance

Haas avocado, the variety produced commercially in California (the principal avocado production region in USA) is not susceptible to infestation.

Post-harvest Safeguards

Packing houses must be screened and have double-door entrances to minimize threat of infestation after harvest. Fruit must be inspected at the packing house.

Phenology

Avocados can be harvested and shipped only during the winter months.

Port of Arrival Inspection

Upon arriving in the USA, fruit must undergo further inspection.

Limited Distribution

Distribution of Mexican avocados is limited to the northeastern USA, where there is no avocado production and the weather would be inhospitable to any flies that emerge.

In many cases, invasion of nonindigenous pests is detected only after they become well established, and eradication is not possible because they have spread over an area that is too large to treat effectively or safely. In this case, the pest's impact is reduced by implementing new pest management programs. Self-sustaining programs such as introduction of biological control organisms are desirable, but not always possible. Education and improvement of management techniques in the invaded area is often possible, though such efforts require additional effort and expense.

Invasive

An organism that is expanding its range, or has a history of expansion.

► Invasive Insects

Inversion

Alteration of the sequence of a DNA molecule by removal of a segment followed by its reinsertion in the opposite orientation.

Invertebrates

Animals lacking an internal skeleton or "backbone," including such animals as insects, mites, and worms.

Inverted Copulation

PIERRE JOLIVET
Paris, France

There are extremely rare cases among insects, and possibly among some mites, where females possess a specialized extensible intromittent organ, that collects the male's spermatophore or the male sperm. The cases are known among certain Lepidoptera: Nymphalidae (*Argynnis*) and Lycaenidae (*Plebejus*) and Coleoptera: Scirtidae or Helodidae (*Cyphon*). It could exist among certain Acari: Canestriniidae, but the fact has to be confirmed. However, the whole concept needs further investigation, and in certain cases (Lycaenidae) other interpretations are to be considered. In all cases, anyhow, the female lightly penetrates the male. In some cases, the female seems to capture and aspirate the spermatophore or the semen and actively collect it from the male genitalia. The extensive organs of certain Lepidoptera families seem to have evolved independently and convergently and are divergent in shape if not in function. It is evident that a reevaluation of the structure and of its functioning is necessary.

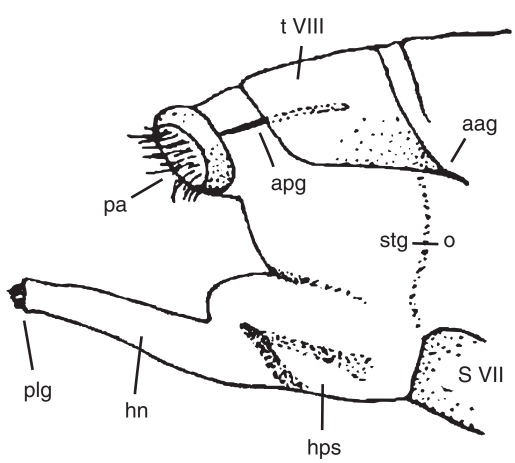
Lepidoptera

Female erection exists only among two families of Lepidoptera, Nymphalidae and Lycaenidae, and only among some genera and species. The only problem is, what is the function of those erections? The structures seem convergent, but completely different anatomically. It is also evident that those organs are extremely fragile and have escaped the attention of most of the authors. The organs are almost transparent. We can see this strange "inverted copulation" only if we capture a male and a female in copula, if the couple does not separate in the net or in the cyanide killing jar, and if we can clear the preparation for the microscope.

In *Argynnis paphia* (L.) (Nymphalidae), André Bayard was lucky enough to obtain a slide with both individuals, male and female, remaining in copula. This coupling, so easy to obtain in rearing cages with Heterocera, was once believed to be impossible to get in captivity for Rhopalocera. Actually, we can get it easily in mosquitoes, bees, and butterflies by manipulating the male and bringing the male abdomen into contact with the female extremity. Among many insects, artificial mating is currently used, and cutting the male head facilitates the operation.

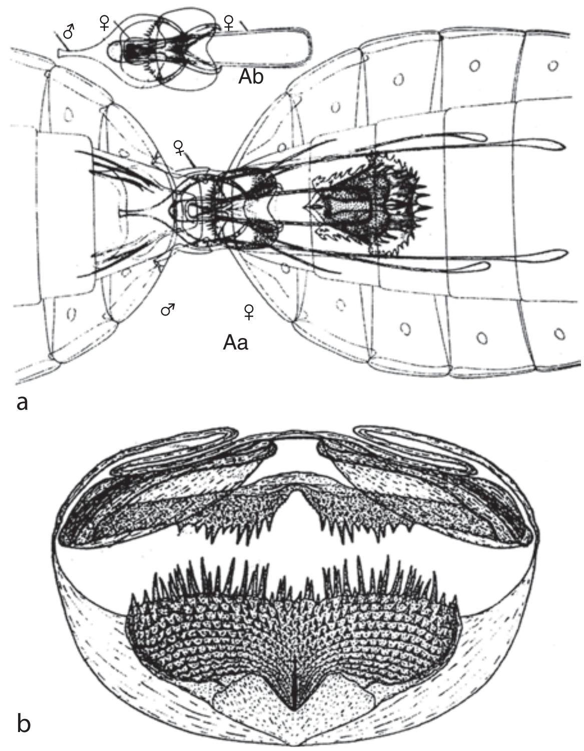
After removal of the left valve in an *Argynnis paphia* male, Bayard showed the strange mating procedures of that butterfly. In the male, the penis seems somewhat modified. The penis here is a massive asymmetric organ, laterally compressed and partly covered with strong spines set sideways. In the female, there exists an enigmatic organ, partly membranous, partly sclerotized, looking when at rest like an accordion in a rosette. It has been called a "clitoris," a "horn of plenty," and a "cornucopia." Mating among these insects seems to be a reversing of the normal relationships between male and female parts. The female enters in erection. In prolongation of the ostium bursae, this cornucopia is transformed into vulvar prolapsus. The inferior grooves of that organ give it a certain rigidity which transforms it into an accordion. This organ pumps the liquid semen from the spermatophore. This prolapsus, when resting, is folded upon itself but enters into erection when acting. In the male, the penis does not seem to move, but the male uncus folds down at its basal part and its terminal hook and crest catch the female prolapsus to direct the opening towards the ductus ejaculatorius. The adjustment of this female organ, extending toward the male during mating, is done through the hooks which grab the cornucopia. Thus, the female penetrates the male in a system which can look extravagant but works perfectly. The origin of the system is difficult to understand due to the fact that the evolution of the structure is not known among the genus *Argynnis* and relatives (Fig. 35).

Bayard describes analogous structures among other species of European *Argynnis*, including *A. pandora* (Denis and SchiffermÜller) and possibly similar facts exist among many or all (including Asian) species of the genus *Argynnis*. The interpretation of the bursa copulatrix remains to be restudied. Artificial mating must be conducted among other species of the genus to study the evolution of this strange morphology (Fig. 36).

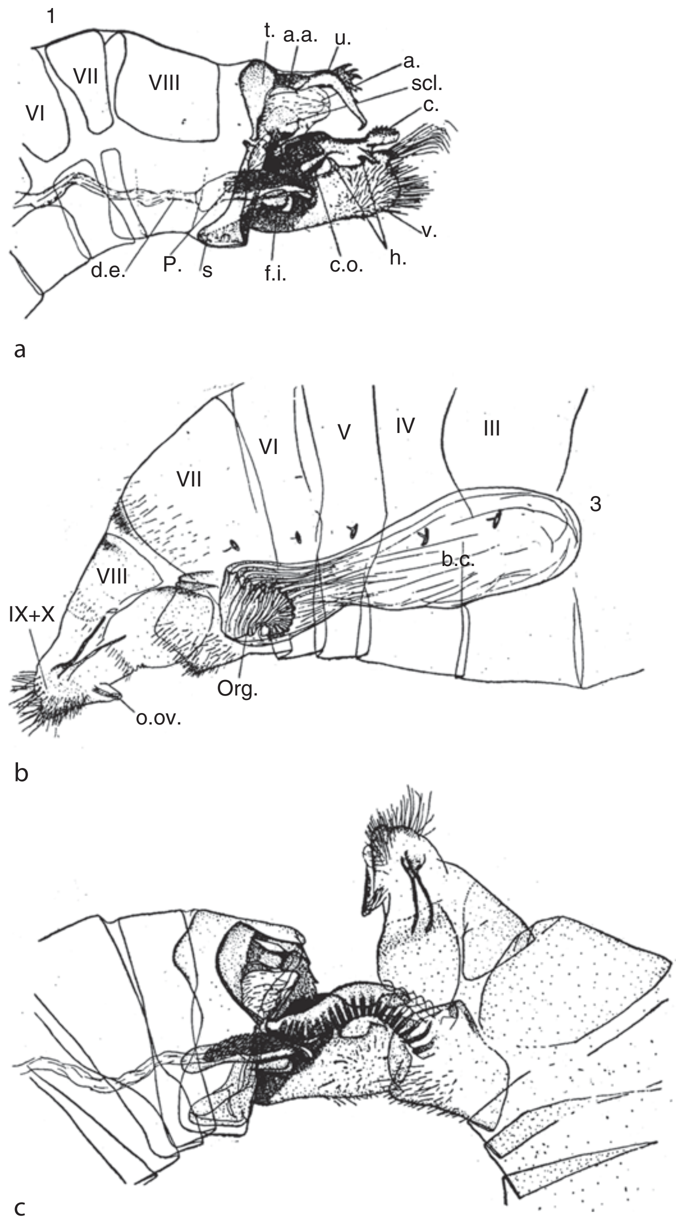


Inverted Copulation, Figure 35 **Evaginated terminalia of a plebejine (Lepidoptera: Lycaenidae). t VIII, eighth tergite; agg, left anterior apophyse; apg, left posterior apophyse; pa, anal papilla; stg, stigmate; s VII, seventh sternite; hps, hypostema; hn, henia; plg, genital plate (after Séguy, 1967.).**

Chapman described what seems to be a similar female erection among the *Plebejus* Klug (Lycaenidae, Polyommatini, Plebejini). According to the author, this phenomenon seems limited to the Plebejini. It is really an erection made with organs different from that of *Argynnis*. The female prolapsus is made of two parts: hypostema and henia. A henia is a distal, membranous, tubular part of an erectile everting apparatus by means of which ostium bursae can be extruded to contact the male in copula. An hypostema is the proximal sclerotized part of an erectile everting apparatus. Chapman gives his explanation without showing an illustration of the mating between the sexes. Several hooks maintain a contact of both female and male organs during



Inverted Copulation, Figure 36 **(a) Mating in *Cyphon kongsbergensis* (Scirtidae or Helodidae). The prehensor is in part inside the male abdomen (Ab). Diagram of the male-female interrelationships during mating. (b) Prehensor acting like a trap in *Cyphon coarctatus* Paykull (female) (after Nyholm, 1969.).**



Inverted Copulation, Figure 37 (a) Genital armature of *Argynnis paphia* (Linné), VI, VII, VIII, sixth, seventh and eighth abdominal segment; t, tegumen; a.a., angular appendix; u, uncus; a, anus; scl, sclerotized rackets; C, cercina; v, right valve, the left valve being removed; h, harpe; c.o., crista obliqua; f.i., inferior fultura; s, saccus; p, penis; d.e., ductus ejaculatorius. (b) Genital armature of *Argynnis paphia* (Linné) ♀, III to VIII, third to eighth abdominal segment; IX + X, last visible segment of the abdomen with its external apophyses; o.ov., ostrium oviductus; org., cornucopia; b.c., bursa copulatrix. (c) Diagram of the mating of *A. paphia* (Linné), according to a slide (after Bayard, 1945.).

the mating. Another interpretation of the evaginated henia would be that of a titillator organ and not a sperm pumping organ. The only way to settle this matter is to see a slide showing the sexes in copula. What is surprising is that in *A. artaxerces*, as in other species, the henia seems terminated by an enigmatic sclerotized genital plate. However, certainly this organ penetrates the male parts and it is difficult to see a titillator in this structure.

Probably, female erection exists elsewhere and has not yet be found. So complex and diverse are these structures that slides are necessary to visualize correctly the matching of the sexes in nature (Fig. 37).

Coleoptera

Among Scirtidae (Helodidae or Cyphonidae) with aquatic larvae, females possess a complex mating apparatus with a kind of forceps at the extremity, which acts as a jaw to receive the spermatophore from the male. This odd organ is found among certain species of the genera *Cyphon*, *Hydrocyphon* and related. However, it remains an exception.

Among Helodidae (Scirtidae), the male genital parts do not seem to penetrate much into the female parts. There exists, at the extremity of the female genitalia, an apparatus, the prehensor, made of two multidentate jaws, evoking a shark mouth. Nyholm distinguishes at the base of the female genital chamber two kinds of prehensors: the bimellater and the konfuser. This prehensor seems to seize the extremity of the spermatophore and to pull it into the vagina, then softening it and liberating the spermatozoa. Does the female organ really penetrate the male? It remains strongly probable. Although Nyholm's drawings are really difficult to interpret, others also have noted that because of the undifferentiated structure of the internal sac, mating was abnormal in the genus *Cyphon*, and that it remained possible that the female ovipositor was penetrating the male in the large median orifice.

Conclusion

More research is needed to clarify the previous examples where the female seems to penetrate the male during the mating to pump the spermatozoa. Other interpretations are possible, but this is the explanation suggested by most entomologists. Moths are easy to mate in the laboratory, but for butterflies artificial copulation is needed. Such observations are necessary among *Argynnis* and Plebejini and probably among other butterflies to interpret correctly this aberrant behavior and the exact mechanism used. At least, there are very peculiar anatomical designs. Mite behavior has also to be reexamined to see if such interpretations are sometimes possible.

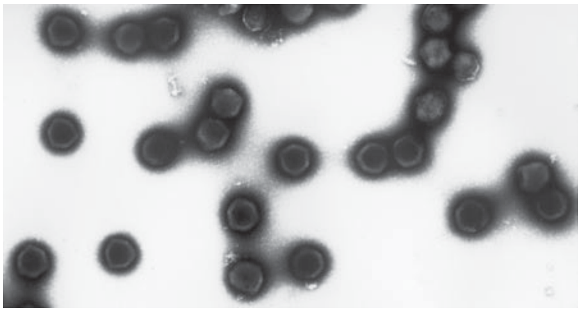
Iridescent Virus Disease

A disease of Diptera, Lepidoptera, and Coleoptera, caused by large icosahedral viruses that impart an iridescent color to host tissue; also known as iridovirus.

Iridoviruses

The iridoviruses produce large icosahedal particles (130–330 nm) which encapsidate a single dsDNA (150–350 kbp). Certain iridoviruses contain an outer envelope, whereas others appear non-enveloped. Various invertebrates, including crustaceans, annelids, nematodes and insects, are known to support iridovirus infections. To date, more than 30 insect iridoviruses have been detected in species of the orders Diptera, Lepidoptera, Coleoptera, Hymenoptera, Orthoptera and Hemiptera. Four genera are recognized: the *Ranavirus* (frog iridovirus), *Iridovirus* (small invertebrate iridoviruses), *Chloroviridovirus* (large mosquito iridovirus), and *Lymphocystisvirus* (fish iridovirus). Comparative restriction endonuclease digests and Southern blot analyses assign members of the genus *Iridovirus* into three subgroups: the *Polyiridoviruses*, *Oligoiridoviruses* and the *Crustaceoiridoviruses* (isopod). Individual iridoviruses have been assigned sequential numbers within a particular group. For example, the iridescent viruses from the cranefly *Tipula paludosa* and the beetle *Tenebrio molitor* have been assigned the types 1 and 29 within the serogroup IV.

Historically, the *Tipula* iridescent virus (TIV or Serotype IV1) was one of the initial models used to examine virus ultrastructure. The two-directional shadowing method, involving coating virus particles at two different oblique angles with metal vapors, demonstrated the icosahedral design of the iridovirus particle (Fig. 38). Structural elements of iridoviruses can be observed in partially disrupted ($CHCl_3$-treated) particles negatively stained with potassium phosphotungstate.



Iridoviruses, Figure 38 Transmission electron micrograph of a negative-stained preparation of icosahedral-shaped iridovirus.

The iridoviruses possess the characteristic 2, 3, and fivefold rotation axes of an icosahedron and consist of 12 pentagons and 20 triangles composed of 1,472 subunits. SDS-PAGE showed that purified iridoviruses contain a major structural protein (MSP, 50–55 kDa) which comprises over 40% of the virion mass as well as over 25 other structural peptides having M_r values ranging from 10 to 230 kDa. In addition to structural proteins, iridoviruses contain various enzymes, including an RNA polymerase, deoxyribonuclease, protein kinase, alkaline protease, phosphorylase, and an ATPase. The nucleocapsid may be surrounded by a viral unit membrane. The lipid composition of this membrane, comprising 4–9% of the virion, is characterized by an abundance of phospholipid and diglycerides.

The iridovirus genome consists of a linear single copy dsDNA molecule ranging in size from 150 to 280 kbp. These linear molecules are terminally redundant with up to 40% of the genome containing repetitive sequence elements. DNA molecules prepared by the Kleinschmidt method revealed linear dsDNA and a small number of circular dsDNA molecules. Tandem exonuclease and restriction endonuclease digestion of iridovirus DNA produced a decrease in amounts of all DNA fragments, suggesting that the genome is circularly permuted. The iridoviruses, which possess characteristics of the T-4 bacteriophage, are the only eukaryotic viruses possessing both terminal redundancy and circular permutation in their

DNA. Screening cloned restriction fragments or the dsDNA by plasmid rescue methods have identified the origin of replication at six sites on the *Chilo* iridescent virus (CIV) genome.

Unlike many DNA viruses, the extracted iridescent DNA is non-infectious when transfected into host cells. Certain insect iridoviruses replicate and produce plaques in insect cell culture. Interestingly, UV-irradiated virus causes the non-genetic reactivation of purified DNA, resulting in cell infection. Evidently, the inner membrane components of the virus particle possess potent biological activity and are capable of selectively switching off host cell biosynthetic events (phosphorylation of host ribosomal proteins and disruption of polyribosomes) and stimulating the transcription of the immediate-early genes of the viral genome.

Acute (patent) infections of host insects by iridoviruses usually result in an iridescent symptom. The coloration is caused by paracrystalline arrays of particles in infected tissues which create Bragg reflections of light. Patent infections result in the production of high numbers of progeny virus, which may comprise more than 25% of the insect body weight. In these cases, the iridovirus undergoes extensive replication in both mesodermal and epidermal tissues. Patently infected insects eventually will die or be cannibalized by conspecifics. The route of transmission of iridoviruses is unclear. Oral ingestion, wound-entry, transovarial transmission, contamination of egg chorion, and entry through spiracles are routes that have been suggested to operate in natural host populations. Under laboratory conditions, feeding healthy insects large quantities of virus results in low infection rates, whereas hemocoelic injection causes significantly higher infection levels.

Historically, surveys of host populations have demonstrated that the frequency of iridoviruses is very low. In most cases the presence of the iridescent symptom has been the chief diagnostic tool and may have caused the underestimation of iridovirus levels. Population samples consisting of more than a million larval blackfly (*Simulium*) contained only 12 individuals exhibiting acute iridovirus symptoms. However, injection of homogenates of apparently healthy-looking blackfly larvae into the permissive larvae of the wax moth, *Galleria mellonella*, revealed that about 40% of the sampled blackflies supported covert iridovirus infections. Utilizing primers designed from the MSP gene, a series of amplification using the polymerase chain reactions (PCR) method were conducted on DNA samples extracted from simuliid larvae. The frequency of PCR-positive larvae was found to vary between 17% and 37%, confirming the chronic nature of iridoviruses. Restriction endonuclease digests of the blackfly iridoviruses amplified in *G. mellonella* larvae produced extensive polymorphisms, suggesting a complex of iridoviruses in these insect populations.

Ironclad Beetles

Members of the family Zopheridae (order Coleoptera).

► Beetles

Ironomyiidae

A family of flies (order Diptera).

► Flies

Ischnopsyllidae

A family of fleas (order Siphonaptera). They sometimes are called bat fleas.

► Fleas

Island Biogeography

The study of species distribution and community composition, on islands or in island-like environments.

Iso-Amyl Acetate

A sting gland alarm pheromone of *Apis* bees. Release of this compound releases attack behavior by bees.

Isonychiidae

A family of mayflies (order Ephemeroptera).
► Mayflies

Isoptera

An order of insects. They commonly are known as termites.
► Termites

Isotomidae

A family of springtails in the order Collembola. They commonly are known as smooth springtails.
► Springtails

Isozyme

An isomer of an enzyme. Various structurally related forms of the same enzyme having the same function but differing from each other in chemical or immunological characteristics.

Issidae

A family of insects in the superfamily Fulgoroidae (order Hemiptera). They sometimes are called planthoppers.
► Bugs

Iteroparous

This term is used to describe insects that are long-lived as adults, and that deposit their eggs singly or in small batches throughout the adult stage. It is used mostly in the description of mosquito biology.
► Semelparous

Ithonidae

A family of insects in the order Neuroptera.
► Lacewings, Antlions and Mantidflies

Ithycerid Beetles

Members of the family Ithycridae (order Coleoptera).
► Beetles

Ithyceridae

A family of beetles (order Coleoptera). They commonly are known as ithycerid beetles.
► Beetles

J

Jacquelin Du Val, Pierre Nicolas Camille

Camille du Val was born at Prades, southwestern France, on July 28, 1828. A sickly child from the age of five, he had no distractions from study and work, and was a brilliant scholar. He travelled to Paris in 1849 to study medicine, and there met some young entomologists, including Laboulbène who helped him join the Société Entomologique de France. This changed his career plans. His first entomological publication was in 1850. His first major entomological paper, a masterly work, was on European species of the genus *Bembidion* (Carabidae) in 1852. This resulted in Guérin Méneville charging him with writing the section on Coleoptera for Sagra's "Histoire physique, politique et naturelle de l' Ile de Cuba. Animaux articulés, insectes, coléoptères," pp 1–136 (1856), pp 137–326 (1857). He published other papers in the Annales de la Société Entomologique de France. A tireless worker, he dreamed of a general work on European beetles. This began as "Genera des coléoptères" in 1857; he managed two more volumes, and Fairmaire achieved its volume 4 in 1868. Equally, the journal that he founded, "Glanures entomologiques," achieved its first two volumes in 1860, but was not continued. His death softened by the presence of his family, he died on July 5, 1862. He left a valuable collection of European beetles, classified according his work "Genera des coléoptères."

The Japanese beetle, *Popillia japonica* Newman, is the most widespread and destructive pest of turf and landscape plants in the eastern United States. Adults feed on the leaves, flowers, or fruits of nearly 300 species of wild or cultivated plants including trees and shrubs, garden plants, fruits, and crops such as corn and soybeans. The soil-dwelling larvae, or grubs, consume roots of turf and pasture grasses, vegetables, nursery seedlings, and field crops. Hundreds of millions of dollars are spent each year for managing the beetles and grubs, and for state and federal regulatory efforts aimed at limiting the beetle's rate of spread within the United States and elsewhere.

Japanese beetles were first found in North America in 1916, near Riverton, New Jersey. The manner by which the species was inadvertently transported from its native Japan is not known;

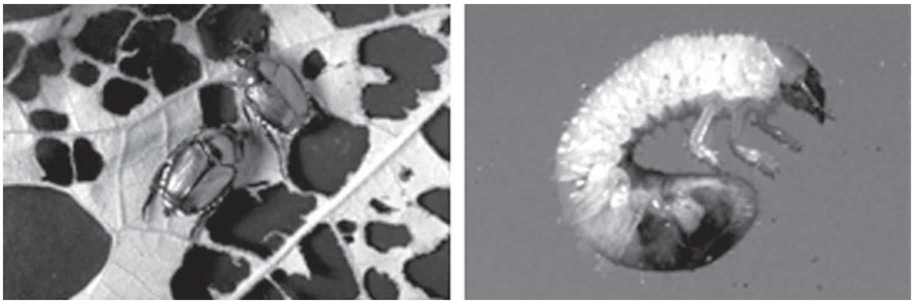
however, the grubs may have arrived in soil about the roots of nursery plants. It is considered a minor pest in Japan, where much of the terrain is unsuitable for larval development, and because natural enemies keep it in check. The eastern United States, however, provided a favorable climate, many adult food plants, lush grassland habitat for the grubs and, at that time, no host-specific natural enemies. Populations rapidly increased and spread. By 2001, the beetle was established in all states east of the Mississippi River except for Florida, and in parts of Arkansas, Iowa, Kansas, Minnesota, Missouri, Nebraska, Oklahoma, Texas, and Wisconsin. It also has spread into southern Ontario and Quebec, Canada. Isolated infestations that were found in California, Idaho, Oregon, Nevada, and Washington probably originated from beetles that were accidentally transported in commerce. Eradication and quarantine efforts have so far prevented establishment in western states.

Japanese beetles belong to the family Scarabaeidae, subfamily Rutelinae. Adults are broadly oval, 8–11 mm long and 5–7 mm wide. The body is metallic green, with coppery-brown elytra that do not quite reach the tip of the abdomen. Each side of the abdomen has five patches of white hairs, and there is another pair of white tufts on the dorsal surface of the last abdominal segment. Females usually are slightly larger than males. The sexes can be distinguished by slight differences in the tibia of the foreleg. The female tibia ends in an elongate, spatula-shaped spur, used for digging. This spur is shorter and more pointed in males.

Larvae are typical scarabaeiform grubs: C-shaped (Fig. 1), whitish to grayish, with three pairs of jointed thoracic legs, a yellow-brown head capsule, and chewing mouthparts. Neonate grubs are about 1.5 mm long; full-sized third instars are about 32 mm long. The ventral side of the last abdominal segment bears a scattering of rather long brown hooked spines, as well as many yellowish hairs at the sides and end. Medially, two rows of shorter straight spines are arranged in the form of a truncated "V." This pattern distinguishes Japanese beetle larvae from other common scarabs. The end of the abdomen appears dark because of ingested soil and food.

Japanese beetles have a 1-year life cycle throughout most of the species' range. In most areas, the beetles begin to emerge in early to mid-June, and adult activity extends into August. Virgin females emit a potent sex pheromone. Early in the seasonal flight period, males fly over stands of grass in search of mates, and jostling clusters of a dozen or more males may accumulate around a single emerging female. Females also re-mate on food plants between bouts of egg-laying.

The beetles typically feed from the upper surface of leaves, leaving only a lace-like skeleton of veins. They also feed on the petals of certain flowers (e.g., roses, hibiscus), as well as developing fruits and berries. Where the beetle is abundant, preferred hosts such as grape, sassafras, and linden may be completely defoliated. Host plants growing



Japanese Beetle, *Popillia japonica* Newman (Coleoptera: Scarabaeidae), Figure 1 ***Left*: Japanese beetles with characteristic feeding damage. *Right*: Japanese beetle grub.**

in sunny locations are preferred. Usually the beetles begin to feed on foliage near the top of a plant, regardless of its height. They tend to aggregate on shoots or plants that have been damaged by other Japanese beetles. This phenomenon results from both sexes being attracted to blends of aromatic volatile compounds released from beetle-damaged leaves.

Despite the beetles' broad host range, some plant species are rarely or never fed upon. Closely-related cultivars within plant species also may differ in susceptibility. The beetles' dietary preferences are probably determined, in large measure, by deterrent or toxic secondary plant compounds. Some plants, e.g., geranium (*Pelargonium × hortorum*), are palatable to the beetles but cause paralysis or other toxic effects when eaten.

After feeding, females fly to a suitable site in which to lay eggs. Areas with moist, loamy soil covered with turf or pasture grasses are preferred. Eggs are deposited in small clutches (1–4 eggs), mostly in the upper 8 cm of soil. The cycle of feeding and oviposition is repeated every few days. A female beetle may live for 30–45 days, during which she may deposit 40–60 eggs.

Eggs are pearly-white, and about 1.5 mm long. They are ovoid at first, becoming more spherical as they absorb moisture from the soil. Eggs hatch in about 2 weeks, usually by early to mid-August, and the grubs feed on fine roots and organic matter, mainly in the upper 5 cm of soil. When grubs are numerous, the root system of turf grasses may be completely severed, such that the turf wilts and dies, and can be pulled from the soil like loose carpet. Most grubs are third instars by late September. They feed until about the time of first frost, and then burrow deeper (about 15–30 cm) to overwinter. They begin to move back up into the root zone in early spring when soil temperatures warm to about 50°C. They feed for another 4–6 weeks, then go slightly deeper and form an earthen cell in which to pupate. The first adults begin emerging a few weeks later.

Skunks, raccoons, moles, shrews, and birds dig in infested areas to forage on the grubs. Indigenous predatory insects, including ants and ground beetles, consume the eggs and young larvae. Birds, toads, fish, and other insectivores eat the adults. From 1920 to 1933, entomologists searched for natural enemies of the Japanese beetle and other closely-related scarabs in Asia, mainly Japan and Korea. Numerous species of predaceous and parasitic insects were imported and released in the hope that biological control could be attained. Only a few of these became established in the eastern United States. The most widely-distributed are *Tiphia vernalis*, a tiphiid wasp whose larvae are ectoparasitoids of the grubs, and *Istocheta aldrichi*, a tachinid fly that parasitizes the adults. Japanese beetle grubs are susceptible to parasitic nematodes (e.g., *Steinernema* and *Heterorhabditis* spp.), as well as several lethal microbial pathogens, especially the milky disease bacterium *Paenobacillus popilliae*.

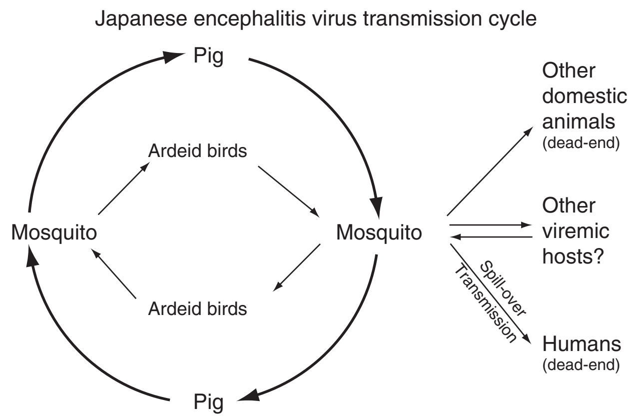
Japanese Encephalitis

FELIX P. AMERASINGHE
International Water Management Institute, Colombo, Sri Lanka

Japanese encephalitis is the most important cause of epidemic encephalitis in the world. Japanese encephalitis is a mosquito-borne viral infection of the nerve cells (neurons) of the brain. Fever, headache, vomiting, depressed mental status, coma and death characterize the disease. The immune systems of most infected humans are able to destroy the virus, but between one in 100 to one in 500 people develop symptoms of the disease. Approximately 3 billion people (60% of the world's population) live in Japanese encephalitis endemic areas, and roughly 50,000 clinical cases are reported each year. Approximately 20% of clinical cases succumb to the disease, and 20–50% of the survivors suffer from temporary or permanent physical and mental disability. The virus, known as the Japanese encephalitis virus is transmitted from host to host by mosquitoes across much of tropical and temperate Asia. It was first isolated in Japan in 1935 (hence the name of both the virus and the disease). Japanese encephalitis outbreaks have been reported from Bangladesh, India, Nepal and Sri Lanka in South Asia, through most countries of Southeast Asia, to China, Japan, Korea, Taiwan and southeastern Siberia in the east. Until recently, Japanese encephalitis did not appear to extend east of Bali in Indonesia, but in 1995 outbreaks of the disease occurred in the Torres Strait islands of Australia near the border with Papua New Guinea. Over the past decade, case rates have been the highest (3–5 cases per 100,000 people per year) in countries like China, Laos, Nepal, Sri Lanka, Thailand and Vietnam, and the lowest (0.1–0.2 cases per 100,000) in countries like Indonesia and Japan.

Japanese encephalitis belongs to a group of viruses commonly known as arboviruses because they are carried (transmitted) by arthropods (jointed-legged invertebrates such as insects, ticks, etc.). It is classified under the *Flavivirus* genus within the family Flaviviridae, and is related to other encephalitis-causing viruses like Murray Valley Encephalitis virus, Saint Louis Encephalitis virus, tick-borne encephalitis virus, and West Nile virus. The virus enters the body of a mosquito via the blood when it feeds on an infected host. The virus particles proliferate inside the mosquito, migrate to the salivary glands, and are expelled with the saliva when the mosquito feeds again. This process can take 7–14 days, depending on ambient temperature. Mosquitoes of the genus *Culex* are the primary vectors (carriers) of Japanese encephalitis virus. The most important vector throughout much of Asia is *Culex tritaeniorhynchus*. Other species are more locally important: *Culex vishnui* in India, Taiwan and Thailand; *Culex gelidus* in Indonesia, Sri Lanka, Thailand and Vietnam; *Culex fuscocephala* in Malaysia, Sri Lanka, Thailand and Taiwan; *Culex annulus* in Taiwan. Also, these mosquito species (especially *Culex tritaeniorhynchus* and *Culex vishnui*) are associated with rice land ecosystems because they breed prolifically in rice fields. Thus, rural rice ecosystems are the major areas where virus transmission occurs.

The virus transmission cycle (Fig. 2) in nature is not well understood, but is thought to involve wild birds, bird-feeding (ornithophilic) mosquitoes, and possibly other susceptible vertebrate hosts. Birds belonging to the Family Ardeidae (egrets, herons, storks, etc.), are believed to be the most important hosts of the virus in nature, and migratory birds are especially important in virus dispersal. Pigs (and in some instances ardeid birds) are the major vertebrate hosts involved in the peridomestic Japanese encephalitis transmission cycle. These animals are extremely susceptible to the virus, develop high levels of virus in their blood and can pass it on to blood-feeding mosquitoes. Thus, pigs are known as "amplifying hosts" for Japanese encephalitis. However, the virus does not adversely affect the health of pigs except in the case of pregnant sows that tend to abort their fetuses as a result of virus infection. Other domestic animals (goats, sheep, cattle, buffalo, chickens, etc.) are known to get infected and show antibodies to Japanese encephalitis virus in their blood. However, it is generally accepted that they do not develop a sufficiently high viremia (blood virus level) long enough for significant transmission to mosquitoes. They are thus known as "dead-end" hosts because they are not involved in the onward transmission of the virus. The "dead-end" domestic animals, too, do not generally show any ill effects



Japanese Encephalitis, Figure 2 **Virus transmission cycle of Japanese encephalitis.**

from virus infection, with the exception of horses that can develop fatal encephalitis. Humans also are dead-end hosts, but as with horses, humans can develop severe illness as a result of virus infection.

The Japanese encephalitis vector mosquito species are primarily zoophilic (i.e., prefer to feed on animals rather than humans), so the main cycle of virus transmission is known as a zoonotic cycle involving mosquitoes and susceptible wild or domestic hosts. Transmission to humans occurs when mosquito abundance reaches such a high level that infected mosquitoes encounter and feed on humans. This is known as "spill-over" transmission. Outbreaks of Japanese encephalitis occur when there is a convergence over time and space of the virus, amplifying hosts and vector mosquitoes. This often occurs in the rainy season in tropical countries or in the spring in more temperate areas when vector mosquito densities increase dramatically. Irrigated rice lands also are prone to Japanese encephalitis outbreaks associated with the increased vector abundance resulting from releases of irrigation water for cultivation. Rearing pigs in irrigated rice lands is especially dangerous, because it brings the amplifier host into a human-occupied environment where there is intense vector breeding. Pigs have a high reproductive rate and are bred almost exclusively for the food industry, so there is a rapid turn-over of these animals – typically they are slaughtered at 6–9 months of age. Thus, newly bred uninfected swine hosts are always available for Japanese encephalitis virus amplification in areas where extensive pig husbandry is practiced.

Measures used to control the transmission of Japanese encephalitis include the control of mosquito breeding in rice fields through proper water management, mosquito-proofing pig sties, personal protection measures against mosquito bites, and immunization of both humans and swine.

► Diplurans

Jeannel, René

René Jeannel was born in 1879. Son and grandson of medical doctors, he was interested in insects since childhood, but studied medicine in Paris. He decided to work on a degree in science followed by doctoral studies at the Sorbonne. Some invertebrates that he had collected in a cave in southwestern France (described in part in 1905 in his second entomological paper) drew the attention of Emil Racovitza, who began to include René in 1905 in a huge project to explore the zoology of the subterranean world. His doctoral thesis in medicine (surgery) was published in 1907. From 1908 to 1912 he worked alongside Racovitza at the Arago laboratory. In 1912 he moved to the entomology laboratory of the Muséum National d'Histoire Naturelle, and worked there until 1914, the outbreak of World War I. In 1919–1920 he worked in the faculty of sciences at Toulouse, France, but in 1920 was appointed professor at the university of Cluj in Romania. In 1927 he returned to France as professor at the Muséum National d'Histoire Naturelle and director of the museum's vivarium. His overseas explorations were with Charles Alluaud in 1912–1913 to eastern Africa, with Arambourg and Chappuis in 1932–1933 to eastern Africa, and on the voyage of the Bougainville to the subantarctic Kerguelen and Crozet islands in 1938. He also explored caves in the eastern USA in August-September 1928 following the International Congress of Entomology in Ithaca, New York. His interests were in systematics and speleology, with a strong component of biogeography. He quickly recognized the importance of Wegener's theory of plate tectonics. His taxonomic interests were in the families Carabidae and Catopidae (now called Leiodidae), and Pselaphidae (subsequently reclassified as subfamily Pselaphinae of Staphylinidae). A long series of publications recounted cave explorations and discoveries, and dozens of these were published in a numbered series called "Biospeologica" in the pages of the journal Archives de Zoologie Expérimentale et Générale. His works on the taxonomic groups of his interests were of worldwide scope, including, for example, studies of all three in southern South America, published in volume 1 of "Biologie de l' Amérique australe" (1962). His huge output of publications was a model for colleagues and students alike. Married and with children and grandchildren, he died on February 20, 1965.

Jerusalem Crickets (Orthoptera: Stenopelmatidae)

David B. Weissman, Amy G. Vandergast
Norihiro Ueshima
California Academy of Sciences,
San Francisco, CA, USA
US Geological Survey, San Diego, CA, USA
Matsusaka University, Matsusaka, Mie, Japan

Four extant New World genera, herein collectively referred to as Jerusalem crickets, comprise the subfamily Stenopelmatinae, family Stenopelmatidae in the order Orthoptera. These genera are *Stenopelmatus* (with 33 described species), *Ammopelmatus* (2), *Viscainopelmatus* (1), and *Stenopelmatopterus* (3). Species are frequently distinguished by a combination of subtle morphological characters present only in adults, karyotype number, geographical distribution, calling-drum patterns, and mitochondrial DNA (mtDNA) profiles.

The Entomological Society of America's common name directory lists "Jerusalem cricket" as applicable only to *Stenopelmatus fuscus*, a species restricted to northern New Mexico and adjoining northeastern Arizona. Unfortunately, this name has been applied by various authors to many species ranging from the California Pacific coast north into Canada, east to the Great Plains, and south into Mexico. Because of such taxonomic confusion and general physical similarities between species, we have decided to call all individuals of the subfamily "Jerusalem crickets" until Weissman's revisionary studies are completed.

Jerusalem crickets are distributed (Fig. 3a) in the western half of the U.S. and throughout Mexico and Central America. Though 17 species are described from the United States and Canada, we estimate that three times that many species are undescribed. Similarly impressive biodiversity occurs in Mexico and Central America where 19 species are named and dozens of taxa are unnamed. Two described species have no locality data. The three heaviest insect species, on average, in California are undescribed Jerusalem crickets that easily reach about 7.5 cm in length and weigh up to 13 g.

Origin of Common Name

In the United States, stenopelmatids are called sand crickets, stone crickets, potato bugs, skull insects, and most commonly Jerusalem crickets. The last name is preferred since using it would eliminate confusion with any other insect group. "Jerusalem cricket" appears to be derived from jargon of young boys of the nineteenth century. The epithet "Jerusalem" was commonly used as a swear word by any young lad who was suddenly startled or surprised by a natural phenomenon. Additionally Berrey and van den Bark's 1953 *American Thesaurus of Slang* lists both "Jerusalem!" and "cricket!" as expletives. Thus, R. Doutt envisioned a rural boy in the western United States turning over a rock and in surprise shouting, "Jerusalem! What a cricket."

In various parts of Mexico, Jerusalem crickets are called niña de la tierra (child of the earth) or cara de la niña (face of the child). They are universally, and mistakenly, thought to be poisonous.

Determination of the Adult Stage

Females: Adult females are distinguished by a darkened (at least at the tips and on the ventral surfaces), sclerotized ovipositor (Fig. 3b), the four components of which develop progressively with each molt.

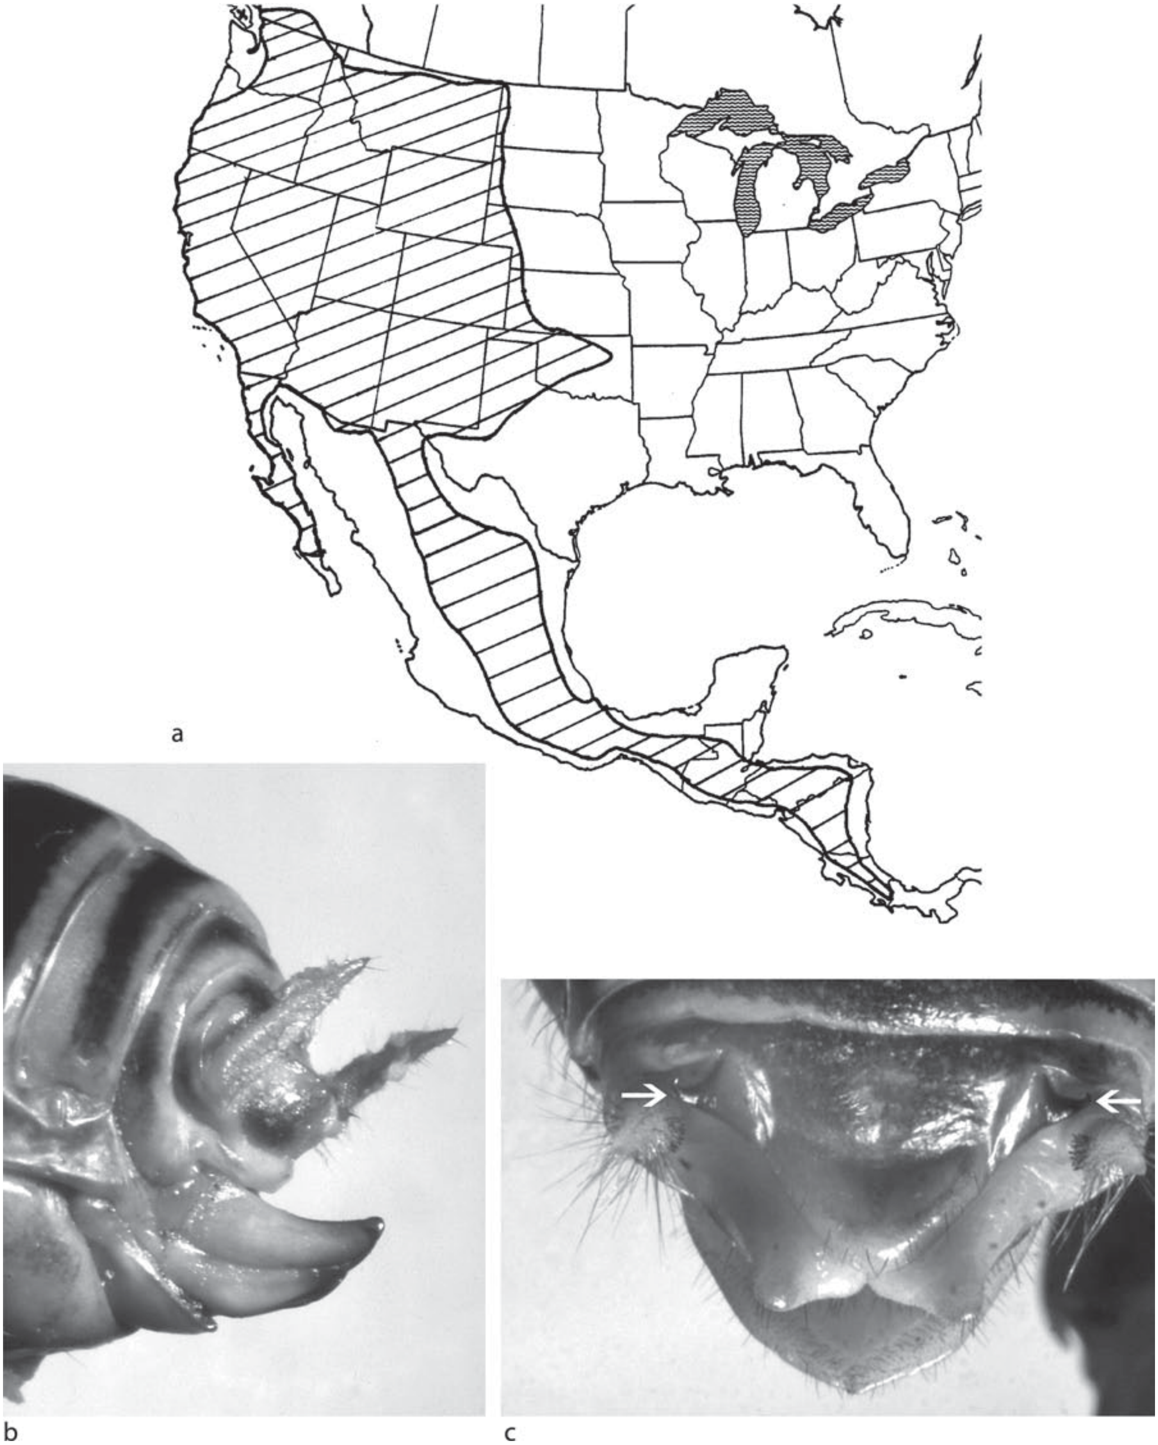
Males: Adult males have two fully developed, black, sclerotized, incurved hooks located medial to each cercus (Fig. 3c). These hooks develop gradually with each molt starting from tiny ridges barely visible in early instars. The hooks are used in mating and their importance is discussed later.

Karyotype

Jerusalem crickets have the typical orthopteran male XO/female XX sex determination system. Analysis by N. Ueshima shows that two Jerusalem cricket species have 19 chromosomes in the male and three species have 21. Another 150 individuals, probably representing some 80–90 species, have been karyotyped, and the 25 karyotype number was found twice as often as the 23 number.

Life Cycle

Most Jerusalem cricket species require 1¾ years from egg hatch to maturity (molt to adult), although some individuals in populations at high elevations and/or northern latitudes, with their shorter growing season, may require an extra year. Individuals of most species become adult in midsummer, with members of some California species maturing a month or two later. There is no obvious protandry, wherein males mature before females. Adult males disappear in the field before adult females, apparently due to a combination of



Jerusalem Crickets (Orthoptera: Stenopelmatidae), Figure 3 **Characteristics of Jerusalem crickets: (a) distribution (*stippled area*) of the Jerusalem crickets in North and Central America; (b) adult female Jerusalem crickets are characterized by a pointed, sclerotized, dark ovipositor; (c) adult male Jerusalem crickets are characterized by completely formed hooks (*arrows*).**

shorter life span (as documented in laboratory specimens) and sexual cannibalism (see below). At least two southern California species have a summer adult aestivation period where they are physically active but do not drum and are sexually unreceptive.

Eggs apparently are laid underground soon after mating, as indicated by the fall appearance of tiny nymphs. It is unknown if eggs have any dormancy period since Weissman has never been able to get females to oviposit in the laboratory, nor has he collected egg clutches in the field. Jerusalem crickets probably have from 9 to 12 molts before becoming adult, but since all individuals quickly eat their cast skins, such determination is imprecise. There is no evidence of prenatal care.

Adult females live from 6 to 12 months in the laboratory. Adult males live about half as long as females.

Ecology

Within the United States, Canada, Baja California, Mexico, and northern mainland Mexico, various Jerusalem cricket species live in most available habitats from oak savannah, grassland, chaparral, coastal and inland sand dunes to above the tree line. These species are generalists and a laboratory diet of organic romaine lettuce (for water), and dry cat and rabbit food, along with uncooked old-fashioned oats, is adequate for rearing. Many sand dune inhabiting species are endemics restricted to that particular dune system. Jerusalem crickets are absent from both salt and fresh water habitats, and desert areas of high alkalinity or salinity.

Once south of the United States-mainland Mexico border, and throughout their distribution as far south as southern Costa Rica, most Jerusalem cricket species are associated with some combination of high elevation, cool and moist, cloud forest type environment. The largest group is characterized by tens of species, most undescribed, where individuals readily hop upwards to 10 cm. These fast moving, good climbing, "spiny" and thin-legged individuals, occasionally with wing pads or completely developed wings, all appear to be active obligate predators. These species seek daytime refuge in downed forest trees (where they may eat co-inhabiting beetle larvae), possibly ascending at night into vertical trees to hunt live arthropods. They are most easily captured by tearing apart such downed, rotting trees, using a pickax or similar tools during daylight. The wetter and cooler the weather, the higher the rate of successful discovery.

Jerusalem crickets are large morsels of food and are eaten by many nocturnal predators, including foxes, skunks, bats, opossums, various owl species, various rodents, tropical vipers, and scorpions. Because of such risks, Jerusalem crickets employ several defensive strategies: they are largely nocturnal in activity; frequently flip on their backs with strong mandibles (which can draw human blood) agape when disturbed; employ abdominal-femoral defense stridulation; can kick with long, sharp, hind leg tibial spines; and some taxa have an offensive-smelling anal discharge. They are parasitized by tachinid flies (Diptera: Tachinidae), hairworms (Nematomorpha), and mermithid (Nematoda: Mermithidae) worms.

Different Jerusalem cricket species are rarely microsympatric, two species having been found together at only 30 localities (out of thousands) involving 20 different species-pairs. They may be commensals in *Pogonomyrmex* harvester ant nests in the southwestern United States.

Drumming and Communication

Jerusalem crickets are generally nocturnal and largely subterranean, thus limiting the effectiveness of visual and olfactory communication. They also do not fly, in spite of several species having fully developed hind wings. Jerusalem crickets have no auditory tympana to detect airborne sounds, nor does any species have wings with a sound producing apparatus. Information on location, distance, and sometimes sex, is exchanged via ground transmission of impulses produced by the abdomen (and sometimes the thorax-abdomen unit) striking the substrate (drumming), producing a percussion wave. These ground impulses are detected by other Jerusalem crickets through their subgenual organs, which are located in the proximal tibiae of all six legs and are the most vibration-sensitive organs in any insect group. Subgenual organs also respond to high intensity airborne sounds. Both sexes of all species drum spontaneously, sometimes producing sounds audible at 20 m.

There are four types of drumming. "Calling" drums are, in many cases, species-specific and spontaneously made by isolated adult males and females. This drumming is as valuable a taxonomic character as the species-specific calling songs of field crickets and katydids because it appears to serve in uniting the sexes. These drums vary in complexity among species and range from a series of single strikes at rates of 0.5–15 drums per second, to groupings of strikes with rates approaching 40 drums per second (Fig. 4b). In several species, the male and female drum differently (Fig. 4a) thus permitting long range sex determination. Calling-song drumming rates in Jerusalem crickets vary linearly with temperature. Those species with fast rates increase their drumming speed more for a given temperature rise than does a slower drumming species. While drumming speed appears to be unrelated to body size, it may be related to substrate consistency and/or density: sand-dune-inhabiting taxa all drum relatively slowly.

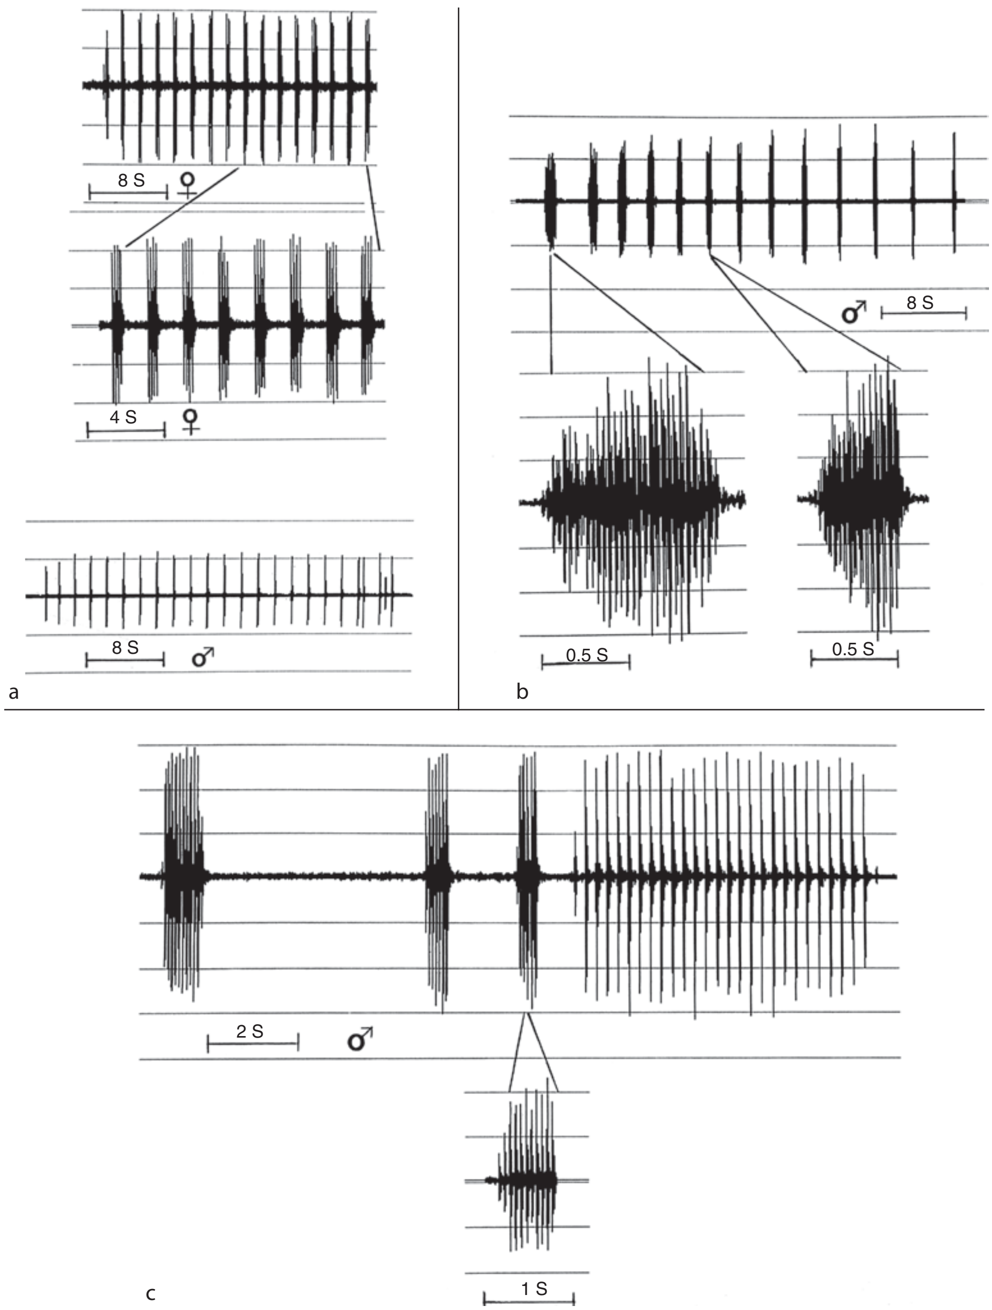
Presumptive "sex clarification" drums are produced by adult males of certain species. These are a series (Fig. 4c) of fast, very loud, non-species-specific drums produced when these males detect their calling drum. Sex clarification drums occur only in species where the male and female have the same calling drum, and one sex cannot tell who they are answering. In the field, this answering strategy should enable males to conserve energy and avoid possible injury or predation by not searching for other males. Sex clarification drums are unknown from any of the eight species where males and females drum differently, since each sex can identify the other sex by drum.

"Courtship" drums are frequently made by males (and less commonly by females) when two adults of either sex are within 6 cm of each other. This drumming consists of short series of barely audible, non-species-specific abdominal strikes or tremulations (where the abdomen does not make surface contact) at a rate of two to four per second.

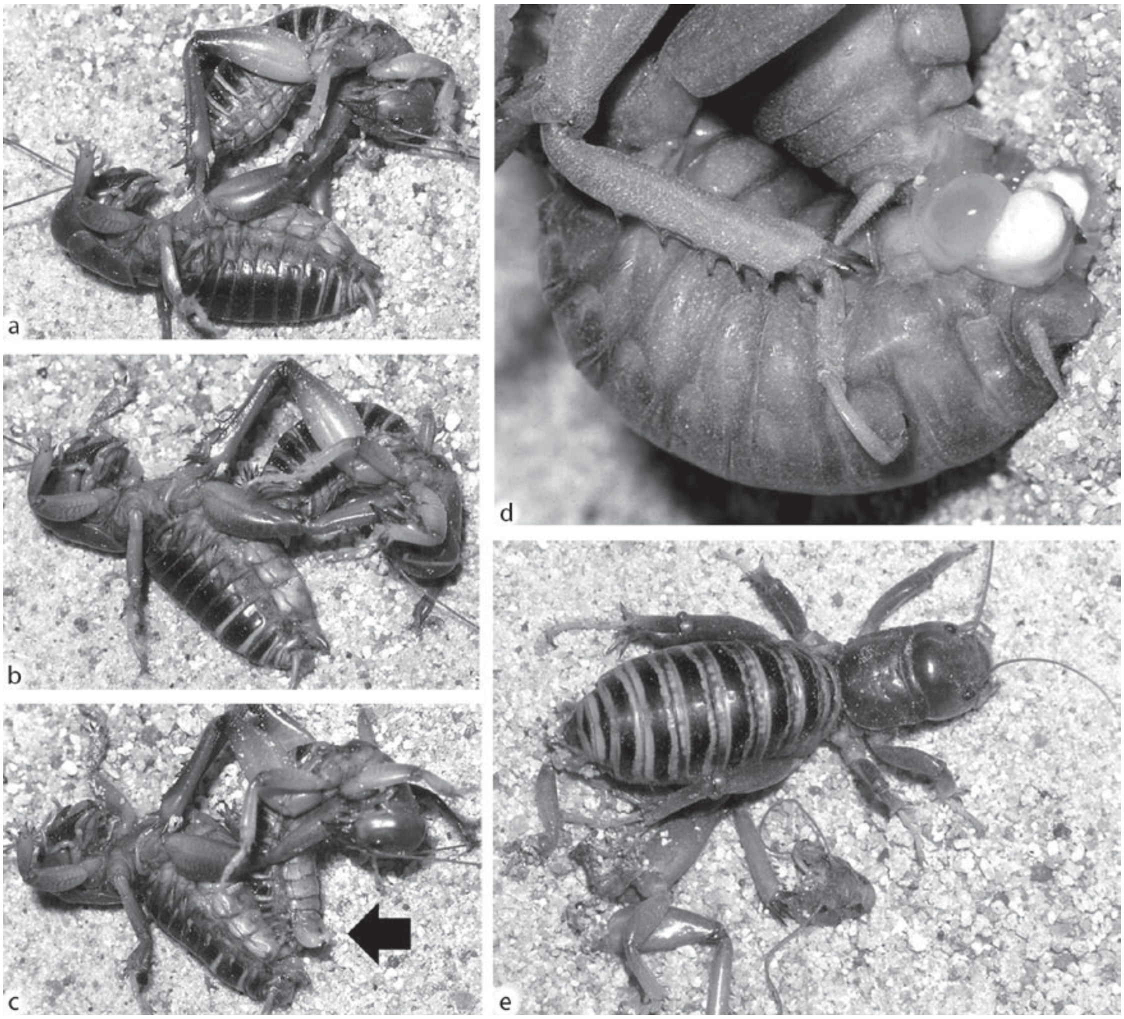
"Nymphal" drums are known from at least 25 species. They have the same pattern as the adult species-specific calling drum, but are produced less frequently, are usually of shorter duration, and are rarely heard during more than one instar. These subadult Jerusalem crickets do duet with other nymphs and adults, although the function of such drumming is unknown.

Mating

Jerusalem cricket orientation during mating appears to be unique among orthopteroid insects, if not among all insects. The male initiates the process by rolling on his side. Once the female is also on her side, the male assumes a lateral position beside her but facing in the opposite direction (Fig. 5a). He bites one of her hind tibiae (doing no damage), positions his hind tarsi near her coxae, and curls his abdomen (Fig. 5b) between his hind legs and her hind legs toward her subgenital plate, a maneuver that often requires several minutes of adjustments. As the male's telescoping abdomen nears the female's subgenital plate, he positions his hooks underneath a terminal ventral plate. This provides the necessary anchor as he everts his phallic lobes (Fig. 5c) and makes contact with her subgenital plate area. Immediately upon contact, a bilobed ampulla containing sperm is passed to the female and the everted phallic lobes then empty and deposit a sticky bilobed spermaphylax lateral to each ampulla lobe (Fig. 5d). The complete structure takes 10–20 s to transfer and weighs from 3 to 7.5% of the male's body weight. The spermatophore is not eaten by the female.



Jerusalem Crickets (Orthoptera: Stenopelmatidae), Figure 4 **Calling song (a) of southern California Jerusalem cricket species where female and male drum differently: female song (*top, middle*) composed of five trills (four drums per trill) in 8.5 seconds at 18°C male song (*lower*) composed of 10 single drums in 16 seconds at 20°C; (b) calling song of central California Jerusalem cricket species consists of grouping of strikes (trills), the drumming rate within a trill approaching 40 times per second at 20°C. This is the fastest drumming Jerusalem cricket; (c) three series of sex clarification drum in a Nevada Jerusalem cricket were followed by a calling song drum, all at 20°C. Sex clarification drum rate around 15 per second; calling drum rate around 4 per second.**



Jerusalem Crickets (Orthoptera: Stenopelmatidae), Figure 5 **The mating ritual: (a) early mating stage in central California Jerusalem cricket species. Male (*top*) is biting female's right hind tibia while facing in opposite direction; (b) male (*top*) is biting female's right hind tibia while positioning his hind legs and starting to curl his abdomen; (c) male (*top*) curling his abdomen between female's hind legs toward her subgenital plate and setting his hooks. Note his everted phallic lobes (*arrow*); (d) mating finished. Male (*top*) has passed spermatophore composed of whitish bilobed ampulla and clear bilobed spermatophylax. Note tip of ovipositor visible between ampulla lobes; (e) female has consumed male after mating.**

In both nature and the laboratory, some 10% of matings end with the male permitting the female to eat him alive. In these first described cases of male-complicit postcoital sexual cannibalism, the male remained motionless while the female consumed him (Fig. 5e). As both males and females can and will mate repeatedly, the function of this behavior is unknown.

Systematics

A. Vandergast has examined the evolutionary patterns of acoustic signaling and karyotype number changes within the context of molecular phylogeny in the North American Jerusalem crickets. These phylogenies are highly concordant with major song characteristics and geographic regions. Specifically, she found that species producing single drums group in a well supported monophyletic clade. Additionally, single drum species that produce a sex clarification drum (see Fig. 4c) also fall out together. Species with groupings of strikes are restricted to the Pacific coast states of California, Oregon and Washington, usually within 100 km of the coast. Lastly, those seven undescribed species from southern California and Baja California, Mexico, where males and females drum differently, also form a well-supported monophyletic lineage. When karyotype numbers were integrated into the molecular phylogeny, she found evidence for at least five independent fusion events leading to loss of chromosomes, and potentially one fission event (2N = 19 to 2N = 21) throughout this group's evolutionary history.

Endangered Species

Because several Jerusalem cricket species have very limited geographical distributions, especially those endemic to small coastal and inland sand dune systems, coupled with all species being flightless, care will be necessary to protect these vulnerable taxa. The importance of limited Jerusalem cricket vagility is underscored by our genetic study of a widespread southern California Jerusalem cricket species. We showed that less than 100 years, or 50 generations, was sufficient to display patterns of genetic divergence between populations correlated with contemporary urbanization. In other words, urban development and roads disrupt gene flow and quickly cause isolated populations of Jerusalem crickets to genetically diverge from their neighbors.

Jewel Wasp, *Nasonia vitripennis* (Walker) (Hymenoptera: Pteromalidae)

DAVID B. RIVERS
Loyola College in Maryland, Baltimore, MD, USA

Nasonia (=*Mormoniella*) *vitripennis* is a gregarious, ectoparasitic wasp that attacks pupae and pharate adults from several families of the higher Diptera, particularly representatives of Calliphoridae and Sarcophagidae. Formerly a monophyletic genus, *Nasonia* is now represented by three species: *N. vitripennis* which appears to be cosmopolitan in distribution; *N. longicornis*, a species found predominantly in western North America; and *N. giraulti*, which ranges from the Mississippi river to the east coast of the United States. *N. vitripennis* has served as invaluable research tool to investigate topics associated with genetics, reproductive behavior, ecology, photoperiodism, host-parasite relationships, sex ratio theory, venom systems, and biological control. Recently, the entire genome of *N. vitripennis* has been sequenced, making it the first parasitoid to be selected for such studies and increasing its use as a model organism for several lines of research. It is considered an important natural enemy of filth flies inhabiting confined livestock facilities and associated with human habitation. Currently, this parasitoid is used as a biological control agent in poultry facilities and confined feedlots, however, its efficacy at reducing fly populations is considered questionable at best.

During host attack, the female parasitoid examines the host puparium through a series of stereotypic behaviors, and, if the fly is accepted, then drills a hole through the host puparium. The female wasp will insert her ovipositor through the newly created hole to probe the pupal surface, and then she plunges the distal third of the ovipositor into fly tissues. Prior to oviposition, the wasp always injects venom into the host, an event that appears to be capable of killing some fly hosts within 24 h. The parasitoid's eggs are then deposited on the surface of the host's body, but within the hardened puparium surrounding the fly pupa. The number of eggs laid is dependent on the host species and size of the host, as well as on the physiological condition of the host. The wasp eggs hatch 24–36 h later. Depending on host species, larval development (four instars) is completed within 5–7 days at 25°C. Larval feeding initially consists of piercing the pupal integument with mandibles so that feeding on host fluids dominates the first two instars. Upon molting to the third instar, larvae switch to tissue feeding, during which time the developing offspring consume all or nearly the entire fly host. Pupal development occurs within the puparium as well and typically requires an additional 4 days before adult eclosion ends the duration of the wasp's lifecycle within the host puparium.

Males eclose approximately 24 h before the females within the puparium. These males will chew an exit hole through the host puparium that will later be enlarged by the females as they make their escape. The males have reduced wings that prevent their dispersal from the site of eclosion. Upon emerging from the host, females are immediately courted by males, typically who are siblings, resulting in intense local mate competition. Mated females then disperse from the emergent site, attracted to the odors emitted from fly-infested decaying animal carcasses.

The sexes are clearly dimorphic. Females are dark in appearance with a metallic hue, which is perhaps why the species is often referred to as the "jewel" wasp. The abdomen is black while the thorax and head are a dark blue. Most of the appendages (legs, ovipositor, pedicel of antennae) are brown in color with the exception of the coxa. Wild type eye color is black with traces of deep red, although many mutant eye colors have also been observed. The female body is much larger than the male. Adult females range from 1.8 to 2.5 mm from head to abdominal tip, with most of the variation in size being attributed to host quality.

Males are substantially smaller than the females; most never reach more than 1.5 mm in length and can be stunted in size dramatically with crowding on hosts or during superparasitism. The color of the males is also more brilliant than the female. Adult males appear metallic green on the dorsal surfaces of the head and thorax, while the abdomen is all black. The legs are light brown, as are the scape and pedicel of the antennae. Males possess two pairs of reduced wings (brachypterous) that are functional but not capable of flight.

In temperate regions, *N. vitripennis* overwinters by entering a facultative larval diapause. Short-day photoperiods, sustained changes in thermoperiod, and host deprivation have all been examined as possible diapause-inducing cues. Interestingly, diapause in sarcophagid fly hosts typically begins 3–4 weeks before that of the wasp. After females interpret environmental tokens for diapause, they lay their last clutch of the season on diapausing hosts. The developing wasp larvae apparently consume the host's cryoprotectants as means to increase cold tolerance during larval diapause. The diapausing host puparia have also been enhanced for winter dormancy, which serves as added protection for the diapausing parasitoids.

Reproduction in this species entails a haploid-diploid mechanism of sex determination with parthenogenesis accounting for the production of males. Courtship between males and females amounts to not much more than males ambushing siblings as they exit host puparia. A successful male typically remains mounted on the female for several minutes before dismounting or being removed by a competing male. Females normally mate only once and store sperm in a spermathecae. Ovulation has been speculated to be directed by the female, as has sperm release from the spermathecae. Fertilized eggs are diploid and develop into daughters. In contrast, males develop from unfertilized eggs and consequently are haploid. Recent genetic studies have also uncovered a relatively common occurrence of diploid males and a more rare condition of haploid females. On favored hosts, such as large sarcophagids and calliphorids, broods will have a characteristic female-biased sex ratio of 3:1. This ratio becomes increasingly more male-biased as the quality of the host declines.

Injection of venom into the fly host seems to be central to the success of *N. vitripennis* in parasitizing a host and in producing viable progeny. Envenomation induces a developmental arrest in most fly hosts that is sustained until host death. During the halt in fly development, a series of biochemical changes in host intermediary metabolism occurs that appear to be associated with parasitoid larval growth. This is preceded by an inhibition of the host cellular immune responses, thereby permitting feeding on host fluids by both adult females and their developing offspring. Eventually, visible signs of tissue necrosis are evident, which is first restricted locally to the site of ovipositor insertion, but then gradually spreads throughout the fly. This generally signals the end of the parasitic relationship because the fly has become nutritionally unsuitable for developing larvae of *N. vitripennis*.

Nasonia vitripennis has served as a test subject for numerous genetic studies due to its mechanism of sex determination (haploid-diploid), small genome (five chromosomes), ease in rearing and handling, and availability of linkage maps for each chromosome. Several types of mutants of *N. vitripennis* are available to investigate inheritance of traits such as eye color, body color, eye shape, and fecundity. Additional comparative molecular genetic data is accumulating for all three species comprising *Nasonia*. Adding to the interest in this wasp is the presence of cytoplasmic bacteria (*Wolbachia* spp.) that may alter sex ratios by inducing hypercondensation of maternally derived chromosomes and contribute to speciation by evoking mating incompatibility.

Few parasites and no predators, at least that specifically target *N. vitripennis*, have been reported. At least one species of microsporidia has been found to be parasitic in this wasp, but the occurrence of the protozoan is not widespread as is evident for other genera of ectoparasitic pteromalids. In fact, only a few strains of *N. vitripennis* from specific geographical locations (e.g., upstate New York, central Florida) display microsporidian infections. When infected, females show a reduced fecundity that continues to decline over time. Spores apparently can be passed into the host either through venom injection or transovumly.

Predatory activity toward *N. vitripennis* seems to be by generalists. Predators of fly pupae, if unable to distinguish between parasitized and unparasitized flies, may consume wasp larvae in various stages of development. This would be especially easy to do since the larvae are feeding on the pupal surface. Such predation, however, has not been documented and would be expected to occur infrequently since the fly pupae are typically buried 2 or more centimeters below the soil surface.

Allospecific competition occurs regularly when *N. vitripennis* utilizes muscoid fly pupae. Several species of ectoparasitic pteromalids can be found searching for fly hosts in areas associated with livestock rearing. In some instances, adult females of other species will enter into confrontation with *N. vitripennis* for fly hosts. Battles are not fierce and usually amount to pushing and shoving with antennae. The frequency of confrontation apparently increases when available hosts are limited. In contrast, allospecific competition among larvae during multiparasitism is not only fierce, but deadly. Solitary wasp species tend to have cannibalistic larvae that will attempt to consume any competitors. *Nasonia vitripennis* does not avoid laying eggs on hosts previously parasitized by these solitary species. The apparent strategy employed to combat the cannibalistic larva is gregariousness. Females of *N. vitripennis* lay very large clutches on the parasitized hosts, and though many are consumed, several larvae reach adulthood. The sex ratios of such broods also tend to be male-biased.

Johannsen, Oskar Augustus

Oskar Johannsen was born in the state of Iowa on May 14, 1870, the son of Danish immigrants. He obtained only an elementary school education before dropping out of school. However, when his older brother decided to go to college, Oskar decided to go too. So, he spent the summer of 1890 studying in order to pass the entrance examination to the University of Illinois, was admitted, and gained a B.S. degree in architectural engineering in 1894. He worked for the next 5 years as a draftsman for a Chicago company. Oskar had wanted to study insects at college, but was persuaded by his father to study engineering instead, as a more reliable way of making a living. In 1899 he was offered and accepted a teaching position at the Civil Engineering College at Cornell University. This provided an income while allowing him to study the biological sciences, in which he obtained an M.A. in 1902 and a Ph.D. in 1904. In 1909 he accepted a position at the University of Maine as professor and entomologist in the Extension Division. In 1912 he returned to Cornell University and was successively professor of biology and professor of entomology until he retired in 1936. He married Harriette Fuller in 1896, and they had three children. With special interests in aquatic Diptera (Chironomidae and Mycetophilidae), he published more than a hundred scientific papers and was coauthor of three books, "Medical entomology" (with W. A. Riley), "Histological techniques" (with B. F. Kingsbury), and "Embryology of insects and myriapods" (with F. H. Butt). He was American representative on the permanent executive committee of the International Congresses of Entomology, president of the Entomological Society of America in 1937, and a member of several other scientific societies. English was his native language, but he learned to speak and read German and Danish, and to read Dutch, Norwegian, Swedish, and some of the Romance languages. He died at Ithaca, New York, on November 7, 1961.

Jordan, Heinrich Ernst Karl

Karl Jordan was born in Almstedt, Hanover, Germany, on December 7, 1861. He obtained a doctoral degree from Universität Göttingen in 1885. In 1892, he became curator of the entomological department of the Tring Park Museum, Hertfordshire, England, the private collection of the "entomological" branch of the Rothschild family, of which the brothers Lionel Walter Rothschild (Baron Rothschild) (1868–1937) published on butterflies, and Nathaniel Charles Rothschild (1877–1923) on fleas. Karl, a full-time professional, published copiously on beetles (especially Anthribidae), butterflies, and fleas. He was president of the Royal Entomological Society of London in 1929–1930, and in 1932 was elected a fellow of The Royal Society. The Rothschilds claimed to be hobbyists, yet published very substantial scientific contributions. Karl died on January 12, 1959.

Jumping Spiders (Class Arachnida, Order Araneae, Family Salticidae)

DAVID B. RICHMAN
New Mexico State University, Las Cruces, NM, USA

The jumping spiders (Salticidae) comprise the largest known spider family worldwide. Over 5,000 species are known, and this family makes up roughly 10% of the order Araneae. Over 300 species are known from North America north of Mexico, and many more occur in the tropics. Although primarily a tropical family, the Salticidae is known to occur from Canada and northern Europe in the north to Terra del Fuego and New Zealand in the south. They have been collected on Mt. Everest and also below sea level in the Salton Sink of California. They were among the first colonists on Krakatoa in the Malay Archipelago after the eruption in 1883 (one of the largest volcanic eruptions in recorded history) and they have been discovered in intertidal zones in Malaysia. Thus, they are among the most successful of spiders and among those most commonly encountered.

The members of this family (Figs. 7–9) are characterized by having a box-like cephalothorax, eyes in three to four rows, anterior median eyes highly enlarged, and a tendency to progress by leaping. They vary in size from about 1 to 25 mm in length, with most around 3–10 mm. The anterior median eyes of jumping spiders have been shown to be among the best in the invertebrates, second only to the cephalopod eyes in visual acuity. They differ from cephalopod and vertebrate eyes in that the lens is a fixed part of the cuticle and the cone-shaped retina is moved by a set of muscles to scan the environment. The eyes have a relatively large focal length to aperture ratio, which allows for better focus without the need for a lens that is perfectly curved. It is thought that these spiders probably evolved from clubionoid or philodromoid-like ancestors, although the exact ancestry is very difficult to establish at present.

The acute visual abilities of jumping spiders allow for a highly varied and complex behavioral repertoire. Studies on jumping spider behavior have shown them to be able to remember prey location, even after losing sight of the prey, and to experiment with prey-catching strategies so as to develop a workable methodology. Their high visual acuity also invests them with the ability to have complex intraspecific interactions, including visual courtship displays and agonistic behaviors. In addition, some of the jumping spiders resemble ants, velvet ants, or beetles, and often behave much like the organism they resemble. Some ant mimics have been shown to be Batesian mimics, being themselves good to eat and not especially venomous (although they can bite). Salticid ant mimics do not normally feed on ants, at least those that have been studied; thus, they appear not to be aggressive (Peckhamian) mimics. There are ant-feeding jumping spiders, but these tend to be not especially ant-like.

Courtship in jumping spiders is primarily visual (although most species employ other methods as well, such as inaudible sounds) and can be quite complex. Male spiders are often (but not always) highly ornamented. Several arachnologists have studied salticid courtship, beginning with George and Elizabeth Peckham at Milwaukee, Wisconsin, in the 1890s and continuing through Jocelyn Crane at Rancho Grande, Venezuela, in the 1940s. Robert R. Jackson and his associates in New Zealand, and in other parts of the Southern Hemisphere, have continued this work to the present day. In many ways, jumping spiders function much like birds in male displays, with the ornate males of many species performing elaborate stepping movements and displaying brightly colored scales and tufts, as well as front leg fringes and knobs and/or spikes on other legs. For example, *Habronattus hallani* not only raises its front legs during courtship to display the metallic pink scales on the underside of the femora, but makes short sideways runs ending in a vertical jump which flashes the metallic scales on the underside of the second pair of legs as well. The minute *Neonella vinnula* (1.8 mm as adults) males vibrate their entire bodies in courtship, while *Habrocestum pulex* goes through a mutual spiral dance, with the female rotating around the displaying male. Males of *Hentzia palmarum* rock their bodies back and forth while twisting their abdomens to the right or left.

Male-male agonistic displays have been less studied, but are almost as varied. In agonistic display, *H. palmarum* performs a mutual zigzag rocking dance with abdomen twisted and chelicerae extended. These displays usually result in an attempt to bite the opposing male. The “losing” male then backs away and runs. Smaller males may attack, but often will retreat before initiating or joining in a display. Similar biting attempts have been observed in *Anasaitis canosa*, but only in approximately equal-sized opponents. Usually smaller males retreat after perceiving the presence of the larger male, apparently gauging its size by sight. For some reason, agonistic displays seem to be rare or even non-existent in certain genera, such as *Habronattus*, with males often only casting cursory glances at other males.

Courtship can also involve other cues, such as stridulation (some *Phidippus* and *Habronattus*), tactile stimulation, and semiochemicals (pheromones). It is probable that cryptic species such as *Menemerus bivittatus* and *Platycryptus undatus* may depend more on these chemical cues, like the wolf spiders in the family Lycosidae. Male lycosids can be stimulated to display by the presence of female silk, but at least some male salticids do not even seem to notice female silk strands. *Menemerus bivittatus*, a cosmotropical tramp species, has been shown to recognize female silk and to spend time palpating it, apparently picking up chemical signals. It does not, however, initiate courtship unless it sees a female. However, many (if not most) salticid males can recognize and enter the silken sacs of penultimate females and mate with them after their molt. This activity probably involves both sight, and chemical and tactile stimuli. Why salticids evolved such a varied methodology in courtship is a mystery, but perhaps this courtship versatility allowed them more chances to reproduce.

Prey capture is another area in which salticids are especially adept. Usually, prey capture involves the sighting of a moving insect or other arthropod, followed by a stalk and final capture jump. *Phidippus*, for example, is an excellent hunter who can use landmarks to find prey items that have been lost from sight. They can occasionally grab web-building spiders from their webs. The Australian *Portia fimbriata*, a medium to large jumping spider belonging to a genus with members also found in South Africa and Sri Lanka, is quite versatile in its approach to prey capture, taking both insects and spiders, but preferring the latter. With spiders, *Portia fimbriata* will experiment until something works. It will use web vibrations on web-building spiders or even perform fake courtship to individuals of different species of jumping spiders. *Portia*, which looks like a piece of lint with eyes, usually wins at this game.

Obviously, jumping spiders are highly versatile in their behavioral repertoire and are excellent subjects for studies of behavior, ecology and evolution. However, their simplified genital structure often make species determination difficult and the sexual dimorphism found in many species has resulted in a number of one-sex descriptions and often complex synonymies. Thus, there is a definite need for more systematic studies to correct the errors and to apply new methods to phylogeny. Such studies will undoubtedly turn up many undescribed species, especially in the tropics, as well as to add to our understanding of the relationships within the family and of the family's relationship to other spiders. Jumping spiders are extremely complex organisms and at times difficult to research, but are always fascinating.

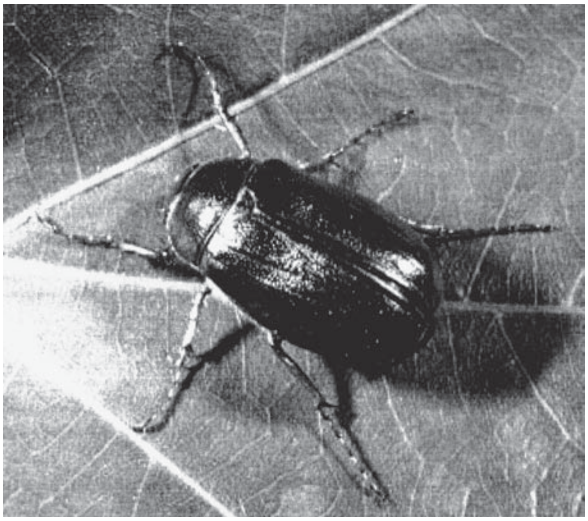
June Beetles, *Phyllophaga* spp. (Coleoptera: Scarabaeidae: Melolonthinae: Melolonthini)

DAVID W. HELD, DANIEL A. POTTER
University of Kentucky, Lexington, KY, USA

June beetles, also known as May beetles, are stout-bodied, brownish, plant-feeding scarabs belonging to the genus *Phyllophaga* (formerly *Lachnosterna*). They occur in both the Old and New Worlds. Throughout the continental United States and Canada about 200 species are known, many of which are found in the eastern and north-central United States. Some species are localized within a particular geographic region whereas others may be more widely distributed. June beetles also occur in South and Central America, the West Indies, eastern and southern Asia, and the islands of the Pacific and Indian Oceans.

Adult June beetles have a cylindrical or oblong body shape (Fig. 10), with different species ranging from 7 to 25 mm in length. Body color ranges from tan, to mahogany, to dark chocolate brown. The metasternum is covered with dense hair. The beetles have lamellate antennae ending in a three-segmented club that is longer in males than in females. The elytra of some species are pubescent, whereas in others they are nearly smooth. Species with a spring reproductive flight are referred to as May beetles, whereas those with summer flights are often collectively called June beetles or "June bugs." Despite these common names, beetle flight of either group can begin or end outside of those months.

The larvae are typical scarab grubs; cream-colored, C-shaped when feeding or at rest (Fig. 11), with a brown head capsule, chewing mouthparts, and three pairs of jointed legs. Full-sized larvae are 25–38 mm long. The hind part of the abdomen is typically dark because of ingested food and soil. The raster, an area of bare spaces and spines on the ventral surface of the last abdominal segment, bears two parallel rows of short spines in a pattern that resembles a zipper.



June Beetles, *Phyllophaga* spp. (Coleoptera: Scarabaeidae: Melolonthinae: Melolonthini), Figure 10 Adult June beetle or "June bug."

June Beetles, *Phyllophaga* spp. (Coleoptera: Scarabaeidae: Melolonthinae: Melolonthini), Figure 11 Larva of June beetle; these often are called "grubs."

Most June beetles feed on the leaves of deciduous trees such as oak, hickory, walnut, and elm. When the beetles are abundant, trees may be stripped of their young leaves in spring. Adults of some species feed on herbaceous plants, or on gymnosperms (conifers and their close relatives). Most June beetles are polyphagous, feeding on as many as 70 plant species, so several species of *Phyllophaga* may be present together on a particular plant. The larvae, called white grubs, develop in the soil where they feed on roots of turf and pasture grasses, young nursery plantings, corn, small grains, potatoes, strawberries, and other agricultural crops. Although some species can be quite destructive, most are not considered to be significant pests.

Adults typically are active from April to June. The beetles emerge after sundown and fly to the tops of trees to feed, returning to the soil or protected sites before dawn. They are clumsy fliers and often are attracted to outdoor lights. Collections at lights consist primarily of males. Mating occurs only at night, either on the surface of turf or pasture, in the soil, or on host plants. Males are attracted by a female-produced sex pheromone. Once mated, females fly to turf, pastures, or agricultural fields and burrow down 5–18 cm to lay eggs. Oviposition can occur during the day or night. Eggs are pearly-white, about 2.5 mm long, and typically laid singly in earthen cells. Newly laid eggs appear elliptical, becoming more spherical as the embryo develops. Each female lays 20–50 eggs in her lifetime. Hatching occurs in about 3 weeks and the young grubs begin feeding on fine roots and organic matter within the upper 5 cm of soil.

Most June beetles have 2- or 3-year life cycles, although a few species have cycles lasting 1 or 4 years. There are three larval instars. Because of overlapping generations and presence of more than one species, several sizes of June beetle grubs may be found together at a given site. Larvae of species with 2-year cycles typically overwinter as second instars. They resume feeding in early spring, molting again in April or May. Third instars attain their full size by summer's end. Pupation occurs underground, in an earthen cell. Most species reach the adult stage by late autumn, but the beetles remain underground until the following spring. Grubs of species with 3-year cycles feed throughout the first two summers, hibernating twice and pupating midway through the third summer. Their adults are usually fully formed by autumn, but do not emerge from the soil until spring.

June beetle grubs are susceptible to entomopathogenic nematodes and various microbial pathogens including fungi (e.g., *Metarhizium anisopliae*) and specific strains of milky disease bacteria, *Paenibacillus popilliae*. Night-active flies in the genus *Pyrgota* (Diptera: Pyrgotidae) parasitize the adults, whereas several species of wasps in the family Tiphiidae are ectoparasitoids of the larvae. Mites are often found on adults and larvae; however, they are probably just phoretic and harmless to their hosts. Predatory insects (e.g., ants, carabids) feed on the eggs and young larvae. The grubs also attract vertebrate predators including insectivorous birds, skunks, raccoons, moles, and armadillos.

In the past, farmers were advised to clean June beetles out of heavily infested fields by pasturing the land with hogs, which would root out and eat the grubs. Management, when necessary, is now accomplished with soil insecticides, or through crop rotation. Control actions can be timed by monitoring adult activity using black light traps. Adults, too, can be controlled with insecticides, but defoliation may continue due to reinfestation of previously treated plants.

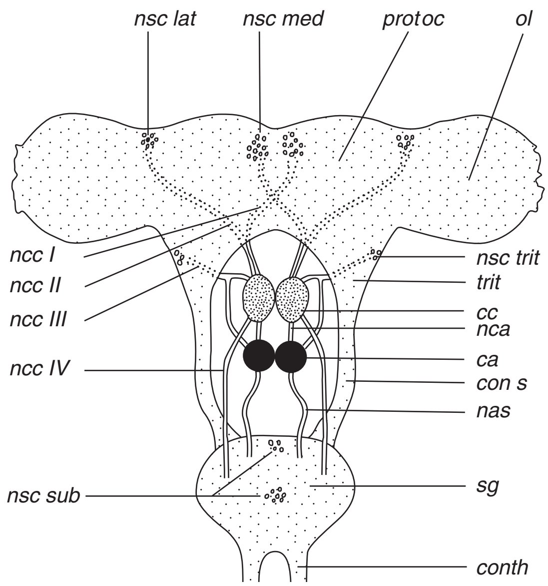
Juvenile Hormone

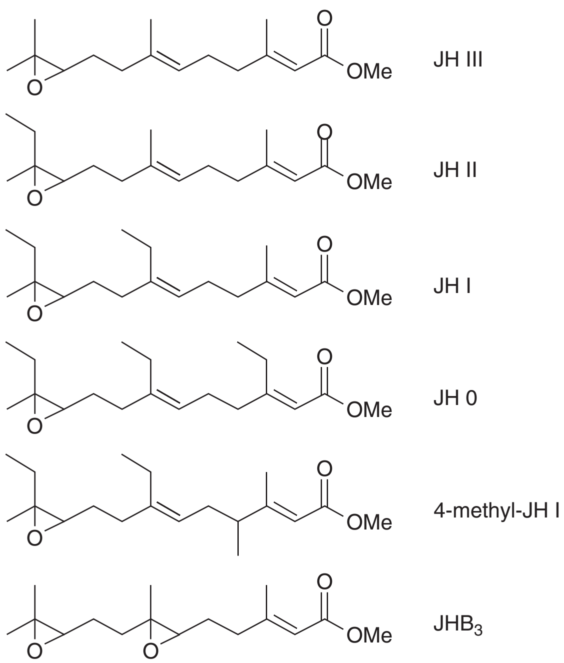
MICHEL CUSSON
Natural Resources Canada, Canadian Forest Service, Sainte-Foy, QC, Canada

Evidence for the existence of a blood-borne factor that influenced or modified the molting process was provided for the first time by Wigglesworth in the 1930s. His innovative experiments on the blood-sucking bug, *Rhodnius prolixus*, pointed to the corpora allata (CA) which are small (usually) paired glands found in close association with the corpora cardiaca, posterior to the insect brain (Fig. 12), as the source of this factor, later termed "juvenile hormone" (JH) due to its status quo action on the molt. In 1956, Williams isolated, from abdomens of *Hyalophora cecropia* male moths, an oil displaying juvenile hormone activity; however, it took an additional 10 years before the chemical structure of a natural juvenile hormone was successfully determined (JH I, by Röller and co-workers).

Juvenile hormones make up a group of lipophilic sesquiterpenes produced by the CA and released to the hemolymph. Six different forms (Fig. 13) of juvenile hormone have been identified so far from insect tissue and hemolymph. All known juvenile hormones are methyl esters of epoxyfarnesoic acid or of one of its homologs (i.e., with one or several methyl and/or ethyl side chains). JH III, the simplest and most ubiquitous one, is the only juvenile hormone found in the majority of insects. In the Lepidoptera, however, five juvenile hormones have been described, including JH III and the homologous JH 0, JH I, JH II, and 4-methyl-JH I. In addition, the CA of cyclorrhaphous Diptera secrete both JH III and a bis-epoxide form of this hormone (JHB_3).



Juvenile Hormone, Figure 12 Schematic representation of the head components of the neuroendocrine system in a Lepidoptera larva, showing the position of the corpora allata relative to the corpora cardiaca, the brain and the suboesophageal ganglion, as well as the nervous connections among these entities. *ca*, corpora allata; *cc*, corpora cardiaca, *con s*, suboesophageal connectives, *con th*, thoracic connectives, *nas*, nervus allatosuboesophagealis, *nca*, nervus corporis allati, *ncc* I–IV, nervi corporis cardiaci, *nsc lat*, neurosecretory cells (nsc) of the lateral part of protocerebrum, *nsc med*, nsc of the pars intercerebralis protocerebri, *nsc sub*, nsc of the suboesophageal ganglion, *nsc trit*, nsc of the tritocerebrum, *ol*, optic lobe, *protoc*, protocerebrum, *sg*, suboesophageal ganglion, *trit*, tritocerebrum (from Sláma K, Romaňuk M, Šorm F (1974) Insect hormones and bioanalogues. Springer-Verlag, New York).



Juvenile Hormone, Figure 13 Chemical structure of the six known juvenile hormones; *Me*, methyl.

Biosynthesis of juvenile hormone proceeds through the mevalonate pathway – the end product of which is cholesterol in most other animals – and thus uses acetyl-CoA as the principal building block. In the case of juvenile hormones with ethyl side chains, one unit of propionyl-CoA, derived from valine and isoleucine, substitutes for one of the three acetyl-CoA units that make up mevalonate, thus leading to the formation of homomevalonate. Condensation of three isoprene units by farnesyl diphosphate synthase results in the formation of the juvenile hormone backbone (i.e., farnesyl diphosphate or one of its homologs). This diphosphate is then sequentially converted to an alcohol and an acid, followed by the formation of a methyl ester and epoxidation.

One of the most intensively studied functions of juvenile hormone is its juvenilizing effect during larval development, whereby high levels of the hormone during larval molts modify the type of cuticle secreted at a molt, thus maintaining the insect in a juvenile state. Consequently, the juvenile hormone titer is maintained at a relatively high level during most of the larval period until the final instar, at which time it drops precipitously, allowing the subsequently released ecdysteroids to induce the larval-pupal or nymphal-adult transformation. With the exception of a rise in its levels during the prepupal stage (at least in some Lepidoptera), the juvenile hormone titer usually remains low until adult emergence when the CA are reactivated.

In adult females of most insects, juvenile hormone induces vitellogenin synthesis in the fat body as well as its uptake by developing oocytes, making it an absolute requirement for egg maturation. In these insects, titers are observed to fluctuate as a function of the various phases of the ovarian cycle. Sex pheromone production and sexual receptivity, the expression of which is often coordinated with the ovarian cycle, are regulated by juvenile hormone in many species of insects. In males, juvenile hormone may be necessary to promote the production of accessory sex gland secretions and to control courtship behavior. Other processes that juvenile hormone has been shown to govern in some adults include migration, polyphenism, caste differentiation and reproductive diapause.

The principal factors regulating the level of juvenile hormone in insect hemolymph are the rate of hormone synthesis by the CA and its degradation in the hemolymph and tissues. These glands do not store juvenile hormone, but they release the hormone into the blood as soon as it is produced. The biosynthetic activity of the CA is controlled chiefly by neuropeptides that either stimulate (allatotropins), or inhibit (allatostatins, allatinhibins) juvenile hormone production. These neuropeptides are produced by neurosecretory cells and are delivered to the CA via neural connections to the brain. Juvenile hormone biosynthesis may also be modulated by factors released in the hemolymph by organs or tissues that are anatomically distant from the CA (e.g., ovary, neurosecretory cells in the ventral nerve cord, etc.).

Catabolism significantly affects the hemolymph titer of juvenile hormone at certain stages of insect development. In this respect, juvenile hormone esterase (JHE) is instrumental in the critical lowering of juvenile hormone titers during the final instar of lepidopteran insects. The same enzyme may also play an important role in juvenile hormone titer regulation following mating in adult females of certain lepidopteran species. Within tissues, an epoxide hydrolase (JHEH) plays a significant role in the degradation of juvenile hormone.

Experimental evidence suggests that juvenile hormone can modulate gene transcription in insects (e.g., induction: transcription of the JHE gene; suppression: transcription of the *Broad Complex* gene), implying that it likely binds to an intracellular receptor in a fashion similar to that described for steroid hormones, including ecdysone. To date, although several hemolymph juvenile hormone carrier proteins have been identified, few cytosolic or nuclear juvenile hormone binding proteins have been isolated, and their role as a juvenile hormone receptor has either been questioned or remains unconfirmed. Some of the effects attributed to juvenile hormone, including the induction of vitellogenin uptake by developing oocytes through the juvenile hormone-dependent formation of openings between follicular cells (patency), appear to result from the interaction of juvenile hormone with a cell-surface receptor, in a manner similar to that described for peptide hormones. Clearly, thus far, juvenile hormone does not fit any single pre-established receptor-ligand model and may well have pleiotropic effects in a given cell mediated by different receptors.

The disruption of juvenile hormone functions in insects has long been viewed as a promising strategy for the development of environmentally safe, insect-specific pest control products. Williams was the first to suggest the use of juvenile hormone or juvenile hormone-like compounds as a means of controlling insect pests, reasoning that an artificial increase in the levels of juvenile hormone at times when such levels are normally low would result in a fatal disruption of insect development. Various compounds, collectively referred to as juvenile hormone analogs (JHAs) or "juvenoids" have, indeed, been developed for this purpose, and a few have enjoyed commercial success for the control of insects whose pest status is restricted to the adult stage (e.g., mosquitoes). These insecticides, however, do not usually provide adequate control of crop and forest pests that feed as larvae, because death usually is not immediate and larvae continue to feed and cause damage, dying only near the end of larval life or at metamorphosis. For this reason, current research efforts are aimed at finding ways of artificially *lowering* juvenile hormone titers, or antagonizing juvenile hormone function at the receptor level; if successful, such strategies would result in the precocious (and fatal) induction of metamorphosis in the larva and in the inhibition of reproduction in the adult.

Juvenoid

Chemicals that act as growth regulators, mimicking juvenile hormone. Ingestion or topical exposure can result in disruption of the normal endocrine functions, including prolongation of the immature stage, induction of supernumerary instars, and loss of fertility. Juvenoids are juvenile hormone analogs, most of which are synthetic, and which are applied as fairly selective insecticides. Plants also produce juvenile hormone-like compounds, however.

K

Kairomone

A chemical produced by one species that is perceived by another species, and benefits the perceiver. Kairomones are a type of semiochemical.

► Chemical Ecology

Kala-Azar

A form of visceral leishmaniasis caused by *Leishmania donovani*. In humans it causes enlargement of the spleen and liver, and can be fatal. It is vectored by sandflies (Dipera: Psychodidae).

► Leishmaniasis

Kalotermitidae

A family of termites (order Isoptera).

► Termites

Kaolin

A white clay or crushed rock derived from feldspar that, when applied to foliage, often reduces insect feeding.

Kaolin-Based Particle Films for Arthropod Control

GARY J. PUTERKA[1], D. MICHAEL GLENN[2]
USDA-ARS, Stillwater, OK, USA[1]
USDA-ARS, Kearneysville, WV, USA[2]

At the beginning of the twentieth century, the few pesticides that were available were applied as spray solutions using steam or gas driven spray gun systems. The high labor inputs involved in spraying orchards and other crops by handgun and the use of large volumes of water motivated researchers to investigate dust applications that used mineral particles as insecticidal carriers. Dust applications gained favor over liquid sprays in the 1920s because of the speed of dust operations, economy in labor, good plant coverage, and comparable insect control with liquid sprays. In the 1930s, researchers discovered that certain inert minerals themselves were toxic agents to insects. The primary mechanisms that inert minerals acted upon insects as summarized in 1939 were (i) ingestion of the dust into the digestive system, (ii) desiccation, (iii) chemical reaction with the body wall of the insect, and (iv) direct mechanical abrasive action. Interest in mineral particles for insect control continued through the 1960s but had little impact on the agricultural industry. Control of insects with inert dusts transitioned from minerals to synthetic compounds like silica aerogels and fumed silicas by 1970. These synthetic dusts were believed to have the greatest potential for the pest control needs of the grain industry; however, inexpensive chemical fumigants became widely used instead. Much of the research on mineral particles after 1970 was limited to pesticide formulations where mineral particles were used as carriers for synthetic insecticides and microbial agents, and in the use of minerals for sunburn control. Certain minerals such as diatomaceous earth (e.g., Celite®, Cryacide®) for insect control, wettable sulfur for plant disease control, and hydrated lime for sunburn prevention are still utilized to a varying degree in tree fruit and grape production.

Development of Particle Film Technology

Mineral particle research and development continued to advance since the 1970s in the paint and plastics industry where particles were being engineered with specific sizes, shapes, and light reflective properties for paper, paint, cosmetic, and plastic products. Congress mandated the United States Department of Agriculture (USDA), Agricultural Research Service (ARS) to develop reduced risk alternatives to chemical pesticides in 1985 as part of the Low Input Sustainable Agriculture (LISA) program; this motivated many researchers to investigate new ideas to control plant pests in an economically sustainable and environmentally safe manner. Particle film technology was conceived by ARS scientists in the mid-1990s as an alternative to chemical pesticides. This technology was based on coating plant parts with mineral films that met the following properties: (i) chemically inert mineral particle, (ii) particle diameter <2 μm, (iii) formulated to spread and create a uniform film, (iv) forms a porous film that does not interfere with gas exchange between the leaf and atmosphere, (v) transmits photosynthetically active radiation (PAR) but excludes ultraviolet (UV) and infrared (IR) radiation to some degree, (vi) alters insect behavior on the plant, and (vii) can be removed from harvested commodities. Various minerals and their properties were investigated but many contained the respirable human carcinogen crystalline silica (SiO_2), and did not transmit sunlight; thus, crystalline silica would adversely affect plant photosynthesis. In 1996, ARS researchers partnered with industry to focused on a novel class of particles based on kaolin, a white, non-porous, non-swelling, non-abrasive, fine grained, plate-like, aluminosilicate mineral ($Al_4Si_4O_{10}(OH)_8$) that easily disperses in water and is chemically inert over a wide pH range. Coating grade kaolin is >90% pure and has a high brightness quality of >85% and is capable of transmitting sunlight. The chemical and physical properties plus the availability of engineered kaolin particles that were heat treated, shaped and sized made this mineral an ideal candidate for study. The term "particle film technology" was coined by the group for the research that led to the development of a multifunctional mineral product capable of controlling many insects pests, certain diseases and improved plant health.

Particle film technology was originally based on kaolin particles made hydrophobic by a silicone coating. Hydrophobic kaolin, M-96–018, (BASF, Research Triangle Park, North Carolina, USA; formerly Engelhard Corporation, Iselin, New Jersey, USA) was initially applied as a dust using various hand-operated dusters or modified sand-blasters for large scale studies because the hydrophobic material could not be mixed and delivered in water. However, the drift associated with dusting operations, plus lack of adhesion to the plant, made M-96–018 dust applications impractical. In 1998, the first particle film formulations were registered with the U.S. Environmental Protection Agency (EPA) under the names M-96–018 and M-97–009 Kaolin. M-96–018 was soon formulated by using a methanol (MEOH)-water system where M-96–018 could be pre-slurried with

99% MEOH (11.3 kg or 25 lbs M-96–018 + 18.0 L or 4 gal MEOH premixed then added to 436 L or 96 gal water) and delivered as a spray to trees. During field tests, it was determined that this formulation was too expensive for practical use, and handling and transportation of 99% MEOH presented logistical and safety problems. Laboratory and field studies determined that formulations based on hydrophilic kaolin particles (M-97–009) plus a spreader sticker were just as effective as M-96–018 hydrophobic kaolin dusts or aqueous sprays in controlling insects and diseases. As a result, the development of M-96–018 was dropped in favor of M-97–009.

Advantages to using hydrophilic M-97–009 kaolin formulations were (i) ease of mixing, (ii) more economical, (iii) compatible with other materials for tank-mixes, and (iv) formulation flexibility to alter spreading and rain fastness. M-97–009 + M03 became commercially available in 1999 under the name Surround® (BASF, Research Triangle Park, North Carolina; formerly Engelhard Corporation, Iselin, New Jersey) and in most cases was applied at 25 lbs kaolin plus 1 pt spreader-sticker in 96 gal water. In 1999, a new formulation of M-97–009 was registered with the U.S. EPA under the name Surround™ WP that had the spreader-sticker system incorporated into the particles as a single packaged system that could be added directly to water. This formulation became available in 2000 and is the main formulation currently in use.

The historical safety record of kaolin in the paint and plastics industry, including a series of health and toxicity tests for EPA registrations, has been used to support the approval of Surround™ products for organic crop production.

Action of Particle Films on Arthropods

Two basic actions of mineral particles against insects have been well addressed in the literature. Minerals (diatomaceous earth, fumed silica) that are abrasive or absorptive to the insect's cuticular waxes can be used for control of insects, mainly stored grain pests. Minerals that were white and reflective to sunlight (calcium carbonate) could potentially be applied as whitewashes to the soil as reflective mulches to repel aphid pests. Although these concepts were sound, these materials had little impact on the arthropod pest control industry, although calcium carbonates have been widely used for sunburn protection in fruit production. Particle film technology diverged from all other mineral-based insecticides in concept where the effects on insect behavior and on plant health were recognized. A major advancement in this technology was in formulation chemistry that enabled kaolin particles to be mixed with water, applied through conventional pesticide sprayers, forming a porous film, and producing a film that could resist rain and wind, yet be easily removed after harvest.

Particle films act on the insect's processes of locating and accepting plants as hosts for feeding and reproduction which are dictated through the senses of touch, taste, sight, and smell. During the process of locating and accepting hosts, the four senses interact to produce both positive and negative cues, the sum of which provokes a positive or negative behavior in insects. Plant tissues coated with white particle films are altered visually and tactilely to insects. Particle films also may alter the taste or smell of the host plant. Choice and no-choice laboratory bioassays on various insects revealed that the primary mechanism of action was repellence of adults from treated foliage, resulting in reduced feeding and oviposition. Repellency is only used tentatively as a mechanism since it has not yet been demonstrated if insects orient away from particle films before film contact (repellence) versus after film contact, which is more appropriately termed a deterrent. Other mechanisms include (i) reduced survival of adults or immature insects (larvae) when born into the particle film coated leaf environment, (ii) reduced mating success of adult Lepidoptera exposed to particle films, (iii) impeded movement/host finding ability within plant canopies,

(iv) camouflage of the host by turning the plant foliage white with the particle film, and (v) impedance of the insect's ability to grasp the plant. Most of the effects particle films have on insects result from particle attachment to the insect's various body parts (Fig. 1). The underlying mechanisms of this technology make it unlikely that insects would develop resistance.

Particle Film Applications for Arthropod Pest Control

Applications of particle films, M-96–018, M-97–009, Surround™ and Surround™ WP for pest control are typically made at 3–6% solids in water (w:w). Particle film solutions can be applied by any type of boom, orchard blast, or hand sprayers and can be applied aerially. Research on film weather ability and functionality on insects have concluded that 3% are as effective as 6% solutions under most circumstances. There are usually at least three applications made 7–14 days apart for control of foliar pests. In certain circumstances, such as dormant applications, only 1–2 applications of 6% solutions are needed for pear psylla control in pear. Applications are typically made to near "run-off" or "drip," and are considered a "dilute application" where 200 gallons/acre (1850 L/ha) are applied to mature fruit trees 8 m in height.

The principal use for particle films is for control of pear psylla, *Cacopsylla pyricola* Foerster, in pear in the USA and (Fig. 2) Europe. Dormant applications of Surround™ WP and Surround™ CF have been used on nearly 100% of the pear acreage in northern Washington over the past several years. Particle films are effective against many key orders of arthropod pests affecting crops

Kaolin-Based Particle Films for Arthropod Control, Figure 1 **SEM of a two-spotted spider mite, *Tetranychus urticae* Koch., that was exposed to a M-96–018 particle film treated apple leaf for 10 minutes. Inset is a 10 μm diameter circle to indicate scale of particle coverage.**

Kaolin-Based Particle Films for Arthropod Control, Figure 2 **Particle film, Surround WP, dormant timing application to pear to prevent infestations of pear psylla near Wenatchee, Washington, USA.**

including hemipterans, coleopterans, lepidopterans, dipterans, rust mites, and eriophyid mites. Examples of other uses are for leafhoppers and sharpshooter control in grapes, plum curculio, *Conotrachelus nenuphar* (Herbst), in apple and plum, and olive fruit fly, *Bactrocera oleae* L., in olive. Particle films are not effective against tetranychid mites and San Jose scale, *Quadraspidiotur perniciosus* (Comstock), in tree fruits. These pests are generally controlled by natural predators and parasites and the particle film is thought to reduce the efficacy of these beneficial organisms. Research continues to expand, with over 25 research papers on the effects of particle films on insects on various crops. Most of the research focuses on crops where particle film residues are either not a concern and are processed with the fruit (e.g., wine grapes, fruits for juices) or are removed in packhouse operations where fruits are washed, brushed, waxed and bagged (e.g., apples, pears, citrus) for the fresh fruit and vegetable market.

Multi-Functionality of Particle Films

Initial studies into particle film technology discovered that plants directly benefited from the film's properties, including film porosity, which allowed gas exchange between the leaf and atmosphere, and the ability of the film to transmit photosynthetically active radiation (PAR) yet exclude ultraviolet (UV) and infrared (IR) radiation to a significant degree. Whole-tree photosynthesis, water use efficiency, yield, size, and quality of apples were compared for the kaolin, Surround™ WP, and calcium carbonate. Only the kaolin formulation increased photosynthesis over the untreated control although water use efficiency was reduced through increases in stomatal conductance associated with reduced leaf temperature. Calcium carbonate, despite its white color, produced none of these effects and reflected more PAR from the tree canopy than processed kaolin.

Increases in plant photosynthesis from kaolin-based particle film treatments can lead to favorable effects on plant productivity. Yield and fruit size increases have been noted in apple, pear, cotton, and citrus. In addition, cooling of the tree canopy through the reflectance of IR can improve fruit color in apple and pear, but these results are variety dependent.

Numerous studies throughout the world have supported the consistent ability of a kaolin particle film to reduce sunburn. Reflectance of IR and UV in conjunction with significant reductions in plant surface temperatures reduce solar injury. The impact of particle film technology as a sunburn prevention agent in agriculture is essentially equal to the pesticidal uses of particle film. Surround™ WP is currently used to prevent sunburn and heat stress in apple, pear, citrus, walnut, banana, cantaloupe, and tomato.

Particle films have many other applications where the properties of the films can be altered by particle physics and formulation chemistry. These potential uses include sprayable reflective mulches, herbicides, frost prevention, and in pesticide delivery.

Kaszab, Zoltán

GEORGE HANGAY
Narrabeen, NSW, Australia

Zoltán Kaszab was born on the September 23, 1915 at Farmos, in Pest- Pilis- Solt- Kiskun Shire in Hungary. Even as a child, he was deeply interested in animals, especially insects. He completed his tertiary education at the University of Science in Budapest, where he was awarded a doctoral degree in zoology, geology and mineralogy. After university he gained employment with Professor Endre Dudich in the Institut of Zoological Taxonomy and eventually joined the staff at the Hungarian Natural History Museum in Budapest. In 1955 he became the chief curator of the zoological collections and from 1970 until 1985 he was the principal director of the museum. Kaszab was an extremely hard worker, totally committed to entomology, specifically to the Tenebrionidae and Meloidae (Coleoptera). He researched the tenebrionid beetles of Bíró's vast New Guinean collection and published the results. In a relatively short time he became a world expert of these aforementioned beetle families. From 1963 until 1968 he dedicated most of his time and energy to the zoological exploration of Mongolia. During this period he undertook six collecting expeditions, mostly on his own, and collected 486,342 specimens, mainly insects. More than 200 workers from the international scientific community participated in the research of this singular collection. By the mid 1980s nearly 500 papers (approximately 7,000 pages in total) were produced, including 60 new genera and 1,600 new species. Zoltán Kaszab appeared to be physically strong, yet he had a weak heart. In 1963, just before his first Mongolian expedition, he overcame a very serious illness and survived a major heart operation. His health improved somewhat and he could work harder than anyone around him. In the mid-eighties his health declined and he had to resign from his directorial post in order to devote himself completely to his beetle studies. On the April 4, 1986 he passed away. Zoltán Kaszab's achievements in entomology are unparalleled amongst the Hungarian entomologists. He described 2,800 new species and published 397 scientific papers, totalling approximately 10,000 pages.

Katydids (Orthoptera: Tettigoniidae)

DARRYL GWYNNE
University of Toronto, Toronto, ON, Canada

Katydids belong to a family of ensiferan orthopterans with over 6, 000 described species and found in a variety of habitats on all continents except Antarctica. Most taxonomic schemes recognize katydids (called bush-crickets in Europe) as a family, Tettigoniidae. Katydids are typically large insects of several centimeters in length. They share with most other Ensifera – a suborder that includes Grylloidea, the true crickets, Rhaphidophoridae, the camel crickets, and Anostostomatidae, the weta – nocturnal activity, long antennae, a long blade-like ovipositor, tibial tympana, and a complex spermatophore that has a spermatophylax serving as a food gift for the female. There are about 17 subfamilies although this scheme is likely to be revised with further phylogenetic study. A formal phylogenetic analysis of the family is currently lacking. The earliest fossil tettigoniids are Permian.

Katydids are best known for the distinct male sounds produced by tegminal (forewing) stridulation and used to attract mates. In many species the tegmina are leaf-like, allowing daytime crypsis in the vegetation habitat. Other species have short tegmina, a robust cricket-like appearance, and inhabit low vegetation, occasionally moving over the ground. The use of vegetation as a retreat during daylight contrasts with most other ensiferans that use burrows or crevices. Features that distinguish katydids from other ensiferans, and indicate that the family is a natural (monophyletic) group, include: four tarsal segments, left-over right tegminal stridulation, and certain DNA sequences. Grylloidea, the second most diverse ensiferan subgroup, also show tegminal stridulation but with the opposite tegminal overlap to that of katydids. Also, in contrast to other ensiferan subgroups, most species of true crickets and katydids have an egg-to-adult life cycle that is completed within one year.

As in other Ensifera, many katydids lay their eggs in soil. However, many others oviposit into leaves, bark and other plant parts, or paste their flattened eggs like overlapped shingles onto leaves. There is a diversity of development patterns typically involving diapause, the temporary cessation of development during favorable conditions in order to survive future severe periods such as winter. Eggs of some species diapause through just one winter, whereas in others several winters may be required to continue development to the adult stage. Depending on the species, there are four to nine instars. A few tropical species show an unusual change during development. For example, the small larvae of *Macroxiphus sumatranus* (Conocephalinae) mimic ants both in structure and movement whereas the adult insect is brightly colored and aposematic.

Some katydids are herbivorous, others carnivorous, but most species are omnivores. A few species have specialized diets such as pollen (the Australian Zaprochilinae). The list of natural enemies of tettigoniids includes predators such as bats that orient to the calls of males. Sphecid wasps (some of which are katydid specialists) use paralyzed katydids as food provisions for their fossorial larvae. Katydid killers also include parasitoids such as ormiine flies (Tachinidae) that larviposit on males after being attracted to their calls, and the thread-like horsehair worms (phylum Nematomorpha) and mermithid nematodes that can virtually fill the body cavity of their hosts. Important parasites include endoparasitic microsporidians and gregarine protozoans. Ectoparasites include mites, stick ticks (ceratopogonid flies) and strepsipterans. Katydid defenses against natural enemies include camouflage with some tropical katydids showing remarkable mimicry to leaves. A few species have chemical defenses including reflex bleeding in which blood squirts can be aimed at predators.

Although most katydids live a mainly solitary existence, a few show gregarious habits which can lead to economic damage. For example aggregations of ovipositing false-leaf katydids (Pseudophyllinae: *Pterophylla*) can damage forest trees. A few species at very high densities show coordinated group behavior. This is best known in the locust-like swarms of flying cone-headed katydids (Conocephalinae: *Ruspolia*) in Africa and, in particular, the massive migrations of bands of North American Mormon crickets, a flightless shield-backed katydid (Tettigoniinae: *Anabrus simplex*). Band-forming populations contrast with other populations of Mormon crickets that are quite solitary in their behavior. Bands form in the early instars and by the adult stage can form huge aggregations several hundred meters wide and kilometers long that show highly directed migrations. Such bands can devastate agricultural crops. Individuals in bands experience a much reduced risk of predation but need to move continuously to avoid cannibalism by conspecifics. Cannibalism reflects intense competition within the band for protein and salt.

Male katydids stridulate by moving a scraper on the top of the right tegmen over a file on the underside of the left tegmen. Stridulatory calling is found in virtually all species and functions mainly to attract females. Calling song can mediate female choice of males and in a few species can serve as a barrier to matings between species. In most species the male song is a series of noisy (broad spectrum of sound frequencies) buzzes, zips or clicks. More musical (narrow spectrum) sounds are produced by many neotropical species, some of which are ultrasonic. Although pairing in most species is accomplished when the female is attracted to the male call, in a few species, including many Phaneropterinae, females answer males with their own call and males move to these sounds. Individuals hear sounds using a complex system of foretibial tympana connected to specialized thoracic tracheae and paired thoracic spiracles. The acoustical systems of katydids have been studied extensively and have been model systems for neurophysiological, behavioral and evolutionary studies.

Copulation typically follows the female mounting the male and the mated pair assuming a position in which the male is curled behind the female. The end of the spermatophore is inserted into the female's genital chamber. The exterior sperm ampullae and attached spermatophylax of the spermatophore comprise up to 40% of the male's weight (Fig. 3).

Katydids (Orthoptera: Tettigoniidae), Figure 3 Photograph: Mormon crickets, the shield-backed katydid *Anabrus simplex*. The female in the foreground has just mated and has a spermatophylax meal attached to her abdomen. The male is in the background. His short singing wings protrude from beneath the pronotal shield.

The need for protein in katydids in band-forming Mormon crickets, and katydids in which food supplies can be limited, underlies extreme variation in sexual selection and mating behavior observed in these species. Starvation decreases male mating (spermatophore producing) frequency but increases the propensity of hungry females to mate as they seek spermatophore meals. This leads to sexual competition among females that is not seen in populations with adequate food. Experimental manipulations of proteinaceous food in these species have supported a central tenet of sexual selection theory that relative investment of the sexes in offspring controls sexual differences in both mate choice and sexual competition.

Kaufmann Effect

The developmental response of insects to temperature is usually determined by exposing different groups of them to various constant temperatures. The relationship between environmental temperature and insect development rate over most of the range between the highest and lowest tolerable temperatures is usually linear, with higher temperatures promoting (up to a point) higher rates of development. However, some nonoptimal temperatures may cause either a retardation or acceleration of development rates; this deviation from what is expected (non-linearity) shows up when insects are exposed to alternating temperatures. The difference between development predicted by linear models, and the development observed under variable temperature conditions (or predicted by nonlinear models) was first observed by O. Kaufmann in 1932, and so is called the "Kaufmann effect" or the "rate summation effect."

Kauri Moths (Lepidoptera: Agathiphagidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Kauri moths, family Agathiphagidae, have only two known species, one each from Queensland and Fiji. The family comprises the monobasic superfamily Agathiphagoidea and the only representative of the suborder Aglossata. Adults small (9–14 mm wingspan), with head vertex rough-scaled; with rudimentary chewing mouthparts (haustellum absent); short labial palpi, 3-segmented; maxillary palpi 5-segmented and folded. Maculation somewhat similar to Micropterigidae but mostly gray with fine speckling spots. Adults are diurnally active. Larvae are seed-borers of kauri pines (*Agathis*, Araucariaceae) of the South Pacific and are modified for this kind of feeding. Thus, they appear much more elongated and different from larvae of Micropterigidae.

Keel

The crest or raised ridge running along the dorsal midline of cockroach oothecae; the median carina (a dorsal raised ridge) on the pronotum of a grasshopper.

Kellogg, Vernon Lyman

Vernon Kellogg was born December 1, 1867, in Emporia, Kansas, USA. He received his B.S. and M.S. degrees from the University of Kansas in 1889 and 1892, respectively. He also was awarded the LL.D. degree from the University of California in 1919 and from Brown University in 1920. He was awarded a Sc.D. from Oberlin College in 1922. Kellogg worked at the University of Kansas as an assistant professor of entomology, and then at Stanford university as an assistant professor, associate professor, and professor. He was a successful teacher of entomology. His areas of expertise were morphology, genetics, and behavior. Kellogg authored several general zoology and evolution texts, and also an economic entomology and zoology book (co-authored with R.W. Doane). Despite a successful career as an educator, Kellogg is best known for his humanitarian work. During World War I, he worked U.S. Food Administration and other relief groups in Europe in the aftermath of the war. He was decorated by several European governments for his humanitarian efforts. He was also instrumental in forming the National Research Council in the USA, an agency that links government and science. He died August 8, 1937.

Kennedy, John S

John Kennedy was born May 15, 1912, in Pennsylvania, USA, but spent most of his early life in London, England. He attended University College, London and then attained a M.S. with G. S. Frankel followed by a Ph.D. in 1938 at the Imperial Institute of Entomology in Birmingham. He studied locusts and mosquito behavior before joining V. B. Wigglesworth at the Unit of Insect Physiology in Cambridge. The unit was dissolved in 1967 but Kennedy moved to Imperial College and started a new physiology research unit. Kennedy was known for his research on many facets of insect behavior, including animal orientation, insect migration, and insect flight. He was a leader in separating behavioral research from anthropomorphic interpretation, an unfortunate result of the influence of Konrad Lorenz and research on "higher" animals. This crusade won him few friends initially, but his disciplined, clear-thinking approach won out and he eventually received considerable acclaim, honors and awards. He died on February 4, 1993, at Oxford, England.

Kershaw, John Crampton Wilkinson

Emmett R. Easton
University of Hawaii at Manoa, Honolulu, HI, USA

John Kershaw was born in Broughton, Nottinghamshire, England, in 1871, and was known as a scholar as early as age 10. His father, George S. Kershaw, was Vicar of Broughton in Nottingham. Very little is known of John's early life but his two younger brothers were also interested in entomology. Colonel Sidney H. Kershaw collected butterflies and moths wherever he was stationed and G. Bertram Kershaw collected them in England, so the family was interested in Lepidoptera.

John grew up during the latter part of the nineteenth century when the need of a college education was not an absolute necessity to work in natural history; however, his lack of it may have influenced success in later life. The coleopterist David Sharp, who was most liberal in giving assistance and encouragement to young persons planning to visit other countries, may have influenced him, as many entomologists as well as zoologists went to Sharp at the Cambridge museum in search of information about suitable equipment and the most profitable method of work. He was surely influenced by Edward B. Poulton, Hope professor of Zoology at the University of Oxford, who collected a wide variety of natural history objects. Kershaw's robber flies collected in Macao are listed in Poulton's pioneering work on *Predaceous insects and their prey* (Transactions of the Entomological Society of London, 1906) and Kershaw and Frederick Muir are listed in several of the *Hope Reports* (Oxford University) for their contributions in entomology in Macao, South China, over several years. He was certainly influenced by his long-lived friend, Dr. Robert C. L. Perkins, with whom he collected *Odynerus* vespid wasps in Hawaii later in 1912.

In 1898, at the age of 28, John Kershaw was in China where he studied natural history. He met the ornithologist and Englishman Frederick W. Styan (a tea merchant in Shanghai) who influenced him to study birds. Kershaw observed and collected them along the South China coast before Hong Kong became established. At that time, the Portuguese enclave of Macao was occupied by the English and other Europeans exploring or doing business in China. John Kershaw occupied one of the beautiful colonial type residences at 19 Praie Grande in Macao on the outer harbor as early as 1900, and used the rooftop of his home to rear the insects he studied.

When the exploratory entomologist Frederick A. G. Muir came to China via Macao in 1906–1907, they collaborated in Hawaiian Sugar Planter Association activities. Kershaw had recently published, and was becoming well known for his book on the *Butterflies of Hong Kong* (1906), the first to be published on South China Lepidoptera. Kershaw probably gained insight on insect parasitoids from his friend, as Muir was looking for biological control agents that could be introduced into Hawaii to control a leafhopper. Biological control had been criticized by economic entomologists, and Muir set out to prove that it would work in Hawaii. The sugar cane weevil, *Rhabdocnemis obscura* (Boisduval), was also affecting sugar production in the islands and Muir was looking for a biological control agent to control it. John Kershaw possessed local experience collecting insects that was not found among others in Macao. He had collected Hemiptera that were sent to G. W. Kirkaldy in Honolulu. This had resulted in several papers they published together until Kirkaldy's untimely death in 1900. Kirkaldy had named a cicada after Kershaw that the latter found in Macao; it remains known as *Balinta kershawi* Kirkaldy. John Kershaw also traveled with Muir to the How-lik Monastery area in the Guangdong province of China, collecting insects that were housed in the former Hawaiian Sugar Planters insect collection (currently in the Bernice P. Bishop Museum, Honolulu).

After collecting in the How-lik area among fine forest trees in virgin forest (in what is now known as the Dinghushan Biosphere Reserve) in search of cane leafhopper parasites, they began to search in other areas of Southeast Asia. In November 1908, they both traveled to Indonesia to look for parasites of the sugar cane weevil in west Ceram (The Moluccas). Although unable to locate parasitized cane borers, their time was still profitable with the discovery of a new velvet worm (Onychophora), a species of *Peripatus* known today as *Paraperipatus ceramensis* (Muir and Kershaw). This invertebrate was earlier believed to be a "missing link" between the Annelids and the arthropods, and they worked out the developmental biology in this animal.

In a later trip to Papua New Guinea in 1909, Muir discovered a tachinid fly, *Lixophaga sphenophori* (Villeneuve) that was affecting populations of the sugar cane weevil and he tried to import it into Hawaii, but failed to bring in enough live material for propagation and release in the fields. John Kershaw was sought from Macao to help him in this endeavor. John had developed exceptional skill in keeping insects alive. For example, he had reared several species of butterfly including the rare lycaenid *Miletus chinensis* C. Felder, and the ant-attended larva of the long-banded silverline, *Spindasis lohita* (Horsfield), in preparation for his book on Hong Kong butterflies. He was also successful in culturing an asilid fly (*Promachus* sp.), the pentatomids *Erthesina fullo* (Thunberg) and *Chrysocoris stollii* (Wolff), a predaceous pyrrhocorid bug *Dindymus sanquineus* (Fabricius), the fulgorid *Fulgora candeleria* (L.), and even a rare primitive grasshopper of the genus *Eumastax*, now known as *Erianthus versicolor* Brunner van Wattenwyl in the family Eumastacidae.

In 1910 Kershaw left Macao and traveled to Mossman in Queensland of northern Australia to establish a rearing colony of *L. sphenophori* at the Mossman central sugar mill. The flies had been collected originally in lowland Papua New Guinea, and work at the mill was pre-arranged by Muir. Kershaw then approximated the natural conditions of the fly by designing very large cages over 2 m in height (screen covered and topped with leafy materials to supply shade during sun-lit periods of the day) and he filled them with sugar cane stalks and placed the cages a foot above the ground on posts to avoid predation by ants. The smaller sized cages used earlier had evidently lacked enough space to allow the pre-nuptial flight necessary for mating behavior in the tachinid flies because although the smaller cages only produced 10 parasitoid puparia, the new large cages produced 300 puparia. Using a relay station in the Fiji islands, Muir brought live larvae and pupae in sugar cane stalks into the state during the latter part of 1910, and Kershaw arrived later with additional stock. Their actions insured that enough parasitoids reached Hawaii's plantations to save the sugar industry from appreciable loss. Without Kershaw's mass rearing skills, this fly would not have been successfully reared and the cane-beetle effectively controlled in Hawaii.

Kershaw was a member of the Hawaiian Entomological Society, a Fellow of the Entomological Society of London, a fellow of the Zoological Society of London, and also a Fellow of the Entomological Society of Belgium. He resigned as assistant entomologist with the Hawaiian Sugar Planters Association in 1912 taking a position in Trinidad, West Indies, working on economic control of the froghopper *Tomaspis* sp. (Hemiptera) of sugar cane. After completing this contract, he returned to England and, following the war, wrote a natural history book with the local historian Charles G. Harper on the *Downs and the Sea, wildlife and scenery in Surrey, Sussex & Kent*, published by C. Palmer, London, in 1923. He then retired as an entomologist/zoologist. He passed away in Whiffen's cottage, Kent County, England, on the August 26, 1959 at age 79.

If not acknowledged as the father of natural history in South China, Kershaw should at least be remembered as the "Father of Entomology in Macao." In addition to the aforementioned accomplishments and abilities, he was skilled in insect embryology, writing on egg development in

Siphanta acuta (Walker), a flatid hemipteran (common at higher elevations in Hawaii), and on *Pristhesancus papuensis*, a New Guinea reduviid. Also, he was an early pioneer in the study of web-spinning Embioptera, and one of the first persons to study egg development in *Antipaluria urichi* (de Saussure) in Trinidad. A skilled craftsman, he was an excellent illustrator in all of his publications. This is particularly apparent in his excellent drawings on the anatomy of the fulgorid homopteran, *F. candeleria*, once believed to possess a snout with luminous qualities and commonly found on trunks of lychee and longan trees in South China.

Kevan, Douglas Keith Mcewan

Keith Kevan was born at Helsinki, Finland, in 1920, but spent most of his early years near Edinburgh, Scotland. He attended Edinburgh University and graduated with first class honors in 1941. He then attended Imperial College, Trinidad for a two-year course in tropical agriculture, and afterwards worked in Kenya with the Kenya Department of Agriculture. He returned to England in 1947 to head the Zoology Section of the University of Nottingham, where he worked on soil fauna but also developed a strong interest in orthopteroids. Kevan relocated to Canada in 1957 to head the Entomology Department at McGill University in Quebec, where he served as chairman from 1957 to 1971. Kevan was an accomplished entomologist as well as an effective administrator. He became one of the world's foremost authorities on grasshoppers, and the undisputed authority on the family Pyrgomorphidae. He also was interested in Neuroptera, and published on cultural entomology and ethnoentomology. He authored several books including "Soil animals" (1962), and several monographs on grasshoppers and locusts. In addition, he authored over 400 technical articles. Kevan served as president, and was named a fellow of the Entomological Society of Canada, as well as receiving many other honors. He also played a key role in initiating the biological survey of insects of Canada. Kevan died in 1991.

Key Factor

The factor most responsible for changes in population trends. In life table studies, key factor analysis is used to identify population regulating mechanisms.

► Life Table

Key Pests

The pests that have the greatest potential to affect the profitability of the crop.

Keystone Species

A species that has a particularly great influence on an ecosystem and, if removed from the system, its loss has a significant effect on the entire ecosystem, especially its other inhabitants.

Khapra Beetle, *Trogoderma granarium* Everts (Coleoptera: Dermestidae)

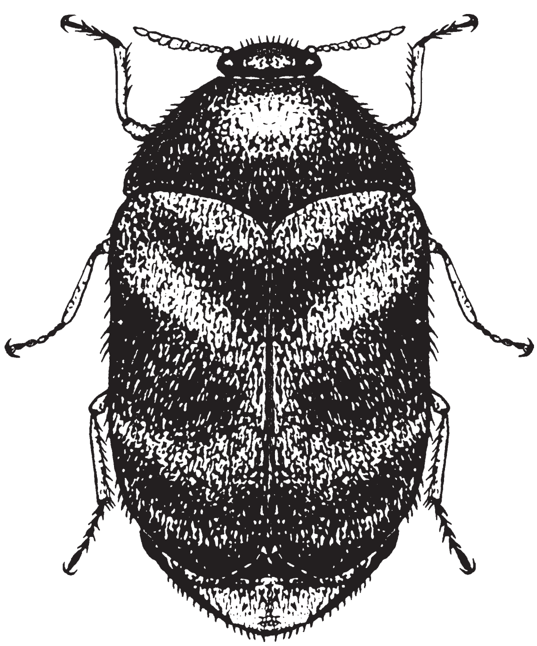
JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

A very serious pest of stored grain, khapra beetle has been the target of many successful eradication efforts in regions of the world where it does not naturally occur. Generally, it thrives in warm dry regions. It is found in northern and central Africa, the Middle East, and east through India to Myanmar. It is generally absent from Europe, though there are a few localized infestations. Presently it is absent from the western hemisphere, Australia, and New Zealand.

The life cycle can be as short as 35 days at about 34°C, but is nearly 150 days long when reared at 10°C. As many as 12 generations are reported annually in India. The adults are short-lived, seldom living more that 10–12 days. Mating occurs immediately at high temperatures but may require several days at cooler temperatures.

After a short pre-oviposition period, females (Fig. 4) deposit up to100 eggs, but mean fecundity is about 35 eggs. The eggs are cylindrical, with one end rather pointed and bearing spine-like projections, but the other end rounded. Normally they measure about 0.7 mm long and 0.25 mm wide. They are translucent white, but yellowish or reddish marks develop on the chorion. The eggs hatch in 3–14 days, depending on temperature.

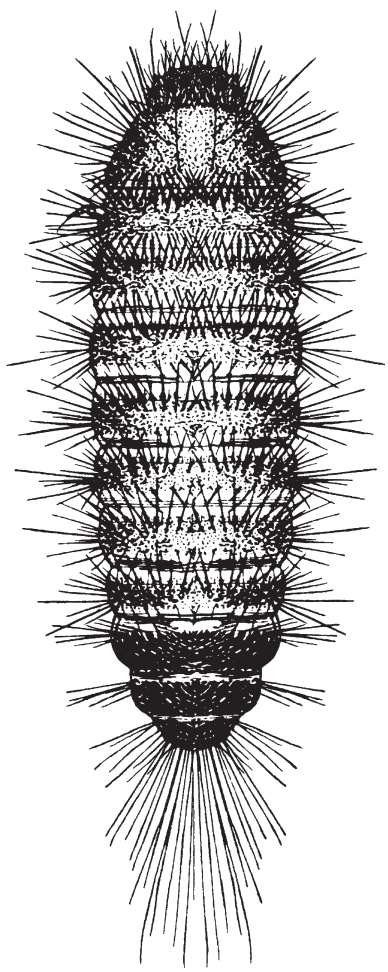
The larvae are yellowish brown or brown, and bear numerous long hairs on the dorsal surface. Younger larvae bear a "brush" of long hair on the ninth abdominal segment that projects like a "tail," and although this look tends to diminish as the larvae grow older, the tuft of hairs remains prominent. The larval period can be completed in 15 days, but when faced with starvation the larvae can persist for 13 months, and with limited food can survive for up to six years! Males typically undergo four instars, females five, though this varies considerably. Larvae attain a length of about 5 mm. Young larvae feed on cracked grain kernels as such food is not protected



Khapra Beetle, *Trogoderma granarium* Everts (Coleoptera: Dermestidae), Figure 4 **Adult Khapra beetle, *Trogoderma granarium*.**

by a seed coat, but larger larvae attack the intact kernel. Larvae (Fig. 5) are usually found feeding on the surface of infested material, but can penetrate several centimeters in search of food. Cast skins also are commonly found on the surface of grain containing infestations. Some larvae are able to undergo diapause when exposed to unfavorable temperature, humidity and crowding, but others lack the capacity for diapause.

When they are ready to pupate, larvae crawl into crevices. Pupation occurs within the last larval exuvium, and typically lasts 3–5 days. Pupae measure about 5 mm long, and are light brown, and bear a medial ridge of long hairs dorsally.



Khapra Beetle, *Trogoderma granarium* Everts (Coleoptera: Dermestidae), Figure 5 **Larva of Khapra beetle, *Trogoderma granarium*.**

The emerging adults are small, only 1.8–3.8 mm long. They are oblong-oval in shape, and females are larger than males. They are yellowish brown to reddish brown, with the pronotum usually darker than the elytra, and indistinct reddish brown marks on the elytra. The males are distinguished from other male *Trogoderma* by an antennal club of five or fewer segments; females by an antennal club of three or fewer segments. The adults can produce eggs without having to drink or eat after emerging. Adults reportedly do not fly.

Several natural enemies are known, including predatory Hemiptera and mites, parasitic wasps, and diseases. Biological suppression is not practiced.

Damage

This species attacks such vital staples as wheat, barley, rice, millet, sesame, corn (maize), sorghum, and peanut. Feeding reduces grain to a powdery mass, reducing weight and grade of the grain. The larvae chew through grain sacks as well, weakening the fibers and resulting in tears. They are favored by hot, dry conditions and cannot compete with other species under moist conditions.

Management

Hygiene is an important element of management, and it is useful to remove old grain, avoid spillage, and fill cracks and crevices. Treatment of grain storage facilities with residual contact insecticides deters infestation, and fumigants are used to disinfest grain. The diapausing larvae are fairly resistant to fumigants, so protracted fumigation is advised. On-farm grain storage in India often used neem seed powder mixed in with the grain. Heat treatment also can be effective. Traps for detecting infestation use both food and sex pheromones as bait.

Kiesenwetter, Ernst August Hellmuth Von

The noted Saxon entomologist E. A. H. von Kiesenwetter was born at Dresden, Germany, on November 5, 1820. He studied law at the University of Leipzig until 1843, and rose to prominence in the Ministry of the Interior. He began taking collecting trips, and publishing entomological articles, in the 1840s. Though known principally as a coleopterist, Kiesenwetter also published on other orders. His principal contribution, other than the numerous papers he authored, was to author much of the Coleoptera section of the "Naturgeschichte der Insecten Deutschlands." He died on March 18, 1880, at Dresden, Germany.

Kin Selection

A theory put forth by W. D. Hamilton (1964) that states that an altruistic act by close relatives is favored because it increases the inclusive fitness of the individual performing the social act. Inclusive fitness is the fitness of the individual as well as his effects on the fitness of any genetically related neighbors. The theory is that alleles change in frequency in a population due to the effects on the reproduction of relatives of the individual in which the trait is expressed rather than on the reproductive success of the individual. A mutation that affects the behavior of a sterile worker bee, even though detrimental to her, could increase the fitness of the worker if her behavior increased the likelihood that a close relative would reproduce. Kin selection could explain the evolution of sociality, which appears to have developed as many as eleven times in the order Hymenoptera.

Kinesis (pl., kineses)

A class of orientation behavior characterized by undirected movements in which the frequency of turning (klinokinesis) or speed of movement (orthokinesis) is related to the intensity of the stimulation. A change in the rate of movement in response to an environmental condition, with the direction of the movement random and unrelated to the stimulus. Often, if conditions are favorable, organisms remain quiescent, moving to another location if conditions are not favorable. Types of kineses include: chemokinesis, stereokinesis, photokinesis, and hygrokinesis (contrast with taxis).

Kirby, William

William Kirby was born in September 1759 at Witnesham Hall, Suffolk, England. Kirby is known as the "father of British entomology." He was educated for the clergy, and graduated from Caius College, Cambridge, in 1781. Kirby successfully conducted his ministry, but also studied insects. His first publication was a monograph on British bees, published in 1802. He also established the Order Strepsiptera. He was a fellow and honorary member of numerous scientific societies. Kirby met William Spence when he was 48 years old, and co-authored, with Spence, the first popular entomology work on insects published in English: "An introduction to entomology," which was published in four volumes between 1816 and 1826. It remained the most important work on insects published in English for over 100 years, and was published in seven editions. The significance of his work is easy to underestimate because we now take for granted that entomology is a legitimate pursuit, whereas until Kirby and Smith authored their book, the common notion was that anyone interested in insects was not entirely sane. He died at Barham, near Ipswich, England, on July 4, 1850.

Kissing Bugs (Hemiptera: Reduviidae: Triatominae)

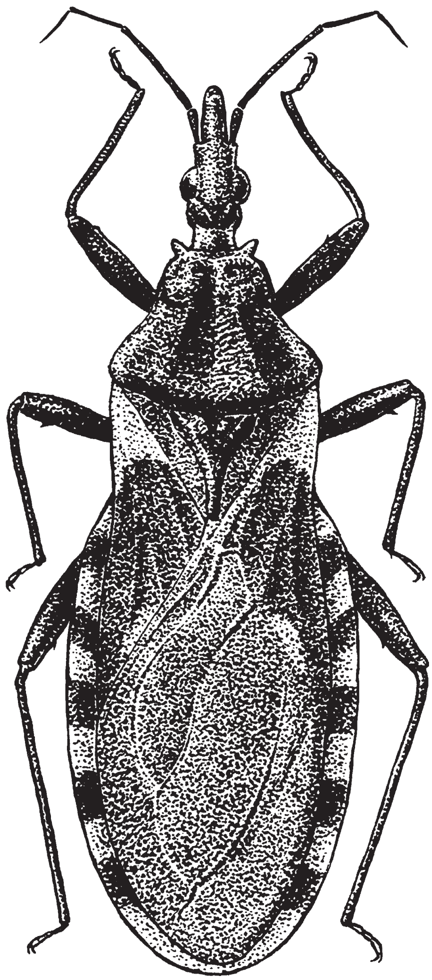
EUGENE J. GERBERG
University of Florida, Gainesville, FL, USA

Kissing bugs of this subfamily are also known as conenoses, Mexican bed bug (Fig. 6), barbeiro, chipo, vichua, pito and other names in Latin America. The head of triatomine bugs is more or less cone-shaped, the sturdy proboscis can be thrust forward or repose beneath the head, and the prothorax is well developed. The antennae are four or five-segmented. They fly readily. These insects are obligate blood feeders. Many species are vectors of the trypanosome *Trypanosoma cruzi*, the etiologic agent of Chagas disease, or American trypanosomiasis. Kissing bugs become infective by imbibing blood from an infected vertebrate host. The parasite develops in the gut of the triatomine and the infective trypomastigotes pass out in the feces. When the infective feces are rubbed into the bite site, skin, or mucous membranes, transmission occurs. Another mode of transmission is through blood transfusion. In vertebrates other than humans, infection may occur by ingestion of the infected bug. The bite of kissing bugs is often painless, a useful adaptation for feeding on vertebrates, but some are capable of inflicting a painful bite. Humans vary in their sensitivity to bites. Some bitten individuals are hypersensitive and may suffer an anaphylactic reaction. Kissing bugs are chiefly nocturnal, and on humans they prefer to feed on exposed skin, such as the face, particularly the upper lip, arms and legs.

Many species of kissing bugs transmit *Trypanosoma cruzi*, but *Triatoma infestans* (Klug), *T. maculata* (Erichson), *T. dimidiata* (Latreille), *Panstongylus megisus* (Burmeister) and *Rhodnius prolixus* (Stål) are common vectors. Humans suffering from infection often exhibit a swelling of the eyelid and face, a symptom known as "the sign of Romaña." Infection can last many years, and affect the heart.

Some species principally inhabit the soil surface, though others frequent trees or other habitats. Natural hosts are generally woodrats or other animals; humans are accidental. The woodrat builds nest of available plant materials, and these nests are favored by triatomes. Kissing bugs will also feed on domestic pets and wild animals that may occur near human habitation.

The development of the kissing bug requires five to eight nymphal instars, which may last



Kissing Bugs (Hemiptera: Reduviidae: Triatominae), Figure 6 **A representative kissing bug, *Triatoma sanguisuga* (LeConte), also known as the "Mexican bed bug."**

from three months to a few years. The length of the nymphal instars depends upon the quantity of the blood meals. The nymphs and adults require blood meals usually of vertebrate animals. The amount of blood ingested varies from approximately 6 mg to over 275 mg. Females are ready to mate shortly after the final molt. The female may oviposit 1–3 weeks after copulation. There is considerable variation in the number of eggs deposited. The eggs are shiny and smooth. Eggs, which are often barrel-shaped, may possess a fringed cap. They are deposited singly or in small clusters, and deposited in the same habitats as occupied by adults. The eggs hatch in 8–30 days.

In addition to transmission of Chagas disease, bugs can also cause anaphylactic reactions. Hypersensitivity follows repeated bites. Patients develop nausea and diarrhea, welts and rashes, edema, and itching.

Klee, Waldemar

G. Waldemar Klee was born in 1853 in Copenhagen, Denmark. He was educated in agriculture in Denmark, but moved to the USA at the age of 19 and worked for the University of California. For many years he studied the biology and management of fruit pests, and was appointed Inspector of Fruit Pests by the California State Board of Horticulture in 1886. Klee received parasitoids of cottony cushion scale from Australia and liberated them in San Mateo County in 1888, initiating the first biological control effort directed at this serious pest. He died in 1891 in Santa Cruz, California, USA.

Knipling, Edward Fred

Edward Knipling was born at Port Lavaca, Texas, USA on March 20, 1909. He graduated from Texas A&M University (B.S. 1930) and Iowa State University (Ph.D. 1947) before joining the United States Department of Agriculture for a 43-year career with that agency. He led the Orlando, Florida, laboratory that developed DDT and other insecticides and repellents to protect American troops during World War II from disease- spreading insects. He also led the Insects Affecting Livestock, Man, Households, and Stored Products Division in Washington, DC, and led the Entomology Division. Knipling is credited with developing the sterile insect technique, and also the use of mathematical models for pest suppression based on the sterile insect technique. This technique has been used successfully to eradicate screwworm fly, Mediterranean fruit fly, tsetse fly, melon fly, and other pests throughout the world. He published over 225 technical articles during his career, including an insightful but oft-overlooked book "Principles of insect parasitism analyzed from new perspectives: practical implications for regulating insect populations by biological means" (1992). He was a member of the prestigious National Academy of Sciences and received numerous honors and awards. He died on March 17, 2000 in Arlington, Virginia.

Knockdown

Incapacitation of an insect following exposure to a sublethal dose. Following such exposure, insects may recover due to metabolic detoxification of the pesticide, or perish. In assessing the response of insects to insecticides, knockdown is usually assessed separately (at about 1 h post-treatment) from mortality (often at 24 h post-treatment).

Koch's Postulates

Criteria proposed by Koch that are commonly used for establishing the pathogenicity of a microorganism: the microorganism must by consistently associated with the disease; the microorganism can be isolated and grown in culture; and when the microorganism is injected into a healthy host, disease is expressed.

Koinobiont

Parasitoids that do not immediately impair their hosts upon oviposition, and host development continues. These are typically endoparasitoids.

Koebele, Albert

Albert Koebele was born in 1852 at Waldkirch, Germany. When he moved to the United States is not certain, but he became a citizen in 1880. His abilities so impressed C. V. Riley that Riley appointed him to the US Department of Agriculture in 1881 and assigned him to work on cotton pests in Florida and Georgia. In 1885 he transferred to California to work on fruit pests. He was sent to Australia in 1888, where he sent a parasitic fly, *Cryptochetum iceryae* (Williston), and a ladybird beetle, *Rodolia cardinalis* (Mulsant), to California. The ladybeetle was a very successful biological control agent, gaining him recognition for saving the citrus industry from cottony cushion scale. On a later trip to the region he also traveled to New Zealand where he introduced some ladybirds from California into New Zealand, and several additional ladybirds into California. His success earned him the ire of some collaborators who were jealous of his recognition, and he resigned from USDA in 1893 to (Fig. 7) join the Hawaii Board of Agriculture and Forestry. There, he continued introductions from Southeast Asia, Australia, Japan, and Mexico. In 1903 he joined the staff of the Experiment Station of the Hawaiian Sugar Planters Association. Koebele suffered from illness (probably malaria) contracted while living in the tropics, and he returned to Germany in 1908 to recuperate. During World War I he suffered considerable hardship and attempts were made to move him back to California. However, Koebele never regained his health, despite his move to Germany, and he was found to be too feeble to be transported. He died in Waldkirch, Germany, his home town, on December 28, 1924.

Kraatz, Ernst Gustav

Ernst Kraatz was born in Berlin, Germany, on March 13, 1831. He began collecting insects at an early age, and published his first paper at the age of 18. From 1850 to 1853 Kraatz studied law at the Universities of Heidelberg and Bonn, but had no real interest in this field, so he moved to the University of Berlin and obtained a Ph.D. in 1856. He was active in German entomological societies, and founded the Deutsche Entomologische Gesellschaft, and served as its president for 25 years. He also was the primary force behind establishment of the Deutsche Entomologisches Nationalmuseum. Kraatz was a very prominent coleopterist, and published nearly 1400 papers. He described hundreds of species. Late in life he lost his eyesight. Kraatz died in Berlin on November 2, 1909.

Kring, James Burton

Jim Kring was born on May 25, 1921, at Monett, Missouri. He graduated from Rockhurst College and received both the M.S. and Ph.D. degrees from Kansas State University. After serving in the military during World War II, Kring became an instructor at Kansas State, then moved to the Connecticut Agricultural Experiment Station, where he worked from 1951 to 1977. In 1977, he became head of the

Department of Entomology at the University of Massachusetts, and later acting Dean of the College of Food and Natural Resources. He retired in 1981 and moved to Florida, but continued to conduct research in conjunction with the University of Florida's Gulf Coast Research and Education Center at Bradenton, Florida. Kring had diverse interests of both basic and applied nature, but he is remembered for his pioneering work in aphid ecology. Kring, along with V. Moericke of Germany and J. S. Kennedy of England, elucidated the changing host selection behaviors of dispersing aphids, namely a positive response to sunlight when dispersing, and a negative response to sunlight and a positive response to plant pigments when alighting. He was the first to demonstrate that aphids could be managed through visual disruption of their host-seeking behavior, which he accomplished by application of reflective mulch to the soil surrounding plants. Subsequently, this practice has been shown to be both effective for reducing aphid and whitefly infestation rates and plant virus infection, and economic for high-value crops such as vegetables. Thus, the practice has been widely adopted in some production areas. An author of over 100 papers, Kring was also very involved in professional society affairs. He served as president of the Connecticut Entomological Society, the president of the eastern branch of the Entomological Society of America, and president of the Entomological Society of America. He received several other honors from this society. He died at Anna Maria, Florida, on October 29, 1990.

K-Strategists

Species with life history characteristics making them well suited for population stability and stable environments ("K" is an expression of carrying capacity of the environment). K-selected species represent an extreme on a continuum of life history characteristics, with r-selected species at the other end of the continuum. K-selected species can also be said to conform to the "competitive strategy" (Table 1).

Kyasanur Forest Disease

This tick-borne virus disease is found in southern Asia.

► Ticks

K-Strategists, Table 1 **A comparison of the characteristics of r-selected and K-selected species**

	r-selected	K-selected
Habitat type	Unstable, not permanent	More stable
Reproduction	Rapid under favorable conditions; many offspring produced	Usually slower; fewer offspring produced
Development	Rapid; often multivoltine	Slower; often univoltine
Mortality	Often density independent and catastrophic	Often density dependent and more gradual
Population size	Extremely variable in time	Less variable in time
Dispersal capacity & mode	High and random	Lower and oriented
Brood care	Absent	Sometimes present
Body size	Often quite small	Often larger
Competition	Variable, but often low	Often very keen
Ultimate effect	High productivity	Efficient use of resources

L

Labellum

The mouth of certain Diptera, consisting of a ridged lip at the end of the proboscis. This term also is used to describe the extension of the labrum covering the base of the rostrum in Coleoptera and Hemiptera, and a lobe at the apex of the glossa in honey bees.

► Mouthparts of Hexapods

Labial Glands

Glands opening at the base of the labium that secrete saliva to aid digestion. Sometimes they also produce silk.

Labial Palpi

Short (one- to four-segmented) sensory appendages on the insect labium.

► Mouthparts of Hexapods

Labiduridae

A family of earwigs (order Dermaptera). They sometimes are called striped earwigs.

► Earwigs

Labiidae

A family of earwigs (order Dermaptera). They sometimes are called little earwigs.

► Earwigs

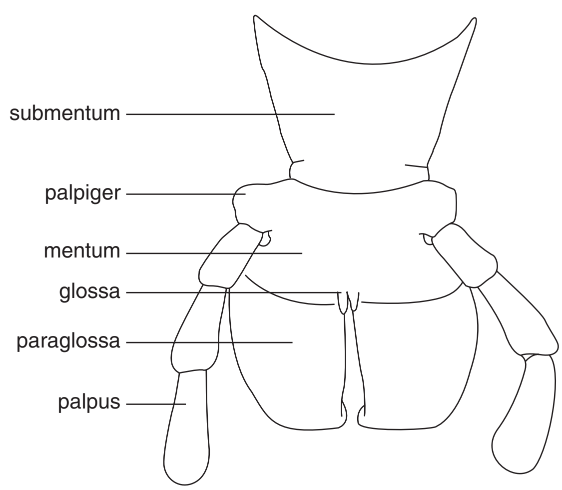
Labium

A structure that forms the floor of the mouth. The lower lip (Fig. 1).

► Mouthparts of Hexapods

Laboubeniales

The Laboubeniomycetes (Ascomycota) contains the order Laboubeniales with the greatest number of ectoparasitic species (more than 1,300). However, in some instances, parasitization by selected numbers of the Laboubeniales may result in pathological symptoms in host insects. These fungi most commonly infect Coleoptera but can be



Labium, Figure 1 **External aspect of the labium in an adult grasshopper, showing some major elements.**

found among other insect orders, usually on the adult stage, and also in mites and millipedes. They may attack only one sex of an insect and may even be site-specific, developing only on certain areas of the cuticle. Their association with arthropod hosts is obligate (essential) for completion of a life cycle.

The Laboubeniales may appear as hair-like structures on the cuticle surface. Careful examination of these structures reveals a thallus, consisting of a receptacle and its appendages. The thallus, as recently described for *Hesperomyces virescens*, arises from ascospores that contact and attach to the host (ladybird beetle) cuticle. The receptacle is attached to the host cuticle by a basal cell called the foot. Antheridia (male gametangia) arising from the receptacle produce non-motile spermatia. Trichogynes (the female receptive hyphae) are borne on young perithecia also located on receptacles. There are no known anamorphs so that infection and thallus development on the cuticle must originate from the sexually produced ascospores. In a few cases, haustoria may grow from the foot and penetrate the cuticle and the underlying hemocoel, as reported for *H. virescens*, to obtain nutrients. Narrow branches of these invasive haustoria (rhizomycelia) may destroy fat body and muscle, thus causing symptoms of severe disease. Premature death may result or basic functions such as egg production and feeding may be affected.

Lace Bugs (Hemiptera: Tingidae)

LAURA T. MILLER
West Virginia Department of Agriculture,
Charleston, WV, USA

Tingids are commonly called lace bugs because the pronotum and forewings have delicate and intricate reticulations resembling lace. Lace bugs can be confused with the Piesmatidae or ash-gray lace bugs, which also have forewings that are somewhat lace-like or reticulated. However, the lack of ocelli in the Tingidae distinguishes them from the Piesmatidae. All tingids are phytophagous and generally are host specific. Some species can be very destructive to plants, some of economic importance.

The Tingidae are distributed worldwide. The family is comprised of approximately 2,000 species placed in three subfamilies. The Cantacaderinae occur mainly in the Southern Hemisphere, the Tinginae are represented throughout the tropical and temperate zones, and the Vianaidinae are a small Neotropical group. The Tinginae comprise the majority of the lace bugs within the family, including some 220 genera out of approximately 250 genera. The higher level classification is:

Order: Hemiptera
- Suborder: Heteroptera
  - Superfamily: Tingoidea
    - Family: Tingidae
      - Subfamily: Cantacaderinae
      - Subfamily: Tinginae
      - Subfamily: Vianaidinae

Diagnosis

Tingids are very small insects, approximately 2–10 mm in length. Their coloration is generally cryptic, ranging from white or yellowish to brown and black. Their general appearance is somewhat flattened dorso-ventrally, and it can vary from quadrate or broadly oval to narrow and slender. Dorsally, they look like fancy lace, the pronotum and forewings having a network of multiple cells or areolae (Figs. 3–7). Many species have very wide wings and their head can be concealed or partially obscured under a hood-like projection from the pronotum. Many others have very narrow wings and very small pronotal hoods or no hoods at all. The pronotum can have extremely diverse structures, from low carinae to globose hoods, bump-like projections, and foliaceous overgrowths. Lace bugs have no ocelli. The antennae are four- segmented, with the third antennomere being the longest. The head can possess spine-like, finger-like, or tubercle-like projections, or it can be completely devoid of such projections. The hemelytra, which are the first pair of wings, are translucent or transparent in many species. Some species have brachypterous forms, meaning that the wings are reduced in some degree, sometimes exposing one or two posterior abdominal segments. The rostrum or beak is elongate with four segments. In repose, it rests in a rostral groove, which has margins that are delimited by foliaceous and areolate carinae. Their legs are generally thin and elongate with the tarsi divided to form two tarsomeres.

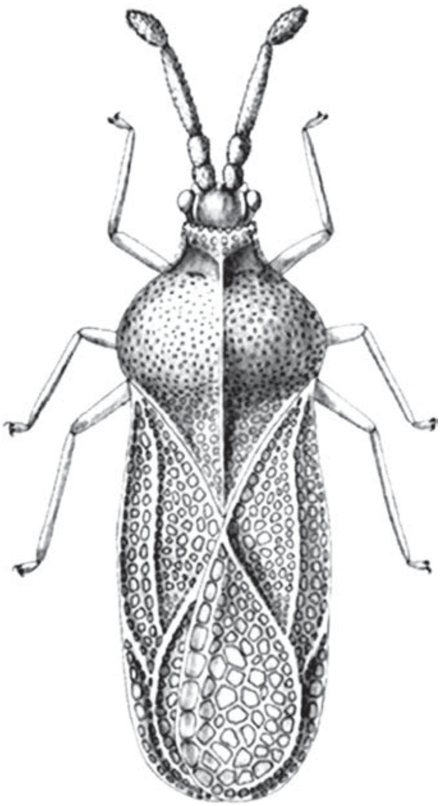
***Phatnoma* sp. lace bug.**

Biology

Most species of lace bugs live on the underside of leaves, but a few can live on the upper and lower parts of stems (*Melanorhopala froeschneri* Henry and Wheeler, *Physatocheila plexa* (Say)) or even on the upper parts of roots (*Coleopterodes*). Species of two Old World genera, *Copium* and *Paracopium* are gall-makers on the flowers of their host plants. Adults and nymphs alike feed on the sap of the host plant by piercing the epidermis. Although each tingid species is usually somewhat host specific, lace bugs collectively feed on a diverse array of plants. They complete their whole life cycle on the same host plant species and on the same part of the plant. Most species of lace bugs are gregarious, and some have shown parental care. Tingids generally have one or two generations a year, although some species have multiple generations. Most species of lace bugs over-winter



Lace Bugs (Hemiptera: Tingidae), Figure 7
***Leptoypha* sp. lace bug.**

as adults, but a few over-winter as eggs (*Stephanitis*) and some as nymphs (*Acalypta*). Lace bugs can lay their eggs deeply into the plant tissues or set them on the abaxial surface of a leaf. They are hemimetabolous or, in other words, have incomplete metamorphosis, in which the immature stages (nymphs) are similar to the adult stage, with the exception of smaller size and the absence of fully developed wings and genitalia. Wings appear as small pads in the second or third instar (nymphal stage) and increase in size with each moult. Most species have five instars before reaching the adult stage, although a few species have four instars (for example, *Stephanitis rhododendri* Horvath). The nymphs' general appearance can be flat with a great number of needle-like spines covering the dorsal surface, or it can be smooth. In some species, the spines seem to produce secretions that afford protection against predators.

Economic importance

Although not all tingid species are of economic importance, some are serious pests. Lace bugs are capable of causing great damage to their host plants during seasonal outbreaks. The piercing of the plant's epidermis can cause extensive tissue damage that diminishes photosynthesis. As a result, especially when high numbers of nymphs and adults are present, chlorosis (yellowing of the plant parts) occurs due to chlorophyll reduction, and as a consequence, the plant loses vigor.

A good number of tingids are common pests of forest trees, agricultural crops, fruit trees, and ornamentals. Some examples are as follows: *Gargaphia tiliae* (Walsh), the basswood lace bug, is a common pest of *Tilia americana* L., a forest and ornamental tree in North America; *Corythucha gossypii* (Fabricius), the cotton lace bug, is an important pest of beans and cotton from the southern United States to northern South America; *C. cydoniae* (Fitch), the hawthorn lace bug, attacks many species of wild and ornamental woody rosaceous plants in North America; *C. mcelfreshi* Drake, the peach lace bug, causes constant defoliation which greatly affects fruit production in some areas of Mexico; *C. ciliata* (Say), the sycamore lace bug, is a very common lace bug that feeds on *Platanus occidentalis* L., the common sycamore tree in North America, and on its ornamental hybrid *P.* x *acerifolia* Ait., the London plane tree; *Stephanitis pyri* (Fabricius), a polyphagous pest in Europe and the Middle East, feeds primarily on a variety of trees and shrubs, including rose, elm, oak, poplar, cherry, etc.; *Habrochila ghesquierei* Schouteden is an important pest of coffee from eastern Africa; and *Stephanitis pyrioides* (Scott), the azalea lace bug, probably a native of Japan, has become an important pest of ornamental azaleas almost anywhere azaleas are grown.

Some species of lace bugs have been considered for the biological control of noxious weeds. The lantana lace bug, *Teleonemia scrupulosa* Stål, feeds on the invasive weed *Lantana* spp. *Oncochila simplex* (Herrich-Schaeffer) is a possible control for leafy spurge *(Euphorbia* spp.) in the U.S.A. *Dictyla* *echii* (Schrank) has been considered for the control of viper's bugloss, *Echium plantagineum* L., an invasive weed of pastures.

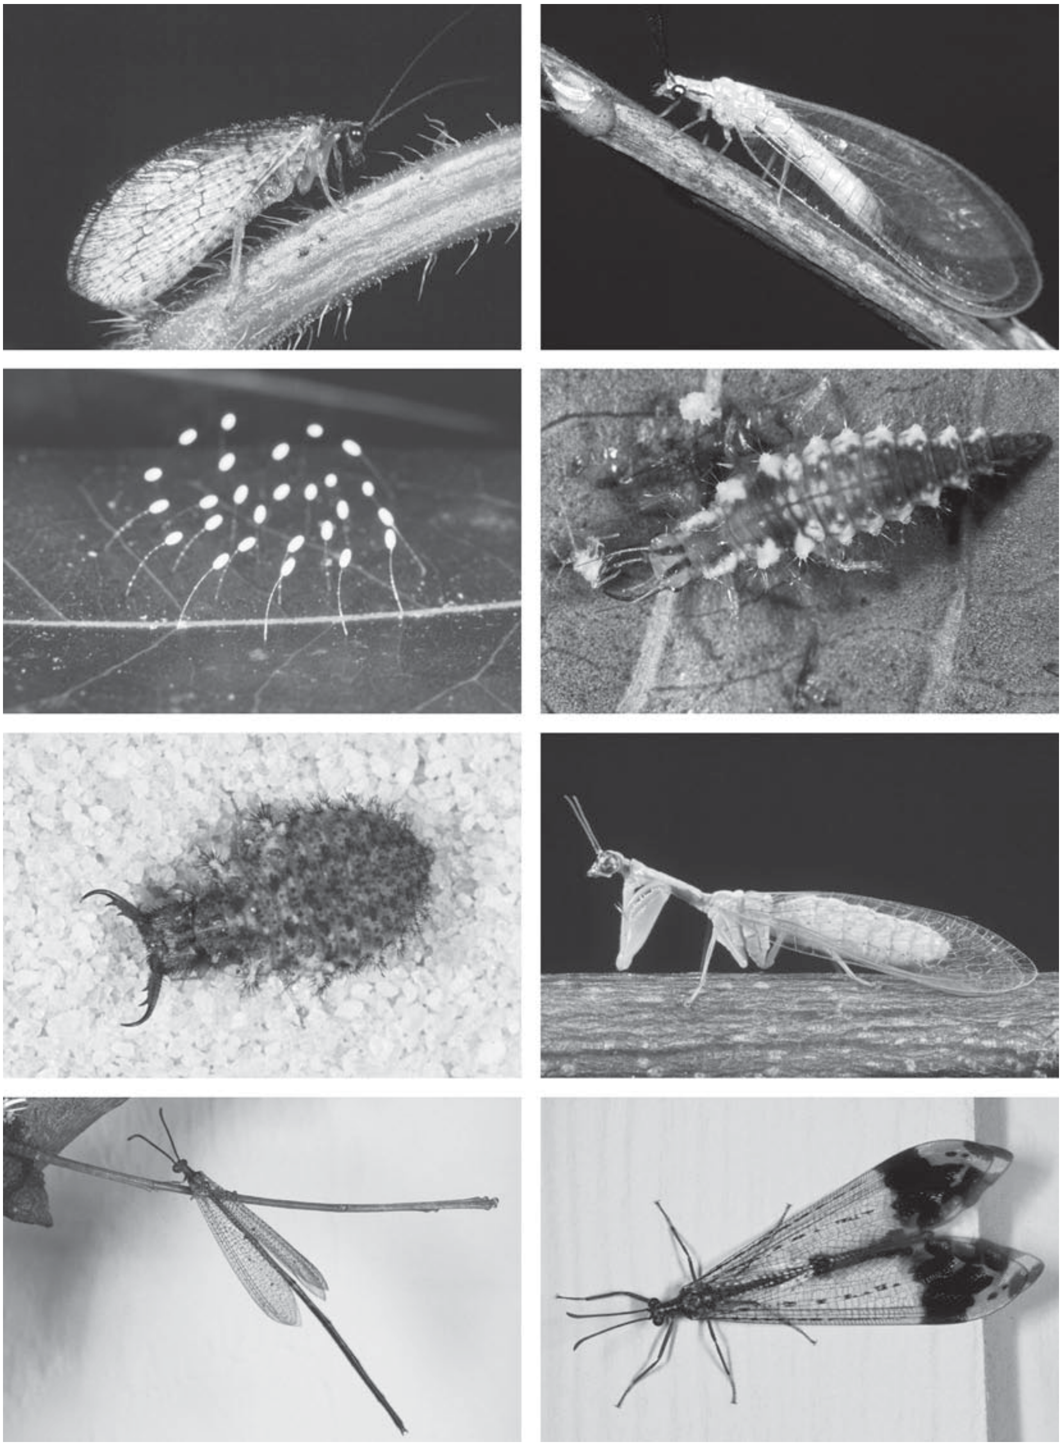
Lacewings, Antlions and Mantispids (Neuroptera)

LIONEL STANGE
Florida Department of Consumer and Agricultural Services, Division of Plant Industry, Gainesville, FL, USA

This is the largest order of the Neuropterida which also includes snakeflies, alderflies and dobsonflies and contains about 5,000 described species. Until the recent split of the order Neuroptera into three orders, the true Neuroptera were also called Planipennia. Seventeen extant families are recognized which include minute insects with a forewing length of about 2 mm (Coniopterygidae) to very large insects with forewing lengths of 70 mm or more (Myrmeleontidae). Most species are moderate-sized insects. They are holometabolous insects in which the families have been grouped by the shape of the larval mandibles. They are short and stout in Ithonidae and Polystoechoetidae (which have subterranean larvae), elongate but straight in the Osmylidae, Sisyridae, Nevrorthidae, Dilaridae, Berothidae and Mantispidae, curved without teeth in the Chrysopidae, Nemopteridae and Hemerobiidae and curved with teeth in the Psychopsidae, Nymphidae, Nemopteridae, Ascalaphidae and Myrmeleontidae. The mandibles of the Coniopterygidae appear to be highly modified which contributes to their phylogenetic isolation from other families. The adults are conservative morphologically with chewing mouthparts, five segmented tarsi and two pairs of wings which have dissimilar venation. Venation is usually dense (Fig. 8) and complete but can be very reduced, especially in small species. The larvae are unique in that the mandible is grooved to receive part of the modified maxilla to form a sucking "jaw." Also, the digestive tube is strange in that the midgut does not empty into the hindgut until the adult emerges from the pupa and deposits a meconium pellet. This is made easier by the fact that food is always taken in liquid form as the larva injects digestive enzymes into the prey to liquefy the tissue. However, they can pass urine. The Malpighian tubules (usually eight in number) are adapted to produce silk which is manipulated by the anal spinneret to construct the silken cocoon. The carnivorous larvae are terrestrial except for the aquatic Sisyridae and some Osmylidae.

The Neuroptera were clearly distinct by the Permian, with extant families (Chrysopidae, Coniopterygidae, Nymphidae, Psychopsidae) present in the Triassac Period. Schlüter (1986) recognized an additional 14 families existing in the Mesozoic Era which are now extinct. Although the primitive Neuroptera flourished during the Mesozoic Era, they now appear to be dying out with many families represented by only a few species. Polystoechotidae are now restricted to the Western Hemisphere and are represented by only four species in three genera. The Neurorthidae with about 10 species is



Lacewings, Antlions and Mantispids (Neuroptera), Figure 8 **Some common Neuropterans: *top left*, brown lacewing (Hemerobiidae); *top right*, green lacewing (Chrysopidae); *second row left*, eggs of green lacewings; *second row right*, larva of green lacewing; *third row left*, antlion larva (Myrmeleontidae); *third row right*, mantispid (Mantispidae); *bottom left and right*, antlion adults (upper photos by Jim Castner, lower photos by Lyle Buss).**

found only in the Old World, the Rapismatidae with 16 species limited to the Oriental Region, the Nymphidae with about 25 species restricted to Australia and New Guinea and the Ithonidae with about 17 species limited to Australia and North America. The Nemopteridae and Osmylidae are now absent from North America but both families are represented in the Florissant shales of Colorado (Miocene). The other 10 families have representatives on all continents but even the most speciose families, Chrysopidae and Myrmeleontidae, have only about 1,700 species each.

  - Ascalaphidae
  - Myrmeleontidae
  - Nemopteridae
  - Nymphidae
  - Psychopsidae

The family Coniopterygidae contains the pygmies of the order with the forewing length ranging between 2 and 6 mm and are called dusty wings. Although considered rare for many years because of their size, they often are among the most abundant Neuroptera in many habitats, living on trees and shrubs although the aberrant Brucheiserinae evidently live under stones. The body, wings, and legs often are coated with white or grey wax secreted by hypodermal glands. The antenna has 15–62 segments with the flagellar segments moniliform, often with scale-like hairs in distinct whorls in the males. The wings are held roof-like over the body. The hindwing usually is smaller than the forewing, sometimes greatly reduced, and the venation is highly reduced. There are never more than two basal costal crossveins, the forewing Sc is forked distally and the posterior branch resembles the distal part of R1; radial sector separating from R1 near middle of wing, often forked and the posterior branch sometimes resembling the distal part of medial vein. The tarsus is distinctive in the order although similar to those of the Sialidae in having the fourth segment modified (flattened and bilobed). The abdomen lacks the spiracle on the eighth segment which is apomorphic and distinctive among the Neuroptera. The genera usually are separated by wing venation, whereas examination of the male genitalia usually is required to identify the species. The larvae are active predators, often feeding on mites, but they also feed on other small, soft-bodied insects in their environment. They have a large head but the mouthparts are mostly concealed and consist of a short labial palpus with the apical segment expanded, short, straight and pointed styles. The eyes consist of 4–5 stemmata. There are about 490 described species in about 30 genera in three subfamilies and is the fourth most speciose family in the order. The aberrant Brucheiseridae are found in arid areas of Argentina and Chile and consist only of the genus *Brucheiser* with several species. These apparently are flightless insects with highly sclerotized, reticulate wing venation. Their biology is unknown. The Aleuropteryginae is mostly cosmopolitan although the genera are not. They possess peculiar and unique structures on the abdomen called plicaturae. These are paired organs which are strongly folded and placed on an oblong, somewhat membranous area. Their function is unknown. Also, the wing venation differs from the other subfamilies in having two radio-medial crossveins in the middle of the wing. The larvae have the mouthparts projecting from beneath the labrum and the antenna is about as long as the labial palpus. There are about 14 genera classified in three tribes. The most common are *Aleuropteryx* (Holarctic), *Neoconis* (Neotropics) and *Spiloconis* (Australia). The Coniopteryginae have two speciose, cosmopolitan genera, *Coniopteryx* Curtis and *Semidalis* Enderlein (except Australia). The members of this subfamily lack plicaturae and have only one radio-medial crossvein. Often the males have scale-like setae on the antennae and a few species have a hook on the frons. This subfamily is the most commonly collected and of great biological control interest since many species live on economic crops such as citrus. The vast majority of coniopterygids fly at dawn or dusk, fluttering slowly between plants where they lay eggs. Many species are specific to certain types of plants like junipers.

The family Ithonidae is similar in appearance to the Rapismatidae but are whitish to brownish in coloration and commonly live in arid regions. They hold their wings relatively flat over the back which is unusual in the order and resemble dull hepialid moths both in appearance and in flight, which has led to the common name "moth lacewings" for this family. The forewing ranges from about 15 to 30 mm. Three monotypic genera occur in the southwestern United States (*Oliarces* Banks), in Mexico (*Narodona* Navás) and in Honduras (*Adamsiana* Penny). Elsewhere, they are found only in Australia (about 24 species in *Ithone* Newman, *Megalithone* Riek and *Varnia* Walker). Ngymata (slightly domed, bare areas on the wing) are found in this family and are of unknown function; similar structures are found in other families of Neuroptera, as well as Trichoptera, Megaloptera and Mecoptera. Claims have been made that the subterranean larvae are predacious on Scarabaeidae grubs but this has not been clearly established. Some species of ithonids (*Ithone*, *Megalithone* and *Oliarces*) have been observed swarming in vast numbers for short periods of time. In most cases, the swarming sites have been detected first by the presence of many frenzied birds which have a feast when these fat, hapless insects are swarming. The adults can run fairly quickly and lay their eggs in the sand by means of a "sand plough."

The family Polystoechotidae is another family of robust sized insects and superficially similar to the Ithonidae and Rapismatidae. The forewing ranges from 15 to 40 mm. There are only four species known in three genera. The genus *Polystoechotes* Burmeister has one species in Chile and another in North America. The genus *Platystoechotes* Carpenter is limited to the Sierra Nevada of California and Oregon where it may be associated with *Libocedrus* (incense cedar). The third genus, *Fontecilla* Navás, lives in arid zones in central Chile. Little is known of the biology of this family although the larva has been described. They are subterranean but claims that they feed on plant roots are unsubstantiated. *Polystoechotes punctatus* (F.) was once commonly distributed through the northern half of the United States. The reason why this species is now restricted to the southwestern United States south to Central America is unknown. Apparently this species is attracted to smoke and all the species are attracted to light.

The family Rapismatidae is found in the Oriental region. These large, sturdy lacewings with complex venation are usually greenish to yellowish in coloration and live in mountainous areas. The forewing ranges from about 20 to 36 mm. There are about 20 species, all in the genus *Raspisma* McLachlan. These insects are relatively rare in collections and little is known about their biology.

The family Osmylidae is a relatively large family of lacewings with about 170 species in about 20 genera. The classification is suspect with eight subfamilies recognized based on simplistic wing venational characters. They are found on most continents except North America. The species are moderate sized insects (forewing 15–30 mm long). Nearly all the species have three ocelli and usually two wing nygmata (sometimes faint) which helps define the family. Also, there is a small stylus at the end of gonapophyses laterales of the female. Most of the species have semi-aquatic larvae which have the jaws elongate and straight or slightly curved. The larvae have long legs and lack gills. The Porisminae is composed of one very brightly colored species from southeastern Australia. Apparently the larvae live under bark of

Eucalyptus. The adults are distinguished by having numerous subcostal crossveins. The Kempyninae contains some of the largest species and is found in southern temperate South America, New Zealand and Australia. The Spilosmylinae is the largest and most diverse group found only in the Old World. Many species have an embossed forewing spot on the posterior margin. *Spilosmylus* has 35 species known from New Guinea. The Stenosmylinae is another disjunct group with species in South America and Australia. The Osmylinae is a Palaearctic subfamily with one well known species in Western Europe. The Protosmylinae (Oriental region), Eidoporisminae (one species from Australia) and the enigmatic Gumillinae (two anomalous species with long antennae from Mexico but are probably Mexican Chrysopidae) complete the survey of this family.

The family Dilaridae consists of small delicate lacewings (forewing length 4–15 mm) and are easily distinguished in the male by the plumose antenna and in the female by the well developed ovipositor. The known larvae are elongate and live in burrows in wood, probably feeding on beetle larvae. There are 67 described species in two subfamilies which are nearly exclusive geographically. The Dilarinae are found only in the Old World (except Australia), and the Nallachiinae are found only in the New World except for recently discovered species in South Africa and India.

The family Sisyridae is a small family with about 30 species in four genera. *Sisyra* Burmeister is cosmopolitan and the large genus *Climacia* McLachlan is found only in the Western Hemisphere. Two other genera exist but are of doubtful validity and with few species in the Old World. These are small insects (forewing length 4–10 mm). The female has the terminalia elongated into an ovipositor like structure. The wings have relatively few crossveins and there are small thickenings (trichosors) on the posterior margin of the distal half of the wings. They are most easily confused with the Hemerobiidae. The larvae are aquatic and feed on freshwater sponges and probably Bryozoa. The larval jaws are the longest in the order, apparently adapted for sucking out the contents of sponges. They are called Spongilla-flies for this reason. They are the only truly aquatic insects in the order with the larvae bearing external gills in the second and third instars. The larvae leave the water to pupate, usually constructing a distinctive double cocoon with a mesh-like covering. The adults are predacious on insect eggs and small insects.

The family Neurorthidae used to be included in the Sisyridae until the terrestrial larvae were discovered and found to be greatly different morphologically. This small family of delicate lacewings (forewing length 6–10 mm) consists of only 10 species found in Europe and North Africa (*Neurorthus*), Asia (*Nipponeurothus*) and Australia (*Austroneurothus*). There is some data suggesting that this family is not closely related to other families of the order.

The family Berothidae, or beaded lacewings, is another family (about 110 species) of small (forewing length 6–15 mm), delicate lacewings occurring on all continents (except Antarctica). Many species have falcate wings and some species have scale-like setae on the wings and sometimes on the body (*Lomamyia* Banks). There are trichosors present on the wing margins. The family is difficult to define and usually keys out at the end of the family key on venational characters. There are four distinct subfamilies. The Rhachiberothinae are found only in southern Africa and have the forelegs raptorial. There are two genera. The Cyrenoberothinae contains one monotypic genus from Chile (*Cyrenoberotha* Adams and MacLeod) and one monotypic genus from southern Africa (*Manselliberotha* Aspöck and Aspöck). Nothing is known of their biology. The adults have the face elongated below the eyes. The Nosybinae contains but one genus, *Nosybus* Navás, known only from Africa. The wings are rounded and have small venational differences from the Berothinae. The Berothinae is the largest subfamily with about 24 genera in all continents. The life cycle of the North American genus, *Lomamyia* Banks, has been described. The larvae live in termite burrows. In one species the first instar waves its abdomen at a termite releasing an "allomone" which paralyzes the termite in a few minutes. Later instars can produce enough gas to immobilize up to six termites per shot.

The family Mantispidae, containing about 350 described species, are easily recognized by having raptorial forelegs and thus can be confused only with the subfamily Rhachiberothinae of the Berothidae in the Neuroptera. The larvae are hypermetamorphic, being very active triungulins in the first instar, and becoming inactive scarabaeiform larvae in subsequent instars. Adults of the same species can vary greatly in size since most species are parasitic on spiders. The forewing can vary between 5 and 30 mm. The pronotum is sometimes many times longer than wide and, in contrast to the snakeflies, the legs originate near the anterior margin. There are four subfamilies. The Drepanicinae is found in Chile and Australia and contains the largest species of the family, *Drepanicus gayi*, from Chile which is green and somewhat leaf-like. The genera *Ditaxis* McLachlan and *Theristria* Gerstaecker are found only in Australia; the latter is the most diverse mantispid genus in Australia. The biology of this subfamily is unknown. The Calomantispinae is a small subfamily with only two genera, *Nolima* Navás (North America) and *Calomantispa* Banks (Australia). The larvae of *Nolima* may be generalist predators. The Symphrasinae is a New World subfamily containing three genera, *Anchieta* Navás, *Plega* Navás, and *Trichoscelia* Westwood. The latter genus has been reared out of larval cells of *Polybia* (Vespidae). The larvae of *Plega* appear to be generalist predators with prey records including the pupae of Noctuidae and Scarabaeidae and the cells of a leaf-cutting bee (*Megachile*). Many of the species of Anchieta resemble bees. This subfamily has a well developed ovipositor and possess other characters which isolate it especially from the largest subfamily, Mantispinae. All of the Mantispidae are "parasites" of spider egg sacs. The triungulins either board the female spider until she makes her egg sac or directly searches for the egg sac without phoretic behavior. This varies between species. Some species of Mantispinae resemble vespoid wasps such as *Cimaciella* Enderlein in North America and *Euclimacia* Enderlein in the Oriental region. These mantispids show considerable variation in color pattern throughout their ranges probably in relation to the variation of the wasp models. Adults are active predators and usually are found in trees and shrubs. They are attracted to light. The genus *Mantispa* Illiger was once thought to be widespread but apparently is paraphyletic and absent in the New World and Australia. The present number of genera is about 30 but some other genera appear to be undescribed (Fig. 8).

The Chrysopidae is probably the largest family of the Neuroptera with more than 1,300 described species in 75 genera and three extant subfamilies. Although called green lacewings, there are many species which are brownish in coloration, especially species that rest on rocks during the day. Also, the greenish color of museum specimens often fades in a few years. The adults lack microtrichia on the wing membrane found in most families of Neuroptera. Nearly all the species possess a tympanal organ on the ventral base of the radial vein. One function of this auditory organ is to detect bat echo-locating sounds, that once identified, will signal the adults to fold their wings and drop to the ground. This family contains the most significant biological control agents in the order, and species of *Chrysoperla* Steinmann are sold worldwide for biological control. The larvae are active predators living on plants and feed on diverse, soft-bodied insects, especially aphids. The most plesiomorphic subfamily appears to be the Nothochrysinae with about 20 species in seven genera found in Australia (*Dictyochrysa* Esben-Petersen, *Triplochrysa* Kimmins), Europe (*Hypochrysa* Hagen, *Nothochrysa* McLachlan), Africa (*Kimochrysa* Tjeder, *Pamochrysa* Tjeder), and North America (*Nothochrysa* McLachlan, *Pimachrysa* Adams). These are mostly robust and moderate sized insects, often dark brown in color and lack the tympanal organ. They seem to live in forests of ancient trees (such as Gymnosperms). The Apochrysopinae contain the giants of the family (forewing length 18–34 mm) and represent a small group with about 25 species in 12 genera. Like the Nothochrysopinae, the genera are limited in distribution such as to Australia (two genera), South America (four genera), Africa (two genera) and Asia (four genera). They appear to prefer the dark areas of dense forests. The Chrysopinae are by far the largest subfamily with more than a 1,000 species in nearly 70 genera. Many genera are now cosmopolitan partly because species of *Chrysopa* Leach, *Ceraeochrysa* Adams, and *Chrysoperla* Steinmann have been released and established in diverse regions of the world. The adults of some of these genera (i.e., *Chrysoperla*) feed on honeydew and employ extracellular symbiotic yeasts to aid in digestion. Many genera (i.e., *Ceraeochrysa*, *Leucochrysa* McLachlan) have trash bearing larvae. Special species communication occurs in the family. Some adults (i.e., *Chrysoperla*) move the abdomen rapidly, transmitting by way of the legs to the substrate a vibration (tremulation), and in the genus *Meleoma* Fitch stridulation is accomplished by moving the hind femur against abdominal sternites. The larvae have long, strong, curved mandibles (no teeth) similar to those of the Hemerobiidae and can be distinguished by the presence of the trumpet like empodium between the tarsal claws. Nearly all species lay their eggs on stalks, either separate stalks or stalks stuck together at the base, which may help to keep emerging larvae from eating each other.

The Hemerobiidae consists of about 500 species in 28 genera and 10 subfamilies. Nearly all species are yellow to dark brown in color but there are a few green species. The species can be distinguished from those of other families by the presence of at least two apparent radial sectors except for the monotypic genus *Adelphohemerobius* Oswald from Chile. The family appears most closely related to the Chrysopidae but differs notably from that family in possessing microtrichia on the wing membrane. Many species are relatively small (forewing length 4–10 mm) but a few species attain 18 mm in wing length. The biology of the family seems similar among the different genera and are similar to those of the Chrysopidae. Larvae of Hemerobiidae lack the trumpet-shaped empodium in instars 2 and 3 but have similar shaped "jaws" which are curved and without teeth. This family is important in biological control with most of the larvae being active predators on mostly soft bodied insects and mites on plants. Several genera are cosmopolitan or very widespread (i.e., *Hemerobius* L, *Micromus* Rambur, *Notiobiella* Banks, *Sympherobius* Banks, *Wesmaelius* Krüger) whereas most are restricted to one biogeographical realm (eight genera restricted to South America; five genera to Australia). This family demonstrates an unusual amount of wing reduction with flightless species of *Micromus* in Hawaii and of *Conchopterella* on the Juan Fernandez Islands. *Psectra diptera* Burmeister has forms with only one pair of functional wings.

The Psychopsidae, or "silky lacewings" contains 26 species in five genera and two subfamilies. The Zygophlebiinae is restricted to southern Africa and contains three genera (*Silveira* Navás, *Cabralis* Navás and *Zygophlebius* Navás). *Balmes* Navás (Oriental region) and *Psychopsis* Handlirsch (Australian) belong to the Psychopsinae. These are moderately large lacewings with broad wings and dense venation (forewing length 10–35 mm). Biology and larval stages are poorly known. *Cabralis gloriosus* Navás is a mostly white species which flutters around in fairly dense and spiny vegetation. *Silveira* contains four relatively small species living mostly in arid zones.

The Nymphidae are found only in Australia and New Guinea. There are about 25 species in eight genera. The Myiodactylinae contain very broad winged lacewings which lack tibial spurs whereas the Nymphinae contains more narrow winged lacewings with short tibial spurs; *Nymphes myrmeleonoides* Leach resembles some antlions and owlflies in overall appearance but have filamentous antennae. The larvae have strongly curved mandibles, usually with one tooth. There are two types of larvae known. Those of the Myiodactylinae (*Myiodactylus* Brauer; *Osmylops* Banks) are strongly flattened and presumably relatively immobile as in most Ascalaphidae. The larvae of *Nymphes* are more antlion-like, being narrower and searching for prey among litter and vegetation.

The Myrmeleontidae currently have the most described species (about 1,700) in the order with 188 extant genera, 15 tribes and three subfamilies. They are found on all continents but are most abundant in xeric areas since the larvae live in sand or loose soil. The adults are small to large (forewing 10–75 mm) with characteristic wing venation with an elongate cell under the stigma, and the male of many groups has a special gland at the base of the forewing ("pilula axillaris"). Antlions are closely related to the Ascalaphidae but lack the elongate, clubbed antennae of that family The larvae are distinguished from other Neuroptera larvae in having the hind tarsal claws much larger than those of the other legs which is an adaptation for burrowing. Studies have shown that the larvae have preferred habitats and some live under the protection of rock overhangs or in tree holes or animal burrows, but the majority live in open sand. Some prefer coarser sand than others, and members of the tribe Myrmeleontini construct pitfall traps, whereas most others do not. Exceptions occur in the Brachynemurini (i.e., *Scotoleon pallidus*), Nesoleontini (*Cueta* Navás) and Myrmecaelurini (*Isoleon* Esben-Petersen; *Myrmecaelurus* Costa); these larvae construct a double structured pitfall trap (funnel shaped pitfall below which is a tubular extension) in hard pan soils. Members of *Callistoleon* Banks (Myrmeleontini) have side furrows to the pitfall trap. There are three extant subfamilies. Palparinae contains the giants of the family with the fore wing length reaching 75 mm. All live in the Old World (except Australia) except for a small group (Dimarini) in South America. One member of the Dimarini, *Millerleon pretiosus* Banks, has larvae that live in extreme desert conditions and can survive in the larval stage for more than 5 years and can exist many months without feeding. The palparine larvae have enlarged setae distally called fossoria which enable the bulky larvae to dig more efficiently. They have been observed to capture ground resting grasshoppers. The Stilbopteryginae is a small subfamily of large antlions with short, knobbed antennae (similar to *Albardia* of the Ascalaphidae) restricted to Australia (two genera). The Myrmeleontinae contains more than 90% of the genera and species in about eight tribes. The Nemoleontini is the largest tribe, found on all continents, and most genera have similar biologies. However, a few genera (i.e., *Navasoleon* Banks) have larvae that live on bare rock surfaces. These larvae can remain motionless for weeks. Species of *Gatzara* of the tribe Dendroleontini, also live on bare rock surface and cover themselves with green lichens for camouflage. Most known larvae of the Dendroleontini have a debris carrying bunch of setae on the metascutum which apparently lures prey. All larvae of the tribe Myrmeleontini and a few genera of the tribe Acanthaclisini move only backwards. Perhaps the most striking species of antlion, *Pseudimares iris* Kimmins of the monospecific tribe Pseudimarini is large, with a large eyespot on the hindwing and has been collected only twice from southern Iran. All the larvae and nearly all the adults are predacious on other insects. A few adults apparently feed on pollen. Most adults are nocturnal but there are a few day-flying species, such as the butterfly-like species of *Pamexis* Hagen from South Africa and *Maracandula* Currie from Mexico.

The owlflies, or Ascalaphidae, contain mostly fast flying insects that resemble dragonflies. Adults are moderate to large in size (forewing length 15–60 mm), robust and usually very pilose with huge compound eyes which suggested the common name. There are about 500 species in about 80 genera and three subfamilies on all continents (except Antarctica). They are mostly crepuscular aerial predators and sometimes swarm in flight. Nearly all species have elongate antennae which are clubbed somewhat like butterflies except for the monotypic subfamily Albardiinae with short antennae that exists in Brazil. The Ascalaphinae is the largest group and is unique in having the eyes divided by a transverse sulcus. This subfamily contains the day-flying and colorful *Libelloides* Schäffer of Europe. The females of the most common New World genus of this subfamily, *Ululodes* Hagen, lay sterile eggs (repagula) coated with ant repellent material at least on the basal side of a string of eggs for protection. The third subfamily, Haplogleniinae, is worldwide. The males of some species of this subfamily (i.e., *Haploglenius*) have an apparent startle display in which a hinged flap covering the pronotum is suddenly lifted to expose a contrasting cream or white patch. The taxonomy of this family is difficult and the only worldwide treatment is by Van der Weele (1908), but much general information is found in Tjeder (1992).

The Nemopteridae are among the most distinctive looking of the Neuroptera with the hindwings often extremely narrowed. The larvae have strongly curved mandibles but lack teeth. The Crocinae have the hindwing threadlike whereas the Nemopterinae have the hindwing broadened distally. The head is often greatly prolonged ventrally similar to the Mecoptera and is a modification for feeding in flowers. The family is found in most continents except in North America. Most species are nocturnal but some are diurnal and very colorful, such as in the genus *Nemoptera* Latreille found in Europe. The Crocinae are mostly nocturnal with species usually very limited in distribution and are often in xeric areas. They flutter around at night and are attracted to white flowers. The crocine larva often has the prothorax greatly lengthened and are among the only Neuroptera to live peacefully together in groups of 30 or more, often in sand and small rocks under rock overhangs. These alert larvae have been seen to escape predators (and a shovel) en masse like a herd. The larvae of Nemopterinae appear more diverse and usually burrow into the sand head first in contrast to the antlions. Some genera (i.e., *Stenorrhachus* McLachlan) have larvae that live relatively deep under the sand and lack ocelli. In that genus, the females are wingless. *Palmipenna* Tjeder contains day-flying species in which the hindwing is greatly broadened, evidently reducing attacks by robber flies.

Lacquers and Dyes From Insects

CHARLES MACVEAN
Universidad del Valle de Guatemala,
Guatemala City, Guatemala

The use of wild organisms as sources of decorative and protective substances has ancient origins, with recorded instances dating as far back as 6,000 years ago in the use of indigo dyes from plants (*Indigofera tinctoria*, Leguminosae) in

China, or pre-Columbian use of scale-insect lacquer (*Llaveia axin,* Margarodidae) in the Mayan civilization of Mesoamerica. While this article deals primarily with insects, it is important to note that natural lacquers, dyes and various types of varnishes have been obtained from a broad range of organisms. Molluscs, for instance, are the ancient source of royal purple dye (from whelks, *Murex brandaris*, Muricidae) and the indelible sepia-brown ink obtained from cephalopods (octopuses, squid, etc.) in the genus *Sepia*. This substance is so durable that extracts from fossil cuttlefish have yielded perfectly viable ink. Plants are the most diverse source of dyes, and also provide raw material for the famous lacquer art of the Orient, which uses sap from a relative of sumac trees (*Toxicodendron verniciflua*, Anacardiaceae).

In the insect world, only a few species, concentrated in the superfamily Coccoidea (Hemiptera) or scale insects, historically have been the source of pigments and artistic and protective finishes. This does not include the use of butterfly wings as decorative materials, or metallic flies, wasps and beetles as ornaments (either dead or as living jewels tethered to a lapel!). Such decorative value stems from structural characteristics in the wing scales or the cuticle which cause various reflection patterns of light, distinct from internal chemical pigments used for dyes.

This article deals primarily with pigments and finishes derived from insects, but other sources are mentioned insofar as they are used together, or for the sake of comparing key characteristics. Basic physical and chemical characteristics of dyes and lacquers are discussed in order to provide working definitions and basic concepts.

Some Basic Terminology of Dyes and Finishes

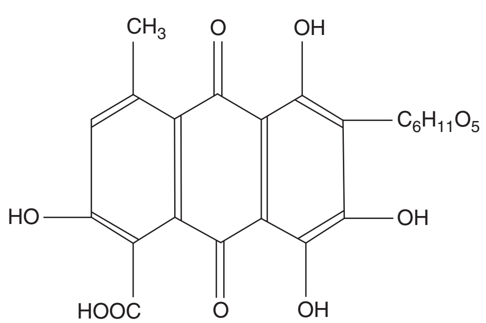
The terms dye and pigment are often used interchangeably, though traditionally dyes were considered of plant origin while pigments were derived from minerals, earths and ground rocks. Usually, a dye is made up of pigments in solution (often in water) which binds to a substrate, such as cloth or leather, in such a way that the color change in the substrate is permanent and difficult to remove. The chemistry of dyeing is still not completely known, though the presence and arrangement of double bonds, C=C, C=O, C=N, and N=N in the dye molecules are important in the production of color. For example, the pigment in cochineal insects, carminic acid, results from the condensation of three benzene rings and contains several such double bonds. To improve the fastness of the dye, substances called mordants are added to the dye and are known to form chemical bridges between the substrate and the pigment, which remain stable after the solvent has evaporated. Salts of various metals are common mordants.

Varnishes and lacquers are also terms used without clear distinctions for liquids or pastes which dry to form durable, protective and decorative semitransparent films when applied to various substrates. A useful distinction is that varnishes produce the desired finish with as little as a single coat, while lacquers are the result of many, sometimes hundreds, of thin coats applied over time to produce the final finish. The process by which the substance converts from a paste or liquid to a dry film also varies, and can include simple evaporation of a solvent, the chemical linking of repeating units into polymers or a combination of the two. Both varnish and plant-derived lacquer consist of resins mixed with essential oils (volatile and fragrant), but varnishes are artificial mixtures while lacquer comes from naturally existing combinations.

Resins are substances found as natural polymers, usually dissolved in ethanol for application, and include the sap of *Toxicodendron verniciflua* used for oriental lacquer, shellac from Indian lac insects (*Kerria lacca*, Kerriidae) as well as many other plant products like water-absorbing gums. Waxes and drying oils are a final group of substances used in producing lacquer finishes, resulting from the presence of reactive double bonds which take up oxygen when exposed to air, and which form extensive polymers linked through the oxygen atoms between the original chains of fatty acids. Linseed oil is a well-known drying oil, which produces a simple but not highly durable finish on furniture, for example.

Production and Use of Insect Dyes and Lacquers

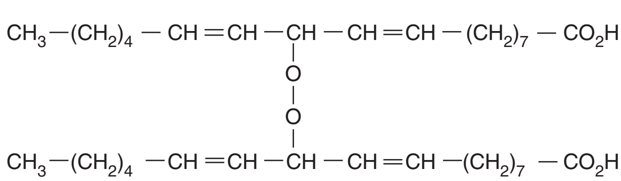
Probably the best known colorant from insects is cochineal dye (Figs. 9 and 10), obtained from the body contents of cochineal scales, *Dactylopius coccus* (Dactylopiidae) which yields a bright red color used in textiles, food, drugs, etc. Pre-Columbian Maya and Aztec cultures used the dye for wood, feathers, cloth and as writing ink for codices. The vermilion pigment is concentrated in the female fat body and is thought to repel ants and parasites. Like all scale insects, cochineal exhibits dramatic sexual dimorphism, with wingless females developing through several nymphal instars on the prickly-pear cactus host plants (*Opuntia* spp.).



Lacquers and Dyes From Insects, Figure 9
Structure of carminic acid, an anthraquinone dye obtained from cochineal insects (*Dactylopius coccus*).

They are readily recognized on *Opuntia* by the stringy white wax masses they produce. The males, which are indistinguishable from females in the early instars, form pseudopupae and emerge as two-winged adults resembling small flies.

The adult females are brushed off the cactus pads, dried and then stored, traded or processed to obtain pure dye. The crimson color is obtained by "reconstituting" the dry bodies (known as "grana" in Spanish) in boiling water to extract the pigment, then precipitating, filtering and drying to a powder. Cultivated from Mexico to Peru by indigenous cultures since before the Spanish conquest, these insects are generally considered native to Mexico and Central America. However, some evidence suggests that they originated in South America and were then traded northward. The cochineal insects found in Mexico and Central America show a long history of domestication and dependence on human protection, along with propagation of the host plants, while production of dye in Peru by ancient Quechua Indians was based on wild *Dactylopius*. Cochineal first became a product for export to Spain and other parts of Europe in the sixteenth century (Table 1). Initially, this new dye was rejected by the traditional textile industry which used a different insect, Mediterranean-grown *Kermes* spp., as a source of dye. But the intense red quality and relative cost advantages of cochineal soon served to expand its market, rendering it an extremely important product in the Spanish colonial economy of the eighteenth and nineteenth centuries. This was particularly so for Central America, which did not enjoy the great wealth of precious metals found in South America or Mexico but was richly endowed in biological resources. The other great agricultural export of



Lacquers and Dyes From Insects, Figure 10 **Formation of a lacquer polymer by uptake of oxygen at double-bond sites, crosslinking individual fatty acid chains through a peroxide bridge.**

Lacquers and Dyes From Insects, Table 1 Characteristics of some natural dyes and lacquers from insects, plants and molluscs

Common/ scientific name	Product obtained	Chemical nature	Sites and history of production
Cochineal insect (*Dactylopius coccus;* Hemiptera: Coccoidea: Dactylopiidae)	Bright red dye from dried bodies of adult females	Applied in solution (often water) to impart permanent color by binding to cloth, leather, wood, etc. To become fast, most dyes require the use of a chemical which binds the due to the substrate, called a mordant. Tannins from insect-induced oak galls are a mordant used since antiquity. Salts of several metals, since as tin, aluminum, iron and chromium, are also well known mordants	Pre-Columbian Central America, major export to Europe between sixteenth and nineteenth centuries, renewed value today as natural dyestuff
Kermes insect *(Kermes illcis* and *K. vermillo;* Hemiptera: Coccoidea: Kermesidae)	Bright red dye, carmine, from dried bodies of adult females		Mediterranean region, the medieval standard red due since 1700 B.C., displaced by cochineal beginning in the sixteenth century
Indigo plant *(Indigofera tinctoria, I. suffruticosa, I. guatimalensis, I. thibaudiana*; Fabaceae)	Blue indigo dye from leaves and stems, obtained by fermentation, then drying to a powder; oxidation in contact with air produces indigotin, the blue color.		Originally from India, *I. tinctoria* was traded widely as of 450 B.C. *I. suffruticosa* and others in genus became a major export from colonial Central America; displaced by cochineal in nineteenth century
Mediterranean (*Murex brandaris*), Central American and Mexican (*Purpura patula*) mollusc or whelk (Muricidae)	Purple dye from mucous glands, the original "royal" or Tyrian purple of Greek, Roman and Phoenician societies		Costly to produce, "royal purple" was traded in the Mediterranean and associated with high rank and wealth; pre-Columbian use for dying cotton fibers on both coasts of Central America and Mexico
Lac insect (*Kerria lacca*, Hemiptera: Coccoidea: Kerriidae)	Natural shellac secreted as a protective shell by female scales, harvested in flakes from a wide variety of host plants.	Resin flakes commonly dissolved in ethanol. Resins are naturally occurring terpene polymers often in mixtures with essential oils, insoluble in water, contrast with varnishes which are man-made mixtures of resins and boiled oils	Known from India since at least 250 A.D. Non-toxic finish used widely on wood furniture and floors, in pharmaceuticals as a coating for pills, applied as a stiffener for hats, as a glossy coating for candy and fruits, as glue for boding glass and metal, and many other uses

Lacquers and Dyes From Insects, Table 1 Characteristics of some natural dyes and lacquers from insects, plants and molluscs (Continued)

Common/ scientific name	Product obtained	Chemical nature	Sites and history of production
Niij (Guatemala) or Aje (Mexico) insect (*Llaveia axin;* Hemiptera: Coccoidea: Margarodidae)	Lacquer used on gourds, wood, ceramic, leather, from the fat body of the adult females, harvested prior to egg production; used also as skin ointment	The fat, which resembles a soft wax, is a mixture of triacylglycerols and free fatty acids; when rubbed onto the substrate, with various pigments. It polymerizes into a durable and decorative film	Cultivated and traded in pre-Columbian Mexico and Central America; now produced only in Uruapan, Mexico and Rabinal, Guatemala, but offers potential as a natural finish for new markets
Lacquer or "varnish" tree (*Toxicodendron vernicifluum;* Anacardiaceae)	Japanese and Chinese lacquer from a milky tree sap	Natural resin; urushiol is the main component, together with a gum and glycoprotein, which undergo oxidative polimerization; hundreds of coats are often applied to achieve the finished lacquer	Developed in China before the Christian era; perfected by the Japanese during Ming Dynasty (1368–1644 A.D.). Lacquerware was at one time restricted to high classes and production was regulated by the state. Currently produced as fine finish and art form.

the Central American colonies was indigo dye, which had been the mainstay of the local economy during the 17th and 18th centuries. Cochineal production surpassed indigo in the 1800s, but then the advent of synthetic aniline dyes around 1860 caused the virtual demise of both products. Interestingly, this decline indirectly stimulated the development of the budding coffee industry in Guatemala and other countries. Currently, the demand for non-toxic red dyes has created new markets for cochineal. Peru is now the world's main producer, and Mexico and Central America are also returning to an ancient ethnoentomological crop.

With regard to insects used for lacquer, two species are of particular interest: lac insects, *Kerria lacca* (Kerriidae), of Asian origin, and the giant margarodid scale insects, *Llaveia axin* (Margarodidae), native to Mexico and Central America, where they are commonly known as "aje" and "niij," respectively (Table 1). While most scale insects are only a few millimeters in size, adult niij females reach a total body length of 2.5 cm and can weigh over 0.5 g (Figs. 11 and 12). The substances produced by these insects and used for lacquer are entirely different, as shellac from *K. lacca* is an external body secretion which encloses the female insect and her eggs in a resinous mass, whereas niij wax is the internal body fat of the adult females. However, both yield a fine, smooth and durable finish for woodwork, ceramic, metal and many other substrates (Fig. 13).

The production of lac insects is an ancient tradition in India, and consists of harvesting the amber-colored resin secretion and eliminating insect and plant remains from the crude "sticklac" to yield clean flakes of shellac. The host plants of lac insects span a wide range of families, including Anacardiaceae, Dipterocarpaceae, Euphorbiaceae, Leguminosae, Moraceae and several others. The purification process is rather complex, and includes dissolving the raw resin or sticklac in a base, such as sodium hydroxide, and bleaching with sodium hypochlorite. Dilute acid is used to precipitate the

Lacquers and Dyes From Insects, Figure 11 **Sexual dimorphism of scale insects, shown here in niij insects (*Llaveia axin*). Adult females are sac-like and wingless, while males possess a single pair of wings and resemble small flies.**

Lacquers and Dyes From Insects, Figure 12 **Raw body fat from an adult niij female, normally used for egg production; extracted by artisans to yield a fine lacquering substance.**

resin in curds like cottage cheese; these are then dried to form dry flakes which can be stored or dissolved in ethanol for use in finishing wood, etc (Figs. 11–13).

Niij insects, on the other hand, are one of the least known sources of artistic and protective lacquer. Adult females are harvested from the host plants (primarily *Jatropha* spp., Euphorbiaceae;

Lacquers and Dyes From Insects, Figure 13 **Traditional black lacquer on rattles and piggy banks made from gourds and finished with niij wax combined with fine soot, then etched to reveal natural pale gourd color.**

Spondias spp., Anacardiaceae; and *Acacia* spp., Leguminosae), boiled and then mashed through fine cloth to produce a crude aqueous extract. The product used for lacquering is the body fat, which is found as a thick liquid in the living females and accounts for about 30% of total body weight. After prolonged beating of the extract, fat globules separate from the other components and coalesce into bright yellow globs of a soft, paste-like material. These are washed thoroughly with water, shaped into patties or cylinders roughly 0.5 kg in weight and are then ready to use or store. The soft fat, with physical properties similar to cocoa butter, can be rubbed onto a substrate alone or in combination with powdered pigments to produce a permanent film. Traditional uses in Guatemala combine black (fine powdered soot) with red (paste from the seeds of anatto, *Bixa orellana*, Bixaceae) on the surface of gourds. Etching into the finished surface to reveal the pale gourd color then produces many intricate patterns and figures. The fat alone provides a durable, satiny finish on pottery, ceramic, leather and metal and is resistant to abrasion, water and heat. In the Uruapan art of Mexico, various figures are scraped out from the initial lacquer layers on wooden plates or furniture and filled in with a different color to produce highly complex inlays.

Niij fat is solid at ambient temperature which makes it similar to many waxes. Chemically, the fatty acid chains that make up its main tryacylglycerol components contain many reactive double bonds. In contact with air, oxygen is taken up at these sites and forms links to neighboring chains, thus forming a polymer film. In this sense, niij "wax" shares the properties of drying oils, such as linseed oil, with which it can be mixed to extend and dilute the insect fat. Chía oil is another plant-derived lacquering substance used in the Mexican community of Olinalá in combination with various pigments, but without the use of insect products.

Like cochineal, niij insects show an old history of domestication and human protection, which has probably influenced the geographic distribution of the species. Cultivation practices for niij insects involve storing the cottony egg masses in covered gourds during the dry season, which protects them against severe egg predation by coccinellid beetles. With the beginning of the rainy season, newly hatched insects are set out at the base of the host plants to initiate a new generation which feed in dense aggregations (Fig. 14) on the host plants. Traditionally, insect rearing takes place on fence rows rather than dedicated plots of agricultural land. However, the high value of niij "wax" relative to other agricultural products that share its arid tropical habitat provides an opportunity for a novel type of agroforestry production. Like cochineal, niij lacquer has suffered a decline in production (although it was never as important in economic terms), but offers great promise as a decorative and protective finish to substitute synthetic and often toxic industrial products.

Lacquers and Dyes From Insects, Figure 14 Dense population of adult niij females on *Jatropha curcas* host tree. The insects are harvested prior to oviposition in order to extract the body fat.

In conclusion, synthetic products have displaced many of the original uses of natural substances, but the current emphasis on non-toxic finishes and dyes, and the premiums often associated with natural products, are providing opportunities to rediscover and improve the production of insect and plant-based compounds. Not only are these of interest for their particular protective or esthetic qualities, but they can also contribute to biodiversity conservation through agroforestry productions systems in native habitats.

La Crosse Encephalitis

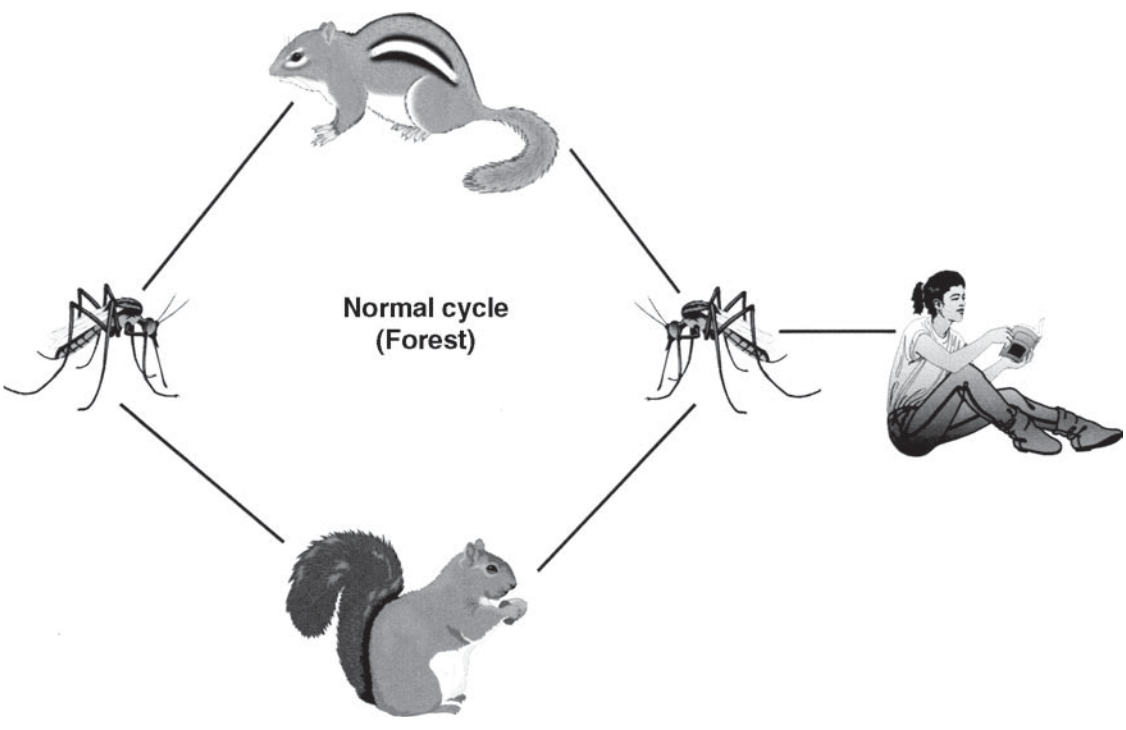
JORGE R. REY
University of Florida, Vero Beach, FL, USA

La Crosse encephalitis is a relatively rare viral disease that is spread by infected mosquitoes. The disease affects the central nervous system and can be serious and even lethal in rare instances. It is named for the city of La Crosse, Wisconsin, where it was first identified in 1963. Since then, La Crosse encephalitis has been identified in several Midwestern and Mid-Atlantic states. On average, 73 cases per year are reported to the Centers for Disease Control (CDC), with the majority being from children under 16 years of age. It is suspected that La Crosse encephalitis has a higher incidence and wider distribution in the eastern United States, but is not reported because the virus is often not identified, and because symptoms are often mild and medical attention is not sought.

The La Crosse encephalitis organism is an arbovirus (arthropod borne virus) of the family Bunyaviridae. It is normally cycled between the treehole mosquito *Ochlerotatus triseriatus* and vertebrate hosts (chipmunks and squirrels) in forest habitats throughout the range of the disease. *O. triseriatus* is a daytime biting mosquito that normally inhabits tree holes, but can also develop in other water-holding containers such as discarded tires, cans, etc. Recently, eggs of the Asian tiger mosquito, *Aedes albopictus*, infected with the La Crosse encephalitis virus have been collected in North Carolina and Tennessee. The virus can be maintained during the winter by transmission in mosquito eggs. An infected female lays eggs that carry the virus and eventually develop into infected adults. This process, where the virus is passed from mother to offspring, is called transovarial transmission.

The Virus Transmission Cycle

In a normal cycle, the virus is transmitted to the vertebrate host through the bite of an infected mosquito (Fig. 15). In the host, the virus replicates and increases in abundance rapidly (a process known as amplification). When sufficiently abundant, the virus can then be passed on to other mosquitoes when they feed on the infected vertebrate host. Infected chipmunks and squirrels do not show signs or symptoms of disease. Although not part of the normal cycle of the disease, humans can also contract the disease by the bite of an infected mosquito. However, humans are "dead end hosts," meaning that an infected human cannot transmit the virus to uninfected mosquitoes because sufficient amplification of the virus does not occur in humans.



La Crosse Encephalitis, Figure 15 **Transmission cycle of La Crosse encephalitis.**

Additionally, the virus is not transmitted from human to human.

Symptomology and Treatment

As the name implies, the disease can cause inflammation of the brain which interferes with brain and spinal cord functions. Initial symptoms of La Crosse encephalitis infection include fever, headache, nausea, vomiting and lethargy. More severe symptoms usually occur in children under 16 and include seizures, coma, paralysis and neurological after effects. The death rate for clinical cases of La Crosse encephalitis is about 1%. Many pediatric cases that present La Crosse encephalitis symptoms are screened for herpes or other viral diseases, but are not specifically tested for presence of the La Crosse encephalitis virus. Many of these cases are reported as "aseptic meningitis" or "unknown viral encephalitis".

Diagnosis of the disease is confirmed by the presence of clinical symptoms and a fourfold rise in serum antibody and specific immunoglobulin M antibody capture in cerebral-spinal fluid (CSF) or serum; and/or by isolation of the virus or detection of the viral antigen in blood, CSF, or brain tissue. Serological test for the virus may be negative early in the course of the infection. New diagnostic techniques such as enzyme-linked immunosorbent assay (ELISA) may now be used soon after infection (they do not require a fourfold increase in titer). The use of monoclonal antibodies has also helped to standardize the testing protocols and have increased our ability to quickly identify viral agents. Viral agents can now also be rapidly identified by polymerase chain reaction techniques, but use of these is still not widespread in clinical settings.

There is no specific treatment for La Crosse encephalitis. No anti-viral drugs are available at this time, and antibiotics are not effective against viruses. Patients with the disease are given supportive treatment for the symptoms, particularly headaches, fever and seizures.

Preventing Infection

Risk of contracting La Crosse encephalitis is highest in children younger than 16 years, in people residing in or near woodlands that harbor the treehole mosquito, in people who maintain water-holding containers in their residences, and in those involved in outdoor activities where *O. triseriatus* is present. Prevention of the disease involves protection against the bite of infected mosquitoes. Personal measures include the use of repellents containing DEET, and the use of protective clothing (long sleeved shirts and long pants) when exposed to mosquitoes. Effective local mosquito control measures can also decrease disease risk by lowering mosquito populations, and thus decreasing the probability of mosquito-human encounters, and possibly, the transmission of the disease among wild populations of mosquitoes and vertebrate hosts. Mosquito control includes the use of appropriate pesticides and cleanup of water- holding containers that may offer breeding sites for *O. triseriatus*. Some mosquito control agencies also fill tree holes where *O. triseriatus* may develop with sand or cement.

Ladybird Beetles (Coccinellidae: Coleoptera)

J. H. FRANK[1], R. F. MIZELL III[2]
[1]University of Florida, Gainesville, FL, USA
[2]University of Florida, Quincy, FL, USA

"Ladybird" is a name that has been used in England for more than 600 years for the European beetle *Coccinella septempunctata* L. As knowledge about insects increased, the name ladybird became extended to all its relatives, members of the beetle family Coccinellidae. Of course these insects are not birds, but butterflies are not flies, nor are dragonflies, stoneflies, mayflies, and fireflies, which all are true common names in folklore, not invented names. The lady for whom they were named was "the Virgin Mary," and common names in other European languages have the same association (the German name Marienkafer translates to "Marybeetle" or ladybeetle). Prose and poetry mention ladybird, perhaps the most familiar in English being the children's rhyme:

"Ladybird, ladybird, fly away home,
Your house is on fire, your children all gone…"

In the U.S.A., the name ladybird was popularly Americanized to ladybug, although these insects are beetles (Coleoptera), not bugs (Hemiptera). Then, the Entomological Society of America decreed that the official name in the USA should be "ladybird beetle." Elsewhere in English-speaking countries it is still ladybird. Now the word ladybird applies to a whole family of beetles, Coccinellidae or ladybirds, not just *Coccinella septempunctata*. There are many species of ladybirds (almost 6,000 now known worldwide). The number of bird species known worldwide is somewhat more than 9,000. Regrettably, newspaper writers are prone to writing about "the ladybird" and erroneously referring to species of ladybirds as "varieties," although few or none of them would write about "the bird" and consider that bird species (from auks through eagles to hummingbirds), are "varieties." Many ladybird species are considered beneficial to humans because they eat phytophagous insects ("pests of plants," often called "plant pests"), but not all eat pests of plants, and a few are themselves pests.

Classification

Coccinellidae are a family of beetles belonging to the superfamily Cucujoidea, which in turn belongs to the series Cucujiformia within the suborder Polyphaga of the beetles (Coleoptera). Their relatives within the Cucujoidea are the Endomychidae (handsome fungus beetles) and Corylophidae (minute fungus beetles). The classification of lady beetles is:

- Order Coleoptera
  - Suborder Polyphaga
    - Series Cucujiformia
      - Superfamily Cucujoidea
        - Family Coccinellidae

The internal classification of the family into tribes and subfamilies is not settled because there are competing systems, none of them clearly correct. In this article, mention of species is grouped according to the food of adults and larvae, an ecological rather than phylogenetic grouping. When subfamilies and tribes are mentioned, it must be understood that these classifications are not universally accepted.

More than 480 species are currently reported to occur in America north of Mexico, just 44 in the British Isles, and 600 in Australia. Most of the

480+ in America north of Mexico are considered to be native, and others to be adventive (having arrived from somewhere else and established feral populations). Among the adventive species, some were introduced (introduced deliberately), and others are immigrants (having arrived by any means except deliberate introduction).

Description

Ladybird adults are oval, range in length from about 1 mm to over 10 mm depending upon species, and have wings. Females on average are larger than males. Adults of some species are brightly colored. Their mandibles are used for chewing. Adult ladybirds are able to reflex-bleed from the tibio-femoral articulations (leg joints). The blood (hemolymph) is repellent by having a repulsive smell as well as containing (in some species) various alkaloid toxins (adaline, coccinelline, exochomine, hippodamine, etc.). The hemolymph is yellow and its repellency and toxicity are believed to be a defense mechanism against predators. Some people have claimed that the bright (red on black, or black on red) colors of some adult ladybirds are aposematic, which is to say that the colors warn would-be predators that the beetles are distasteful or toxic.

The immature stages (eggs, larvae, and pupae) also contain the toxins that their adults have. Toxins are said to be produced by dorsal glands in the larvae. Eggs are elongate-ovoidal, and in just a few species are protected by secretions of the adult female. Cannibalism of eggs, larvae and pupae is common, especially when prey is scarce. Larvae are mobile, and in some species (for example of *Scymnus* and *Cryptolaemus*) are protected by waxy secretions. Pupae are unprotected by a cocoon (some other beetles pupate in a cocoon) but larvae may wander some distance from feeding sites (where they may be at risk from cannibalism) before pupating.

Life Cycle and Behavior

Ladybird eggs are laid in clusters by at least most aphid-eating species and singly by at least most scale-insect-eating species. Eggs produce larvae that undergo four instars before pupating, metamorphosing, and giving rise to adults. One scale-eating ladybird is reported to have only three instars. Ladybirds may have one or, more typical of warmer climates, several generations each year, and reproduction is slowed or halted by cooler winter weather, when adults may hibernate. In hot, dry climates, ladybirds may aestivate (become inactive) during the hottest months.

Ladybirds that feed on aphids develop faster, age faster, move faster, typically are larger, and lay their eggs in clusters. Those that feed on scale insects develop more slowly, live longer, move more slowly, typically are smaller, and lay their eggs singly.

Food

Pest Species – Feeding on Plants

Adults and larvae of the subfamily Epilachninae feed on plants. Some 500 species are known worldwide. In America north of Mexico, this subfamily is represented only by *Epilachna borealis* (Fabricius) and *E. varivestis* Mulsant. *Epilachna borealis*, the squash beetle, feeds on members of the squash family (Cucurbitaceae). *Epilachna varivestis*, the Mexican bean beetle, feeds on members of the bean family (Leguminosae). Mexican bean beetle is native to southern Mexico, but it is an immigrant to the USA, first detected in the west in 1849. Now, its distribution is from Costa Rica north through Mexico to the Rocky Mountain states of the USA, and with a separated eastern population which extends southward to northern Florida. In the eastern USA, it has been controlled efficiently by annual releases of the parasitoid wasp *Pediobius foveolatus* (Crawford) (Eulophidae). This wasp was initially imported from India, where it attacks *Henosepilachna sparsa* (Herbst), which likewise belongs to Epilachninae. *Epilachna philippinensis* Dieke, a pest of solanaceous crop plants in the Philippines, has been the object of a biological control program by *Pediobius epilachnae* (Rohwer), native to parts of the Philippines.

Innocuous Species – Feeding on Mildews

Ladybirds of the tribe Halyziini (until recently called Psylloborini, of the subfamily Coccinellinae) feed on fungal growths (mildews, Ascomycetes: Erysiphales) on the leaves of plants. Their greatest species diversity is in the tropics, with only six species in America north of Mexico. One of them is the West Indian *Psyllobora nana* Mulsant which has invaded the extreme south of Florida. In the neotropics, the coccinellid genus *Neocalvia* feeds on larvae of Halyziini.

Predatory Species – Feeding on Mites

Adults and larvae of the tribe Stethorini (of the subfamily Scymninae) feed on tetranychid mites. The tribe is distributed worldwide, and has only one genus. There are five species in America north of Mexico. An example is *Stethorus utilis* (Horn), a minute ladybird which is distributed in the coastal plains of the southeastern states from North Carolina south through Florida and west through Texas. Another is *S. punctillum* Weise, a European species that was reported in 1950 as detected in Ontario and Massachusetts.

Predatory Species – Feeding on Whiteflies

Four species in America north of Mexico appear to be more-or-less specialized predators of whiteflies. They are *Delphastus catalinae* (Horn), *D. pallidus* (LeConte), and *D. pusillus* (LeConte) (tribe Serangiini), and *Nephaspis oculatus* (Blatchley) (tribe Scymnini). The first and probably the fourth seem to be immigrant species from the Neotropical region. The others (*D. pallidus* and *D. pusillus*) are considered to be native. After *D. pusillus* was found to be a very useful biological control agent against sweetpotato whitefly (*Bemisia tabaci* (Gennadius)) including the "form" that later was named silverleaf whitefly (*Bemisia argentifolii* Bellows and Perring), "it" was exported from Florida to California and made available commercially and used in other parts of the USA. Somehow this resulted in commercial biological control companies selling *D. catalinae* under the name *D. pusillus*.

Predatory Species – Feeding on Cottonycushion Scale

Cottonycushion scale (*Icerya purchasi* Maskell), native to Australia, belongs to the family Margarodidae (commonly called "ground pearls," although this name hardly fits this species) in the superfamily Coccoidea (scale insects). It is a major pest of citrus, and an important pest of several other trees and shrubs including *Acacia*, *Casuarina*, and *Pittosporum*. After its arrival in California, presumably as a contaminant of imported plants, it threatened to ruin California's citrus industry in the late 1800s. It was controlled by importation, release, and establishment (as classical biological control agents) of *Rodolia cardinalis* (Mulsant) and a parasitoid fly, *Cryptochetum iceryae* (Williston). When cottonycushion scale became a problem in many other countries, *R. cardinalis* was the biological control agent of choice, so stock of it has been shipped to other continents and countries.

Predatory Species – Feeding on Mealybugs

Mealybugs are the homopterous family Pseudococcidae, which includes some notable pests of plants. *Cryptolaemus montrouzieri* Mulsant, a ladybird native to Australia, is a notable predator of mealybugs. It was introduced into California first in 1891, and some time later from California into Florida. It has been marketed commercially as a control agent for mealybugs and is often effective, but has one unfortunate characteristic: its larvae produce waxy filaments making them look to the uninitiated like their mealybug prey. Many owners of plants have sprayed the larvae with chemicals in the mistaken belief that they are pests. This misidentification must be overcome by education. *Cryptolaemus montrouzieri* does not confine its attentions to mealybugs, and also eats soft scales (Coccidae) and armored scales (Diaspididae). Such a catholic diet is normal for a long list of ladybirds, so that their diet cannot neatly be pigeonholed as armored scales or soft scales or mealybugs – they may eat some prey in all of these families, and a few of the larger ones may even eat an aphid from time to time. For that reason, many genera and species are placed below under "Feeding on Scale Insects."

Predatory Species – Feeding on Armored Scale Insects

Some species appear to feed largely or entirely on armored scale insects (Diaspididae). Examples include *Microweisea coccidivora* (Ashmead), *M. misella* (LeConte), and *M. ovalis* (LeConte) of the tribe Microweiseini, *Zilus horni* Gordon, *Z. eleutherae* Casey, and *Z. subtropicus* (Casey) of the tribe Scymnillini, and *Cryptognatha nodiceps* Marshall of the tribe Cryptognathini. One of these, *Cryptognatha nodiceps*, is not native to America north of Mexico, having been imported in the 1930s, released, and established as a classical biological control agent for coconut scale (*Aspidiotus destructor* Signoret).

Predatory Species – Feeding on Scale Insects

A large trophic group has scale insects as its prey, meaning members of the superfamily Coccoidea (the scale insects). This superfamily includes various related families, notably Coccidae (soft scales), Diaspididae (armored scales), Pseudococcidae (mealybugs), Dactylopiidae (cochineal scales), Kermesidae (gall-like scales), Eriococcidae (felt scales), Cerococcidae (ornate pit scales), and Asterolecaniidae (pit scales). Examples of ladybird genera belonging to this group are: *Decadomius*, *Diomus*, *Nephus*, and *Scymnus* (all in tribe Scymnini), *Brachiacantha*, *Hyperaspidius*, and *Hyperaspis* (all in tribe Hyperaspini), *Axion*, *Chilocorus*, *Curinus*, and *Exochomus* (all in tribe Chilocorini), *Rhyzobius* (tribe Coccidulini), and *Azya* (tribe Azyini). It is not yet clear how, or whether, they divide up the scale insects between them, because reliable prey records are too incomplete. However, there is at least some level of prey specialization in these (and the three aforementioned groups) that feed on scale insects, which seems not to be the case for the next-discussed trophic group (those that feed on aphids). *Brachiacantha* has a curious life history in that its larvae so far as is known feed on scale insects within ant nests.

Rhyzobius lophanthae (Blaisdell) was introduced to California from Australia in 1892 to control scale insects, and somehow later made its way to Florida (there is no record of an early introduction into Florida). *Chilocorus circumdatus* (Schoenherr) [other writers give the author name as Gyllenhal] is native to southeastern Asia and is adventive in Australia; it was imported from Australia to the U.S.A. and was released in Florida in 1996 against citrus snow scale, *Unaspis citri*, and is established. *Azya orbigera* Mulsant is an immigrant from the Neotropical region. *Decadomius bahamicus* (Casey) is an immigrant from the Caribbean or the Bahamas or Bermuda. *Diomus roseicollis* Mulsant is an immigrant from Cuba.

Predatory Species – Feeding on Aphids

Adults and larvae of many species (the tribe Coccinellini) probably feed primarily on aphids. Amomg many others, they include *Coccinella* *novemnotata* Herbst, *C. septempunctata* L., *Coelophora inaequalis* (F.), *Coleomegilla maculata* DeGeer, *Cycloneda munda* (Say), *Cycloneda sanguinea* (L.), *Harmonia axyridis* Pallas, *Harmonia dimidiata* (Fabricius), *Hippodamia convergens* Guérin-Méneville, *Mulsantina picta* (Randall), *Naemia seriata* (Melsheimer), *Neoharmonia venusta* (Melsheimer). Although *Olla v-nigrum* Casey feeds on some aphid species, it has been shown to be an important predator of psyllids (Figs. 16 and 17).

Four of these, *C. septempunctata* (from Europe), *C. inaequalis* (from Australia), *H. dimidiata* (from China), and *H. axyridis* (from Japan) were introduced into North America, although there is some doubt that the presence of *C. septempunctata* and *H. axyridis* is due to introduction; their presence may be due to immigration, albeit as hitchhikers aboard ships.

Two of these genera, *Coleomegilla* and *Mulsantina*, include adelgids (Adelgidae), which are closely related to aphids, in their diet. Further, *Coleomegilla* also includes pollen whereas *Mulsantina* also includes scale insects in the broad sense.

Alternative Food

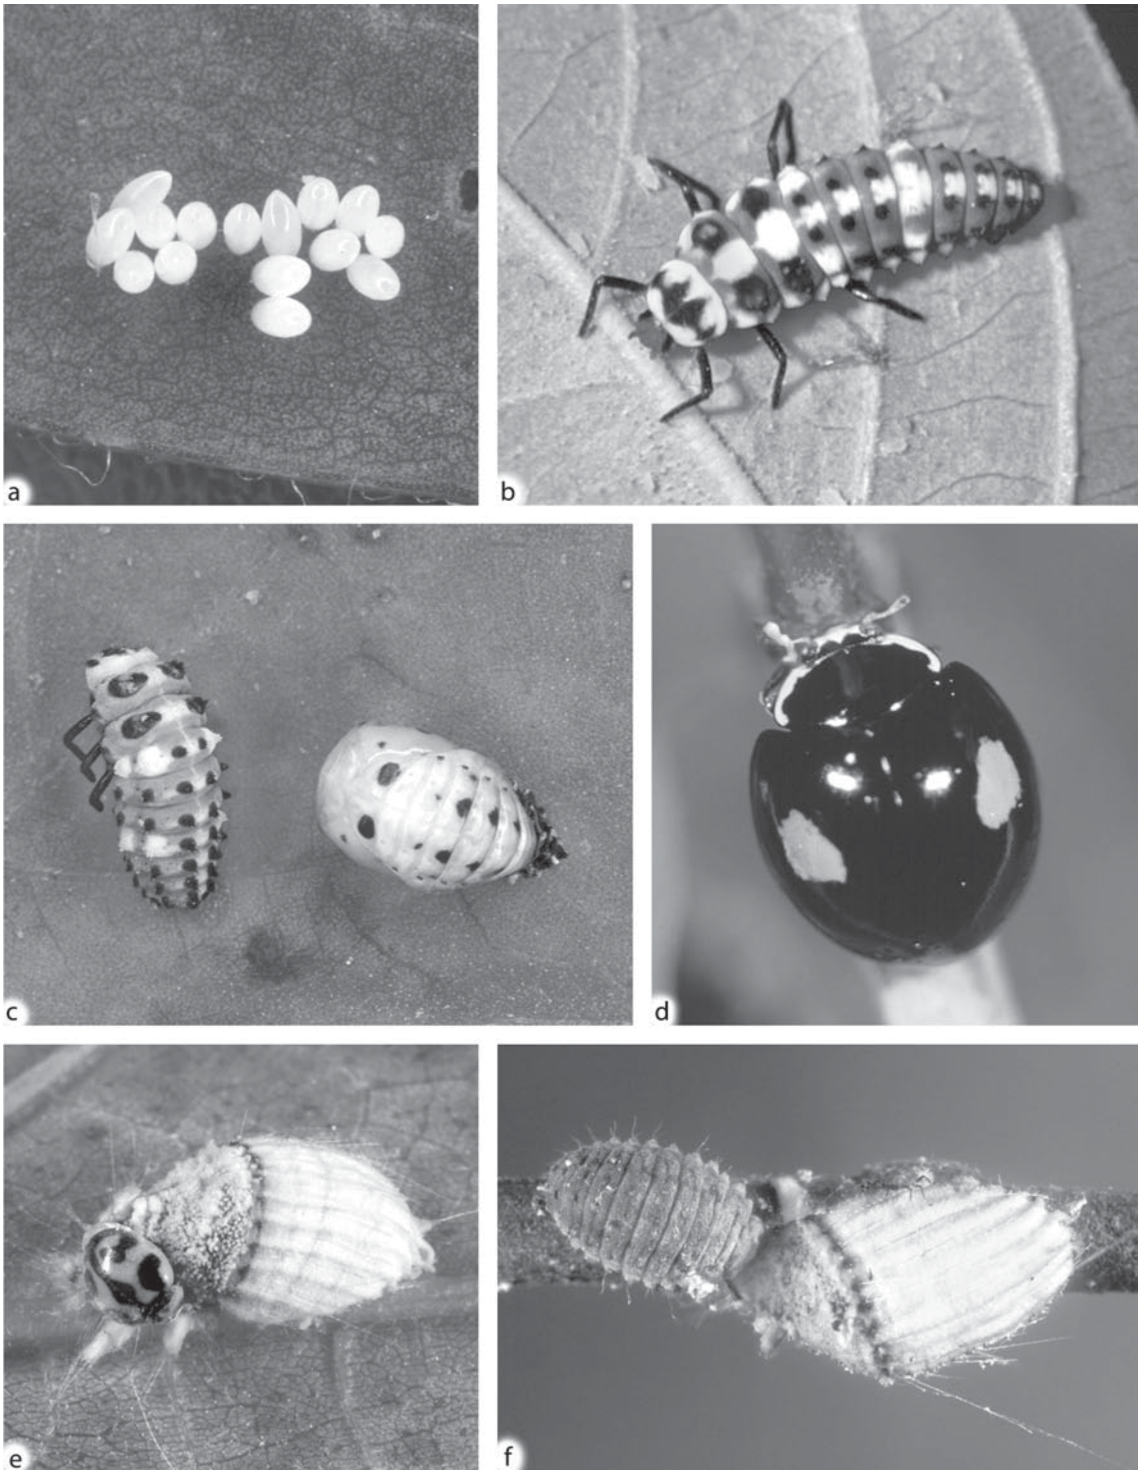
Ladybird larvae and adults may supplement their normal prey in times of scarcity with other types of food. They consume flower nectar, water and honeydew – the sugary excretion of piercing-sucking insects such as aphids and whiteflies – or pollen. Many plant species also contain organelles in locations on the plant other than the flower – termed extrafloral nectaries – that produce a nutrient-laden secretion. While it was first thought that extrafloral nectaries were used by the plant for excretion, it is well substantiated that most plants actually use the extrafloral nectaries to attract predators and parasites for protection from their herbivores. Over 2,000 species of plants in 64 families have extrafloral nectaries. Extrafloral nectaries may be located on leaf laminae, petioles, rachids, bracts, stipules, pedicels, fruit, etc. Ladybirds often use the secretions from extrafloral nectaries in their diet and are just some of the many beneficial insects that use extrafloral nectary secretions.

Natural Enemies

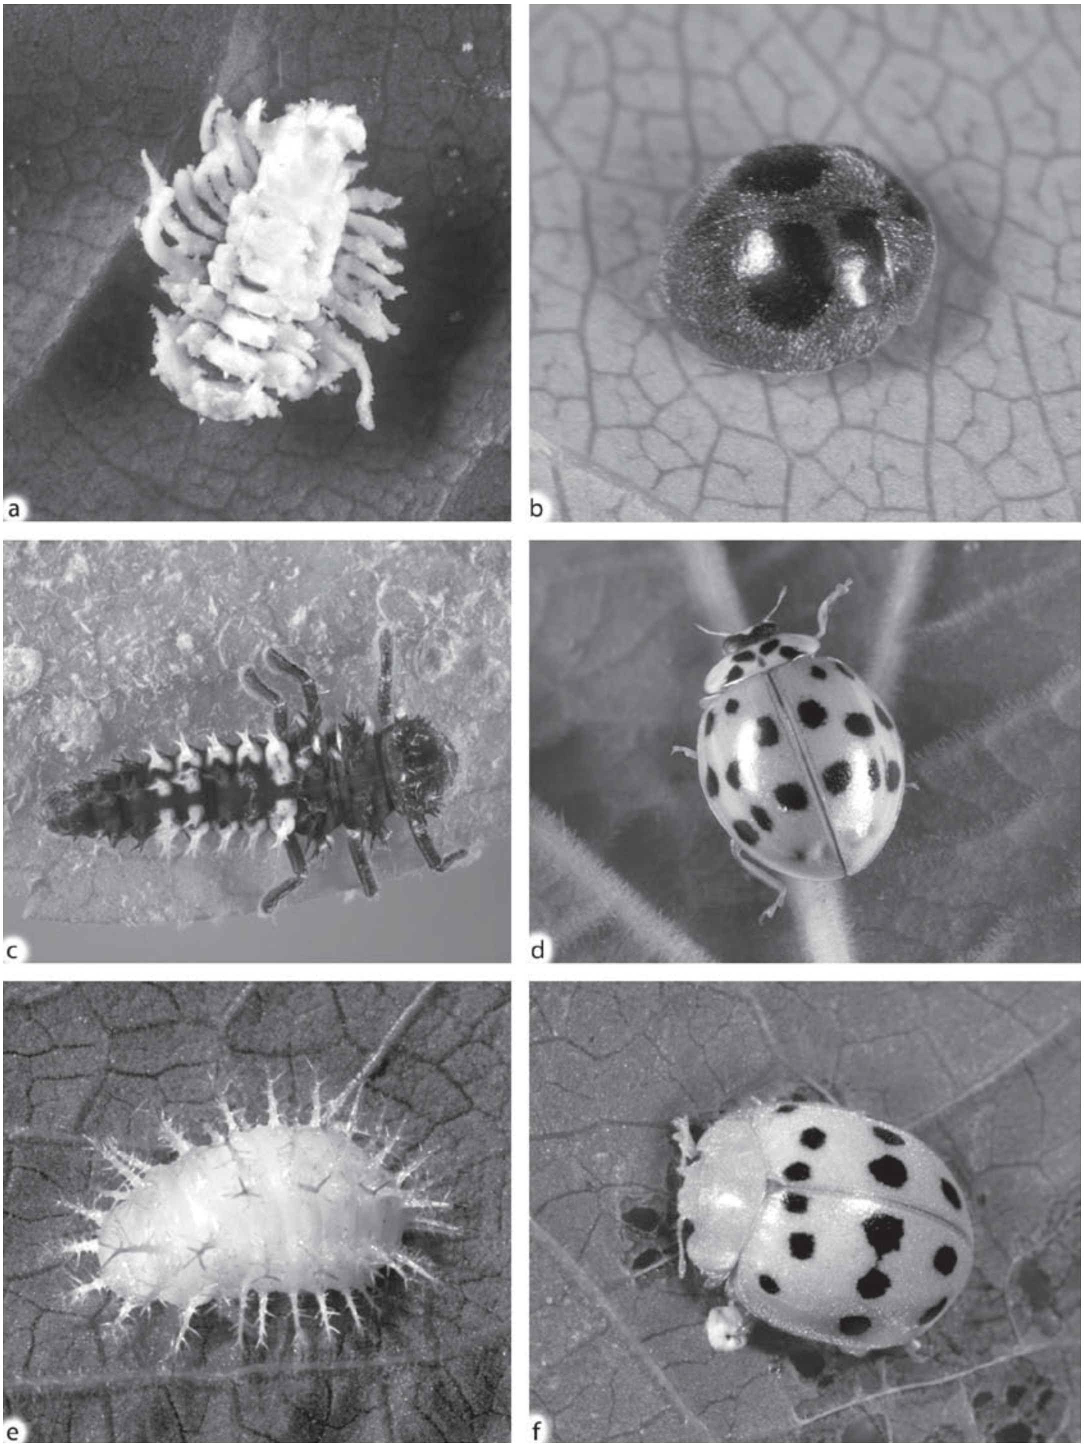
All insects have predators, parasites/parasitoids, and/or pathogens. Ladybirds are not exempt. Larvae of *Epilachna borealis* and *E. varivestis* are attacked by a North American tachinid fly (*Aplomyiopsis epilachnae* (Aldrich)) which specializes in the genus *Epilachna*. Larvae of *E. varivestis* also are attacked by an introduced eulophid wasp (*Pediobius foveolatus*, see above). Another native tachinid fly, *Hyalmyodes triangulifer* (Loew), is less specialized, attacking larvae not only of *Epilachna varivestis*, but also of *Coleomegilla maculata*, several weevils, and a pterophorid moth. Perhaps the best known of the parasitoids of ladybirds is the braconid wasp *Perilitus coccinellae* (Schrank). It attacks adult ladybirds and to a lesser extent larvae and pupae of *Coccinella septempunctata*, *Coleomegilla maculata*, and several other species. Microsporidial diseases include *Nosema hippodamiae* Lipa and Steinhaus, *N. tracheophila* Cali and Briggs, and *N. coccinellae* Lipa (Fig. 18).

Use of Ladybirds in Biological Control

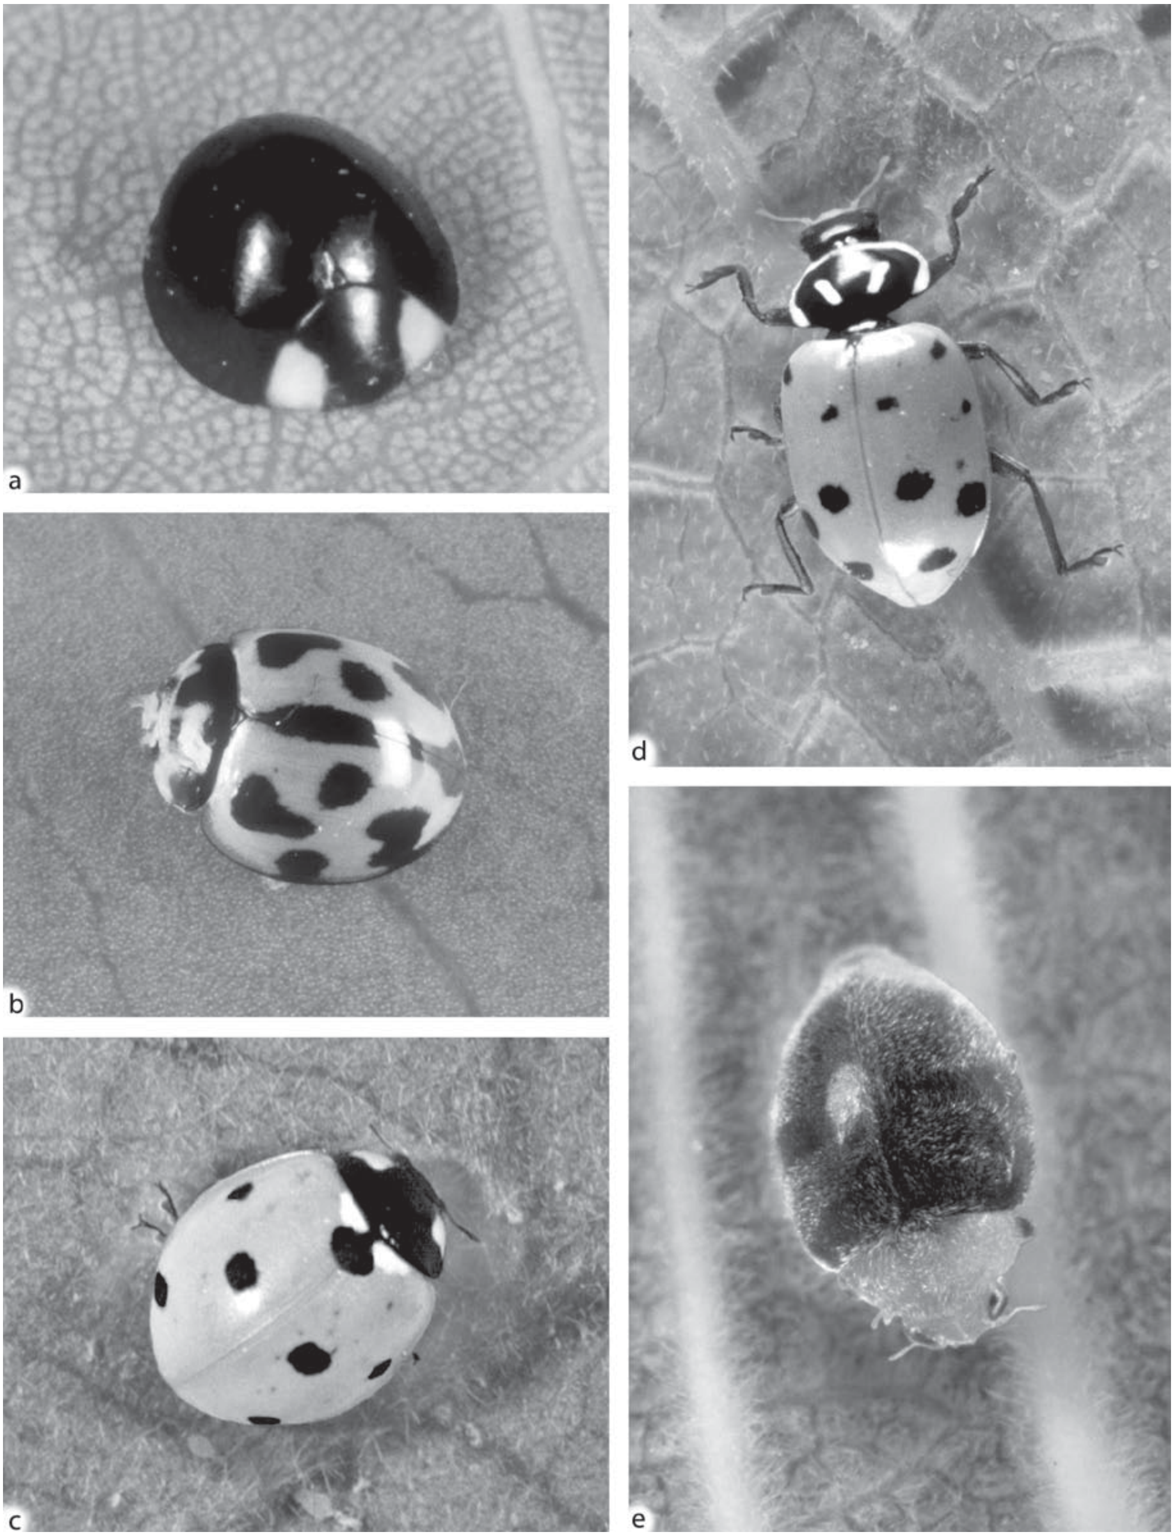
Most species of ladybirds are considered beneficial because they are predators of Hemiptera: Sternorrhyncha or Acarina, many of which are considered to be pests. These predatory ladybirds contribute to the regulation of populations of their prey, and in some situations contribute a high level of regulation. When ladybirds naturally contribute a high level of control of pests, or in combination with other predators and/or parasitoids and diseases contribute a high level of population regulation of pests, people may benefit. That is to



Ladybird Beetles (Coccinellidae: Coleoptera), Figure 16 **Ladybird beetles: *Olla v-nigrum* eggs (a), larva (b), prepupa (c, *left*) and pupa (c, *right*), and adult (d). This species is dimorphic in the adult stage and also occurs as an orange beetle with small black spots. Vedalia beetle, *Rodolia cardinalis*: adult (e) and larva (f) feeding on cottony cushion scale. This beetle saved the California citrus industry from destruction by cottony cushion scale.**



Ladybird Beetles (Coccinellidae: Coleoptera), Figure 17 **Larvae and adults of some ladybird beetles: *Azya orbigera* larva (a) and adult (b). This species is typical of those that produce waxy secretions in the larval stage. The multicolored Asian ladybird beetle, *Harmonia axyridis*, larva (c) and adult (d). This species, though predatory, has become a serious nuisance due to its habit of aggregating in buildings during the winter. Mexican bean beetle, *Epilachna varivestis*, larva (e) and adult (f). This species is one of only a small number of phytophagous ladybird beetle species.**



Ladybird Beetles (Coccinellidae: Coleoptera), Figure 18 **Some typical adult ladybird beetles: *Curinus coeruleus* (a), *Coleophora inaequalis* (b), *Coccinella septempunctata* (c), *Hippodamia convergens* (d), and *Cryptolaemus montrouzieri* (e).**

say that gardeners, growers and farmers may benefit, at no cost, because they have no or negligible pest problems.

Sometimes, gardeners mistake the ladybird larvae for pests and spray chemical pesticides that kill them (this is much less of a problem with growers and farmers because they have more experience). The result is increased problems from real pests. The answer is a constant educational effort to inform people about ladybirds and what their larvae look like. This effort cannot end, because people knowing nothing about ladybird life cycles are born each minute.

One type of biological control is thus called manipulative biological control (of which a subset is conservation biological control). The objectives are simply to capitalize on the ladybirds (or other beneficial organisms) that already are present, to make conditions as favorable as possible for them (manipulation), and especially to avoid spraying chemicals (insecticides, fungicides, or herbicides) that will harm them (conservation).

A second type of biological control is augmentative biological control. This begins with the recognition that ladybirds in a given pest situation are present but too few to do the job required, and buying more from a commercial producer to release to augment those already present. A risk is that if adult ladybirds are released, many of them may fly away. But, if ladybird larvae are released, they have the option of eating the pest with which they are presented, or starving – they cannot fly away. Obviously, this requires matching the pest to a purchased ladybird species that will eat that pest (see above for species options). The rub here is that the number of purchased ladybirds needed for a given pest situation may not have been worked out in detail – it demands a huge amount of practical experience to tie down the details for at least hundreds of situations. Documentation of this experience is progressing very slowly.

A third type of biological control is classical or inoculative biological control. Here, some individuals of a ladybird (or other) species that is not already present are released in the hope that they will establish a population and eventually control the pest that is of concern. Classical biological control typically applies to a situation in which a new pest has invaded, and researchers (from a university, or a national or state department of agriculture) import and release a ladybird (or other kind of organism) that is believed to control the pest elsewhere. Typically, the imported ladybird (or other organism) becomes established or does not become established; if it becomes established, it may or may not control the pest in this new situation. Typically, the foregoing things are done under the name of "research," and either are cost-free to gardeners, growers and farmers (especially if done by state or federal departments of agriculture) or, if done by university researchers, then gardeners, growers and farmers are asked to contribute toward a grant that will pay for the cost of importation and research on the biological control agent (but subsequently, after it has become established, there are no further costs). The archetypical example is control of cottonycushion scale of citrus by the introduced ladybird *Rodolia cardinalis*. Although chemical pesticides of the time were failing to control it, and although it threatened to ruin California's citrus industry, nobody was willing to invest funds in biological control research. Nevertheless, biological control research was "bootlegged" onto other operations by dedicated researchers, was astoundingly successful, and saved California's (and later Florida's) citrus industry from ruin: there was no subsequent need to use chemicals against this pest, thus saving billions of dollars as against a trivial expenditure (about $1,500 at the time, for foreign travel).

Glasshouses (greenhouses) provide a habitat for plants and pests and biological control agents that differs from outdoor habitats. Typically, culture begins with initiation of a crop of plants that has no pests (or seems to have none). But then pests somehow show up, and there are no ladybirds (or other organisms) to control them. The situation is very much like that of classical biological control, and ladybirds (and/or other beneficial organisms) released into the greenhouses may control the pests and eliminate need to use chemical pesticides. Here, the question is not about funding new research into a new pest, but into buying the right numbers of ladybirds (or other organisms) of the appropriate species to control a pest that has already been researched. For many such situations, ladybirds (or other organisms) can be purchased from commercial supply houses to control the pest(s).

Commercial Availability

The following is a partial species list of commercially available ladybirds posted on the California Department of Food and Agriculture's website, which can be accessed to provide information about commercial suppliers in Canada, Mexico and the USA in 1997 (it is not up-to-date). The URL (http://www.cdpr.ca.gov/docs/ipminov/bensuppl.htm) still works.

Coleomegilla maculata – a predator of aphids.

Cryptolaemus montrouzieri – a predator of mealybugs.

Delphastus pusillus – a predator of whiteflies.

Harmonia axyridis – a predator of aphids.

Hippodamia convergens – a predator of aphids. Some suppliers do not rear the beetles but collect overwintering adults from the mountains of eastern California; these overwintering adult beetles (i) may be heavily parasitized and many may die, and (ii) may be programmed at the end of the winter to end the hibernation by flying west, which may do you no good if they all take to flight and leave your property.

Rhyzobius lophanthae – a predator of scale insects.

Rhyzobius ventralis – this name is listed in error, it should be called *Rhyzobius forestieri* (Mulsant).

Stethorus picipes – a predator of tetranychid mites; this name is listed in error, it should be called *Stethorus punctum picipes* Casey, a subspecies of *Stethorus punctum* (LeConte).

Stethorus punctillum – a predator of tetranychid mites.

Commercial suppliers of biocontrol agents in Australia are listed by the Association of Beneficial Arthropod Manufacturers (ABA: http://www.gc.goodbugs.org.au), and some of these suppliers sell ladybirds. Commercial suppliers of biocontrol agents in Europe (and some other countries around the world) are listed by the International Biocontrol Manufacturers Association (IBMA: http://www.ibma.ch), and some of the listed companies sell ladybirds. Commercial suppliers belonging to the Association of Natural Biocontrol Producers, a North American Organization, are listed (ANBP http://www.anbp.org). By examining the individual sites of these companies, you may determine what ladybird species are available and, from the websites of some of these companies, some of the characteristics of the species available.

There is yet no website listing insect cultures available worldwide for purchase, with a list of suppliers for each species. Insect Production Services, Natural Resources Canada, is beginning to compile such a list (http://www.insect.gflc.cfs.nrcan.gc.ca).

However, just because a biocontrol agent such as a ladybird species (or subspecies), is available somewhere in the world for purchase, does not necessarily mean you will be able to obtain it. Your own national (and perhaps provincial or state) department of agriculture (or some other government agency) may regulate importations. It is most probable that you will only be able to import species (and subspecies) that already exist in your area. For example, all shipments of living insects into Florida are required to have permits from the Florida Department of Agriculture and Consumer Services, Division of Plant Industry; in general, a permit will be supplied for importation of species (and subspecies) that already occur in Florida. It is the vendors who are required to obtain the permits for commercial shipments. Furthermore, no reputable producer is likely to ship living ladybirds to you unless there is a rapid commercial shipper. Stated policies of some international shippers (e.g., Federal Express, DHL, UPS) say that they will not accept consignments of living animals (including insects) for reasons that they do not explain. The lesson is that you should buy from a local supplier wherever possible.

Despite all the difficulties in purchase and shipment, some biocontrol producers can provide you with a good product rapidly. Please see the website of the Belgian producer Biobest (http://www.Biobest.be), which also has websites in other countries (at least Canada, France, Greece, and Spain) as an example of how it can work. That company provides you an online description of the product and what it can do.

Four ladybird species (*Coleomegilla maculata*, *Cryptolaemus montrouzieri*, *Harmonia axyridis*, and *Hippodamia convergens*) have been reared on purely artificial diets, thus promising to reduce labor costs and thus the price of commercially available ladybirds. Diets for others may now be available or under development.

The Downside of Ladybirds

The great success of the imported *Rodolia cardinalis* in controlling cottonycushion scale in California and then in various countries around the world led to great enthusiasm among growers to attempt importation of additional ladybirds to control a long list of pests of plants. Many of these additional ladybirds failed to establish where they were introduced. Others became established but did not provide the required level of control. Relatively few achieved the required level of control. One of the reasons for success of *R. cardinalis* was its high level of specialization to cottonycushion scale – it would control that pest effectively, but no others.

Growers of many crops encounter pest aphids. Ladybirds that prey on aphids are widely distributed, and native ladybirds are often recruited to aphid infestations on crop plants in North America and elsewhere. Perhaps it was a sense of lack of effectiveness of native ladybirds in rapid and complete control of aphid infestations that led to attempts to import additional aphid-feeding ladybird species into North America. At all events, considerable effort was made by USDA entomologists (in collaboration with state and university entomologists) to import the Eurasian *Coccinella septempunctata* and the Asian *Harmonia axyridis* to eat more aphids than were consumed by native ladybirds. Whether those efforts succeeded or whether those two ladybird species arrived as immigrants is unclear, but eventually both species became established and spread widely. They proved to be more successful than native ladybirds at controlling aphids in general, and their populations grew and spread. Perhaps if this had happened in the 19th century the success would have been welcomed. But, by the late twentieth century, it was their side-effects that received publicity – there is some evidence that in some places native ladybird populations have declined because of the efficiency of the introduced ladybirds in killing aphids and thus denying food to the native ladybirds. It is undeniable that adult *H. axyridis* may hibernate in some places (loosely constructed houses, railway electrical boxes, etc.) where they are not welcome. It matters little that houses and railway electrical boxes should and could have simple physical screens to exclude insects (building codes in the southern U.S.A. require screening of houses against mosquitoes) because the public has become incensed against *H. axyridis*. The era of importation of generalist biological control agents has ended (even, for example, those that feed on many aphid species but no other prey may no longer be welcome), and only specialists may in future be permitted.

Lagenidium giganteum

Lagenidium giganteum (Lagenidiales) is the best-known entomopathogen belonging to the class Oomycetes. It has been described as a facultative parasite; it infects and kills available insect hosts, but also is capable of surviving saprophytically. *Lagenidium giganteum* most often infects young mosquito larvae; only occasionally does it infect older larvae and pupae. In addition, infection also has been reported to occur in certain species of gnats and biting midges. The infective propagules are asexually produced biflagellate zoospores that migrate upward and concentrate at the surface of the water to contact surface-breathing mosquito larvae. Once contact is made, the zoospores recognize and attach to the insect cuticle. Zoospores may attach over the entire larval surface or may concentrate in the head region (e.g., in the buccal cavity). After encystment and attachment, the zoospores (cysts) form delicate germ tubes that penetrate the cuticle. Mechanical and enzymatic disruption of the cuticle and underlying tissues produced by apical growth of the fungal germ tube promotes the penetration of *L. giganteum* into host larvae. Successful infection by *L. giganteum* is host-specific in terms of the ability of a particular strain of the fungus to bypass the defensive reactions exhibited by challenged host larvae. Mycelia eventually fill the body cavity, and this extensive vegetative growth results in the starvation of the insect. At this time, septation of the mycelia occurs, and the resulting segments may become asexual sporangia or male and female gametangia. Zoosporogenesis takes place in the asexual sporangia. In *L. giganteum*, the sporangia produce exit tubes that pass through the host cuticle and form bubble-like vesicles. The sporangial protoplast moves through an exit tube into a vesicle; the protoplast then divides into individual zoospores, which are released into the water when the vesicle ruptures. The free-swimming, wall-less zoospores, which do not represent a resistant or resting stage of the fungus, must contact host larvae within several hours in order to initiate another infection cycle. The male and female gametangia (i.e., antheridia and oogonia, respectively) may form from segments of the same mycelium or from segments of contiguous mycelia. The antheridium forms a fertilization tube that attaches to the oogonium, and the contents of the antheridium move into the oogonium. Plasmogamy (fusion of the sex cells) and karyogamy (fusion of the nuclei) occur in the oogonia, and the zygotes resulting from these fusion events form into thick-walled oospores. Oospores represent the dormant, resting spore stage of *L. giganteum*, and their existence insures survival of the fungus during environmental extremes (drought, cold temperatures). Under proper conditions, oospores germinate, and the fungus may then grow saprophytically, or the germinating oospores may act as zoosporangia, releasing infective zoospores.

Lagenidium giganteum is a sterol auxotroph that requires exogenous sterols for both zoosporogenesis and oosporogenesis, but not for vegetative growth. Oospores of *L. giganteum* are resistant to environmental extremes and can be stored indefinitely at room temperature. In vitro, oospores may be produced in yeast extract-basal media supplemented sterols, unsaturated fatty acids; calcium, and magnesium. Sterols such as cholesterol also regulate the cellular uptake of unsaturated fatty acids. Unsaturated fatty acids increase bilayer fluidity when they become incorporated into plasma membranes and, as in the case of sterols, may affect adenylate cyclase activity by changing membrane fluidity. In addition, there is an increase in oospore viability if the unsaturated fatty acids are added as triacylglycerols, which can function as storage products in dormant cells such as oospores. Calcium is required during all stages of oospore formation from induction to spore maturation. At antheridial induction, calcium interacts with the regulatory cyclic nucleotides, and it may be involved in membrane phase transitions during gametangial fusion.

Lag Phase

A phase in the typical growth cycle of a population when there is no growth, typically between the introduction of an organism and the period of exponential growth.

Lamarck, Jean-Baptiste

Jean-Baptiste Pierre Antoine de Monet, Chevalier de Lamarck, was born near the village of Bazentin-le-Petit on August 1, 1744. After study at a Jesuit seminary, military service, and work as a bank clerk, he began to study medicine and botany. He earned great recognition for his book "Flore Française," published in 1778. During the French Revolution he called for a reorganization of the Jardin du Roi, where he worked, and when it was implemented he was appointed a professor of the natural history of insects and worms, a subject about which he knew nothing. This was a period when few naturalists considered invertebrates worthy of study. In fact, the word "invertebrates" did not exist at the time, so Lamarck coined it to describe his responsibilities! Lamarck published a series of books on invertebrate zoology and paleontology. Publication of "Histoire naturelle des animaux sans vertèbres" in 1815 and 1822 greatly advanced the classification of invertebrates. However, his work never became popular, and in particular his theories on evolution brought him considerable criticism. "Lamarckism" is now used in a derogatory sense to refer to the discredited theory that acquired traits can be inherited. However, Lamarck's beliefs were actually more complex, and not so out of step with what became known as Darwinism. Lamarck believed that environmental change affects organisms so that they change their behavior. Altered behavior leads to greater or lesser use of a structure or organ; use would cause it to be enhanced over several generations; disuse would cause it to disappear. The concept that use or disuse would cause structures to enlarge or shrink was called the "first law" in Lamarck's book "Philosophie zoologique" published in 1809. His "second law" stated that changes were heritable. The result of his first and second laws is that organisms change and adapt to their environment. So although the mechanism proposed by Lamarck to explain evolution is different than Darwin's, the outcome is about the same. Thus, Lamarck should be credited with advancing the concept of evolution, though Darwin should be justifiably credited with the stronger mechanistic argument and the stronger set of supporting data. He died on December 28, 1829.

Lance-Wing Moths (Lepidoptera: Pterolonchidae)

John B. Heppner
Florida State Collection of Arthropods,
Gainesville, FL, USA

Lance-wing moths, family Pterolonchidae, total only 11 species, mostly Mediterranean, with two in South Africa. The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (24–27 mm wingspan), with head smooth-scaled; haustellum absent; labial palpi porrect; maxillary palpi absent. Wings elongated. Maculation mostly light shades of brown or mostly white. Adults may be mostly crepuscular. Larvae are root borers as far as is known. Only recorded host plants are in Compositae.

Lappet Moths (Lepidoptera: Lasiocampidae)

John B. Heppner
Florida State Collection of Arthropods,
Gainesville, FL, USA

Lappet moths, family Lasiocampidae (also called tent caterpillars), include 2,130 species worldwide, with the most in Africa (790 sp.). Subfamilies remain unclear and need more study, but five are now recognized: Chondrosteginae (African), Chionopsychinae (African), Poecilocampinae (Palearctic), Macromphalinae (New World), and

Lasiocampinae. The family is in the superfamily Bombycoidea (series Bombyciformes), in the section Cossina, subsection Bombycina, of the division Ditrysia. Adults small to very large (19–172 mm wingspan), with head vertex rough-scaled; haustellum absent (rarely vestigial); labial palpi short, upcurved or somewhat porrect; maxillary palpi absent (rarely vestigial); antennae bipectinate; body robust and usually with very long hair-like setae. Wings broadly triangular and usually rounded, but sometimes with forewing apex somewhat acute; hindwings rounded; some with micropterous females. Maculation mostly somber browns or grays, with various markings, but can be more colorful with pink spotting or completely bright green or yellow, for example, or white with black spotting. Adults mostly nocturnal but some males are diurnal. Larvae are leaf feeders, sometimes communally in silken tent-like webbings. Larvae typically have many lateral secondary hair-like setae that cover the prolegs when on the host leaf. Host plants are various, with many records in Betulaceae, Compositae, Fagaceae, Gramineae, Lauraceae, Leguminosae, Myrtaceae, Rosaceae, Salicaceae, and Tiliaceae, among others. Some species are economic as tree defoliators (Fig. 19).

Lappet Moths (Lepidoptera: Lasiocampidae), Figure 19 Example of lappet moths (Lasiocampidae), *Lasiocampa quercus* (Linnaeus) from Italy.

Large Cabbage White Butterfly, *Pieris brasicae* (Linnaeus) (Lepidoptera: Pieridae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

This species occurs widely in Europe, east to India and southwestern China, and in North Africa, but is not yet found in North America, unlike the similar cabbageworm or small cabbage white, *Pieris rapae* (Linnaeus). Large cabbage white was accidentally introduced to Chile, in South America, in 1971, and to South Africa in 1994.

Life history

The number of generations per year depends on day length. In the northernmost regions it displays only one generation, but four generations are common in central Europe and six generations may occur in northern Africa. It is highly dispersive, regularly migrating from continental Europe to the United Kingdom, often in mixed swarms with other pierids such as *Pieris rapae* (Linnaeus) and *P. napi* (Linnaeus).

Adults lay cone-shaped eggs bearing sharp vertical ridges. They are yellow, about 1.2–1.4 mm high, and resemble the eggs of *P. rapae* but are laid in groups of 20–50 instead of singly or in pairs as in *P. rapae*. The eggs may be deposited beneath or on the upper surface of the leaves, but the former position is favored. The eggs hatch in 3–13 days, depending on temperature.

Upon hatching, young larvae consume the egg chorion before consuming foliage. The young, pale green larvae remain clustered together, though they soon acquire a mottled blue-green appearance. Larvae remain gregarious until nearing their maturity. Usually there are 3 instars (though up to 5 has been reported), and mature larvae wander considerable distances before pupating. Mature larvae are 25–40 mm long, yellowish brown, with black spots and yellow longitudinal stripes. The larva is densely clothed with hairs. About 30 days are normally required for larval development.

Typical pupation sites include crop plants, weeds, fence posts, stone walls and other protected areas above the soil. In preparation for pupation, the larvae attach themselves by a supporting silken girdle and posterior hooks; the anterior end faces upward. The chrysalis is 20–24 mm long, 5–6 mm wide, and gray-green to yellow-brown but marked with small black and yellow spots. It bears lateral ridges and a dorsal ridge, and several blunt spikes on the abdomen. Pupation requires 7–60 days, depending on temperature. The butterfly, after it escapes from the pupal case, climbs and expands its wings to dry.

The adult is a white butterfly with a wingspan of about 63 mm in males, and 70 mm in females. The forewings have black tips, and the hindwing has a small amount of black at the front margin. Dorsally, the female, but not the male, also bears two prominent black spots and a black dash on the forewing. The ventral surface of the wings is usually pale yellow. The adults favor sunny areas containing flowers, and are most active in hot weather. Adults mate 1–4 days after emergence. The male butterfly of *P. brassicae* can be distinguished from *P. rapae* by the presence of one dark spot on the forewing of *P. rapae*.

The natural enemies of cabbage white butterfly are numerous, but perhaps most important are a baculovirus and the parasitoid *Cotesia (Apanteles) glomerata* (L.) (Hymenoptera: Braconidae). *Trichogramma* sp. (Hymenoptera: Trichogrammatidae) has been reared from eggs, but normally is not a very important mortality factor. General predators such as ground beetles (Coleoptera: Carabidae) and birds also can be locally important.

Damage

This species feeds predominantly on cruciferous species, but adults are attracted to mustard oil glycosides so other plants containing these chemicals also are attacked. Crops damaged include broccoli, Brussels sprouts, cabbage, cauliflower, horseradish, kohlrabi, mustard, rape, radish, rutabaga, sarson, toria and turnip. Many weeds are affected, including shepherd's purse, *Capsella bursa-pastoris*, flixweed, *Descurainia sophia*, hoary cress, *Cardiaria draba*, and many others. It is a defoliator, and because it is a fairly large insect, it can cause impressive levels of defoliation when present. However, damage tends to be limited to margins of fields.

Management

Large cabbage white now is much less damaging in Europe than formerly, possibly due to better weed management and better insecticides. The principal concern is that due to its dispersive nature, large numbers of butterflies may suddenly appear in some areas, suddenly triggering the need to control them. Normally, a single application of insecticide to foliage provides season-long protection to vegetables; field crops are usually not treated. The bacterial insecticide *Bacillus thuringiensis* is effective if applied to young larvae, though use generally requires more frequent application. For small-scale cultivation, netting may be used to cover the crop and prevent oviposition.

Large Milkweed Bug, *Oncopeltus fasciatus* (Hemiptera: Lygaeidae)

DOROTHY FEIR
St. Louis University, St. Louis, MO, USA

The large milkweed bug, scientific name *Oncopeltus fasciatus* (Dallas), is the most common of the five known species of this genus in the U.S. There are at least 24 species of *Oncopeltus* worldwide and these may all be called milkweed bugs because they feed on milkweed plants. Although all the bugs look quite similar, there are some differences in the color patterns. *Oncopeltus fasciatus* is found from the east coast to California, north to Massachusetts and south to Florida and Texas. Related species are found wherever species of milkweed grow. Asclepiadaceae is the very large family of milkweed species. *Oncopeltus fasciatus* (Dallas) has also been found on live oak in Florida, on the foliage of willow and flowers of goldenrod in Indiana, on the flowers of avocado in Texas, on oleander in Florida and on *Apocynum* in Missouri. The reports do not indicate whether the insects were actually feeding on the plants. In the laboratory, the bugs were tested on the following, but none would go through their life cycles on them: black walnuts, English walnuts, pecans, Brazil nuts, almonds, seeds of *Helianthus*, seeds of *Arachis hypogaea*, raisins, whole kidney beans, rolled oats, cantaloupe seeds, wheat, bluegrass, parsley, gelatin, cabbage, hamburger, peanut butter, fresh string beans and coconut. The bugs have been successfully reared through their life cycles in the laboratory on watermelon seeds that had the coats cracked, raw or blanched peanuts, sunflower seeds, pumpkin seeds and squash seeds. After several generations, milkweed bug strains became adapted to sunflower seeds, cashews and almonds. Survival and reproduction were poor for several generations until the insects became adapted. The sunflower seeds produced the best results in terms of survival and reproduction, but the results were never on a par with the results obtained from feeding them on milkweed seeds. Even after several years of generations fed on sunflower seeds, the bugs seem to still prefer milkweed seeds in choice tests.

The bugs are easy to rear in the lab on milkweed seeds and water. It is quite labor intensive to collect a year's supply of milkweed seeds in the fall when the seeds are ripe, and a number of attempts have been made to develop a chemically defined diet, but these attempts have not been very successful. Milkweed pods and seeds can be kept in a dry condition in a freezer, or at room temperature for years and still be adequate food for rearing the bugs.

Although a few laboratory studies have shown that adult milkweed bugs can live for short periods of time under freezing conditions, it is generally agreed that these bugs survive the winter only in warm climates. It is thought that all instars die in the fall in northern areas and that new insects migrate up from the south in the spring or summer because, in some states, they have not been seen until July. The large milkweed bug was found to be a migratory insect principally from laboratory studies using tethered insects to determine how long they could fly. The evidence does seem to be rather strong and there is no other explanation as to why they are never found over-wintering in the midwestern and northern states. The adult female large milkweed bug undergoes a reproductive diapause before it enters its migratory phase.

The large milkweed bug is described as a hemimetabolous insect that has five immature stages and the adult stage. The immature stages look very much alike except for size. Wing pads appear in the third instar and increase in size in the fourth and fifth instars. The adults have two pairs of fully developed wings in *O. fasciatus*. The temperature and the amount of available food affect the rate of growth and the size of the insects, but, in general, the adult female is about three-quarters of an inch long and is bigger than the male. At 29.5°C in one experiment, the egg stage lasted 4 days, the five immature stages lasted 5.8, 5.9, 6.1, 4.5 and 6.8 days, respectively. There is considerable variation in the life history of the bugs reported in the literature. There is great variability in the length of the adult stage, but many adults live for 2 months. The longest life span seen in the literature was 24.7 weeks for virgin females. Higher temperatures, longer photoperiods and lower densities of the insect increase their reproduction and also their mortality. As long as there are milkweed seeds available and the temperatures are not very cold, milkweed bugs will go through a series of life cycles and all stages of the bug may be seen at the same time on the plants.

The preferred food of the milkweed bug in the field seems to be *Asclepias syriaca* and some of the reasons given for the preference are that this species has a relatively large number of pods and the plants grow in clumps or groups. Some of the clumps can be very large and include hundreds of plants. Because the immature large milkweed bugs cannot fly, the adult female has to lay her eggs where there will be abundant food for the offspring. The eggs are usually laid in clumps of 30 or so on the undersides of the leaves, on the unopened pods, or on the fluff of the opened pod. The sucking mouth parts of *O. fasciatus* are fairly long compared to the size of the insect, but the mouth parts of the young stages cannot penetrate the seed pod to reach the seeds inside. The young insects can feed on the leaves and green pods, but they seem to prefer the ripe, brown seeds when they are available. When feeding on the ripe, brown, hard seeds, the insects build a short sheath or tube that can be seen on the surface of the seed. Some scientists theorize that this serves as a support or a guide for the stylets (mouth parts). The functional mouth of the milkweed bug and its relatives is made up of a pair of elongated maxillae and a pair of elongated mandibles. The maxillae form the inner members of this stylet bundle, and each maxilla has two deep grooves that are opposite the grooves of the other maxilla, and thus, two canals or tubes are formed. Saliva is pumped down one tube and fluids are sucked up through the other tube. There are barbs on the tips of the mandibles that aid in the penetration of foods. When feeding on ripe seeds, the insects eject their salivary secretions into the seeds and then suck up the digested or dissolved seed material. In this way, they completely remove all edible parts of the seed and leave nothing but the seed coat.

A number of species in the milkweed family and the closely related family, Apocynaceae, have been shown to contain cardenolides (digitalis-like, toxic compounds). Cardenolides are specific inhibitors of Na, K-ATPase activity, and, therefore, are toxic to many vertebrates and invertebrates. The milkweed bug (and probably other insects that feed on these two families of plants) sequesters the ingested cardenolides into the dorso-lateral space fluid by an energy-dependent physical process. The Na, K-ATPase activity of the milkweed bug is highly resistant to cardenolides, and the bug can tolerate high doses of cardenolide that would be lethal for vertebrates and many other invertebrates. The presence of the cardenolides in the milkweed bugs protect them from predation by many vertebrates and invertebrates. The predators learn that the milkweed bugs are toxic for them and they do not prey on them. There are many red and black insects (the colors of the milkweed bugs) who benefit from mimicking the colors of the toxic milkweed bugs. The cardenolides cause some birds to vomit, which is a quick way to determine the susceptibility of birds and other animals to cardenolides. Some investigators have shown that milkweed bugs feed preferentially on milkweed species that have higher levels of cardenolides, and that seed cardenolide content was a good parameter for the growth efficiency of *O. fasciatus*.

The large milkweed bug has been used extensively as a research insect because of the ease with which it can be reared. Some of the research has shown that the large milkweed bug is somewhat different from the majority of insects. One of these differences is that makisterone A is the major molting hormone of *O. fasciatus*. Ecdysone and 20-hydroxyecdysone are the principal molting hormones in most other insects that have been studied. Because insects cannot synthesize cholesterol, they must use precursor molecules to make the molting hormones. Campesterol has been suggested as the precursor for the synthesis of makisterone A. Precocenes are compounds derived from the plant, *Ageratum houstonianum*, and they have been shown to destroy the corpora allata of insects, principally in the Order Hemiptera. The corpora allata are the site of juvenile hormone synthesis, and the inactivation of the corpora allata in the younger large milkweed bug instars resulted in precocious metamorphosis to a small adult, inhibition of oogenesis in females and inhibition of long-term (migratory) flight in both males and females. The effects of precocene can be counteracted by an appropriate application of juvenile hormone.

The large milkweed bug midgut is made up of four subdivisions, and the residues of nymphal meals seem to be retained in the third region until after the molt to the adult when the residues are voided. The fourth region does not have a complete lumen until the adult ecdysis (molt).

The ovaries of Hemiptera are different from other insects. In the Hemiptera, each ovariole has a region of nutritive cells at the anterior end of a string of oocytes. Therefore, there is a nutritive tube that carries nutrients from the nutritive cells to the developing oocytes. This is called a telotrophic ovary.

Variations on the typical or normal appearance of *O. fasciatus* have appeared spontaneously in different laboratory strains around the world. A gynandromorph appeared in Oslo, and a white strain or a partially white strain has appeared in several different labs in the U.S. Interspecific hybridizations of *O. fasciatus* have been found rather frequently in nature, and, in some cases, hybrid individuals have been collected. The authors concluded that both pre- and post-mating isolating mechanisms work to prevent introgressive hybridization. In general, there is a gradual change in color in captive milkweed bugs, which is much less dramatic than in the preceding examples. However, the gradual change (often a lightening of the orange-red color) should be remembered because it might indicate that other changes occur in the bugs with prolonged cultivation. These changes are different in different laboratories; therefore, it might be wise to obtain insects from various laboratories when doing any type of research on milkweed bugs.

l-amino acids are by far the most common amino acids in animals. *O. fasciatus* has d-alanine in its hemolymph. This isomer must be produced during intermediary metabolism because it is not present in the milkweed plant. An antibacterial agent, active against *Staphylococcus aureus* and one strain of *Bacillus subtilis*, has been found in the hemolymph of the fifth instar. The formula of this compound was determined to be $C_{13}H_{14}O_3$, and it was suggested to have a three-ring structure. The hemolymph of the fifth instar also contains an agglutinating factor for human erythrocytes. However, its activity was lost after 45 min at room temperature.

O. fasciatus is a natural host for three species of trypanosomatids: *Leptomonas oncopelti*, *Phytomonas elmassiani* and *Crithidia oncopelti*. *Leptomonas oncopelti* has been found in various parts of the digestive tract and in the salivary glands. Binary fission switches to budding in the midgut of the bug. The flagellates do not appear in the rectum until adulthood. The flagellates form a "carpet" attached to the cuticular intima of the rectal glands of adults. Because the milkweed plant dies back every fall, and there is no continuity of latex tubules in the roots, the flagellates have no way of overwintering in the plants and, therefore, the plants have to be reinfected every year. Reinfection is probably done by *O. fasciatus*. The flagellates pass from bug to bug, probably by fecal contamination.

Photoperiod affects several aspects of the large milkweed bug's life. Mating and feeding activities reached the maximum levels at the end of the light phase. Long photoperiods produced higher levels of mating and feeding than did short photoperiods.

Large milkweed bugs have a very characteristic odor, which is readily picked up when handling the bugs. This odor probably comes from the accessory gland of the metathoracic scent apparatus in the adult. The odor is probably not a defensive secretion. The dorsal scent glands of the larvae do not function in the adult.

Larger Grain Borer, *Prostephanus truncatus* (Coleoptera: Bostrichidae)

CHRISTIAN BORGEMEISTER
University of Hannover, Hannover, Germany

As are most other beetles in the family of Bostrichids, the larger grain borer, *Prostephanus truncatus* (Horn), is a wood-boring beetle. It is native to Central American and Mexican forests and has long been known to occasionally attack stored commodities such as maize and cassava, sporadically causing serious damage in small-scale farmers' stores. However, the beetle attracted much greater public and scientific interest after its serendipitous introduction into Africa in the late 1970s and early 1980s. The beetle was first observed by farmers in the Tabora region of Central Tanzania. This new pest caused tremendous damage to their maize harvest, and because of the resemblance of the flattened head of the beetle to commonly used trucks in East Africa, farmers called it "scania beetle." Later, the pest was identified as *P. truncatus*, which was probably introduced to Tanzania through maize imports from Mexico that had not been properly fumigated. A second independent introduction of *P. truncatus* happened around 1984, when the pest was first recorded in the greater Lomé area, the capital of the small west African state of Togo. From these two focal points of introduction, the beetle has spread, to date, to a total number of 17 African countries, thus covering a great part of the maize-producing region of sub-Saharan Africa. In some of these countries, *P. truncatus* has become the most serious pest of farm-stored maize, sometimes causing losses of up to 30 to 40% of the harvested commodity.

Biology, Ecology and Damage Potential

The larger grain borer attacks a whole variety of stored commodities besides the various tree species that are their natural host plants. However, the greatest damage is inflicted to farm-stored maize and cassava, though it is a more serious pest of maize than of cassava. Infestations often commence in the field when the adult beetles bore into the maize cobs prior to harvest. Female *P. truncatus* usually lay up to eight eggs in clutches in maize grains, and their offspring develop within the grains, feeding on the starchy-rich endosperm of the maize kernels. However, the greatest damage is caused by the tunneling behavior of the adult beetles that often turn the maize into flour. The enormous amount of frass caused by the feeding pattern of the adults is often the first and most conspicuous sign of a *P. truncatus* infestation. Larger grain borer attacks cause greater damage when the maize is stored on the cobs than as shelled grain, unlike the two other important pests of post-harvest maize in Africa, the maize weevil *Sitophilus zeamays* Motschulsky (Coleoptera: Curculionidae), and the Angoumois grain moth *Sitotroga cerealella* (Olivier) (Lepidoptera: Gelechiidae). Moreover, *P. truncatus* can thrive on maize even when the moisture content of the grain drops below a level of 10%, the threshold for most of the other pests attacking stored maize. In southern Togo, maize losses after an average storage period of 6 months increased from 11% prior to the introduction of *P. truncatus*, to more than 35%. In areas with high incidence of *P. truncatus* in Tanzania, up to 34% losses of maize have been observed after three months of on-farm storage. When male *P. truncatus* locate a suitable breeding substrate like maize where there are no females present, they produce a pheromone that is highly attractive to individuals of both sexes. Once the females have been guided to these sites, the males cease pheromone production. However, beetles feeding and reproducing on maize or other suitable food substrates are no longer receptive to the pheromone. Thus, the pheromone is of paramount importance for the host-finding behavior of the beetles. In the late 1980s, the chemical composition of the pheromone was identified. The pheromone was subsequently synthesized, and is currently commercially available. It is primarily used for monitoring purposes, particularly to document the spread of infestation of *P. truncatus* throughout sub-Saharan Africa. Larger grain borer adults are rather poor flyers. Pheromone trap data revealed that the beetles only fly during short periods at dusk and at dawn. Thus, the spread of the beetle in Africa is mainly due to movement of infested commodities, i.e., within and between countries trading maize and cassava.

Conventional Control Strategies

After its first detection in Tanzania, campaigns were launched in the early 1980s to eradicate the beetle from the African continent. Prostephanus truncatus is highly susceptible to synthetic pyrethroid insecticides like permethrin and deltamethrin, and also to fumigants like phosphine and methyl bromide, (though the latter is now banned in many African countries). However, since the beetle not only attacks stored commodities, but also breeds in natural forest habitats, these eradication efforts were not successful. Yet, binary insecticide programs, consisting of a synthetic pyrethroid for control of *P. truncatus* and an organophosphorus insecticide for control of other storage pests like *S. cerealella*, were successfully implemented in many affected East African countries. However, the adoption rate of such a chemical control strategy was much lower in West Africa, mainly due to socio-economic constraints on behalf of the farmers, and logistical difficulties in the distribution of the insecticides.

Classical Biological Control

As an exotic outbreak pest in Africa that caused spectacular damage in its new area of distribution but was of considerably lower economic importance in its area of origin in Mexico and Central America, *P. truncatus* was considered to be a prime candidate for a classical biological control program. Hence, in the mid 1980s, intensive surveys were carried out in Mexico and several countries of Central America to identify efficient natural enemies of *P. truncatus*. However, the natural enemy complex of *P. truncatus* turned out to be rather poor in diversity. Several hymenopteran parasitoids, mainly pteromalids, were found to be associated with *P. truncatus*. Yet, all of these parasitoids were of cosmopolitan distribution, already existed in Africa, had a very broad host range, and showed no clear host preference for *P. truncatus*. Therefore, they were not considered for importation into Africa. The only specialized natural enemy that was identified during these surveys was the predator *Teretrius* (formerly *Teretriosoma*) *nigrescens* (Lewis) (Coleoptera: Histeridae). A close association between *P. truncatus* and *T. nigrescens* had already been observed prior to the introduction of the larger grain borer into Africa. During the subsequent search for natural enemies of *P. truncatus* in Mexico and Central America, the predator was always found in grain stores that were infested by the larger grain borer. Moreover, once the synthetic pheromone of *P. truncatus* became available, consistently high by-catches of *T. nigrescens* were recorded in pheromone traps located both in areas with agricultural production as well as in forests. Later, studies revealed that the predator uses the pheromone of *P. truncatus* as a kairomone to locate its prey. Electro-antennograms then showed that *T. nigrescens* reacts as sensitively to the pheromone as *P. truncatus* itself. In a large series of laboratory experiments by British and German researchers, *T. nigrescens* was able to fully suppress *P. truncatus* populations at a predator:prey ratio of 1:10. Both the adults and the larvae of *T. nigrescens* feed on the eggs and the larval stages of *P. truncatus*, though the larvae are far more voracious than the adult beetles. Adult *T. nigrescens* are strong flyers, long-lived with a longevity exceeding 20 months, and can survive extended periods of starvation (more than 60 days). Based on these findings, the predator was considered for importation into Africa. However, prior to the release, concerns were expressed about the potential ecological risks associated with a wide spread deployment of *T. nigrescens* in Africa. Histerids are, in general, oligo- to polyphagous predators. Therefore, prior to the release, the prey behavior of *T. nigrescens* was investigated in laboratory experiments. Results of these studies showed that *T. nigrescens* readily preys on other insects, mainly other coleopteran and lepidopteran larvae that occur in the maize storage environment, but it strongly prefers *P. truncatus* as prey in a choice situation. A post-release prey composition study, using electrophoretic gut content analysis techniques, showed that *T. nigrescens* clearly prefers *P. truncatus* as prey. The predator was first released in 1991 in southern Togo, and three years later in Ghana and Kenya. Between 1992 and 1997, a long-term impact assessment study was conducted in southern Togo and the neighboring Republic of Benin. Data from pheromone traps, as well as from large-scale storage experiments and surveys of farmers' maize stores showed a rapid spread of the predator, with substantially decreased trap catches of *P. truncatus*, as well as significantly reduced infestation levels and post-harvest losses of maize, particularly in the south of Togo and Benin. In Kenya, where the predator had been released in a bush land region dominated by forests, long-term pheromone trapping revealed a substantial decline in trap catches of *P. truncatus*. Thus, *T. nigrescens* is capable of controlling *P. truncatus* both in the maize store environment, as well as in its native forest habitat. To date, the predator has been released in eight African countries and several impact assessment studies are ongoing. This is the first case where classical biological control has been rather successfully used against a post-harvest pest.

Largidae

A family of bugs (order Hemiptera).

► Bugs

Larva

(pl., larvae) The growing stage of an insect (usually an insect with complete metamorphosis). The feeding stage between the egg and pupal stages. The immature stages of mites also are called larvae. Larval insects usually bear little resemblance to the adult stage, and often feed on different items.

Larvicide

An insecticide used to control the larvae of insects. This term is often used to describe the insecticides used for suppression of mosquito larvae (contrast with adulticide).

Larviform

Shaped like a larva.

Larviporous

A method of reproduction, especially in flies, wherein the eggs hatch within the female's body, and the larvae are deposited. In some cases the larvae obtain nutrition from the female, and pupate almost immediately upon being deposited.

Lasiocampidae

A family of moths (order Lepidoptera). They commonly are known as tent caterpillars, lappet, or lackey moths.

► Lappet Moths
► Butterflies and Moths

Lasiochilidae

A family of bugs (order Hemiptera).

► Bugs

Latent Infection

An inapparent infection in which the pathogen is still present in a "dormant" or noninfective phase, and in which a certain pathogen-host equilibrium is established.

Latent Learning

This form of learning, also called exploratory learning, involves the ability to recognize and remember landmarks. Social insects use landmarks as a means of finding their way back to their nest after they leave to forage for food.

► Habituation
► Associative Learning
► Insight Learning

Lateral Oviduct

A tube of the female reproductive system that connects the ovaries to the common oviduct, through which eggs pass prior to fertilization (Fig. 20).

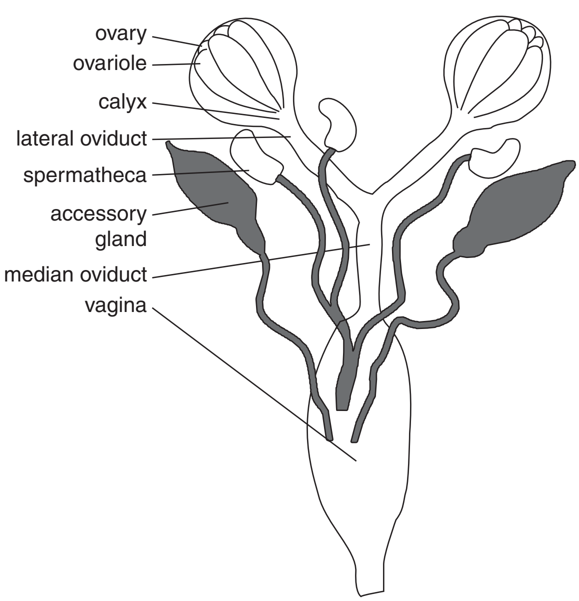
Lathridiidae

A family of beetles (order Coleoptera). They commonly are known as minute brown scavenger beetles.

► Beetles

Latreille, Pierre André

Pierre Latreille was born on November 29, 1762 at Brive, in the province of Limousin, France. An illegitimate child of the baron d'Espargnac, he was abandoned by his mother at a church in Brive. His biological father eventually made financial arrangements for his son's education,



Lateral Oviduct, Figure 20 **Diagram of female reproductive system, as found in *Rhagoletis* (Diptera) (adapted from Chapman, The insects: structure and function).**

and he was educated at the Collège des Doctrinaires at Brive and the Collège du Cardinal Lemoine at Paris. He also was awarded a Master of Arts from the Paris University in 1780, entered a seminary and was made a Deacon in 1786. He likely was made a priest, though there is no record of this, and he was acting vicar at Lostanges in October 1789. At this time he became interested in entomology, living on the income that his father, the général baron d'Espargnac, had established for him. However, the French Revolution would cause him to be imprisoned, and sentenced to death or deportation. His interest in insects was recognized while he was in prison, and a sympathetic official terminated Latreille's sentence. He remained in prison until 1794, however, and he gave up the priesthood and became a teacher. In 1796, encouraged by Fabricius, he published the "Précis des caractères génériques des insectes." This innovative treatise created the concept of insect families. In 1798 he received an appointment at the Muséum, where he worked closely with Lamarck. In 1814 he was named a member of the Académie des Sciences, and he entered a very productive stage of his life, but he remained very poor. He often assisted others in their natural history publications, though he also published his own work. In Cuvier's "Règne Animal" (1829) Latreille laid down the taxonomy of the entire Arthropoda. Eventually he replaced Lamarck as the dominant scientist of the institute. In 1830 he was awarded a new chair at the Muséum. Thus, he received recognition only late in life, despite a legacy of innovative contributions and decades of toil. Latreille is remembered primarily as a taxonomist, though he made important contributions in other areas. He introduced new methodologies and examined an enormous number of taxa. He believed in basing taxonomic groupings on the natural order: assembling species into genera, then into families, etc. Indeed, he was most interested in establishing genera, and named hundreds of new genera. Latreille also had profound impact on zoological nomenclature, emphasizing the principle of

Latreille, Pierre André, Figure 21 **Pierre Latreille.**

priority, insisting that families be named after an included genus, and emphasizing the concept of type species of a genus. Latreille was interested in morphology, and created several new terms. Interestingly, he considered field work most important, and was particularly interested in behavior. He sometimes incorporated behavioral characteristics into his taxonomic treatments. Though Latreille's achievements were often overshadowed by better-known scientists of the era, he eventually became known as the foremost entomologist of his time, and has even been called the "prince of entomology." He died at Paris on February 6, 1833 (Fig. 21).

An abbreviation for lethal dose, with the subscript denoting a proportion of the population tested. LD_{50} is the dose of a substance that kills half of the test organisms

Lea, Arthur Mills

GEORGE HANGAY
Narrabeen, NSW, Australia

Arthur Mills Lea was born on August 10, 1868 in Sydney, Australia. He began collecting beetles at an early age. During his frequent visits to the Australian Museum where he was assisted and encouraged by Sir William J. Macleay and George Masters. He enrolled in night school to learn Latin and that was the only supplementary education he received, as his family could not afford to give him more. At the age of 15 he began work with an accountant firm in Sydney and remained in this employment for 6 years, during which he pursued entomology as a hobby, winning prizes for his excellent insect collection and drawings of insects. He also taught himself French and German in order to understand entomological articles published in those languages. In 1891 he was appointed as entomologist's assistant in the New South Wales Department of Agriculture in Sydney and later became Entomologist in the Western Australian Department of Agriculture. In 1899 he took up the position of Government Entomologist in Tasmania. In little more than ten years Lea has built the largest collection of Tasmanian Coleoptera (most of this collection is now in the South Australian Museum, Adelaide) and established himself as a recognized authority in applied entomology and biological control. In 1910 he became Museum Entomologist in the South Australian Museum. He worked for this museum until his untimely death on February 29, 1932. During his 21 years in the South Australian Museum more than a million specimens were added to its collections. Arthur Lea was undoubtedly the most productive Australian Coleopterist. He described and named 5,432 species new to science and published a staggering number of works. He had an exuberant personality and gave inspiration to many of his colleagues and students.

Lea, H. Arnold

Arnold Lea was born on November 13, 1907, and was raised in Transvaal, South Africa. He was educated at the University of Pretoria, and in 1930 joined the Division of Entomology in Pretoria, the start of a 42-year career with the South African Department of Agriculture. South Africa experienced severe plagues of locusts beginning in 1932, and Lea joined a newly organized Locust Research Institute. His first task was to improve insecticidal control of red locusts, using improved bait formulations of sodium arsenite. Later he worked on identification of breeding areas and disruption of incipient locust outbreaks. With the onset of World War II, his area of responsibility was changed to North Africa and he developed desert locust campaigns, based on distribution of BHC-treated bait, to help protect the food supply of the area. Returning to civilian life in 1946, he again tackled the sodium arsenite bait problem because ranchers were increasingly reluctant to use this toxic material, which often killed livestock. He enlisted use of BHC against brown locusts beginning in 1947. Lea was responsible for effective emergency locust suppression campaigns, but he also found time for a disciplined, scientific approach to understanding the locust problem. Throughout his career, he studied locust forecasting, population dynamics, and phase transformation. A principal product of his investigations was "Locust control and research in southern Africa" (1972), and he is widely acknowledged as being one of the eminent locust researchers. Lea was fellow of several scientific societies and served as president of the Entomological Society of Southern Africa, and editor of its journal. He died at Pretoria, South Africa on August 25, 1989.

Leaching

The movement of pesticides through the soil, assisted by water.

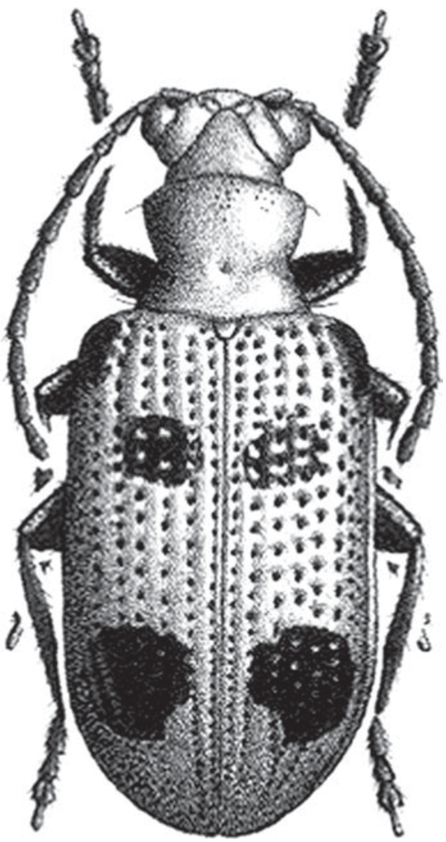
Leaf Beetles (Coleoptera: Chrysomelidae)

R. WILLS FLOWERS
Florida A&M University, Tallahassee, Florida, USA

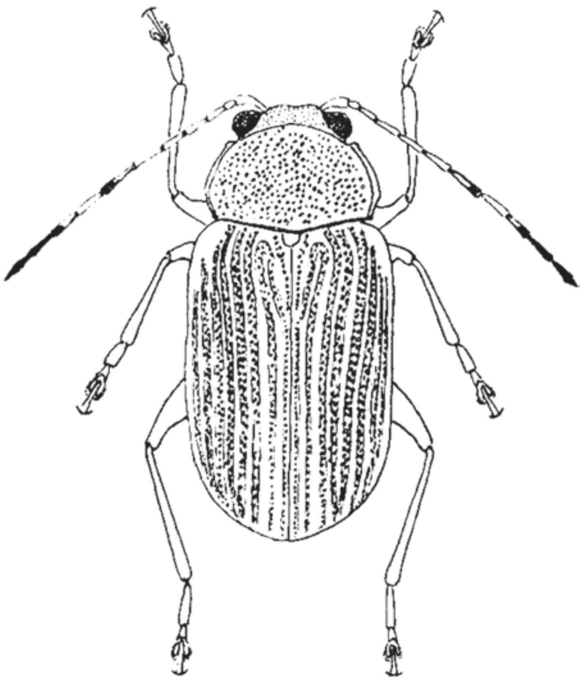
The Chrysomelidae, or leaf beetles, are the third largest family in the Coleoptera, with 37,000 described species and possibly as many as 60,000 when estimates of undescribed species are included. Only the Curculionidae and Staphylinidae are larger families. As the common name implies, Chrysomelidae are intimately associated with plants, although specific associations are known for only a small minority of the species. Chrysomelid adults are small to medium-sized beetles, often brightly colored, boldly patterned, or metallic. Some species are covered with hairs or scales. Most species are ovate or elongate-ovate, but body shape can vary from elongate to almost spherical (Figs. 22–26).

Classification

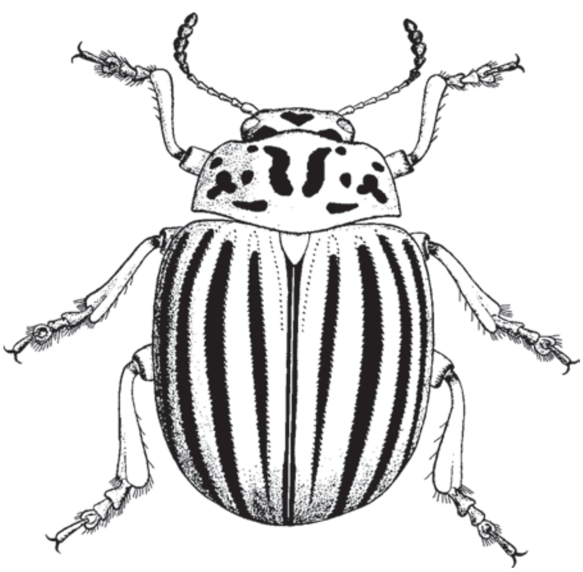
Chrysomelidae belong to the infraorder Phytophaga of suborder Polyphaga within the order Coleoptera



Leaf Beetles (Coleoptera: Chrysomelidae, Figure 22 Criocerinae: ***Neolema sexpunctata*** **(Olivier).**

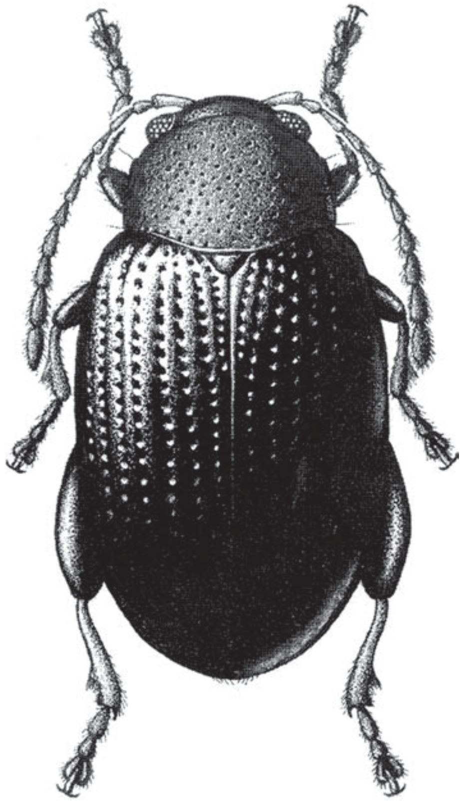


Leaf Beetles (Coleoptera: Chrysomelidae, Figure 23 Eumolpinae: ***Colaspis louisianae*** **(Blake).**

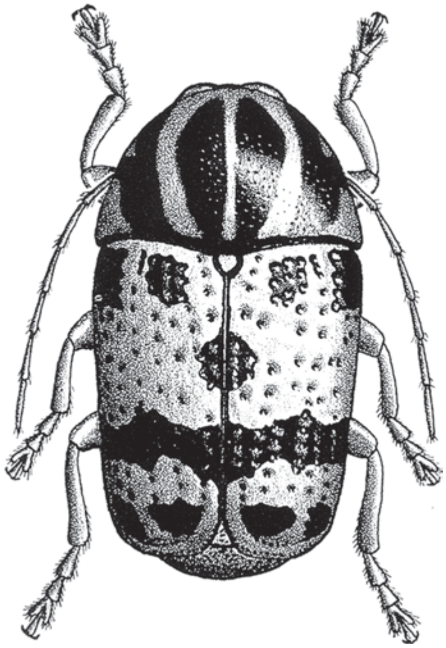


Leaf Beetles (Coleoptera: Chrysomelidae, Figure 24 Chrysomelinae: ***Leptinotarsa decimlineata*** **(Say).**

(beetles). The Phytophaga are characterized by crytopentamerous tarsi, in which the fourth tarsal segment is greatly reduced (sometimes entirely absent) and largely hidden by the third segment. The



Leaf Beetles (Coleoptera: Chrysomelidae, Figure 25
Galerucinae: *Chaetocnema pulicaria* (Melsh).



Leaf Beetles (Coleoptera: Chrysomelidae, Figure 26
Cryptocephalinae: *Cryptocephalus maccus* (White).

Phytophaga contain the superfamily Chrysomeloidea, which includes the Chrysomelidae, and the superfamily Curculionoidea (weevils and their allies). The Chrysomelidae are one of two major families in the Chrysomeloidea (the other being the Cerambycidae) and are distinguished by having antennae not partially surrounded by the eyes, and by the presence of a basal hood on the median lobe of the male genitalia.

Although the major groups within the Chrysomelidae have been generally recognized, the taxonomic ranks and boundaries of these groups continue to be actively debated. Recent phylogenetic analyses have resulted in the removal of several small problematic groups from the Chrysomelidae to other families, and some realignments and changes of the traditional subfamily classification. In the United States, the following subfamilies occur.

Bruchinae

Until recently classified as a separate family, bruchids, or seed beetles, are now regarded as a subfamily of the Chrysomelidae, closely related to the Old World and Neotropical Sagrinae. Seed beetles are distinguished by their robust bodies, elongate heads, and enlarged hind legs. Larvae feed within seeds of legumes and other plants.

Donaciinae

Adults in this subfamily somewhat resemble lepturine cerambycids in body shape. The head and pronotum are narrower than the width of the elytra at the base, and the general color is bronze or sometimes dark metallic. The family is aquatic in the larval stage and adults are found on emergent aquatic plants such as waterlilies or arrowheads. The underside of the adult is densely covered with hydrofuge hairs, and the hind femora often bear small teeth. This subfamily is world-wide except South America; in the Western Hemisphere representatives occur only as far south as Costa Rica.

Criocerinae

Adults of this subfamily are generally brightly colored and all have a characteristic constriction across the pronotum. As in the preceding family, the head and pronotum are narrower than the basal width of the elytra, and the head has deep frontal grooves forming an “X” on the facial area (Fig. 22). Larvae feed openly on plants, covering themselves with their own feces for protection. Native North American species feed for the most part on plants of the families Solanaceae or Commelinaceae and cause little economic harm. However, three introduced species have become pests. One, the cereal leaf beetle (*Oulema melanopus* (L.)) is a serious pest of grain, and two species of *Crioceris* feed on asparagus.

Hispinae

This subfamily has recently been expanded to include the tortoise beetles (Cassidini). The nominate tribe, Hispini, contains elongate beetles, frequently with the elytra very strongly punctate and costate. Members of the tribe Cassidini, on the other hand, are very broadly ovate to hemispherical, with margins of the pronotum and elytra explanate. In many species the head is concealed under the front margin of the pronotum. Many adult cassidines have striking gold or other metallic colors on the dorsal surface which in some species can be turned on or off by the animal. Becauce these colors reside in the living tissues, they unfortunately disappear in pinned specimens. Although ‘typical’ hispines and cassidines have contrasting shapes, intermediate species occur and are not uncommon in tropical areas. All Hispinae have mouthparts that appear crowded into a constricted opening in the head capsule, and all have four-segmented tarsi, in which the reduced fourth segment found in the rest of the Chrysomelidae has been completely lost. Larvae of the Hispini are leaf miners or, in a widespread Neotropical tribe, specialists in the unrolling terminal leaf of large monocots such as Heliconia; cassidine larvae are open feeders on many plants and cover their bodies with fecal shields for protection. In some tropical cassidine genera, maternal care of larvae has been observed.

Chrysomelinae

The Chrysomelinae include some of the largest species of Chrysomelidae. As adults, most are robust oval to hemispherical beetles. The third tarsal segment is entire or at most weakly bilobed (it is strongly bilobed in some Eumolpinae that resemble chrysomelines), and a membrane between the clypeus and labrum is present. A more subjective but quite reliable method of separating chrysomelines from other robust Chrysomelidae is that, viewed from above, the head capsule of most Chrysomelinae appears rectangular with the eyes set diagonally at the anterior corners. Many chrysomeline adults have striking color patterns or bright metallic colors. Adults of Neotropical Doryphora, Platyphora and Metastyla have a prominent horn arising from the ventral surface between the middle and hind legs. Species of Doryphora are among the largest known Chrysomelidae. Adults of the New Guinea genus Promechus are large, elongate and bear a close resemblance to large Buprestidae. Larvae of Chrysomelinae are open feeders on leaves and many are chemically protected. The Colorado potato beetle, (*Leptinotarsa decemlineata* (Say)), one of the most destructive insect pests in the world (Fig. 24), belongs to this subfamily.

Galerucinae

This subfamily is characterized by antennae set close together between the compound eyes, antennal calli above the insertions, and the pronotum often narrower than the base of the elytra but without the transverse constriction found in the Criocerinae. This is the largest subfamily in the Chrysomelidae, the more so since the formerly independent Alticini (flea beetles) are now included in this subfamily. Although most species from the two major tribes Galerucini (rootworms) and Alticini can readily be distinguished by the size of the posterior femur (greatly enlarged in the flea beetles), many intermediate forms exist and a recent phylogenetic analysis indicates that the Galerucini is paraphyletic with respect to the Alticini. Adult galerucines display feeding behaviors ranging from narrow oligophagy to polyphagy. Larvae are mostly subterranean root feeders, but some open leaf feeders occur in both the Galerucini and Alticini. While most species are of no economic significance, several Galerucini species in the subtribe Diabroticina are extremely serious pests of corn and beans. Control of the corn rootworms (*Diabrotica* spp.) is the one of the costliest insect pest problems in North America.

Eumolpinae

This group, which reaches its greatest diversity in South America, is the second largest subfamily in the Chrysomelidae. Adults range from large to very small, most are broadly oval with glossy dark or metallic colors. Recent phylogenetic studies have placed the formerly independent Synetini and Megascelidini within the Eumolpinae. Although the body shape found in these tribes (slender and elongate) is not typical for the subfamily, intermediate genera exist and genitalic characters strongly support their inclusion in the Eumolpinae. Larval eumolpines apparently are all root feeders; the biology is known for only a few species. Adults are leaf or pollen feeders and tend to be oligophagous or polyphagous. Some appear to specialize on young leaves. In North America, a few species are intermittent pests of strawberries and sweet potatoes, and other species cause occasional short-term damage to corn, grapes, and other crops.

Lamprosomatinae

This small subfamily is worldwide with most of its diversity in the American tropics. Only one species, *Oomorphus floridanus* Horn, occurs in North America and it is limited to the tip of the Florida Peninsula. Adults are small and oval to almost spherical, with legs and antennae that can retract into groves on the lower body surface. The upper surfaces are always smooth and shiny. Adults feed on leaves of various trees and known larvae feed on the young bark of trees, living in cone-shaped cases constructed of fecal matter and wood particles.

Cryptocephalinae

Members of this subfamily are characterized by a compact body, the second to fourth abdominal sterna narrowed medially, and the pygidium exposed. The subfamily contains three tribes until recently considered separate subfamilies: Cryptocephalini, Clytrini, and Chlamisini. Larvae of all species are case-bearers. Cryptocephalini larvae are found in leaf litter and detritus, on which they are thought to feed. Many larvae of Clytrini are found in association with ants, although it is not known whether this trait holds true for the majority of the tribe. Larvae of Chlamisini feed on leaves alongside the adults. Adult Chlamisini are noteworthy for the extreme rugosity of their dorsal surfaces, giving many species the appearance of pieces of caterpillar frass. While the effectiveness of this mimicry on birds and lizards has not been tested, there are documented instances of entomologists being fooled by the resemblance.

Chrysomelidae and Pest Management

Relatively little research has been done on natural enemies of pest Chrysomelidae. Before the era of modern pesticides, several natural enemies of the Colorado potato beetle had been identified and their effectiveness as control agents was beginning to be investigated. The introduction of synthetic pesticides following World War II put an end to this line of research, since it was assumed that the new miracle chemicals would eliminate the need for alternate forms of control. Now, after decades of attempts at chemical control, the Colorado potato beetle has evolved a complex, multifaceted spectrum of resistances virtually unmatched in any other insect. Not surprisingly, there are the beginnings of renewed interest in the natural enemies of this pest.

While the economic damage inflicted by the corn rootworm complex and the Colorado potato beetle are among the best known effects of the Chrysomelidae, this family also has its positive aspects as a source of biological control agents of weeds. One of the success stories of classical biological control is the use of two species of the chrysomeline genus *Chrysolina* to control the Klamath weed in the western United States. Another success story has been the importation of the alligator weed flea beetle from Argentina. Alligator weed is an aquatic plant accidentally introduced from South America into the Southeastern United States. The weed was highly invasive in fresh water bodies, and its uncontrolled growth choked lakes and rivers. Once the flea beetle was introduced, its feeding reduced alligator weed to a relatively rare species in the U.S. More recently, Palearctic *Apthona* flea beetles have been introduced into western rangelands to control leafy spurge, and several European Galerucini have been introduced in an attempt to control purple loosestrife in northeastern United States. Invasion by weeds is a continuing and growing problem (e.g., tropical soda apple in Florida and Melastomataceae in Hawaii), and Chrysomelidae are now routinely investigated as potential control agents of these emerging weed problems.

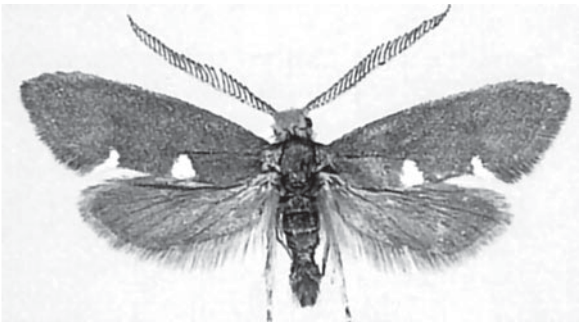
Leafcutter Moths (Lepidoptera: Incurvariidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Leafcutter moths, family Incurvariidae, total about 116 species from all regions, but most are



Leafcutter Moths (Lepidoptera: Incurvariidae), Figure 27 Example of leafcutter moths (Incurvariidae), *Incurvaria masculella* (Denis and Schiffermüller) from Italy.

Palearctic (64 sp.), divided into two subfamilies, Incurvariinae and Crinopteryginae. The family is in the superfamily Incurvarioidea, in the section Incurvariina, of division Monotrysia, infraorder Heteroneura. Adults small (7–18 mm wingspan), with roughened head; haustellum reduced, scaled; labial palpi upcurved; maxillary palpi 5-segmented and folded. Maculation usually is somber, with large spots or bands and some iridescence. Adults are mostly diurnal in shaded habitats. Larvae are leafminers at first, then switch to leaf skeletonizing on a variety of host plants; some are casebearers or shoot borers (Fig. 27).

Leaf-Cutting Ants (Formicidae: Myrmicinae: Attini)

KLAUS JAFFE
Universidad Simón Bolívar, Caracas, Venezuela

All ant species in the tribe Attini (Formicidae: Myrmicinae) cultivate a symbiotic fungus (Basidomycete: Lepiotacae) in order to feed their brood. The most conspicuous members of this tribe are undoubtedly the leaf-cutter ants from the genera *Atta*, *Acromyrmex* and *Trachymyrmex*. These ants cut leaves, which they prepare by removing surface waxes that normally harbor fungicides, before feeding their symbiotic fungus with it. The fungus helps to detoxify the leaves by degrading the insecticides which are normally found inside the leaves. The larvae feed basically on the fungus, whereas workers feed also on sugary plant sap flowing from the leaves while they are being cut. These ants build subterranean nests in which they grow their fungus which also needs a symbiotic bacterium in order to prosper. The workers regulate nest conditions so as to maintain humidity, temperature and carbon dioxide concentrations between narrow ranges. Workers avoid contaminations from other fungi and bacteria thanks to antibiotic secretions from their metapleural glands and the action of the symbiotic bacterium. The filamentous bacterium (Actinomycete) of the genus *Streptomyces* produces antibiotics specifically targeted to suppress the growth of the specialized garden-parasite *Escovopsis*. The symbiotic fungus is known only to occur in association with Attini ants. The lower Attini, which are not considered to be leaf-cutting ants, feed their fungus flowers, fruit pulp, dead insects, and animal excrements.

The Colony

The leaf-cutting ant colony is normally monogynic, that is, it contains a single queen. A few cases of polygynic colonies (2–6 queens) have been reported, but this certainly is not the norm for these ants. The colony is formed by different individuals and each type of individuals is called a caste. The leaf-cutting ant colony contains normally only female individuals of at least two different castes, the queen and the workers. Just before the beginning of the tropical rain season, the colony produces winged individuals, fertile males and females which wait inside the nest for their nuptial flight after the first rains. All these types of individuals or castes are found in their different life stages such as eggs, larvae, nymphs and adults in a single colony. The architecture of the subterranean nest is characteristic for each species. Workers also have behavioral castes. Young workers are more often engaged in caring for the fungus whereas older workers forage or engage in dumping rubbish and dead ants. The different components of a typical colony are:

The Queen

Most mature leaf-cutting ant colonies have a single fertile queen, i.e., they are monogynic. The queen is the fertile female individual, inseminated during the nuptial flight by various males, in charge of laying eggs. The eggs might have been fertilized by a male spermatozoon or not. In the first case, they will produce females; in the second, they produce males. Depending on the amount of food the larvae of females receive (and may be on hormones provided by the colony), they will become either virgin queens, ready to start a nuptial flight and eventually a new colony, or sterile worker ants.

The Workers

Workers are sterile female ants. A single *Atta* colony has workers of different sizes – they are polymorphic – whereas those from *Acromyrmex* and *Trachymyrmex* colonies are monomorphic, i.e., they are all approximately the same size. Polymorphism among workers from *Atta* species is continuous, that is, sizes of workers vary from just above a millimeter to over 2 cm in length. The smallest workers are found mostly inside the nest, caring for the fungus and larvae, whereas the bigger ones engage in foraging, leaf cutting, and transport of leaf fragments to the nest. *Atta* colonies have a special soldier caste, formed by very large workers with strong mandibles, which make them have big heads with small brains.

Winged Sexual Individuals

The sexually active individuals are born with transparent wings that allow them to engage in the nuptial flight, at the beginning of the rain season, where they copulate. Males die shortly after a single copulation. Once the winged female is inseminated, she lands on the ground, sheds her wings, looks for an appropriate sandy spot, and starts digging her initial nest. Often winged individuals are found inside the nest. These are virgin males or a queen that failed to swarm or will do so in the future. Virgin females in addition have much smaller gasters compared to their physogastric mothers. Males have much smaller heads than females. Males show little activity and their main role is transferring their sperm to the female's spermatheca.

The Super-Organism

In a given leaf-cutter ant colony we generally find only a single queen and her daughters, the workers. Thus, a colony is a family unit. The coordination between the members of a colony-family is so tight that some authors consider the colony to be a superorganism. That is, each individual acts to optimize the adaptive value of the colony rather than itself. The queen dedicates herself to produce eggs, the gut of the larvae and that of workers works like a communal digestive system, the foragers work as the movable extremities of the colony providing the required food, and the glandular secretions of all individuals mingle so as to produce a characteristic colony odor. Thus, the colony has properties that are known to characterize an organism. This is especially true when we look at the systems regulating the temperature and humidity of the nest.

The Uninvited Guests

A leaf-cutting ant colony hosts a number of other animals. They range from invertebrate ectoparasites to vertebrates such as snakes, lizards and birds. They normally feed on the brood and/or use the nest as shelter. Reptiles especially profit from the nice temperature in a leaf-cutting ant nest, which is suitable for their eggs. That is certainly the case with the snake *Elapomorphus lemniscatus* (family Boidae) which is a frequent visitor of *Acromyrmex* nests. Once inside the nest, the reptile houses in a fungus chamber, eats the ant's larvae, and exits the nest only when searching for a mate. Beetles, spiders, isopods, flies, collembolans, mites and other arthropods are known to live inside the ants' nest. A large number of these ectoparasites live in the refuse chamber where they feed on dead ants and other refuse of the colony.

The Nest

Atta Nests

The nests of the ants from the genus *Atta* are among the largest and more complex known among insects. A typical nest may occupy a subterranean space of 20 m in diameter and 5 m in depth. It consists of interconnected galleries leading to chambers where ants cultivate their symbiotic fungi. Other galleries lead to the surface and are used to regulate the flux of fresh air so as to maintain the temperature, carbon dioxide concentration and humidity constantly at the optimum inside the nest. A large chamber is used to dispose of the colony's waste which consists mainly of dead fungus and dead ants. This chamber produces heat and carbon dioxide that allows for a better regulation of the colony's climate. Other galleries lead deep into the soil for access to the ground water. Galleries leading to the surface end beneath an earth mound with a crater, allowing the exit and entrance of workers. These mounds work as chimneys, helping to regulating the flux of fresh air and stopping running water from flooding the nest after torrential rains. Often workers seal the nest entrances with dry leaves and earth, especially when fighting other colonies. Some underground galleries lead up to 200 m from the nest to the colony's foraging areas. Each *Atta* species builds nests with its own characteristics. For example, *Atta colombica* has no refuse chamber but throws its rubbish outside the nest. The form of the mounds with craters depends on the soil's texture. The depth of the nest is also dependent on soil conditions; for example, nests are shallower in more humid areas.

The Nests of *Acromyrmex* and *Trachymyrmex*

Nests of *Acromyrmex* species have variable architecture, depending on the species that builds it. *Acromyrmex landolti* builds nests with a single vertical gallery with nest chambers connected on the sides of the gallery. The vertical gallery can go as deep as 3–4 m. *Acromyrmex octospinosus* builds more superficial subterranean nests with many chambers and galleries connected in all directions. *Acromyrmex coronatus* sometimes builds superficial nests under accumulated dry leaves. These nests are often found in caves of dead tree trunks. Nests of *Trachymyrmex* species are less elaborate. They are subterranean but normally close to the surface and rather small compared to those of *Acromyrmex* and *Atta* (Figs. 28 and 29).

The Life Cycle

Reproduction

Leaf-cutting ants reproduce sexually, with copulation occurring during the nuptial flight. Normally a virgin queen mates with several males. Nuptial flight occurs at the beginning of the rainy season. After the first heavy rain, thousands of winged individuals start flying from all affected nests in an area. They fly

Leaf-Cutting Ants (Formicidae: Myrmicinae: Attini), Figure 28 **Nest of *Atta laevigata*.**

Leaf-Cutting Ants (Formicidae: Myrmicinae: Attini), Figure 29 ***Acromyrmex landolti*** **(drawing by Eduardo Perez).**

normally in the early evening and concentrate in a given space several meters above the ground. As males die shortly after mating, dead bodies of males that have copulated rain to the ground, just under the visible swarm. Once successfully inseminated, the new queen flies to the ground, sheds her wings and starts looking for an appropriate site to excavate a nest. Queens also reproduce asexually; non-fertilized eggs will produce haploid males (as are all hymenoptera, these ants are haplodiploid).

The Birth of a Colony

Once the recently fertilized queen has found an adequate site (often next to a small tree), she starts digging using her mandibles to remove earth. She digs a small gallery about 15 cm long leading to a small chamber about 7 cm wide. After digging is completed, she seals the nest entrance. In the chamber she lays some unfertilized eggs upon which she deposits the mycelium of the fungus she has taken from her mother's nest, stored in a cavity in her mouth. If available, roots are also used as a substrate for the fungus. Then she lays her first fertilized eggs. The first larvae that emerge are fed with special unfertile "trophic" eggs produced by the queen. Eventually small "nanitic" workers emerge. During that period, the queen survives on her fat reserves and by metabolizing her wing muscles, now useless. Once the first nanitic workers emerge, they open the nest entrance and start foraging for leaves, flowers, insect droppings, seeds, etc., to feed the fungus. After this initial phase, larger workers emerge capable of cutting fresh leaves.

The Life Cycle of a Worker

Leaf-cutting ants have four phases in their life cycle: egg, larvae, nymph and adult. The white larvae feed mainly on the symbiotic fungus. They have very little mobility. After several molts, the larvae initiate its metamorphosis without spinning a cocoon and eventually emerges as an adult worker. The amount of food ingested during the larval stage will determine the final size of the worker, as adult workers stop growing. Young workers have a lightly pigmented soft cuticle, whereas older ones are darker. Adult workers have different nutritional requirements than larvae do; they feed mainly on plant sap because their protein requirement is less than that of the larvae, which mainly feed on the fungus.

The Life Cycle of a Colony

The colony starts with the birth of the first nanitic workers. During the first few years, the colony grows continuously in number of workers and in the space occupied by the nest. During that period, workers forage every day, except when it is raining copiously, and feed their fungus, which occupies ever more chambers which must be prepared by the workers. When the colony reaches maturity (4–6 years after being initiated by the queen for *Atta*, and less for *Acromyrmex* and *Trachymyrmex*), the colony produces winged individuals that accumulate in the nest until the initiation of the next rainy season, when they will leave the nest for their nuptial flight. We know little of how the leaf cutter ant colony produces winged females instead of workers, or how the queen decides to fertilize an egg with sperm, producing female offspring, or lay unfertilized eggs that will produce males. It is likely that these ants use hormones for this purpose, as bees do, but little is known for leaf-cutting ants. After a few nuptial flights, the colony is left without winged individuals and with few workers. The colony then has the whole year to again build its workforce, forage for food to grow its fungus, and eventually produce a new batch of individuals capable of sexual reproduction. This cycle is repeated until the old queen dies, which may take several decades.

Communication

Pheromones

The most common communication system between workers of leaf-cutting ants consists of volatile chemicals or odors called pheromones. These ants produce their pheromones through a series of exocrine glands located in different parts of their body. Each of these glands produces a specific secretion composed of a mix of chemicals which are used to communicate information between workers. These multicomponent pheromones are perceived through the insect's antennae. Some pheromones are detected only upon contact of the antenna with the substrate containing the pheromone; these are called contact pheromones. For example, larval recognition in leaf-cutting ants seems to be achieved using contact pheromones that are located on the cuticle of the larvae.

Alarm Pheromones

Leaf-cutting ant workers produce an alarm pheromone in their mandibular glands. This pheromone is composed of highly volatile compounds that disperse rapidly in the air and alarm nestmates up to distances of 60 cm. This same pheromone helps workers and soldiers to orientate to the source or location that caused the alarm, thus helping to coordinate cooperation in defense. This coordination can be very fast and effective when fighting other ant colonies or when deterring an intruder. The compounds of this pheromone are absorbed on the cuticle of these insects, thanks to the cuticular hydrocarbons that cover the insect's surface. There, the alarm pheromone serves as an individual recognition signal, helping ants to differentiate between nestmates and intruders.

Recruitment Pheromone

Another well studied pheromone is the recruitment or trail pheromone. This pheromone is produced in the poison gland located in the gaster. Workers lay trails using this pheromone when returning from a palatable food source. The less volatile compounds in the pheromone serve as orientation cues, whereas the more volatile ones regulate the amount of new workers recruited to the trail, which in turn will depend on the quality and quantity of food to which they are recruited. Some of the compounds of this pheromone, isolated from leaf-cutting ant species, are 4-metyl-2-pyrrol-carboxilate for *Atta laevigata*, *Atta cephalotes*, *Acromyrmex octospinosus*, and 3-ethyl-2,5-dimethyl-pyrazine for *Atta sexdens rubropilosa* and *Acromyrmex niger*.

Territorial Pheromones

These are used to mark the colony's territory using a secretion from the Dufour's gland. Workers on territories marked by their colony are more aggressive and fight longer, whereas workers over territories of a foreign colony try to escape. During ant wars, many small workers swarm outside their nest to mark the surroundings of their nest entrance and the battlefield, whereas larger workers engage in combat. These combats can last weeks if the food source they are defending is especially scarce or attractive. This pheromone helps achieve the harmonious cohabitation of neighboring colonies of similar size, which seems to be the norm in nature.

Individual Recognition

Leaf-cutting ant workers recognize their nestmates and differentiate them from foreign ants, even if they are of the same species. They achieve this by detecting odors absorbed on the cuticle. These odors mainly come from the mandibular alarm pheromone. This system allows them to recognize individuals even at a distance, and is also used to recognize nestmates from different parts of the nest.

Other Pheromones

Other pheromones are less well known. The queen is recognized as such by pheromones, and so are the larvae. Leaf fragments are marked using the Dufour's gland, probably to ascertain the colony's property and to help detect it when workers drop it from the trees. Other communication systems remain to be discovered.

Visual Communication

Although known from other ants, nothing is known for leaf-cutter ants.

Communication by Sound

Leaf-cutter ants have a stridulatory apparatus between the gaster and the second petiole. This apparatus consists of a stridulated cuticular surface on the dorsal part of the gaster and a cuticular tooth extruding from the petiole that serves as a bow producing vibrations when gliding over the stridulated surface. The ants produce rhythmic ultrasounds with this apparatus by vibrating and elevating their gaster. The sound is barely perceived by some humans. The ants use this sound to guide workers toward branches on trees that need leaf-cutters. They also stridulate when buried, guiding workers to dig in their direction. The sound is transmitted over solid substrate and is perceived thanks to special receptors at the end of their legs.

Trophalaxis and Antennal Contacts

Workers exchange liquids through their mouthparts. They do this after contacting the other ant with their antennae. We do not know what information they are transmitting with these behaviors but they might transmit information about the quality of food.

Foraging

Leaf-cutting ants have especially sophisticated foraging behaviors. They use trunk trails that they maintain free of leaves and obstacles, facilitating their movement from the nest to the foraging areas. From this trunk trail, smaller trails lead to the plants they harvest. Scout ants use the same trail system but eventually leave it to explore new terrain. When finding a palatable food source, they return to the nearest trunk trail, leaving trail pheromone behind. Foragers might cut a leaf fragment and carry it through the trail system to the nest. Alternatively, they might do it in stages; some workers cut the leaves and let them drop from the tree, or just carry the leaves to the nearest junction, where other workers collect the leaf fragments and carry them to the nest entrance, where still other workers remove the superficial waxes from the leaves and carry the clean leaves inside the nest, where other workers cut them into fine pieces to feed the fungus. Very small or minima workers are often seen climbing on leaf fragments that are carried by larger workers. The minima help fend off flies from the family Phoridae and other parasites that attempt to attack the carrying worker or enter the nest via the leaf fragment. Older workers remove dry leaves, dead ants and dry fungus from the nest chambers and drop it in the refuse pile.

The Decision Making System

The colony has to coordinate its efforts in order to forage efficiently. Not all ants are required at the same place at the same time. Specifically, in the case of recruitment to food, leaf-cutting ants use a decision making system that is different from that used by all other ants studied and which resembles the system used by termites. It works as follows: a scout discovering food will return to the nest or the trunk trail while laying a pheromone trail. The concentration of pheromone on the trail will depend on the quality of the food. Workers encountering this trail, according to their motivation for food, will follow the new trail. On their way back, they will reinforce the pheromone trail but in such a way that the total concentration of pheromone is roughly constant. They will not just add their pheromone onto that of others (as done by *Solenopsis geminata*, for example), but will restrain from adding pheromone if enough of it is already on the trail. In this way, the concentration of pheromone on the trail will not depend on the amount of ants laying trails or returning from the food source but only on the quality of the food. This system allows leaf-cutters to recruit to various different food sites at the same time.

Orientation

Foraging scouts need to find their way back to the nest. They achieve this by integrating various keys or environmental signals when foraging and homing. We know that they can use polarized light, visual cues, spatial memory, olfactory cues and tactile cues. They might possibly also use gravitational cues and the earth's magnetic field. Each species seems to have its own hierarchy in which these cues are used in actual orientation in the field.

Defense

Organisms need to defend themselves against predators and parasites in order to increase their odds for survival. Leaf-cutter ants possess no functional sting but they do secrete a toxic fluid from their anal region which they deposit onto enemy combatant ants. This secretion dries or polymerizes quickly, helping to immobilize the affected worker. It also seems to contain neurotoxic substances and volatiles that attract other ants. Large workers and soldiers also use their mandibles to cut wounds on molesting vertebrates and then add irritant secretions to the wounds. The mandibles can cut appendages from invertebrate enemies or even cut them into pieces. Another form of defense is using cryptic behavior, including cessation of all movement until the danger has passed. This behavior is often used by lone foraging scouts. The thick, hard cuticle and the spines over the thorax help the insect to avoid being eaten by predators such as lizards, birds and spiders. In addition, the secretion of the metapleural gland is spread all over the body of these insects, helping to fend off fungi, bacteria and other potential illness-causing agents. The main predators of these ants are spiders, armadillos and anteaters, which feed copiously on them.

Ecology

Leaf-cutting ants are only found in the neotropics. They might have an important effect on plant growth, on occasion achieving pest status. Densities of up to 60 adult *Atta* nests per hectare, or hundreds to thousands of *Acromyrmex* nests per hectare, can cause serious harm to plantations and crops. On the other hand, the large accumulation of organic material inside the nest, once the queen and the colony die, makes it a formidable substrate for plant growth. In nutrient poor savannas, old collapsed *Atta* nests are colonized by trees and shrubs, forming forested islands. It is the occasional status as agricultural and forestry pests that has made leaf-cutters most famous. Leaf-cutters with the highest economic importance as pests are all *Atta* species and some *Acromyrmex* species. An adult *Atta laevigata* colony, for example, may cut an average of 5 kg of plant material each day. They target especially young plant tissue, which can be especially damaging to the plants. Estimates of the economic damage caused in the Americas by these ants are close to a hundred billion US dollars per year (Figs. 30 and 31).

Control of Leaf-Cutting Ants

There are three basic methods for reducing the populations of these pest ants: (i) Stopping the ants from accessing the plant. Asphalt or other sticky greases painted at the base of tree trunks, plastic or rubber rings that retard ants from reaching the plants, or water barriers that deter the access of these ants are useful ways of dealing with this pest. (ii) Direct control, killing the ants with insecticides. For large nests this might be difficult and expensive. Fogging and powder pumps may help to get the insecticide inside a nest. (iii) Indirect control, using poisoned but attractive baits, is the most efficient way known to manage large areas with this pest. Attractants (such as citrus pulp) mixed with slow acting insecticides, allow the foragers to carry the poison into the nest so that it is distributed to all chambers by the workers before it starts killing the insects.

Leaf-Footed Bugs

Members of the family Coreidae (order Hemiptera).
► Bugs

Leafhoppers (Hemiptera: Cicadellidae)

CHRIS H. DIETRICH
Illinois Natural History Survey, Champaign, IL, USA

Leafhopper adults and nymphs are active, jumping insects recognized by their piercing-sucking mouthparts and by the presence of four rows of enlarged, spinelike setae on their hind tibiae.

Order: Hemiptera
Infraorder: Cicadomorpha
Superfamily: Membracoidea
Family: Cicadellidae

Cicadellidae, the largest family of hemimetabolous insects and one of the largest families of plant-feeding insects, comprises nearly 25,000 described species and over 3,200 genera. their great diversity may be due to a combination of their long (ca. 125 million years) evolutionary history, their association with a wide variety of flowering plants, and their success at occupying a broad range of habitats and climates. Their closest living relatives are the treehoppers and related families (Membracidae, Aetalionidae and Melizoderidae), and the relict southern hemisphere family Myerslopiidae. More distant relatives include the other two superfamilies of infraorder Cicadomorpha: Cercopoidea – the spittlebugs or froghoppers; and Cicadoidea – the cidadas.

Leafhoppers occur in terrestrial habitats worldwide, wherever vascular plants are found. They are most diverse and abundant in the tropics; however, temperate grasslands, savannas and forests also harbor diverse leafhopper faunas and a few species inhabit high elevations and latitudes. A few generalist species occur worldwide and utilize dozens of plant species as hosts, but most species are associated with particular host plants and/or habitats and have relatively small geographic ranges. The oldest fossil Cicadellidae are known from the lower Cretaceous Period.

External Morphology

Adult leafhoppers range from 2 to 30 mm in length and are usually somewhat cylindrical or wedge-shaped. Less commonly, species may be strongly flattened dorso-ventrally, greatly elongated, or globular in appearance. They differ from their close relatives, the treehoppers, because they lack a posteriorly produced pronotum and because (with a few exceptions) the setae of their hind tibia are enlarged and spinelike. Most leafhopper species are brown or green but many, particularly in the subfamilies Cicadellinae and Typhlocybinae, are strikingly marked with various color patterns. As in planthoppers (Fulgoromorpha), the head of leafhoppers is highly variable in shape, ranging from short to elongate, from round to strongly flattened, and sometimes bears spines or other ornamentation (Fig. 32). The median ocellus is absent and the position of the two lateral ocelli, when present, is also highly variable and is one of the main features used to distinguish subfamilies. Other important differences among the major lineages are found in the wing venation, the arrangement of setae on the legs and the male and female genitalia. Although some leafhopper species are easily recognized by their distinctive shapes and color patterns, many groups contain species that closely resemble one another and are difficult to distinguish. In many genera, the most reliable morphological features for distinguishing species are the male genitalia.

Life History and Habits

Details of the life cycle vary from species to species. In general, the female inserts several eggs into the living tissue of the host plant. The eggs either remain dormant for a period ranging from a month to over a year, or they develop and hatch within a few weeks. The young, known as nymphs, feed on plant sap by inserting their beaks into the vascular or parenchyma tissues of the host plant and go through a series of five molts, reaching the adult stage after a period of several weeks. Adult males and females seek each other out for mating, locating each other through vibrational signals made by sound producing organs at the base of the abdomen called tymbals. Leafhopper songs are

(Photos by C. H. Dietrich.)**

transmitted through the substrate and, in most cases, are too faint to be heard by human ears without special amplifying equipment.

As implied by their name, most leafhoppers are strong jumpers as both adults and immatures. The adults of most species are also strong fliers, but many species, particularly in arid environments, have the wings reduced or absent and are incapable of sustained flight. Most species are solitary as nymphs and adults, but a few species are gregarious and ant-mutualistic. Some of these, in turn, exhibit parental care (presocial) behavior-females guard their eggs and remain with the nymphs throughout their development. Another interesting aspect of leafhopper behavior is a phenomenon known as anointing, in which the leafhopper collects a special fluid secretion from the anus and spreads this secretion over the body using the legs. When the secretion dries, a residue of minute spherical granules called brochosomes remains and provides a hydrophobic coating to the integument. Brochosomes are produced in a specialized glandular segment of the Malpighian tubules. In the leafhopper tribe Proconiini, females of several genera store large globs of brochosomes on the forewings and use their hind legs to scrape the brochosomes onto their egg masses after oviposition.

Predators and Parasites

Leafhoppers are attacked by a wide variety of predators, including birds, lizards, spiders, assassin bugs, robber flies and syrphid flies. Mymarid and trichogrammatid wasps parasitize the eggs; dryinid wasps, pipunculid flies, strepsipterans and epipyropid moths parasitize the nymphs and the adults.

Economic Importance

Several leafhopper species are important agricultural pests, injuring plants either directly through feeding, or indirectly through the transmission of plant pathogens. Among the most important are the aster leafhopper (*Macrosteles quadrilineatus* (Forbes)), the African maize leafhopper (*Cicadulina mbila* (Naude)), the potato leafhopper (*Empoasca fabae* Harris), the beet leafhopper (*Neoaliturus tenellus* (Baker)), the corn leafhopper (*Dalbulus* spp.), the green rice leafhopper (*Nephotettix* spp.), the glassy-winged sharpshooter (*Homalodisca coagulata* (Say)), and various grape leafhoppers (*Erythroneura* spp.).

Control Measures

Control of injurious leafhopper populations is most often accomplished by using conventional contact insecticides. However, use of resistant plant varieties and cultural control (e.g., removal of crop debris used in overwintering) is effective for some species. The potential for biological control using entomopathogenic fungi or parasitoids is a topic of active research.

Leaf-Miner Flies (Diptera: Agromyzidae)

STÉPHANIE BOUCHER
McGill University, Lyman Entomological Museum, Ste-Anne-de-Bellevue, Québec, Canada

The Agromyzidae, also known as leaf-miner flies, is a large family of phytophagous flies. The family contains approximately 2,860 described species occurring from the tropics to the high arctic, although the majority of known species live in temperate areas of the Northern Hemisphere. There are still many more species of agromyzids to be discovered; as many as half the actual number of species may not yet be described.

Biology and Economic Importance

Larvae of all species of Agromyzidae are internal plant feeders. Although they are best known as leaf-miners, many species feed inside other plant parts such as stems, roots, seeds and flowers, while a few species are gall inducers. There are about a hundred species of particular economic importance that may cause damage to cultivated crops and ornamental plants (see examples in Table 2). The degree of damage inflicted on plants may depend on the part of the plant being attacked, the plant's growth stage at the time of infestation and more importantly, the size of the agromyzid population on the plant. Under normal conditions, agromyzids are naturally controlled by a large complex of hymenopteran parasitoids, keeping agromyzid populations below the economic threshold. Unfortunately, this natural balance has often been disrupted by the use of insecticides. This is because the agromyzids often have higher resistance to chemicals than the parasitoids.

When present in large numbers, leaf-miners may affect the general health of the plant by reducing its photosynthetic capacity. They also cause aesthetic damage due to their highly visible feeding traces, reducing the commercial value of ornamental plants. For those commercially grown plants, the presence of only a few agromyzid leaf-mines is often enough to make a plant unmarketable. Stem-borers also cause considerable damage by affecting the vascular system of the plant, disturbing water and nutrient supplies. This is especially injurious when the larval feeding occurs in young plants or seedlings.

Although most of the damage to plants is caused by the agromyzid larvae, the adult females may also injure plants by inserting their well-sclerotized ovipositor into the plant tissues (Fig. 33a). This is primarily for egg-laying purposes, but the females use these scars also as feeding sites, sucking plant sap through the punctures. These punctures increase the risk of infection of the plant by fungi and bacteria.

Some agromyzid species feed on noxious and invasive plants, and are regularly considered as potential natural control agents for those plants. Unfortunately, many attempts at biological weed control using agromyzids have so far failed or encountered problems (Table 3).

Host Plants

Agromyzidae have colonized a wide range of host plants including primitive lineages such as horsetails and ferns, but more importantly, over 160 families of flowering plants, including some economically important ones such as the Poaceae (rice, wheat, corn, barley, etc.), Fabaceae (beans, peas, soybeans, lentils, etc.), Solanaceae (potatoes, tomatoes, pepper, etc.) and Asteraceae

Leaf-Miner Flies (Diptera: Agromyzidae), Table 2 Examples of some important agromyzid pest species

Species	Host plants	Larval habits	Localities
Ophiomyia simplex– Asparagus miner	Asparagus (*Asparagus officinalis*)	Root and stem miner	Western Europe, North America
Ophiomyia phaseoli– Bean fly	Various species in family Fabaceae including snapbeans (*Phaseolus vulgaris*), soybeans (*Glycine max*), cowpeas (*Vigna unguiculata*), garden pea (*Pisum sativum*)	First instar larva as leaf-miner. Older larva bores into the stem. May also mine towards the roots in seedlings or highly infested plants	Southern Asia (China, India, Indonesia), Hawaii, Australia, East Africa
Melanagromyza obtusa– Pigeon pea pod fly	Various species in family Fabaceae, especially pigeon peas (*Cajanus indicus*)	Eggs laid inside pods. Larvae are seed feeders	Southeast Asia, Papua New Guinea. Also recorded in Neotropical region (Guadeloupe)
Agromyza frontella– Alfalfa blotch leafminer	Fabaceae: Alfalfa (*Medicago sativa*) other species of *Medicago*. Also *Melilotus* spp.	Leaf-miner	Europe, Afghanistan, Israel, North America
Liriomyza sativae– Vegetable leafminer	Polyphagous. Nine plant families including Cucurbitaceae (cantaloupe, cucumber, squash), Fabaceae (pigeon pea, alfalfa, lima bean and others), Solanaceae (pepper, tomato, egg-plant, potato), also ornamentals (e.g., *Chrysanthemum*)	Leaf-miner	Cosmopolitan
Liriiomyza trifolii– American serpentine leaf miner	Highly polyphagous. Approximately 400 host species known from 25 families. Attack various cultivated crops such as onions, beans, potatoes, tomatoes, celery, ornamentals (e.g., *Chrysanthemum*)	Leaf-miner	Cosmopolitan. Spread around the world mainly with cut flowers. Restricted to greenhouse in temperate regions
Liriomyza huidobrensis– Pea leafminer	Polyphagous. Known from 14 plant families. Attack various cultivated crops such as beets, peas, beans, lettuce, onions, tomatoes, potatoes. Also some ornamental plants	Primarily leaf-miner. May feed occasionally on outer surface of young pods	Central and South America. Expected in all tropical and subtropical regions of Europe, Asia and Africa. Restricted to greenhouse in temperate regions. So far absent from North America (previous records represent cryptic species *Liriomyza langei*)

Leaf-Miner Flies (Diptera: Agromyzidae), Table 2 Examples of some important agromyzid pest species (Continued)

Species	Host plants	Larval habits	Localities
Chromatomyia horticola– Garden pea leafminer	Highly polyphagous. Known from 35 plant families, including many cultivated plants (onions, peas, cabbages, alfalfa), and ornamentals	Leaf-miner	Europe, Africa and Asia

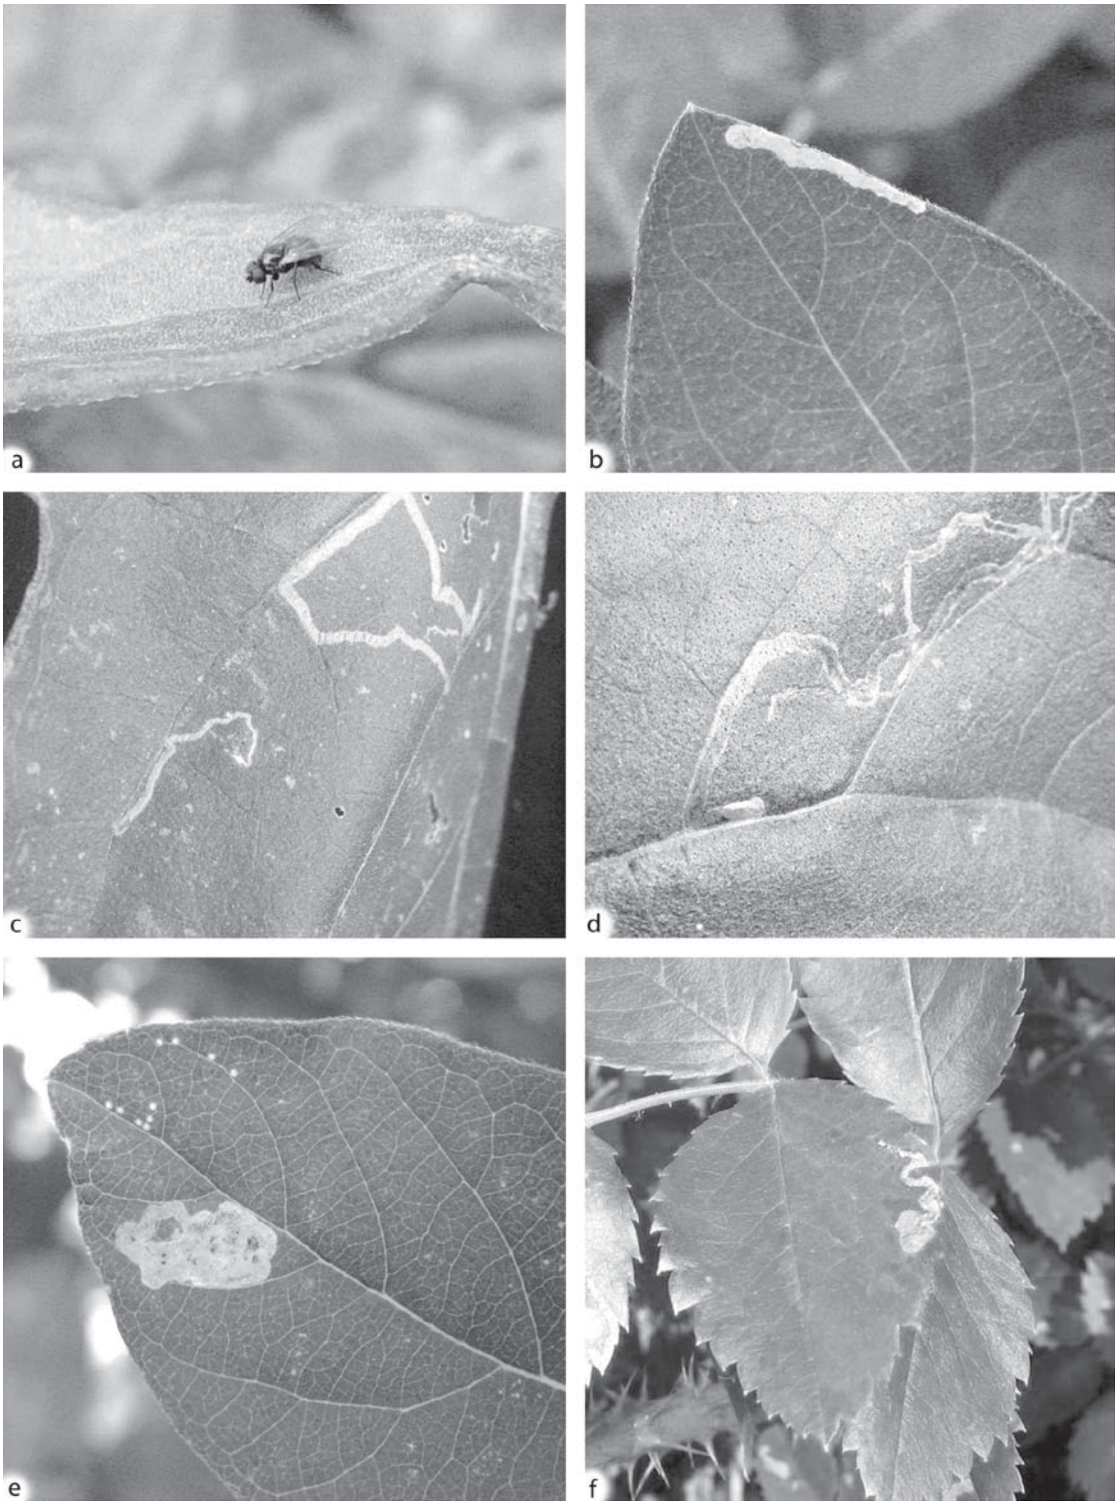
(lettuces, artichokes, chrysanthemums, etc.). There are no species of Agromyzidae that are known on mosses and very few species have been reared from gymnosperms: one record is from Tropicomyia atomella, an agromyzid species that forms leaf mines on Gnetum sp. in Malaysia and further records consist of feeding channels in wood of gymnosperms that are possibly caused by agromyzid larvae. The host plants are known for approximately 50% of the described agromyzid species. Most agromyzid species show a high degree of host specificity. These are known to feed on plants from a single genus (monophagous) or from multiple genera in the same family (oligophagous). Only a few species (<10%) are truly polyphagous and feed on a number of unrelated families. These include some of the most serious agromyzid pests worldwide. At the generic level, some agromyzids have a narrow range of host plants. For example, species in the genus *Cerodontha* are only known from four plant families (Poaceae, Cyperaceae, Iridaceae and Juncaceae) while species in the genus *Liriomyza* are known from 76 different families, showing the widest range of host plants of all agromyzids.

Leaf Mines

The mines formed by agromyzids can be of different forms such as linear (larva tunnels in a straight line), serpentine (linear winding mines) or blotch-like (larva forming a broad patch) (Figs. 33 and 34). In some cases the first instar larva forms a linear or serpentine mine and later instars form a blotch mine. These feeding patterns are species-specific and often helpful in the identification of Agromyzidae. Most species feed in the upper surface of the leaf, in the palisade parenchyma, or less often immediately beneath the leaf epidermis. Others feed on the lower surface of the leaf, in the spongy parenchyma. The part of the leaf where the mine is formed is also helpful in the identification of the agromyzid. Some species feed along the margin of the leaf, while others stay along the midrib or along a strong lateral vein. Other than the mine itself, the arrangement of the frass inside the mine is also characteristic. The frass may be in the form of small pellets or short strips, and these may be widely separated, interconnected, deposited alternately on each side of the mine, or in some cases the frass is excreted only at the very end of the mine.

Life History

After choosing the host plant, an adult female lays a single egg into the plant tissue at the appropriate oviposition site. The number of eggs laid by females varies considerably (e.g., the female of *Agromyza frontella* may lay between 25 and 294 eggs during her lifetime). After a few days, the larva emerges and starts feeding on the plant tissues, causing a mine or sometimes a gall. Larval feeding may last from a few days to several



Leaf-Miner Flies (Diptera: Agromyzidae), Figure 33 **Agromyzid leaf miner and characteristic mines: (a) Female Agromyzidae inserting ovipositor in a leaf of *Rudbeckia* sp.; (b) Linear leaf mine on *Lonicera* sp.; (c) Serpentine leaf mines; (d) Serpentine leaf mine with larva visible; (e) Blotch mine on *Lonicera* sp.; (f) Serpentine-blotch mine on *Rosa* sp.**

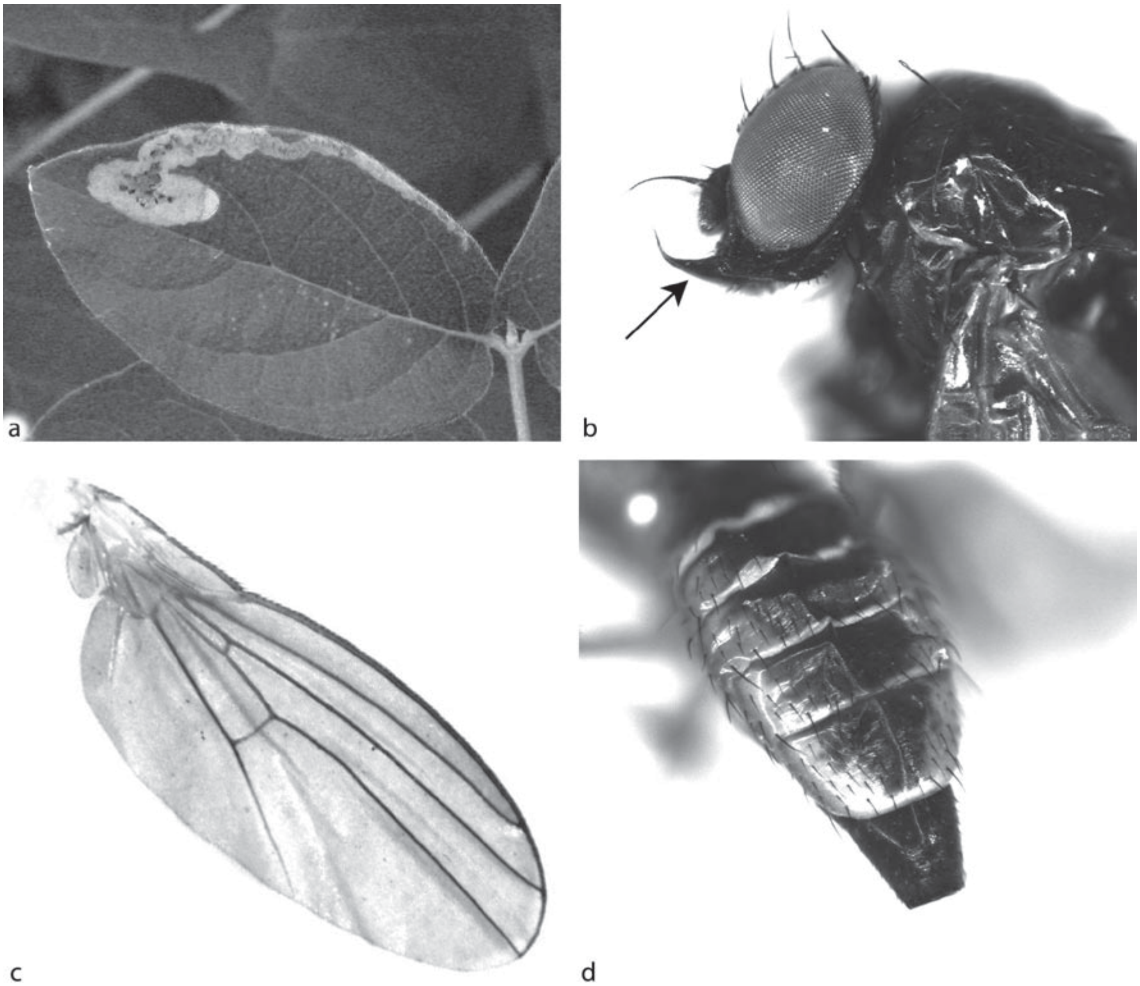
Leaf-Miner Flies (Diptera: Agromyzidae), Table 3 Examples of Agromyzidae that have been used or considered as potential biological control agents of invasive plant species

Species	Host plant	Larval habit	Distribution	Problems
Ophiomyia lantanae	*Lantana* spp.	Seed feeder	Southern United States, Caribbean, Central and South America. Introduced (deliberately or with its host plant) in many other regions, including Hawaii, Australia, India, Hong Kong, Kenya, South Africa, Malaysia	Seed embryo often not affected. Do not reduce significantly the spread of lantana
Ophiomyia strigalis	*Striga* spp.	Stem and root miner	East Africa	Flies attack mainly mature plant, having little effect on seed production
Napomyza lateralis	Many species in family Asteraceae, including, *Matricaria* (scentless chamomile). Also plants in the family Linaceae and Fabaceae	Leaf and stem miner. Also found in flower heads	Europe, Middle Asia, North America	Considered as possible control agent for scentless chamomile in Canada, but host range and behavior of this fly may suggest the presence of cryptic species. Further studies are required
Phytomyza orobanchia	*Orobanche* spp.	Seed and fruit feeder	Palaearctic region, Ethiopia. Deliberately introduced in Chile	Efficiency of the fly reduced by parasitoids. Often requires mass release of agromyzid species to insure success. Control of *Orobanche* was successful in many regions

months. Larvae of species having many generations a year develop more rapidly than univoltine species. In most cases, when the third larval instar reaches maturity it cuts a semi-circular exit slit and drops to the ground for pupation. But for most seed feeders, stem borers, and a few leaf-miners pupation takes place within the plant, at the feeding site (Figs. 33 and 34).

Diagnosis and Classification

The Agromyzidae are minute to small-sized flies, generally from 2–4 mm in wing length (but extremes range from 0.9 mm to 6.5 mm). They are often yellow and/or black, brown or grey, a few have some metallic greenish, bluish or coppery coloration (e.g., genus *Melanagromyza*). Most have clear wings, but



Leaf-Miner Flies (Diptera: Agromyzidae), Figure 34 Leaf mines and leaf miner characteristics: (a) Linear-blotch mine on *Lonicera* sp.; (b) Vibrissal fasciculus (*arrow*) of male *Ophiomyia*; (c) Wing of the agromyzid *Cerodontha dorsalis*; (d) Oviscape of female agromyzid *C. dorsalis*.

they may be patterned or infuscated in a few tropical species. Agromyzidae are generally divided into two subfamilies: Agromyzinae and Phytomyzinae. These can be differentiated by the wing venation. The combination of the following characters are used to recognize the family: vibrissa well developed, some males (genus *Ophiomyia*) have a vibrissal fasciculus; fronto-orbital and ocellar bristles strong; postocellar bristles divergent; fronto-orbital setulae in one or more rows, usually reclinate, but sometimes proclinate, upright or absent; dorsocentral bristles varying from 2 to 5; acrostichal bristles may be present (in up to 10 rows) or absent; wings with costal break present near the end of R_1, humeral break absent; Sc incomplete distally or reaching C as a linear fold (subfamily Phytomyzinae), or Sc complete and fusing with R_1 (subfamily Agromyzinae) before reaching costa; CuA_2 and A_1 present, forming a small cell *cup*; A_1 does not reach wing margin; abdomen tapering, composed of six visible segments; females with abdominal segment 7 modified into a large conical nonretractile oviscape (Fig. 34d).

Leafminer Moths (Lepidoptera: Gracillariidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Leafminer moths, family Gracillariidae, comprise the major leafmining family of Lepidoptera, with about 1,740 species from all regions. The actual world total probably exceeds 6,000 species. There are three subfamilies: Gracillariinae, Lithocolletinae, and Phyllocnistinae. The family is part of the superfamily Tineoidea, in the section Tineina, subsection Tineina, of the division Ditrysia. Adults minute to small (4–25 mm wingspan), mostly with roughened head scaling, but some with smooth heads (Phyllocnistinae); haustellum naked; maxillary palpi porrect, 4-segmented (sometimes reduced). Maculation various but often colorful or strongly marked with contrasting spots or lines, and many with metallic-iridescence (especially Phyllocnistinae); venation reduced (especially on hindwing) and with long hindwing fringes. Adults are active diurnally. Larvae are usually leafminers but change form in later instars (hypermetamorphism) from sap feeders with reduced legs, to later instars with a 3-proleg pair larval form, which is unique among the Microlepidoptera. Later instars sometimes feed externally as leaf skeletonizers. The leaf mines have various forms, from blotch mines to elaborate serpentine mines, often unique to particular genera (serpentine mines are typical for Phyllocnistinae). Host plants include a great number of plant families. A few species are of economic importance, such as the citrus leafminer (*Phyllocnistis citrella*).

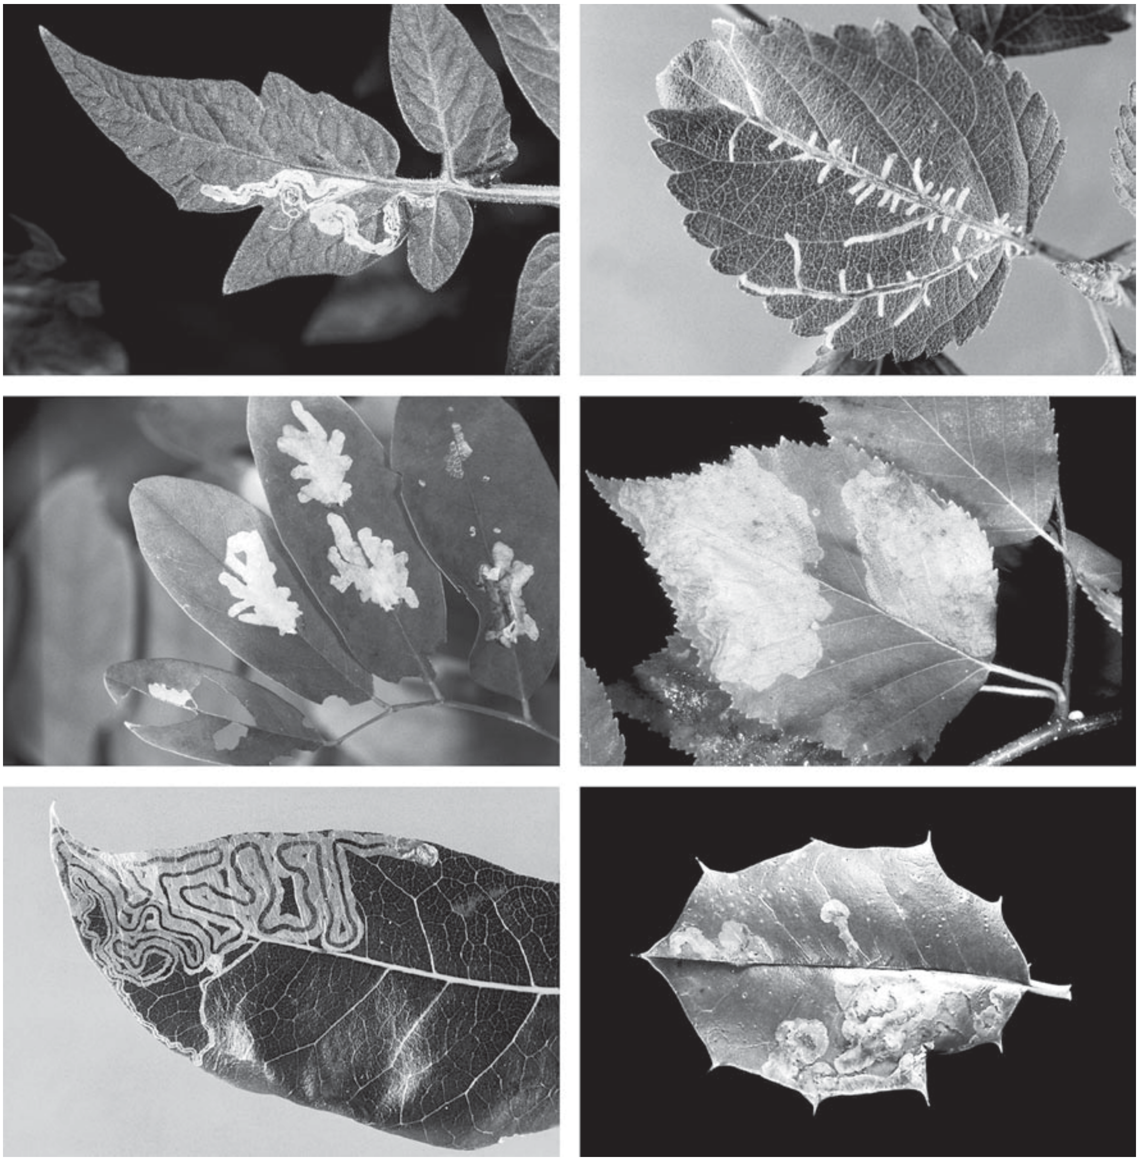
Leafminers

WHITNEY CRANSHAW
Colorado State University, Ft. Collins, CO, USA

For at least part of their lives, several insects develop while chewing between the surfaces of leaves and needles. These include species found in several families of four insect orders notably including Diptera (Agromyzidae, Anthomyiidae), Coleoptera (Chrysomelidae), Lepidoptera (Gracillariidae, Gelechiidae, Yponomeutidae, Tortricidae, Elachistidae) and Hymenoptera (Tenthredinidae). Species that tunnel internally into the needles of conifers are called needleminers. Most needleminers in North America are Lepidoptera in the families Tortricidae and Gelechiidae. In some cases, insects tunnel beneath the surface of the stem or fruit tissue in a leafminer fashion, but such insects are usually just called "miners" to indicate that they do not inhabit true leaf tissue.

Leafminers are sometimes classified by the pattern of the mine that they create (Fig. 35). Serpentine leaf mines wind snake-like across the leaf, gradually increasing in diameter as the insect develops. Blotch leaf mines are irregularly rounded and often filled with frass. One subgroup of these are the tentiform leafminers that produce blotch-type mines that bulge upon drying to



Leafminers, Figure 35 **Leaf mines caused by leafmining insects. Top left is a serpentine mine caused by the American serpentine leafminer (Diptera). Top right is a linear mine (insect unknown). Middle left is a digitate mine caused by a caterpillar (Lepidoptera) affecting locust. Middle right is a blotch mine caused by the birch leafminer (Hymenoptera). Bottom left is a rather long winding mine caused by the citrus leafminer (Lepidoptera). Bottom right is a blotch mine caused by the holly leafminer. (Birch leafminer photo by J. L. Capinera, University of Florida; others by J. L. Castner, University of Florida.)**

curve upward somewhat like a tent. Digitate leaf mines spread from the center like rays of a flower or fingers on a hand. Linear mines, which are not common, are relatively straight. Mines of all types are often restricted by larger leaf veins, at least during the early life of the insect. Some leaf miners can move to other leaves when they exhaust their food resources.

Some insects may develop entirely as leaf or needleminers, pupating within the galleries that they form, and ultimately, emerging as adult insects. Other insects, notably many Lepidoptera, feed in a leafmining habit during early instars and later have a more generalized defoliating habit. The spruce budworms (*Choristoneura* spp.), are important North American forest insects that develop in this manner. Others may mine leaves during early instars then later emerge from the mines to feed externally. Subsequently, the foliage may be tied together with silk and the later- stage caterpillars will feed in a leafroller manner. Alternately, the larvae of some moths that produce tentiform mines originally develop on the exterior of the leaf then subsequently act as leafminers in later growth stages.

► Leaf-miners Flies

Leafrollers

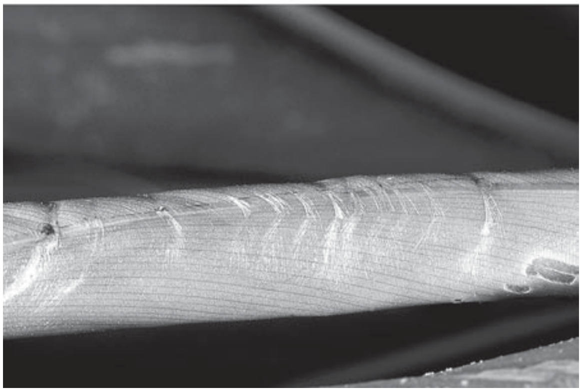
WHITNEY CRANSHAW
Colorado State University, Ft. Collins, CO, USA

Leafroller is a term given to insects that, during their larval development, use silk to tie together the leaves of various plants. The term is limited to insects that are not gregarious and that individually produce a structure of folded, enclosed leaves on which they feed. The common name intergrades with insects of similar habit, including leaftiers and certain webworms. During very high populations, structures produced by leafminers may coalesce and resemble the more elaborate silken structures that are produced by gregarious, tent-making Arctiidae and Lasiocampidae. All leafrollers are in the order Lepidoptera with the great majority found in the family Tortricidae. Leafrolling caterpillars are also present in other families including the Gracillaridae, Crambidae, Galacticidae and Hesperiidae. Economically important species in North America include the fruittree leafroller, *Archips argyrospila* (Walker), the obliquebanded leafroller, *Choristoneura rosaceana* (Harris), the orange tortrix, *Argyrotaenia citrana* (Fernald), the bean leafroller, *Urbanus proteus* (Linnaeus), the larger canna leafroller, *Calpodes ethlius* (Stoll), and many others. (Fig. 36).

Leafroller Moths (Lepidoptera: Tortricidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Leafroller moths, family Tortricidae, are a large family of 8,945 described species from all faunal regions; the actual fauna likely will exceed 12,000 species. Three subfamilies are known: Tortricinae, Chlidanotinae, and Olethreutinae. The family is its own monobasic superfamily, Tortricoidea, in the section Cossina, subsection Cossina, of the division Ditrysia. Adults small (rarely medium sized) (7–60 mm wingspan), with head rough-scaled (rarely smooth-scaled); haustellum naked; labial palpi usually porrect (sometimes upcurved); maxillary palpi usually 4-segmented (rarely minute). Body relatively robust. Wings elongated, but often rather truncated distally, or somewhat pointed (rarely irregular margined); hindwings usually more rounded or somewhat blunt pointed (Fig. 37). Maculation highly variable and sometimes very colorful, with metallic-iridescent markings (especially in diurnal species), but usually subdued shades of brown and gray, with various spots, lines, or other markings; hindwings often pale and unicolorous, or



Leafroller, Figure 36 **Leaf rolling by caterpillars in the family Hesperiidae. Above are two small leaf rolls made by the bean leafroller. These caterpillars cut a section of the leaf and then fold the edge of the leaf over to make increasingly large rolls as they mature. Below is a leaf roll constructed by the larger canna leafroller. In this case, the leafroller simply webs together the leaf before it unfurls, forming a large tubular structure within which it feeds. (Bean leafroller photo by J. L. Castner; canna leafroller photo by J. L. Capinera; both from University of Florida.)**

dark. Adults mostly nocturnal or crepuscular, but some are diurnal. Larvae mostly leafrollers, but some are borers (advanced groups in this family, rather than more typically being the primitive forms) in various plant parts, including stems, branches, flowers, and seeds; a rare few are leaf litter feeders. Most species are restricted to certain host plants, but innumerable

Leafroller Moths (Lepidoptera: Tortricidae), Figure 37 **Example of leafroller moths (Tortricidae), Olethreutes osmundava (Fernald) from Florida.**

plant families have recorded host plants. Many species are economic.

Learning in Insects

SPENCER T. BEHMER
University of Oxford, Oxford, UK

Learning encroaches upon virtually every aspect of the natural history of an insect. Where it has been investigated in insects, it has typically been found. Most of what is known about learning in insects comes from studies on the social Hymenoptera. For example, honeybees, *Apis mellifera*, have been shown to learn to use both flower color and shape as a way to increase their foraging efficiency for nectar and pollen, and foraging workers of the desert ant, *Cataglyphis fortis*, have been shown to associate directional information with landmarks. More recently, as researchers turn their attention to other insects, particularly phytophagous ones, the wider occurrence of the phenomenon is being appreciated. For instance, numerous studies have demonstrated that learning in grasshoppers is a mechanism that is commonly used to help regulate the intake of important macro- and micronutrients. However, the small size of insect brains and central nervous systems may place a limit on what and how much they can learn. Variation in learning ability also exists among individual insects, and those that are good learners may be at an adaptive advantage over those that are poor learners. However, conclusively demonstrating that learning in insects has an adaptive advantage that translates into increased individual fitness can be difficult.

What is Learning and How Does an Animal Learn?

Most people probably have a vague notion of what learning is, but an unambiguous definition is often hard to provide. Interestingly, even among scientists that study learning, an all-encompassing definition seems to be elusive. Therefore, the following is a broad description of what constitutes learning.

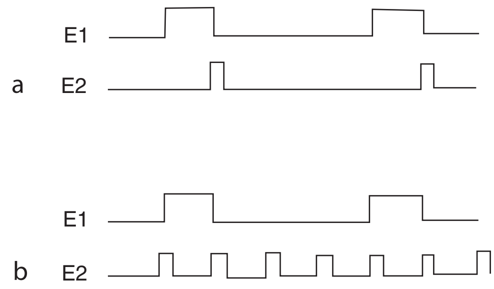
In general, learning involves attention, concentration and effort. However, specifying that learning has taken place requires that at least one of the following is occurring. One, an animal changes its behavior in a repeatable manner as a result of experience. Usually, the repeatability of a behavior is determined by statistical analyses on the results collected from a properly designed learning experiment. Two, with experience, a behavior gradually changes. Typically, the concept of a "learning-curve" is invoked here. Three, an observed change in behavior that was the result of a previous experience diminishes as that experience becomes less frequent. More simply put, in the absence of experience, it must be demonstrated that an animal forgets what was learned. In some cases, a new or traumatic experience may alter, or even purge altogether, a previously learned behavior.

It is worth noting that one prominent author, Thorpe (1963), defined learning as "…that process which manifests itself by adaptive change in individual behavior as the result of experience." Some, especially contemporary biologists, have objected to the use of "adaptive change" since it implies that learning has evolved under the action of natural selection and that it has some definable function, which is not always the case. For example, some larval lepidopteran species, after they have become accustomed to feeding on a particular host-plant (a phenomenon called food imprinting), will die from starvation rather than feed on a different host-plant species.

If, however, "adaptive" is taken to mean that animals generally learn to do what is sensible (e.g., turn toward, not away from, a rewarding stimuli), then the above definition becomes less controversial.

There are a number of different forms of learning, but conditioned, or associative learning, is probably the most thoroughly studied. An example using the common housefly, *Musca domestica*, in a laboratory demonstrates how conditioned learning works. First, a fly is secured to a vertical rod, using a specially designed harness, so that it faces forward and has its legs hanging at its sides. Next, one of its tarsi is brought into contact with either salt or water. This does not cause extension of the proboscis (feeding). Directly following this, the fly is presented with a droplet of sugar water, which causes its proboscis to extend. After this sequence of events had been repeated a number of times, the fly will start to extend its proboscis as soon as its tarsi comes in contact with the salt or water. This suggests that the fly has learned that the salt or the water, both previously neutral stimuli, predicts the arrival of the sugar water. In the above example, the formation of the learned association occurred by way of three steps. First, an unconditioned stimulus (US), the sugar water, triggered an unconditioned response (UCR), the proboscis extension. Next, the pairing of the unconditioned stimulus with a conditioned stimulus (CS), the salt or the water, led to an association forming between the US and CS. Finally, the US (the salt or the water) itself a conditioned response (CR) triggers the proboscis extension. Diagrammatically, the nature of this relationship can be expressed by Figure 38.

It is important to note, however, the CS will only become associated with the US if two criteria are met. First, there must be a positive correlation between the two stimuli. Second, the conditioned stimulus must have a certain intensity and duration. In the case of the fly, both criteria are met because the salt or the water always came into contact with one of the tarsi prior to the presentation of the sugar solution, and the salt or the water is readily "felt" and distinguished from other forms of "background noise".



Learning in Insects, Figure 38 Different patterns of correlation between two stimuli. In (a) the stimuli E2 occurs during, or shortly after, E1 and an association is formed. In (b) E2 is equally likely to occur when E1 is present or absent, so no association is formed.

A second form of associative learning is operant conditioning (also called instrumental or trial-and-error learning). This form of learning is distinguished from associative learning because it is characterized as "learning to do," rather than "learning to recognize." In operant learning, an animal learns to optimize a novel behavior through repetition and practice. Documented examples of operant learning in insects is rare, but is certainly the case when a honeybee becomes more efficient at collecting pollen after repeated visits to the same flower type.

Finally, it is worth discussing two other forms of non-associative learning that seem to share a relationship: sensitization and habituation. Sensitization is a short-term response that is the result of a sudden and intense stimulus. For instance, when a caterpillar is touched with a probe, its immediate reaction is to curl into a ball. However, if it is repeatedly touched in the absence of any significant event, its reaction to the probe begins to wane. This reduction in the level of behavior to the same stimulus over time is called habituation.

What do Insects Learn?

If learning permeates every aspect of life, then insects should be able to learn about locating and securing food and mates, caring for their offspring, escaping and defending themselves from natural enemies and navigating to and from their homes. However, the extent to which they are able to do this will depend on two things. The first is their ability to pay attention to what is happening in their immediate vicinity. Like other animals, insects gather information using their various senses, which include seeing, hearing, touching, smelling and tasting. The second is their ability to access the importance of any novel events. Usually, importance is measured by noting what happens shortly before or after a sequence of events has occurred. For example, a fly that has recently been attacked by a predator (or attacked with a fly swatter) will be acutely aware of any stimuli that are in any way similar to those it experienced immediately prior to the attack.

The easiest type of learning in insects to study relates to food acquisition, and both associative and non-associative examples have been identified. However, the degree to which an insect learns useful information about its food largely depends on the breadth of its diet. In general, learning tied to food acquisition is potentially more useful for an insect that feeds on a wide range of foods than for one that feeds on a single food, or food type, over its lifetime. For instance, associative learning seems to be a regularly employed mechanism used by honeybees when foraging for nectar. In most situations, the nectar is the unconditioned stimulus and some aspect of the flower, be it odor, color or shape, is the conditioned stimulus. Experiments investigating the strength of different floral characteristics as conditioned stimuli for honeybees suggest that there is a hierarchical structure, where odor>color>shape. Other pollinators, including bumblebees and butterflies, also show the ability to rapidly learn to associate flower colors and shapes with the presence of food rewards. Among foliage feeding insects (e.g., grasshoppers), learned associations between odors and major essential nutrients, and between particular color/light intensity cues and high-quality food, have been documented. However, there are examples of specialist insects learning, particularly among parasitoids and specialist butterflies that require specific hosts for their offspring. For example, *Microplitis croceipes*, a specialist parasitic wasp, uses plant volatiles released from the plant following feeding by caterpillars, which are hosts of the parasitic wasp. Its response to these volatiles is not, however, innate. Rather, an association of the plant volatile (the CS), as a result of damage to the plant following feeding by its caterpillar host (the US), is learned after a few successful oviposition events.

Learned associations between a neutral stimulus and a bad feeding experience are particularly valuable for insects because they provide a reliable and rapid mechanism for avoiding foods that contain toxins or unsuitable nutrients. However, examples of learned aversions to foods by insects are rare. Part of this may be because aversion learning tends to occur only in generalist herbivores, as feeding in specialist insects is driven by innate behavior. Additionally, demonstrating learned aversions in insects in the field can be difficult, so a laboratory approach is often required. Nonetheless, examples of learned aversions in insects do exist, particularly among generalist grasshoppers. For instance, two laboratory experiments have revealed that the generalist grasshopper *Schistocerca americana*, uses aversion learning to regulate the intake of an unsuitable dietary nutrient that cannot be tasted. In an initial experiment, grasshoppers were allowed to feed on spinach, which contains the unsuitable nutrient. After they finished eating, the unsuitable nutrient, or a closely related suitable one, was injected with a syringe directly into their hemolymph (blood). They were then allowed to take a second meal. Interestingly, those injected with the unsuitable nutrients took significantly shorter second meals on spinach (on average 3 sec) than those receiving the suitable nutrient (on average 90 seconds), suggesting that the unsuitable nutrient was detected post-ingestively, and that learning was occurring centrally rather than peripherally. The second experiment, using artificial foods with manipulated nutrient profiles and added flavors, indicated that the grasshoppers were learning to associate the taste of the food with the presence of the unsuitable nutrient. This example, plus others that show grasshoppers develop aversion responses to foods after being injected with various toxins, suggest that aversion learning may have an important role in the maintenance of dietary mixing.

In addition to securing food, insects must also find and choose mates. Although it is generally assumed that mate location and acquisition is innate and unresponsive to change through experience, the behavior of male apple maggot flies, *Rhagoletis pomonella*, seems to suggest otherwise. The males spend time on host fruit (either apples or hawthorns) waiting for females to arrive so they can mate. Research has shown that prior positive experience with females on one of the two host fruits influences the time a male will spend on the two fruits. That male insects may learn to assess the characteristics of females has also been suggested. For example, males of sacrophagous *Drosophila* learn to distinguish between females in particular physiological states, and the male *Lasioglossum* bees have been shown to learn characteristics of individual females. Where parental care is practiced, insects also must be able to recognize their offspring and feed them accordingly. For species of digger wasps that provide food to several burrows at once, evaluating food demands on an individual basis can be important because offspring may be at different developmental stages (newly hatched to nearly pupating). To assess food requirements, a mother will visit each burrow before setting off to gather food and, over the course of the day, will provide the appropriate amount of food to each burrow. However, experimental manipulation of the larva belonging to one species of digger wasp showed that there is considerable inflexibility in this system. When the larva in the burrows were exchanged following the female's morning inspection, the amount of food that the mother provided to each larvae upon returning to each burrow was shown to be based not on the current occupant, but on the individual that had been in the burrow during the morning inspection period.

Learning to escape from danger (specifically predators) would also be highly beneficial for insects, but when danger is sufficiently predictable and can be recognized innately, the use of sign stimuli should be favored over associative learning. Because of this, examples of learning to avoid danger are rare. Some butterfly larvae have an innate response to the sound of hunting wasps, and quite a few moths are able to counteract the echolocation used by bats. Also, in the laboratory, bees have been shown to associate sound with impending shock, but within a more natural situation, no examples of learning to associate sounds with danger are documented. The limited resolution of the insect compound eye greatly hinders visually based learning of danger, and no evidence exists to suggest that shapes associated with danger can be learned. At least one example of olfactory-based learning of danger is known. In a laboratory experiment, *Drosophila* maggots, using associative conditioning, learned to avoid electrical shocks associated with an odor.

Some insects have homes (either localized like a nest, or diffused like a home-range) and learning may aid in navigating to, from and around their homes. Most insects use innate mechanisms when navigating through their home territories, but the role of learning appears to be an important factor in calibrating their movements. Bees, for instance, appear to learn the direction of the sun's movements (left to right or visa versa) before they begin their foraging, and their memory seems to be irreversible. Learning related to navigation in bees is thought to depend on two alternative systems. If large, unambiguous landmarks are visible, the sun's course relative to these objects is memorized. If large objects are not available, the sun's rate of movement over the previous 40 minutes is measured and that value is used to calculate the change in the solar azimuth. Among experienced bees, large and unambiguous landmarks may be used in preference to celestial cues.

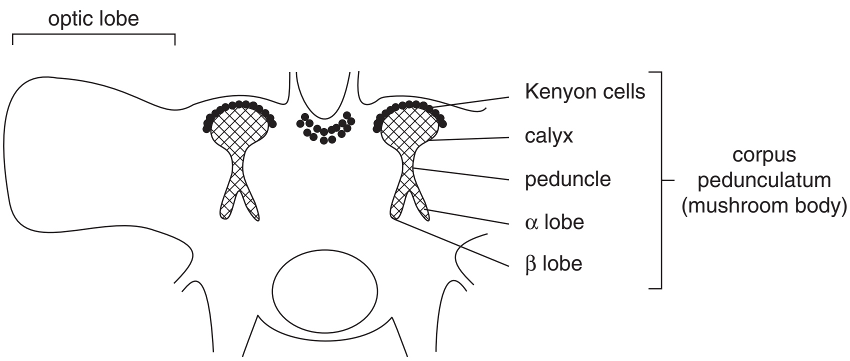
When Should Insects Learn?

In general, insects should learn in situations where the information necessary for guiding behavior is highly predictable, or too complex for innate responses to handle. That innate responses should be favored over learning makes sense because learned information is not as efficient and as reliable as innate information. It is also true that learning takes time, and mistakes (particularly during the initial stages of learning) are inevitable. Interestingly, learning is most favored in environments that are described as being "predictably unpredictable." This concept is best understood by viewing predictability along a continuum, with 0 being completely unpredictable and 1 being completely predictable. Using feeding as an example, specialist insects live in a predictable world because they only feed on a single plant species over their lifetime (a predictability value near 1). As a result, they will have no need to learn about their food since it is always the same. Likewise, at the other end of the scale, a generalist insect that feeds on a wide range of foods, but that never encounters the same food twice (a predictability value near 0), would never have the opportunity to learn since its experience would never be repeatable. This latter situation is unlikely to occur, and, for most generalist insects, remembering a bad experience with a toxic plant would be beneficial. However, if the plant on which the bad experience occurs is rare, there is limited opportunity to reinforce the learning experience. Where unsuitable foods occur with regularity, the combination of learning and sampling foods before taking large meals is one way in which highly mobile, generalist insects can increase the speed with which foraging decisions are made. However, learning related to food acquisition is probably only practiced in highly mobile insects that are in the latter stages of larval development or in the adult stage. Among generalist grasshoppers, for instance, learning may not be important during the first few instars because they are likely to spend the majority of their early life feeding on only a small number of plants.

What Constrains Learning?

The brain is the central processing center of information for all animals, including insects, and is responsible for transmitting signals that coordinate all behaviors (Fig. 39). However, the small size of the insect brain may place a great constraint on learning ability. The brain of an insect is split into three main regions (the protocerebrum, deutocerebrum and tritocerebrum) and it is generally thought that learning abilities in insects are in some way related to the size of a region of cells called the mushroom bodies, or corpora pedunculata. These bodies are given their name based on the shape of the five identifiable cell types. The uppermost region of these bodies consists of a flattened cap of neuropiles, called Kenyon cells. Below it lies the calyx, which has a peduncle running from it that eventually splits into two or three lobes, which are designated α, β and γ. The mushroom bodies, which occur at the sides of the pars intercerebralis in the protocerebrum, are small in the Collembola, Heteroptera, Diptera and Odonata, are largest in the social insects (where most examples of learning are documented), and are of intermediate size in Coleoptera, Orthoptera, Blattodea, Lepidoptera and sawflies. Researchers have shown that changes take place in the mushroom bodies with age and experience, but perhaps more interestingly experiments with *Drosophila* and *Apis* indicate that mushroom bodies also increase with experience, and are involved in associative learning (Fig. 39).

A second constraint on learning relates to the idea that intelligence is modular and that some associations formed between stimuli are more readily learned than others. For instance, experiments with rats show that illness following a meal is more easily associated with the taste and/or smell of the food that caused the illness than is a burst of light or a loud noise given at the time of the meal. This type of constraint may arise because taste and olfactory systems are intimately intertwined with digestion, whereas hearing and vision are not. That such constraints on learning occur makes sense because, evolutionarily, perceptual systems that respond to the most ecologically relevant stimuli in a rapid and reliable manner should be favored.



Learning in Insects, Figure 39 **The insect brain is divided into three main regions: the protocerebrum, deutocerebrum and tritocerebrum. The mushroom bodies, found in the protocerebrum, are thought to be a primary region of the insect brain associated with learning. This body consists of the Kenyon cells, calyx, peduncle and two or three lobes running from the peduncle. It has been suggested that the size of the mushroom bodies (specifically the number of neuropiles found in this region of the brain) is positively correlated with learning abilities.**

Can Learning Evolve?

If learning is to evolve in insects in an adaptive manner it supposes that genetic-based variation in learning exists, and differences in learning are associated with differences in fitness. Clearly, insect populations show genetic variations, and in *Drosophila* and *Phormia* flies, existing genetic variations within strains have been used to analyze the physiology of learning. Variation in learning has also been documented in honeybees and it has been shown to be heritable. In phytophagous insects, however, little information on genetically based variation in learning exists. Since documented cases of variation in learning are rare, it is not surprising that so little is known about the extent to which such differences translate into differences in fitness. One study has suggested that learning in generalist grasshoppers translates into higher growth rates, but this study only explored performance over a single instar. Because evolutionary fitness is defined as the ability of an individual/s offspring to survive and reproduce, there are significant logistical problems associated with demonstrating a fitness enhancement associated with learning. Clearly, more work in this field is needed, and a larger number of taxa need to be examined before any conclusive judgments can be made on the evolution of insect learning.

Conclusions

Learning in insects probably occurs with a greater frequency than is appreciated. Of the two main types of learning normally recognized, associative learning is probably easier to document, but operant learning (e.g., learning to handle food, to negotiate different types of substrates, etc.) probably occurs with greater regularity and is likely to take place over the entire life of an insect. Much remains to be discovered about insect learning, particularly the neural-basis of learning and the extent to which learning in insects evolves, but new technologies and methodologies are generating rapid advances. As model systems to explore learning, insects offer many great advantages, and their potential for contributing to a greater understanding of the mechanisms animals use to aid in learning provides a rich opportunity for future research.

Learning in Insects: Neurochemistry and Localization of Brain Function

FRED PUNZO

University of Tampa, Tampa, FL, USA

Research studies conducted over the last decade on the cellular and molecular mechanisms associated with learning (behavioral plasticity) have led to several generalizations: (i) learning involves changes in neural pathways that are correlated with alterations in synaptic efficacy; (ii) training procedures result in changes in membrane currents; (iii) learning involves second messenger systems; and (iv) behavioral plasticity is associated with changes in macromolecular synthesis within the central nervous system (CNS). These macromolecules include RNA and protein. Proposed cellular mechanisms for learning include reverberating circuits, modification of dendritic processes and synapses, voltage-dependent membrane channels and use-dependent modification of neural pathways. Although these ideas have been applied to both the vertebrate and invertebrate CNS, invertebrate models are particularly well suited for this type of analysis owing to their relative simplicity in contrast with vertebrate systems.

Invertebrates that have been used in studies on the cellular and neurochemical basis of learning and memory include gastropod molluscs, decapod crustaceans, theraphosid spiders and insects. Specific neurochemical changes that accompany learning include an increase in RNA and protein synthesis, a decrease in cholinesterase activity and changes in biogenic amines and amino acids. These neurochemical events have also been used to identify specific anatomical loci within the arthropod brain (cerebral ganglion) that have been implicated in the mediation of the learning process.

Inhibition of protein synthesis within the CNS was found to impair learning in vertebrates as well as orthopteran and coleopteran insects and theraphosid spiders. It was also found to impair the innate phototactic behavior of tenebrionid and passalid beetles suggesting that even rigid (closed) behavioral programs are dependent upon ongoing neurochemical events.

This elucidation of the neurochemical correlates of learning and memory in arthropods has occurred in conjunction with advances in behavioral ecology and neuroethology. The importance of learning in many diverse animal groups has been widely discussed. The ability of an organism to modify its behavioral response to varying environmental conditions is often essential to survival and can increase overall fitness. Learning encompasses adaptive changes in individual behavior that increase survival capacity and occur as the result of previous experience.

Insects and other arthropods have traditionally been viewed as creatures of instinct characterized by relatively rigid, stereotyped behavioral patterns. Nevertheless, although the behavioral repertoires of many insects are endowed with a rigidity of structure characteristic of Tinbergen's concept of Fixed Action Patterns (FAPs), there have been many studies demonstrating behavioral plasticity in insects and other arthropods. Furthermore, environmental parameters can influence the neuroarchitecture of specific brain regions in insects. The number of neuronal fibers in the brain of adult *Drosophila melanogaster* varies according to age, sex, early experience and olfactory conditioning.

Traditional categories of learning such as habituation, avoidance learning, trial-and-error learning, association and latent learning, and classical conditioning have been demonstrated in insects. The capacity for correcting behavior, imprinting and olfactory conditioning have been reported as well. More recently, investigators have been primarily concerned with the adaptive significance of learning. The contributions of behavioral ecologists and neuroethologists have made it clear that any analysis concerning the adaptive significance of behavior must take into account: (i) the evolutionary history of the behavior; (ii) processes related to the development and/or modification (learning) of the behavior under present conditions; and (iii) the environmental setting in which the behavior occurs. The ability of an organism to learn can also be used to obtain answers to questions concerning how the organism perceives its world, the role of CNS integration in the learning process (molecular mechanisms of learning), and what specific regions of the CNS are involved in the consolidation and storage of experiential information (localization of brain function). This contribution summarizes some of the recent work concerning the neurochemical correlates of learning and localization of brain function in insects.

Learning and Development: Brain RNA Synthesis and the Retention of Learning Through Metamorphosis in Holometabolous Insects

The insect brain (cerebral ganglion) (Fig. 40) is divided into three major anatomical divisions: protocerebrum, deutocerebrum and tritocerebrum. The tritocerebrum innervates the muscles and sensory organs of the mouthparts. The deutocerebrum innervates the antennae which contain a rich array of chemo- and mechano-receptors. The protocerebrum innervates the optic lobes of the compound eyes and the ocellar nerves, and also contains several major ganglionic centers including the protocerebral bridge, central body and the corpora pedunculata (mushroom bodies) (Fig. 40).

Insects exhibiting complete metamorphosis (Holometabola) are characterized by distinct egg, larval, pupal and adult life cycle stages. During pupation, some larval tissues and organ systems undergo an extensive breakdown and are eventually reorganized to form the adult animal. As a result, holometabolous insects provide an excellent model for an analysis of the effects of development and CNS reorganization on learning and memory. The degree to which a behavioral response learned during the larval stage is retained by adults can be used to assess the extent of CNS reorganization during development.

The retention of an associative learning task following metamorphosis was reported for the locust (Hemimetabola), *Locusta migratoria*.

However, the degree of CNS reorganization exhibited by hemimetabolous insects does not compare with that exhibited by the Holometabola. However, because relatively few species of holometabolous insects have been studied, the degree of CNS reorganization during pupation may vary widely between species, depending on specific life history characteristics.

Research has been conducted on the retention of learning through metamorphosis in the holometabolous darkling beetles, *Tenebrio molitor* and *Tenebrio obscurus*, using a more complex spatial learning task (complex maze). These studies were also interested in studying neurochemical events (brain RNA synthesis) associated with learning. The maze consisted of a start chamber, goal chamber and six blind alleys. Only older larvae (<10 mm) were used for learning experiments. Adults were tested in the maze within 24 h of eclosion without regard to sex. Because the larval and adult stages of this insect are negatively phototactic, a fluorescent lamp placed directly over the maze served as an aversive stimulus. Larval insects were randomly assigned to an experimental group (L group) that was subjected to learning trials and a control group (no exposure to the maze). The number of blind-alley errors (BAE) was recorded for each trial as the insect progressed through the maze. The goal chamber was opaque and allowed the insect to avoid the aversive light stimulus. Mean number of BAE were recorded for trained larvae (L), adults previously trained as larvae (PTA), and adult controls (CA) which had no previous larval training.

The results indicated that T. obscurus larvae and adults are capable of learning a relatively complex maze. There was a significant improvement in performance over the 7-day training period for all test groups. For larvae, BAE decreased from a mean of 132.4 ± 21.8 S.D. (day 1) to 17.1 ± 4.9 (day 7). Over a similar 7-day training period, mean BAE decreased from 51.6 ± 11.2 to 7.3 ± 3.2 for PTA insects. However, adults with no previous maze training as larvae (CA), exhibited a mean of 90.5 ± 10.1 BAE on day 1 which decreased to 11.2 by day 7. This represents a significantly higher number of errors than the 51.6 BAE shown by adults previously trained as larvae and clearly demonstrates the retention of maze learning through metamorphosis in this species.

These findings strongly suggest that those specific brain regions associated with the consolidation and storage of experiential information do not undergo an extensive reorganization during pupation in *T. obscurus*. Previous studies on insects have identified the corpora pedunculata (mushroom bodies) and protocerebral bridge of the protocerebrum as playing an important role in complex behaviors including learning and memory. Future studies should include a detailed histological analysis of brain morphology throughout metamorphosis to ascertain the extent of reorganization of these and other brain regions.

Neurochemical Correlates of Learning and Memory in Insects and Localization of Brain Function

It is well known that specific neurochemical changes within the brain accompany the learning process in both vertebrates and invertebrates. Changes in the concentrations of amino acids, proteins, neurotransmitters and RNA have been shown to accompany learning and memory. An analysis of these neurochemical changes will result in a more complete picture of the molecular mechanisms underlying behavioral plasticity. In addition, such neurochemical events can be used to identify specific brain regions involved in the consolidation and storage of information within the CNS.

Neurochemical correlates of learning have been identified in insects and other arthropods. It has also been suggested that biochemical changes in RNA, proteins, neurotransmitters and amino acids may cause changes in the structural (number of synaptic connections, degree of dendritic branching) and functional (dynamics of gated channels and neurotransmitter release, postsynaptic thresholds) properties of neurons that participate in a learned response, thereby rendering such neurons more effective in later trials.

With respect to insects, studies on the cockroach (*Periplaneta*) indicated that leg-position learning (learning to flex the leg to avoid electric shock) was associated with an increase in protein synthesis and a decrease in cholinesterase activity in the CNS. Several ninhydrin-positive neuropeptides were identified from whole-brain extracts of a mantid, *Stagmatoptera biocellata* trained to attack a moving object. These compounds were not found in brains from non-trained controls or from insects that had been subjected to similar handling procedures. This strongly suggests that the neurochemical changes observed in trained insects were the result of learning procedures and not merely stress. Alterations in brain peptides have also been associated with ontogenetic changes in learning and memory in praying mantids. It was also demonstrated that arginine enhanced memory consolidation in mantids. Additional studies reported a correlation between biogenic amine concentrations (catecholamines such as norepinephrine, octopamine, dopamine) and conditioned responses to olfactory cues in honeybees (*Apis mellifera*). These findings are consistent with previous work showing that pools of amino acids and amines enhance acquisition and memory formation when injected into vertebrates.

Studies on a cricket, *Pteronemobius* sp. reported a significant change in the concentrations of urea, alanine, histidine, glutamine, cysteine and arginine in whole-brain extracts from animals trained in a simple Y-maze. Since alanine, arginine and urea are all related to the urea cycle, it appears that this metabolic pathway plays an important role in memory consolidation. Further studies showed that injections of alanine, arginine and glutamine blocked anoxic retrograde amnesia and enhanced memory formation. More recent studies have demonstrated a significant increase in hemolymph levels of taurine, urea, threonine, histidine and gamma-amino-butyric acid (GABA) following an aversive conditioning task. These findings are consistent with biochemical models of learning and memory in which information entering the CNS results in morphological and functional alterations at synapses.

Neurochemical events have also been associated with leg-position, shock-avoidance learning in a number of arthropod species. Through the use of H^3-labeled uridine (for RNA) and amino acids (for proteins), a significant increase in brain RNA and protein synthesis was found to accompany avoidance learning in a grasshopper, *Schistocerca americana*. Furthermore, these macromolecular changes were restricted to the corpora pedunculata and protocerebral bridge of the protocerebrum. No significant changes in RNA and protein were found in the deutocerebrum, tritocerebrum or other major ganglionic centers of the protocerebrum including the central body. These results indicate that learning experiments can be used to determine specific brain regions involved in the learning process (localization of brain function). Using similar procedures, a significant increase in RNA and protein synthesis were found to accompany learning in the protocerebral bridge and central body of the mud crab, *Eurypanopeus depressus* (Decapoda), and a theraphosid spider, *Aphonopelma chalcodes* (Orthognatha). In addition to RNA and protein, changes in neurotransmitter (catecholamine) levels were found to accompany olfactory conditioning in the honeybee, *Apis mellifera*.

Similar neurochemical correlates of learning have been reported for the hunting behavior of a spider wasp, *Pepsis formosa*. Nectivorous adult female wasps selectively hunt large, fossorial tarantula spiders (host species) which provide a food source for their carnivorous larvae. The hunting behavior of these wasps can be divided into several distinct sequential acts. The wasp locates an active host burrow while walking rapidly over the surface of the ground utilizing visual and olfactory cues. Once a burrow occupied by a tarantula has been located, the wasp enters the burrow, forces the spider to the surface and begins to explore the surface of the spider's body with its antennae. The wasp then moves a short distance away and cleans its antennae using its mouthparts. During this time, the spider makes no attempt to escape or move back into its burrow. The wasp then returns to the host and again explores the spider with its antennae. This is followed by a rapid movement whereby the wasp positions itself beneath the body of the host. The wasp grasps the hindlegs of the spider with its mandibles and inserts its stinger into the thoracic ganglion of the host causing rapid paralysis. The paralyzed spider is then dragged into its burrow and a single fertilized egg is deposited on its abdomen. The wasp then seals the entrance to the burrow and initiates a search for another host. Each of its eggs must be provided with another host spider. Upon hatching, the wasp larva feeds on the paralyzed host and completes its larval development.

This hunting sequence has traditionally been considered a classic example of instinctive behavior characterized by rigid, stereotyped behavioral acts. However, recent studies have shown that previous encounter experience can improve hunting behavior. Naive female wasps encountering a host for the first time require a mean of 251.7 min to complete the entire hunting sequence (from the initial approach through closure of the burrow). After eight encounters with spiders, the time required was reduced to 159.6 min. This significant improvement in performance associated with increasing number of encounters indicates that experience (learning) can modify hunting behavior and contribute to the overall fitness of these spider wasps. In terms of energy budgets and optimal foraging theory, time spent in locating a required resource is rendered unavailable for other important activities such as mating and reproduction in addition to increasing exposure to potential predators. By decreasing the time spent on hunting, *P. formosa* can minimize its foraging costs and thereby increase fitness.

It has also been shown that improvement in hunting behavior was accompanied by changes in brain chemistry. Increasing encounter experience resulted in a significant increase in protocerebral RNA and protein synthesis as compared to control wasps exposed to the same rearing and handling conditions but without any encounters with a spider. This difference reflects neurochemical events within the CNS attributable to the learning process and not merely to stress or a general increase in motor activity. Control wasps were allowed to fly, feed and explore a host-free encounter chamber on a daily basis. They were also within the same size and age range as wasps used in the encounter trials. The only consistent difference between these two groups was the encounter experience with host spiders. This represented the first demonstration of changes in brain neurochemistry associated with a naturally-occurring behavior consisting of sequential acts.

The importance of macromolecular events in learning and memory consolidation is also supported by experiments in which the animal was treated with a protein synthesis inhibitor prior to training. Injection of cycloheximide (CXM) has been shown to impair the learning process in crustaceans, spiders, grasshoppers, and mantids, as well as in reptiles and mammals.

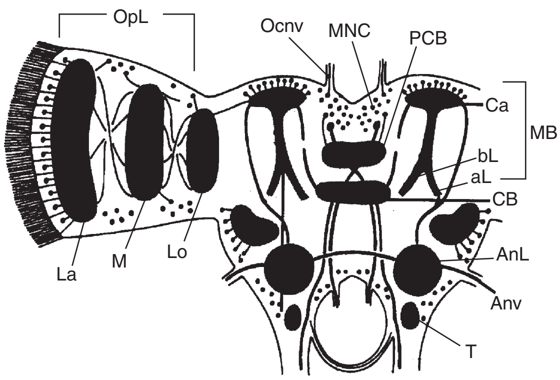
It should also be mentioned that macromolecular synthesis appears to play an important role in the expression of innate behavior as well. A fundamental question that has been asked metaphorically but never tested experimentally, concerns the functional relationship (if any) between instinct and the retrieval of learned information. Molecular mechanisms that could serve as models for the storage of information within the CNS should also be involved in learning and instinctive behavior and thus have access to the genome. It is well known that neurons are characterized by significantly higher rates of RNA synthesis than are other somatic cell types. RNA is essential to the expression of gene function. Regulatory molecules such as cyclic AMP, calmodulin and other second messengers, as well as some hormones, are known to activate genes. It has been suggested that environmental and behavioral factors could also activate genes. Behavioral events, either learned or instinctive, could trigger conformational changes in neuronal proteins through differential gene activation. Studies have been conducted on the effects of protein synthesis inhibition on the innate negative phototactic responses of the beetles *T. molitor* and *Popilius disjunctus*. Injection of CXM resulted in a pronounced impairment in the ability of *T. molitor* larvae to burrow into a cereal bran substrate to avoid an aversive light stimulus. Only 27% of the larvae treated with CXM exhibited burrowing with a mean burrowing time of 219 sec. One hundred percent of the non-treated controls burrowed with a mean time of 51 sec. All CXM-treated insects moved freely across the surface of the grain indicating that CXM did not impair normal motility. There was also no apparent deleterious effect of CXM on developmental processes; CXM-treated larvae and non-treated controls both completed pupation and emerged as functional adults. Cycloheximide treatment had a similar effect on the time required by *P. disjunctus* adults to traverse a runway to avoid light.

It is interesting to note that changes in CNS amino acids and biogenic amines have been found to accompany ontogenetic behavioral changes (age polytheism) in a number of insects and other arthropods. One of the most intriguing questions in neuroscience pertains to the relationship between brain chemistry and behavior. Neurotransmitters and comodulators have been implicated in a variety of ontogenetic behavioral changes in honeybee workers (*A. mellifera*) including shifts in discrimination between olfactory cues and the onset of guarding behavior. Brain dopamine (DA) levels were significantly higher in forager honeybees than in nurses or food storers. Similarly, amino acids and biogenic amines have been implicated in age polytheism in a carpenter ant *Camponotus floridanus*. A significant increase in the concentration of 5-hydroxytryptamine (5-HT, serotonin) has been reported in the brain of a solpugid, *Eremobates palpisetulosus* (Arthropoda, Arachnida, Solpugida) between the first and second nymphal instars. Dopamine levels increased significantly after the second nymphal instar. No changes were observed for octopamine (OA) throughout postembryonic development, and *N*-acetyldopamine (NADA) concentrations were found to decrease. Thus, lower DA and 5-HT concentrations were associated with those developmental stages characterized by low levels of locomotor activity and the absence of aggressive behavior between nymphal conspecifics. Agonistic interactions between siblings and other conspecifics first appeared in second-instar nymphs and are correlated with increasing concentrations of 5-HT and DA in the brain. It is also during this developmental stage that solpugid nymphs begin to burrow and actively hunt for food. The neurotransmitter acetylcholine as well as acetylcholinesterase levels also increased between the first and second nymphal instars.

Learning, Experience, and Brain Morphology

A link between macromolecules associated with learning, early experience, and specific cells (neurons) within the insect brain has been established in a number of insects including fruit flies (*Drosophila melanogaster*), honeybees (*Apis mellifera*), and several species of ants. The mushroom bodies (MB), also known as the corpora pedunculata, have been identified as an important brain region mediating complex behavior in insects. The neurons of the MB are called Kenyon cells (KC). To a lesser extent, other areas of the insect brain implicated in the learning process include the antennal lobes, the central body, and protocerebral bridge. This is not surprising since the MB represent convergence sites for chemosensory, visual, and mechanosensory pathways in the insect brain (Fig. 41).

The MB in *Drosophila* are bilateral clusters comprising about 2,500 cells which send their dendrites into a centrally located neuropil receiving neural inputs from the antennal lobes and central body. The MB consist of a calyx and two lobes (alpha and beta).



Learning in Insects: Neurochemistry and Localization of Brain Function, Figure 41 **Frontal view of insect brain. aL, alpha lobe of mushroom body; bL, beta lobe of mushroom body; AnL, antennal lobe; Anv, antennal nerve; Ca, calyx of mushroom body; CB, central body; La, lamina of optic lobe; Lo, lobula of optic lobe; M, medulla of optic lobe; MB, mushroom body – corpora pedunculata; MNC, median neurosecretory cells; Ocnv, ocellar nerve; OpL, optic lobe; PCB, protocerebral bridge; T, tritocerebrum.**

Evidence suggesting the involvement of the MB in olfactory learning was first observed in fruit flies. Localized cooling of these brain structures within 8 minutes after olfactory/reward training produces a type of retrograde amnesia. In addition, mutant flies with defective MB exhibit defective learning capacity.

The MB of honeybees, each consisting of about 170,000 cells, have been shown to change morphologically as the result of experience and training. There is a significant, age-dependent increase in the volume of the neuropil which is further enhanced following the first foraging flights by workers. The volume of the MB is significantly larger in nurses and foragers as compared to newly emerged bees.

In the ant *Camponotus floridanus*, the volume of the MB and neuropil increases by almost 50% between the time of pupation and 10 months of age. This increase in volume is associated with the increase in behavioral complexity associated with brood care and foraging. This increase in volume has been attributed to the growth of cellular axons and dendrites rather than an actual increase in the number of cells.

Summary

The present neuropharmacological evidence from invertebrates and vertebrates strongly suggests that the consolidation, storage and retrieval of experiential information within the CNS is dependent on macromolecular events involving second messengers, neurotransmitters, amino acids, proteins and RNA. It also seems that training procedures exert an effect on RNA and protein synthesis mediated by changes in neuronal transmission properties resulting from activation of neural circuits involved in the learning process. Environmental stimuli can alter steady-state levels of messenger RNA molecules encoding neurotransmitters resulting in changes affecting neuronal, synaptic and dendritic connections over time. The processing of experiential information alters electrogenic events causing changes in membrane depolarization and ultimately in the expression of specific neurotransmitter genes.

In animals exposed to learning trials, postsynaptic membrane changes within well-defined neural systems associated with learning appear to be involved in encoding the learned response for later recall. Specific ionic currents across neuronal membranes undergo changes that can last for variable periods of time following training procedures. For example, it is known from the study of invertebrate and vertebrate neural systems that intracellular calcium increases during acquisition accompanied by a concomitant decrease in potassium that persists for days after conditioning. This increase in calcium facilitates calmodulin-dependent phosphorylation of proteins involved in the regulation of specific gated ion channels. This may form the basis of a biophysical/biochemical memory trace. There is also evidence that conditioning causes an increase

in the excitability of dendritic membranes caused by a voltage-dependent Ca^{2+} current responsible for excitatory postsynaptic potentials (EPSPs) at synapses of neural pathway(s) involved in the learned response. This may lead to the formation of activated sets of neurons involved in the mediation of a learned response. A particular association could then activate specific neuronal convergence sites on the dendritic membranes of those neurons thereby enhancing recall.

The evidence supports the assumption that specific neuronal electrogenic events associated with learning and memory cause intracellular metabolic changes resulting in alterations in macromolecular synthesis. The synthesis of specific proteins could stabilize the changed cellular metabolism in its new state. This intracellular change could result in the release of molecules affecting the membrane's permeability characteristics and postsynaptic thresholds. In addition, the numerous studies demonstrating changes in RNA and protein concentrations in specific brain regions that accompany learning indicate that these macromolecular events are involved in acquisition and the consolidation of memory. Lecanicillium

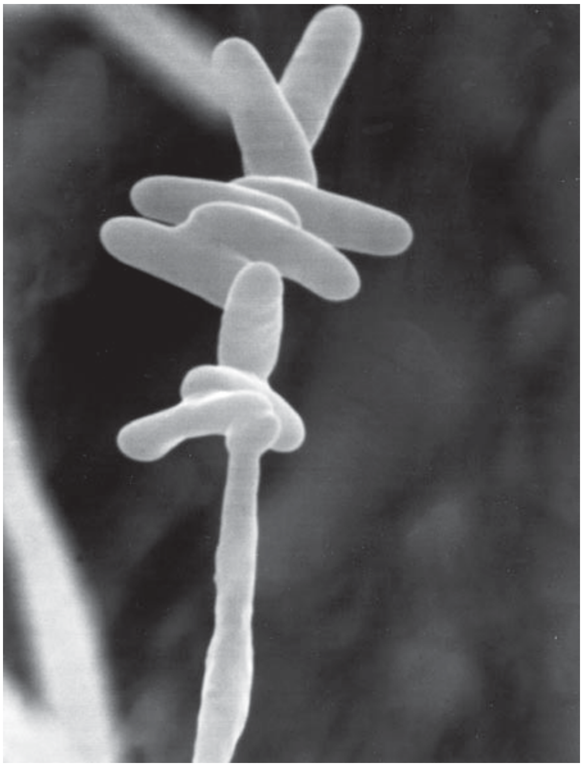
DRION BOUCIAS
University of Florida, Gainesville, FL, USA

This is a newly formed genus within the family Clavipitacae (Hyocreales) that contains many of the entomopathogenic species that were once placed in the genus *Verticillium*. This genus contains 17 anamorph species that are closely related to the teleomorphs in the *Cordyceps* and *Torrubiella* groups. Members have been distinguished from *Verticillium* by their frequent formation of octahedral crystals in culture, entomogenous or fungicolous habit, phialides discrete and aculeate, conidia accumulating at phialide tips, mostly single-celled conidia (Fig. 42). Historically, the best-known entomopathogenic species, *V. lecanii*, known to contain strains that infect whiteflies, aphids, scales, thrips and grasshoppers, has been split into segregate species. The type species *Lecanicillium lecanii* (Zimmerman) Gams and Zane = *Verticillium lecanii* (Zim.). Viegas is restricted to those strains that infect scale insects in the tropical and subtropical habitats. Several other strains developed previously as *V. lecanii*-based microbial controls for greenhouse insect pests have been given new names. For example, the whitefly biocontrol Mycotrol is now considered to be *L. muscarium*, whereas the long-spore strains, such as the one developed into the Vertalac formulations, are contained within *L. longisporum*.

Different species of *Lecanicillium* have been used in greenhouses for whiteflies and aphids. The whitefly strain has not proven to be as efficient a control agent as the aphid strain, perhaps because whiteflies are sessile, so the fungus is not dispersed



Lecanicillium, Figure 42 **Scanning electron micrograph of *L. muscarium* conidia. Note how the conidia are stuck together in clusters.**

as easily from one insect to another as in the case of mobile aphids. *Aschersonia aleyrodis*, another Deuteromycete, has been suggested to be a better control agent of greenhouse pests than *L. muscarium*. For example, *A. aleyrodis* appears to be more virulent to whiteflies, and the spores survive on host plant leaves longer than those of *L. muscarium*. *Lecanicillium muscarium* conidia are relatively unstable and must be stored frozen or at 4°C. Multiple passaging of the fungus on mycological media does not seem to cause attenuation, but can alter colonial morphology and growth rates, which indirectly affect the use of the fungus in biocontrol programs. Interestingly, certain species of *Lecanicillium* display a broad spectrum of activity. For example, various strains of *L. longisporum* have been shown to be infectious to a spectrum of aphids including species of *Aphis*, *Macrosiphum*, and *Myzus* as well as being antagonistic to powdery mildews. Application of such a fungus may play a dual biocontrol role causing a lethal mycosis in the insect pest and in preventing plant disease.

Leconte, John Lawrence

J. L. LeConte was born May 13, 1825, in New York, New York, USA. He came to be known as the greatest coleopterist in North America. His education was typical for the period, a time when study of natural history was not popular. However, John LeConte's father had a passionate interest in beetles, and young John was introduced to entomology at an early age. In fact, they later would publish together. LeConte graduated from Mount St. Mary's College in 1842 and from the New York College of Physicians and Surgeons in 1848. In 1852 the LeContes moved to Philadelphia. John traveled extensively in North America, Europe, and North Africa, and served as a surgeon in the American Civil War (Fig. 43). At one point John sent 10,000 beetles in alcohol from his collections near San Francisco, and his father mounted them and made notes on the important characteristics of each. From 1878 to 1883 he served as assistant inspector of the United States Mint in Philadelphia. LeConte introduced a high degree of precision in the description of insects, establishing new standards for taxonomy. He published 184 papers, including some monumental works, including "Classification of Coleoptera of North America" (with G. H. Horn, in 1883). At the time of his death, he had described about one-half of the beetle fauna of North America, approximately 6,000 species. LeConte was a member of all the leading entomological societies and served as president of the Entomological Club of the American Association for the Advancement of Science, the forerunner of the American Association of Economic Entomologists. He died in Philadelphia, Pennsylvania, on November 15, 1883.

Leech, Hugh Bosdin

Hugh Leech was born in British Columbia, Canada, on May 10, 1910. His interest in entomology, especially beetles, began early, and his first paper was published in 1930. His employment at the Canadian Forest Entomology Laboratory in Vernon in 1930–1947 was interspersed with university studies. He attended the University of British Columbia, from which he received a B.Sc. degree in agriculture in 1933, and then the University of California at Berkeley, receiving the degree of M.Sc. in 1938. In 1936, he married Frances Quail, and eventually they had a daughter and three sons. In 1947 he took his family to California, having accepted a position as Assistant Curator in the Entomology Department of the California Academy of Sciences. He served for a time as editor of the Pan-Pacific Entomologist. His collecting expeditions, curation of specimens, promotion, and publications progressed until, at his retirement in 1975, he had almost 250 publications, and was recognized as a leading authority on water beetles. His contributions on water beetles of western North America are especially valuable. After retirement, with the status of Curator Emeritus, he indulged a passion for gardening. He died on November 8, 1990 in California.

Lefroy, Harold Maxwell

Harold Lefroy was born on January 20, 1877, at Itchel Manor, Crondal, Hamsphire, England. He graduated from King's College, Cambridge, in 1898 and served as entomologist to the Imperial Department of Agriculture for the West Indies from 1899 to 1903. He then served as Imperial Entomologist for India from 1903 to 1912. After his service in India he moved to the Imperial College of Science and Technology in England, where he remained until his death except for some service with the military in the Middle East and Australia. Lefroy (Fig. 44) was interested in both systematic and applied entomology. He made major contributions to human health through improved sanitation, and published major works based on his time in India: "Indian insect pests" (1906), "Indian insect life" (1910), and "Manual of entomology" (1923). His activities at Imperial College were controversial. Lefroy enjoyed popularizing entomology, including publishing popular accounts for newspapers and appearing on the radio - activities that were frowned upon by his more conservative colleagues. His success at saving the roof of an important historical building from the ravages of wood-boring beetles with a fumigant insecticide paved the way for new approaches to wood preservation. He went on to protect many more buildings and eventually founded a company to market his products. Unfortunately, he did not live to see the full success of his company, and died prematurely on October 24, 1925, while experimenting with new fumigant gases.

Legs of Hexapods

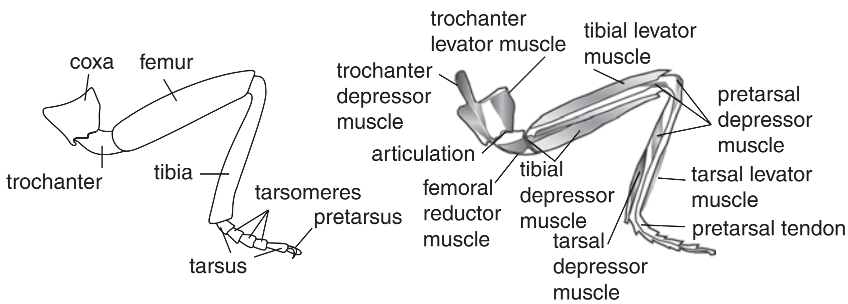
SEVERIANO F. GAYUBO

Universidad de Salamanca, Salamanca, Spain

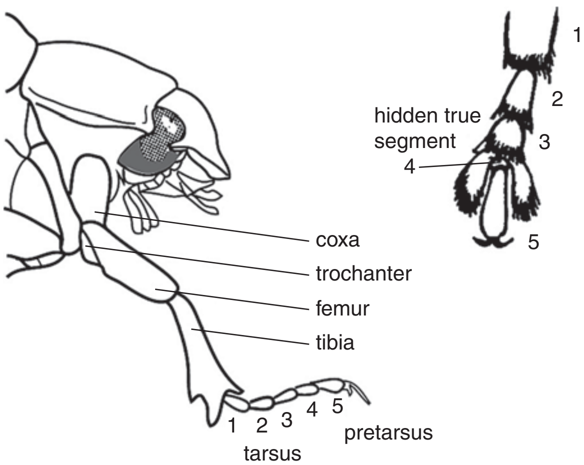
Despite the controversies that currently exist about the origin of the legs of the hexapods, and of the arthropods in general, the majority of authorities consider that the legs exhibit common morphological characteristics, and that their development is controlled by similar genetic mechanisms. Thus, the uniramous legs of the hexapods probably are derived from biramous appendages similar to those found in certain present-day groups of crustaceans.

Hexapods have three pairs of legs, situated in each one of the thoracic segments, from which comes the name of the group. There are certain exceptions, like the apodous larval forms and some adults with a specialized life form (e.g., adaptation to parasitism).

The locomotor appendage, basically adapted to walking on the ground, is formed by one branch with two parts: one basal or protopodite and the other distal or telopodite. The protopodite is formed by just one segment named the coxa, while the telopodite comprises five segments (Figs. 45 and 46) that, from the basal to the apical part, are named trochanter, femur, tibia, tarsus and pretarsus. The segments are joined by means of monocondylic and dicondylic articulations, differentiating extrinsic



Legs of Hexapods, Figure 45 **Basic leg components (*left*) and musculature (*right*).**



Legs of Hexapods, Figure 46 **Leg of a beetle (Coleoptera: Scarabaeidae) showing tarsal components.**

musculature and, in each one of the segments, intrinsic musculature.

The coxa generally has a globular shape. In its basal region is a submarginal suture named the basicostal suture, which internally corresponds to a crest called the basicosta. That suture separates a basal sclerite (basicoxite) that bears coxal cavities in which are articulated the condyles of the pleuron. In some orders, the basicostal suture has the form of "U" or of "V" on the posterior surface, delimiting an enlarged sclerite called a meron. In Thysanura, three points of articulation with the coxa (anterior, median, and posterior) are generally distinguished. In Pterygota the posterior point of articulation disappears due to development of the pleural crest, and the median condyle becomes the posterior. In certain insects, a longitudinal suture named the coxal suture can be distinguished over the external surface of the coxa, passing between the basicoxite and the anterior articulation of the trochanter. This suture corresponds internally to a reinforcement crest.

The trochanter is generally a small segment that articulates with the coxa through a horizontal hinge, which permits only movements in the vertical direction. It may be subdivided in two, as in Odonata, or be fused to the femur, as occurs in the last two pairs of legs of Strepsiptera. The articulation with the femur varies according to the group. In the majority of insects, the femur is the most robust segment; its greater or lesser development is related to its function, such as in the jumping insects in which it is very well developed to accommodate strong musculature.

The tibia is generally a narrow segment and the longest one, displaying a dicondylic articulation with the femur that enables it to carry out movements in a vertical plane and to fold back on the internal surface of the femur itself. The basal part of the tibia forms what is called the articular head and is known commonly as the knee, while in the distal part it bears one to many spurs.

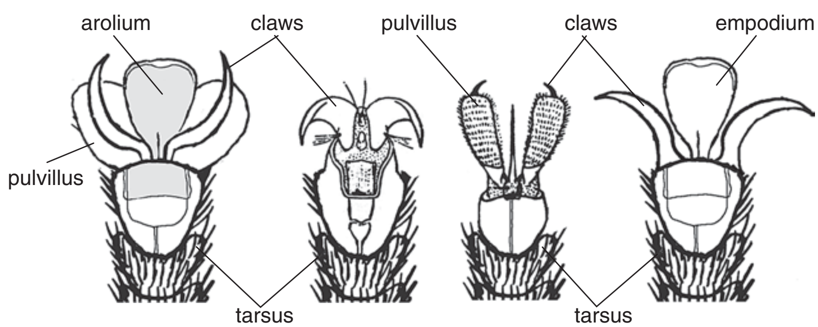
With regard to the tarsal-pretarsal region, two clads are distinguished in the hexapods; on one hand, Protura, Diplura and Collembola, with undivided tarsi (fused with the tibia in Collembola) that end in just one claw; on the other hand, the rest of the hexapods (the insects), with the tarsi subdivided basically in 3–5 tarsomeres that terminate in two pretarsal claws.

The tarsomeres do not exhibit intrinsic musculature, being articles and not true segments, although for practical purposes a few authorities use the name "subsegments." The whole tarsus is traversed by a tendon that is joined to the flexor muscle of the pretarsus, whose fibers originate in the tibia and, at times, in the femur. Although some authorities consider that the basal tarsomere (basitarsus) is a true segment that is named eutarsus, the majority think that convincing arguments do not exist to consider it in that way. It has already been noted that the number of tarsomeres can vary in distinct groups of hexapods; thus, in Archeognatha and Thysanura (Zygentoma) three tarsomeres exist. In Pterygota the number varies according to the group, with one tarsomere (nymphs of Ephemeroptera, and holometabolous larvae), with three (Odonata, Plecoptera, Embidiina; and Orthoptera, Acridoidea and Gryllidae), or with a variable number of one to three (Hemiptera). Pentamerous tarsi exist in the majority of Pterygota. There are special characteristics of the tarsomeres including the development of structures that support the insect in walking, such as the euplantulae (pad-like formations without hairs, situated on one or more tarsomeres) and the plantar lobes (special adhesive spiny formations).

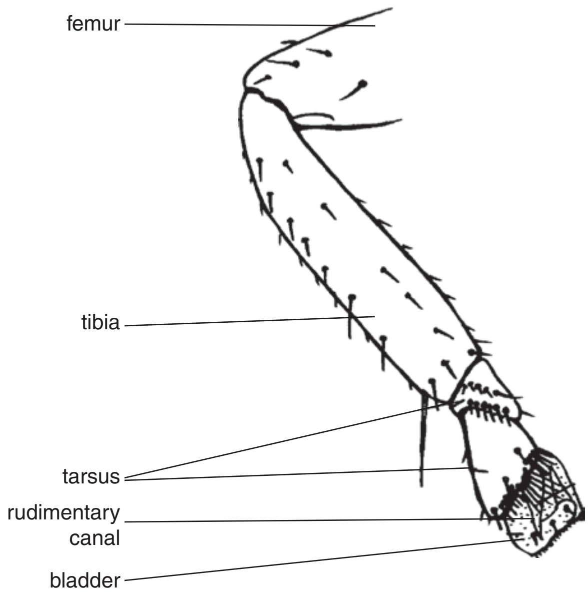
As a general norm, in the entognathous apterygotes, in the fossil group of the Monura and in the larvae of certain pterygotes, the existence of a single tarsomere is associated with the existence of a single pretarsal claw, while in the Ectognatha (Archaeognatha, Thysanura, and generalized Pterygota) the presence of three or five tarsomeres carries with it the existence of two claws (Fig. 47). In some apterygotes like Japygidae and many Thysanura, there is a third, a middle one, which at times is not obvious.

The pretarsal segment (post-tarsus of some authors) constitutes the apical part of the leg. It is formed by a complete annulus plus the unguiform structures in entognathous hexapods, while normally in the ectognathous insects two ventral sclerites are differentiated, the planta and the unguitractor plate, in which is inserted the tendon of the flexor muscle, which permits the movement of the two claws. There are also different structures in the pretarsus that enable the insects to join with the substrate over which they move, whether through the claws or by the development of structures like suction cups that let them grasp smooth surfaces such as glass (Fig. 48). Among these structures are the auxiliae (auxiliary sclerites of some authors), sclerites situated ventrally in the base of the claws. The pulvilli are smooth or setaceous membranous lobes situated ventrally to the claws and above the auxiliae, which take part in the movements of the pulvilli themselves. The empodium is a median process situated between the pulvilli, in the form of a spine or lobe, which is joined to the unguitractor plate. The arolium is a hollow and membranous lobe (at times partially sclerotized) in the median position. The arolium is morphologically and ultrastructurally different from the empodium.

As indicated in the section dedicated to the hexapod thorax, this tagma is basically dedicated to the locomotory functions, which are carried out



Legs of Hexapods, Figure 47 **Some variation among tarsal claws (*left to right*): Diptera: Tabanidae; Hemiptera: Cicadidae; Diptera: Asilidae; Blattodea: Blattidae.**



Legs of Hexapods, Figure 48 **Leg of a thrips (Thysanoptera) lacking tarsal claws.**

through the wings (see the corresponding chapter) and the legs. The locomotory function of the legs is developed in a different manner, taking into account, in the first place, if the environment in which a particular insect lives is aquatic or terrestrial and, in this last case, if the legs serve to walk or to jump. Moreover, whether it is an aquatic or terrestrial environment, the legs can be adapted to different functions than the original locomotory ones. All of that is translated into morphological modifications of the legs, with the following standing out among the most important:

Swimming Legs

The adaptation to the aquatic environment of different groups of insects carries with it a series of morphological modifications, which generally affect the posterior legs. The tibiae and tarsi are flattened and are bordered by long hairs that permit the legs to swim in a rowing manner and at times can be used as a rudder. Characteristic examples exist in the families of aquatic Coleoptera and Hemiptera. Less important modifications are found in hemipterans that live on top of the water (*Gerris, Hydrometra*) and that affect only the apex of the leg, over which are developed moisture-proof hairs that enable these insects to "skate" on the surface film of the water.

Running and Jumping Legs

The prior description of the segments corresponds to one typical for the running leg. The greatest velocity of running is usually related to a predatory behavior (e.g., Coleoptera: Carabidae, Cicindellinae). On the contrary, prey species should escape from their predators; one of the forms most commonly utilized in insects is the jumping form through the posterior legs, the insects being called for that reason jumpers. In these legs, the femora are particularly thick and long, since they accommodate a strong extensor musculature in the tibiae. They are longer than those in the anterior pairs of legs. The jump is produced by the rapid stretching of the femur-tibia complex. This type of leg is typical of groups like Orthoptera and Halticinae (Coleoptera: Chrysomelidae).

Digging Legs

The anterior legs of certain insects are usually adapted to dig, displaying different morphological modifications. Thus, in Coleoptera, Scarabeidae the tibiae are flattened and toothed, having the tarsus reduced. In species of *Gryllotalpa* (Orthoptera: Gryllotalpidae) with a subterranean life, the tibia and tarsus form a robust blade with strong teeth to make galleries. In the case of the nymphs of Cicadidae that also have a subterranean life, the femora are more robust and toothed apically, while the tibiae are thin; in this way, the nymphs can remove the earth to find the roots of plants that they eat.

Raptorial Legs

They are developed in species with predatory habits. In the most generalized model, the first pair of legs experiences modifications that enable them to act as a pincer to capture the prey. In the case of Mantida, the femur and the tibia are covered with strong spines on their opposite surfaces, which upon joining form a strong chela where the prey remain trapped. In Hymenoptera, Dryinidae the pincer is formed by the elongation of one of the pretarsal claws and the extension of the fifth tarsomere; both structures can be toothed.

Other Functions

In the adults of Odonata, the legs do not serve to walk, but rather the anterior legs are directed forward and serve to capture the prey in flight and to affix to the substrate when at rest. In the males they serve, in addition, to grasp the females during mating, and in certain cases, during oviposition.

In Orthoptera, Ensifera the anterior legs have crevices containing communication devices, the tympanic organs. In contrast, in many Orthoptera, Caelifera, structures for the production of sound are found above the internal surface of the femora. In the case of Siphunculata, the adaptations for ectoparasitism include modifications in the legs to grasp the hairs or feathers of the hosts.

In some species of aquatic coleopterans like that of the genus *Dytiscus*, the males have the first three tarsomeres flattened in the anterior legs, whose surface forms a structure that bears lines of small cuticular suction cups, except two of greater size situated in the first tarsomere. This structure serves to grasp the females during mating and, on occasion, to grasp prey.

The Hymenoptera can display on the anterior tarsi a structure called the "cleaning organ," consisting of the spatulated spur of the tibia and the contiguous notch (bordered with bristles) of the metatarsus. These form a zone through which the insect passes the antennae repeatedly and, at times, the mouthparts and even the last pairs of legs. The females of predatory wasps (e.g., Hymenoptera: Spheciformes) can use the legs to transport the prey to the nest. The bees (*Apis*) and bumblebees (*Bombus*) have the third pair of tibiae grooved in their external surface and bordered with long bristles, forming the corbicula that they use to transport pollen.

Leishmaniasis

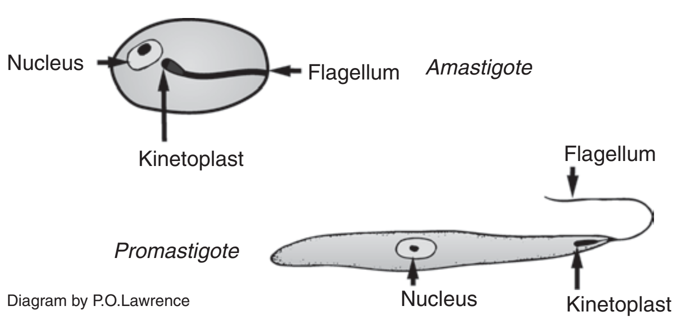
PETER E. KIMA
University of Florida, Gainesville, FL, USA

The World Health Organization (WHO) currently estimates that there are 1.5–2 million new cases of leishmaniasis each year and a total of 12 million cases worldwide. With ongoing epidemics of leishmaniasis in high conflict areas like Afghanistan and Somalia, and the recent discovery of a focus of infections in hunting dogs in North America, it should be of no surprise if there is an increase in *Leishmania* infections, in a manner consistent with other emerging infections. Leishmaniasis is caused by the eukaryotic parasites, *Leishmania* sp., of the order Kinetoplastida, which exist in two morphological forms (Fig. 49). The flagellated promastigote or insect form that develops in the sandfly vector (*Lutzomyia* sp. and *Phlebotomus* sp.) is deposited in the human or animal host during a blood meal. Soon after, promastigotes infect cells (primarily macrophages) that are recruited to the vector-feeding site. Within macrophages, *Leishmania* parasites reside in vacuoles wherein they transform into aflagellated amastigotes, the replicative form of the parasite in the animal host. For largely undetermined reasons, some *Leishmania* species in infected macrophages remain at the infection site where the interactions of recruited inflammatory cells, activated cells and parasites result in cutaneous lesions. Alternatively, some *Leishmania*-infected cells are transported to the viscera (spleen, liver and bone marrow). There too, inflammatory cells are recruited to sites of amastigote propagation where they form visceral lesions. Leishmaniasis manifests as a disease spectrum such that infected persons can develop self-limiting cutaneous lesions, disseminated cutaneous lesions that exhibit minimal tendency to self-cure, grossly disfiguring mucocutateneous lesions, or lethal visceral disease. A noted trend in leishmaniasis disease presentations has been a tendency for visceral symptoms to be associated with multiple parasite species, even those that are known to mostly cause cutaneous symptoms. Such was the case with the American service personnel whose manifestations of "Gulf War Syndrome" was the result of "viscerotropic" *L. tropica* infections. *L. tropica* infections are most often associated with cutaneous infections.

It should be expected that several factors, in addition to the parasite species and strain, determine the site of parasite propagation and disease severity. Recent studies have illustrated that the vector too plays an important role in determining the establishment of organisms and maybe even disease severity. During a blood meal, the sandfly vector releases molecules (vector saliva) in the host to facilitate feeding. The magnitude of the host's response to the vector saliva components can determine the fate of transmitted organisms. In naïve hosts, where the response to vector saliva is minimal or absent, vector saliva components apparently disarm initial host responses and thus permit transmitted organisms to establish themselves within those hosts. This latter observation might explain the high incidence of leishmaniasis in children and travelers or migrants through endemic areas. It is also noteworthy that in experimental visceral leishmaniasis, addition of saliva appears to be requisite for the establishment of infections.

The Immune Response and Consideration of Drug Therapy

Another worrisome trend in leishmaniasis is the "reactivation" and/or exacerbation of leishmaniasis as a result of co-infection with human immunodeficiency virus (HIV). In one study from Spain, leishmaniasis in 40 out of 40 patients co-infected with HIV was found to have resulted from reactivation of a previous *Leishmania* infection. The observations in immunocompromised hosts



Leishmaniasis, Figure 49 **Promastigote and amastigote forms of *Leishmania* sp.**

highlights the critical role of the cell mediated immune response, specifically CD4+ T cells in the control of leishmaniasis. It is widely accepted that the production of interferon-gamma (IFNγ) and interleukin 12 (IL12) as well as other T_H1 cytokines are the primary immune mediators of parasite control. In contrast, reduced production of these T_H1 cytokines, as appears to be the case in experimental infections with *L. mexicana* complex parasites or the production of IL4, IL10, transforming growth factor (TGF-β) and other T_H2 cytokines enables or promotes progressive Leishmania infections. Based on the current understanding of immunity to leishmaniasis, it is plausible to expect that vaccination strategies, which elicit protective T cell responses against *Leishmania* sp., would be effective at limiting leishmaniasis in the future. At present, therapeutic control of leishmaniasis is achieved with pentavalent antimonials (sodium stibogluconate [pentostam by GlaxoSmithKline] and meglumine antimonate). The use of these drugs in *Leishmania*-endemic areas, however, is limited by the fact that pentavalent antimonials need to be administered parenterally and preferably under controlled clinical conditions. Recent reports of the spread of *Leishmania* strains that are resistant to these drugs in *Leishmania*-endemic regions will increasingly limit their usefulness. In light of this reality, the new drug, miltefosine, which can be administered orally, would be a welcome addition to treatment options.

Mechanisms that Promote Parasite Persistence

A significant proportion of *Leishmania* infections exhibit a minimal tendency to self cure. From a review of the literature, there is evidence that two major mechanisms might contribute to the parasite's capacity to persist in the infected host. These are: (i) infection of macrophages by certain parasites results in the production of cytokines that inhibit the elaboration of and response to protective host responses, which consequently permits parasite growth and persistence; (ii) infected cells minimally present endogenously synthesized parasite antigens to CD4+ T cells. The result is that there is minimal T cell activation in response to infected cells. This assures parasite propagation and persistence. These mechanisms are discussed further below. It should be expected, however, that other factors such as host genetics, and the health status of the individual also would determine the extent of the host's capacity to control infections.

Induction of Inhibitory Host Responses

A well-documented feature of visceral leishmaniasis is that infected hosts have measurable levels of IFNγ in their serum. In addition, their peripheral blood mononuclear cells (PBMC) can produce IFNγ in response to parasite antigen. Similar observations also have been made in experimental studies of visceral leishmaniasis. Since these subjects have ongoing infections, it can be concluded that although IFNγ is an important mediator of parasite control, its presence is not sufficient to ensure control. In contrast, the production of IL10, IL4 and TGFβ appear to exert a greater effect on the host's capacity to control *Leishmania* infections. Experimental infections in $IL10^{-/-}$ animals and transgenic animals have confirmed the role of these cytokines in parasite persistence. It is presumed that these inhibitory cytokines function by suppressing T cell activation or the response of cells to leishmanicidal T cell products such as IFNγ.

In light of these findings, it has become of interest to determine what factors result in the production of immune inhibitory cytokines in leishmaniasis. There is some evidence that the differential engagement of phagocytic molecules on the surface of the macrophage by the parasite during infection might result in differential cytokine production. Following from the observation that *Leishmania* amastigotes that are recovered from tissue are opsonized with antibody, it was shown that engagement of macrophage Fc receptors by these opsonized parasites induced the production of IL10. Production of IL10 by macrophages then would block the leishmanicidal effects of IFNγ and thus promote parasite persistence. At the initiation of *Leishmania* infections, vector saliva that is released into the feeding site contains molecules that suppress the host response in addition to potent vasodilatory activities. The suppressive effects of such vector saliva components can be overcome by inducing a specific host response to them. Such an approach has been shown to limit the establishment of *Leishmania* infections.

Immune Evasion by Limitation of Infected Cell Recognition

In infections with *L. amazonensis*, there is increasing evidence that the host's responses to the pathogen are low or minimal. Many patients don't mount a Montenegro skin (delayed type hypersensitivity reaction to *Leishmania* antigens) test response. In addition, PBMC's from *L. amazonensis* patients exhibit lower recall responses *in vitro* to parasite antigens, as compared to recall responses of patients infected with other *Leishmanias*. Complementary observations have been made in experimental infections of C57BL/10 mice. These mice are resistant to *L. major* infections but they develop progressive *L. amazonensis* infections. C57BL/10 mice don't mount either a T_H1 response or a T_H2 type response of much significance, when infected with *L. amazonensis*. Further, neither the addition of IFNγ or IL12, nor the absence of IL4 or IL10 in knockout animals (lacking the genes that encode for these cytokines) significantly alters the course of *L. amazonensis* infections in most mouse strains tested. Paradoxically, it has been shown that CD4+ T cells are required for the establishment of *L. amazonensis* infections, presumably because the products of T cell activation results in cell recruitment to the eventual lesion site.

The absence of a significant T helper cell response in *L. amazonensis* infection might be explained by observations that have shown that amastigote-infected macrophages minimally present endogenously synthesized parasite antigens to CD4+ T cells. Those studies showed that while promastigote-infected macrophages could present parasite antigen transiently to parasite antigen-specific CD4+ T cells, amastigote infected macrophages were unable to activate the same antigen-specific CD4+ T cells. The effects of the parasite on antigen presentation were shown to be limited to parasite molecules in the parasitophorous vacuole, since parasite molecules fed exogenously could be presented by infected macrophages. Neither the reduced expression of MHC class II or accessory molecules could account for the phenomenon. The mechanism that underlies this process is not known presently. However, it is known that parasitophorous vacuoles that harbor parasites of the *L. mexicana* complex (*L. amazonesis*, *L. pifanoi* and *L. mexicana*) can selectively acquire particles ingested by the infected macrophage. Zymosan particles and live *Listeria* that are ingested by the macrophage, enter the Leishmania parasitophorous vacuole, in contrast to latex beads and antibody-opsonized *Listeria* that are excluded from entry into these vacuoles. In light of these observations of parasitophorous vacuole selectivity, it has been suggested that vesicles that play a role in antigen processing might similarly be excluded by the parasite.

The capacity of parasites to either limit CD4+ T cell recognition of infected cells or inhibit the response to T cell effector molecules is an evasion strategy that ensures parasite persistence. Studies that elucidate the mechanisms that underlie these processes should prove valuable in the design of new strategies to limit leishmaniasis.

Leng, Charles William

Charles Leng was born at Staten Island, New York, on April 6, 1859. As a child he collected insects and at the age of 16 joined the Brooklyn Entomological Society. He graduated from Brooklyn Collegiate and Polytechnic Institute as an engineer, and commenced work with his father's company. However, he remained interested in entomology. He coauthored, with W. S. Blatchley, "The Rhynchophora or weevils of northeastern North America," a monumental undertaking that includes descriptions of 1,800 species. He also published the "Catalogue of the Coleoptera, north of Mexico" (1920), with supplements in 1927 and 1933. His "Catalogue" became an essential tool for all coleopterists. Leng died at Staten Island on January 24, 1941.

Lepeletier, Amédée Louis Michel

A. L. M. LePeletier, Comte (count) de Saint-Fargeau, was born at Paris on October 9, 1770. He was educated in the seminaries of Paris, and seemed destined for an ecclesiastic life. However, the French Revolution of 1789 disrupted his life, as it did for most French nobility. Also, LePeletier discovered that his principal interest was natural history, including botany and entomology.

He became particularly interested in Hymenoptera, and devoted his efforts to understanding the social behavior of these insects. He promoted a system of classification for Hymenoptera based on sociality, not recognizing that sociality had evolved independently several times in this group. He was prominent among the entomologists of the time, and assisted in the preparation of "Dictionnaire des insectes de l' encyclopédie méthodique," published in 1825, and he authored "Monographia Tenthredinetarum" in 1823. He died on August 23, 1845.

Lesser Date Moth, *Batrachedra amydraula* Meyrick (Lepidoptera: Cosmopterygidae)

YOUSIF ALDRYHIM
King saud University, Riyadh, Saudia Arabia

The lesser date moth is a serious pest infesting flowers and immature fruits of the date palm, *Phoenix dactylifera*. The lesser date moth occurs over a large area in Asia from Bangladesh to western Saudi Arabia and Yemen, and most areas of North Africa.

Description

The adult moths have a wing span of 10–14 mm. The front wings are lanceolate with brownish scales. The hind wings are narrow, light grey and long-fringed. The eggs are small, light yellow and are laid singly on the flowers and immature fruits. The larvae, when full grown, are about 10–12 mm long. The head and the prothorax are light brown while the rest of the body is translucent white. The prolegs are on the abdominal segments 3–4 and on the last. Pupae are slender, long and light-brown in color.

Life Cycle

The lesser date moth has three generations annually. The longevity of the first and second generations is about a month. The first generation is called the flower generation because its larvae mainly attack the inflorescences, while the second generation is called the young fruit generation. The fully grown larvae of the third generation pass the winter protected in a cocoon that is spun in the inner base of fronds (petiole) and other tissues of a palm tree. Adults usually emerge by mid-April. Females lay eggs singly on the flowers, on which the young larvae feed. Larval feeding causes about 20% of the damage to the inflorescences. Moths of the second generation appear in early May and lay eggs singly on young fruit strands. Pupation takes place in early June and adults of the third generation emerge by mid-June. The eggs of the third generation are laid singly on the young fruits. The fully grown larvae of the third generation leave the fruit and go into dormancy throughout the remaining summer, fall and winter. In late March or early April of the following year, they pupate and emerge as moths of the first generation.

Economic Importance

The damage by this pest can cause up to 80% fruit loss. The importance of this pest varies from one year to another. It causes more damage in the internal oases than in the coastal ones. Each larva may attack and damage up to five fruits. A larva seldom feeds on more than a third of the fruit before it seeks another one. The damaged fruit becomes dry, brown in color, and half the size of a healthy one. Larvae egress by a hole bored close to the attachment at the perianth. Frass and silk can be seen protruding from the holes. Injured fruits usually fall, although the stout webbing spun by the larvae attaches some of the fruits to the strands or to other fruits.

Control

There are no biocontrol studies of this pest. However, larvae are parasitized by hymenopterous species at a low rate of parasitism. *Bacillus thuringiensis*, however, showed rather promising results. Chemical control is not effective unless insecticide is applied early in the season at the time of pollination, preferably using a pyrethroid to dust the fruit fronds. A spray may be needed 2–3 weeks following pollination. Aerial application achieves good results in Saudi Arabia, but scale insect populations can increase due to the death of its natural enemies.

Lettuce Root Aphid, *Pemphigus bursarius* (Linnaeus) (Hemiptera: Aphididae)

JOHN L. CAPINERA

University of Florida, Gainesville, FL, USA

This species is likely of European origin, but is now found widely around the world, including the Middle East, Central Asia, Siberia, North and South Africa, Australia, and North America. It thrives in temperate environments.

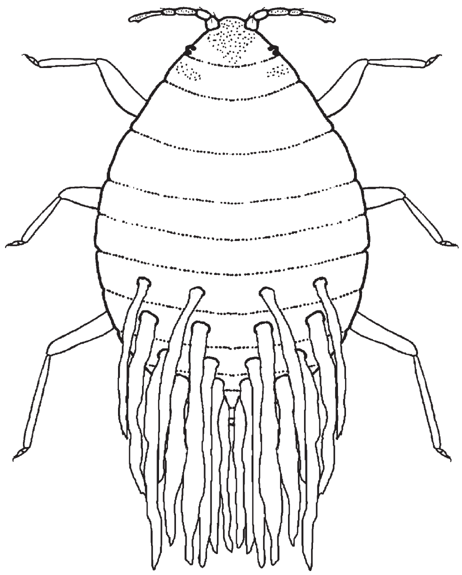
Life History

Lettuce root aphid normally overwinters in the egg stage on poplar trees, *Populus* spp., hatching in early spring. The females hatching from these eggs are large, rotund, and highly fecund. They reproduce parthenogenetically, and after two generations on poplar, winged forms (alatae) disperse to summer hosts. Dispersal of alatae usually occurs in early summer, and on summer hosts the aphids produce about three generations of parthenogenetic wingless aphids (apterae). Beginning in late summer, winged aphids are again produced, with dispersants migrating to the overwintering hosts. On poplar, small non-feeding male and egg-producing female aphids are produced, mating occurs, and eggs are produced. However, some aphids can also remain on lettuce or weed roots throughout the winter, colonizing nearby plants in the spring.

The egg is elongate oval in shape, initially greenish white but eventually orange in color, and enveloped in slender strands of waxy material. The egg measures about 0.48 mm long and 0.23 mm wide. Eggs are deposited in cracks and crevices of poplar bark at various heights on the tree to a height of at least 9 m.

Nymphs infesting foliage are green in color, and initially are found within poplar leaf petiole galls caused by feeding of the first generation adult. The nymphs have five instars, and may require 50–60 days in the spring to complete their development. Nymphs also are present on summer hosts, where development time is much shorter, and where they respond to increasing density and declining host quality by producing winged progeny that disperse to poplar trees. Nymphs on roots of summer hosts are not green; rather, they are light gray and covered with bluish wax. Nymphs are not capable of burrowing through soil, but they move freely through cracks on the soil, and over the surface of the soil, sometimes moving from plant to plant in this manner. Nymphs of all instars can overwinter belowground on summer hosts, often occurring at depths of 10–20 cm.

Adults of this species lack elongate cornicles; cornicles are porelike or absent. Adults possess relatively short antennae and legs. The adult female resulting from overwintering eggs is enveloped in bluish white wax. It is greenish in (Fig. 50) color, with dark appendages, and measures 2.0–2.2 mm in length. The feeding of this adult induces formation of a gall on the leaf petiole of poplar. The gall measures 6–18 mm in diameter and can eventually contain about 100 aphids or more. Adults emerging from the gall are winged (alate), disperse



Lettuce Root Aphid, *Pemphigus bursarius* (Linnaeus) (Hemiptera: Aphididae), Figure 50
Adult female lettuce root aphid, *Pemphigus bursarius* (Linnaeus).

to summer hosts, and immediately begin reproduction. The new females produce 15–25 nymphs within the first hour, which give rise to wingless (apterous) adults. Wingless adult females produced during the remainder of the year are oval in shape, yellowish white, and measure 1.6–2.5 mm in length. The short antennae are grayish to dark in color, the head black. The dorsal surface of the body bears six longitudinal rows of circular wax glands which produce waxy threads over the body. The entire aphid also is dusted with a fine white powder. The population of aphids peaks in August, at which time some nymphs move close to the surface and molt into winged adults. Winged adult females (alatae) are gray, green, or brownish in color, with darker head, antennae, thorax and markings on the abdomen. The wing veins are dusky brown. The alatae also produce a waxy secretion, and are 1.7–2.2 mm long. The reproductive forms produced late in the season on poplar are orange and lack functional mouthparts. The sexual forms are quite small, the males measuring 0.65 and the females 0.75 mm long. The abdominal cavity of the female is filled with a single egg that is deposited in a bark crevice.

The primary, or winter, host of lettuce root aphid is poplar, *Populus* spp. The Lombardy poplar, *Populus nigra* var. *italica* is the most common host, but other varieties of *P. nigra* and of *P. deltoides* also are recorded as hosts. The secondary, or summer hosts of lettuce root aphid are normally plants in the family Compositae such as wild lettuce, *Lactuca seriola*; sow thistle, *Sonchus arvensis*; and dandelion, *Taraxacum officinale*. Plants from other families such as redroot pigweed, *Amaranthus retroflexus* (Amaranthacea); shepherdspurse, *Capsella bursa-pastoris* (Cruciferae); lambsquarter, *Chenopodium album* (Chenopodiacea); and white campion, *Lychnis alba* (Caryophilaceae), have been reported to support small populations of these aphids, but these records are suspect. Lettuce is the principal crop affected, but chicory and endive are also infested.

Several natural enemies are known, but the natural enemy complex varies considerably depending upon the host plant and location of the aphids on the host. It is difficult for large predators to gain access to aphids feeding within intact galls, but galls are sometimes damaged by birds, and small predators can gain entry through the gall exit hole. The pirate bugs *Anthocorus* spp. (Hemiptera: Anthocoridae), the flower flies *Syrphus ribesii* (L.) and *Metasyrphus musculus* (Say) (both Diptera: Syrphidae), the chaemaemyiid *Leucopis pemphigae* Malloch (Diptera: Chamaemyiidae), and the lacewings *Hemerobius* and *Chrysopa* spp. (Neuroptera: Hemerobiidae and Chrysopidae) feed on aphids within galls. Aphids on the surface of poplar leaves and lettuce leaves also are subject to predation by such insects as lacewings, *Chrysopa* sp.; spined assassin bug, *Sinea diadema* (Fabricius) (Hemiptera: Reduviidae); the damsel bug *Nabis ferus* (Linnaeus) (Hemiptera: Nabidae); and such ladybird beetles as *Adalia* sp., *Coccinella* spp., *Coleomegilla maculata* (De Geer), and *Hippodamia* spp. (all Coleoptera: Coccinellidae). Aphids feeding on roots are less exposed to predation, but *Thaumatomyia glabra* (Meigen), *T. bistriata* (Meigen) (both Diptera: Chloropidae), *Sphaerophoria menthastri* (Linnaeus) (Diptera: Diptera: Syrphidae), rove beetles (Coleoptera: Staphylinidae), and ground beetles (Coleoptera: Carabidae) have been recorded feeding on these aphids. Fungal disease readily infects aphids belowground, and protozoa and a nematode were occasionally observed.

Damage

Feeding on lettuce by lettuce root aphid results in wilting, yellowing and stunting of leaves. Rootlets may turn brown and die, and roots will be covered with masses of bluish white, woolly material if aphids are present. Heavy infestations can cause softening and collapse of the lettuce head, and death of the plant.

Management

Insecticides may be applied to the soil for protection of lettuce varieties that are susceptible to root aphid attack. Contact and systemic materials, liquid and granular formulations, and planting-time as well as side dressed applications can be made, but effectiveness varies among products, and most insecticides work better as a preventative.

Destruction of old lettuce plants, particularly root stumps, and alternate hosts is often recommended to reduce the likelihood that aphids will be present when future crops are planted. Although the practice of sanitation always has considerable merit, it is most effective if soil temperatures are warm. This is due to the fact that at cool temperatures lettuce root aphids can survive for months without food. Also, the presence of Lombardy poplars near lettuce fields is detrimental to aphid management, and though planting of Lombardy poplars in lettuce production areas should be avoided, few advocate destruction of these short-lived trees if they already exist.

Soil water management can be important in minimizing aphid damage. Adequate and even levels of soil moisture promote rapid growth of lettuce, enabling the plants to mature quickly and escape the eventual population increase of the aphids. Plants also are more tolerant of injury if they are provided with adequate moisture. Constant soil moisture also limits cracking of the soil, limiting access to the roots by aphids and interplant movement.

Lettuce varieties differ considerably in their susceptibility to damage, with some commercial romaine (cos) and crisphead varieties displaying some resistance.

Life Cycle

The complete sequence of changes undergone by an organism during its life, often expressed as hatching of the eggs through the immature and adult stages of development, to hatching of the eggs produced by the insects developing from the first eggs.

Life History

An organism's lifetime pattern of growth, behavior, and ecology.

Life Table

A system of assessing population growth through tabulation of reproduction and survival within and among generations, and a method of recording age-specific survival. This approach usually analyzes the fate of a cohort – a group of individuals born at the same time. Females are the focus of life table analyses due to their reproductive potential, and the analysis partitions the life history of the insect into convenient stages, often the egg, young larva, older larva, pupa, and adult. The sex ratio of adults is also considered. An

accounting of the mortality rate at each stage, and the factor(s) responsible, are the key elements of the analyses. The life history elements recorded, and the standard method of notation, are:

x – the age interval at which the sample was taken
lx – the number surviving at the beginning of the stage noted in the x column
dx – the number dying in the age interval stated in the x column
*dx*F – the mortality factor responsible for dx
100 *qx* – percentage mortality
Sx – survival rate within x

Generation survival is a product of survival in the individual life stages. survivorship among cohorts is often assessed using "key-factory analysis," which evaluates the relative contributions of various mortality factors to generation survival. The individual mortality factors that are most correlated with (Table 4) intergenerational survival are called "key factors." Key factors are those that determine population trends, and often determine whether insect populations will grow or decline.

Lightningbugs

Members of the family Lampyridae (order Coleoptera). These are also known as fireflies.

► Beetles
► Fireflies
► Fireflies: Control of Flashing
► Glowworms

Lignicolous

Referring to organisms that dwell within wood, usually tree-feeding species.

Ligula

The central or terminal portion of the labium, often formed from the merger of two lobes. It is sometimes used in a manner synonymous with "glossa" or "tongue."

► Mouthparts of Hexapods

Limacodidae

A family of moths (order Lepidoptera). They commonly are known as slug caterpillars.

► Slug Caterpillar Moths
► Butterflies and Moths

Limiting Factors Concept

The concept of limiting factors holds that there are a number of individual factors that limit insect population size, and if any one of these is in short supply (or over-supply), population size will be limited. Examples of limiting factors include food, space, temperature, predators, parasitoids, and disease agents.

Limnephidae

A family of caddisflies (order Trichoptera). They commonly are known as northern caddisflies.

► Caddisflies

Limnichidae

A family of beetles (order Coleoptera). They commonly are known as minute marsh-loving beetles.

► Beetles

Limoniidae

A family of flies (order Diptera).

► Flies

Lindroth, Carl H

Carl Lindroth was a Swedish naturalist, and was born on September 8, 1905. As a child, Lindroth was interested in natural history, and frequently visited the Natural History Museum in Gothenburg. He commenced with beetle collecting in the 1920s. He was educated at the University of Uppsala, where he received a doctoral degree in 1931. He worked for many years at Lund University, in Lund, Sweden. Lindroth is known for his contributions to our knowledge of carabid beetles of northern Europe ("Die fennoskandischen Carabidae," published from 1945 to 1948), but more particularly to historical biogeography emphasizing the distribution of European and North American carabids. He examined critically the routes of introduction of European fauna into North America in both recent times and the late Pleistocene. He began some important field work in 1949 with visits to Newfoundland, and by the early 1950s had discerned the true identities of the carabid fauna of Newfoundland, Nova Scotia and Labrador. His 1957 treatise "The faunal connections between Europe and North America" identified the species shared between western Europe and North America, but he then continued to study the entire carabid fauna of Canada and Alaska, which was published in a 6-volume series, "The ground beetles of Canada and Alaska" (1961–1969). Lindroth discovered that over 40% of the carabid species shared between Europe and North America owe their introduction to humans, but also that ancient trans-Atlantic land bridges were important in connecting the Palearctic and Nearctic. He emphasized the significance of isolation in the evolution of brachyptery, and identified probable refugia during the ice ages. He also wrote about zoogeography in other regions of the world. His lasting contributions include a secure nomenclature for the northern carabids, identification of many new species, and the highest standards of descriptions and illustrations. Lindroth died on February 23, 1979.

Linnaeus, Carolus (Linné, Carl Von)

Carl Linnaeus was born in Roeshult, Sweden, on May 2, 1707. Carl disappointed his father, a Lutheran minister, by displaying no interest in the priesthood. His parents were pleased when he entered the University of Lund in 1727 to study medicine, but after only a year he transferred to the University of Uppsala. There he studied botany, which was part of the medical curriculum. He then went to The Netherlands in 1735 and completed his degree in medicine at the University of Harderwijk, and immediately enrolled for additional studies at the University of Leiden. That same year he published his first edition of the classification of living things, his "Systema Naturae." He returned to Sweden in 1738, where he worked as a medical doctor until employed by the University of Uppsala in 1740. Linnaeus was known principally as a naturalist and botanist, but he had profound effects on entomology. He established the binomial system of nomenclature, which made possible the modern classification of insects and other organisms. Thus, he is rightly known as the "father of biological systematics and nomenclature." He also developed the wing vein-based system for separation of orders, and established the chronological starting point for the naming of insects. Linnaeus traveled extensively in Europe, but also received specimens from other countries, so many of the common species from all over the world were named by him. Linnaeus' publication "Systema Naturae," 10th edition (1758) is considered the starting point for naming of insects. All names pre-dating this publication are considered invalid. His scientific works were written in Latin, with his author name as Carolus Linnaeus. In 1761 he was ennobled, and subsequently was known as Carl von Linné. He died in Uppsala, Sweden, on June 10, 1778.

A family of sucking lice (order Phthiraptera). They sometimes are called pale lice.

► Chewing and Sucking Lice

Linsley, Earle Gorton

Earle Linsley was born at Oakland, California, on May 1, 1910. As a child he became interested in insects, and attended the University of California at Berkeley. There he received all his degrees in entomology, with the Ph.D. awarded in 1938. His doctoral dissertation was on the Cerambycidae of California, and he worked on this subject throughout his career, culminating in a publication on the Cerambycidae of North America in 1997. Linsley became known as one of the world's leading authorities on this group. He also worked on the classification of solitary bees. Linsley joined the faculty of the University of California in 1939, chaired the Department from 1951 to 1959, and served as dean from 1960 until his retirement. During his productive career he published over 400 articles and books, named several hundred species or subspecies, and named 132 genera. Among his major publications were "Principles and methods of systematic zoology" (1953), which was co-authored with E. Mayr and J. A. Chemsak, and the 9-volume "The Cerambycidae of North America," in which Chemsak also participated. Linsley received numerous awards and honors, served as editor of "The Pan-Pacific Entomologist," and was president of both the Pacific Coast Entomological Society and the Entomological Society of America. He died at Oakland, California, on March 8, 2000.

Literature and Insects

DIANE M. CALABRESE
Silver Spring, MD, USA

Insects enliven literature in many ways. Even authors who typically ignore the natural world mention insects now and then. Jane Austen (1775–1817) is a good example of such a writer. In *Sense and Sensibility*, Austen's character Marianne reports she has been told in the East Indies, "the mosquitoes are troublesome."

The attachment of writers to insects seems to be as old as the existence of writers. Two early nineteenth century entomologists, William Kirby and William Spence, highlighted the link. Kirby and Spence saw students of insects in Virgil, Shakespeare and (Edmund) Spenser. In their 1812–1826 series about insects, compiled as the *Introduction to Entomology*, they quoted poets who reminded them of "the connection between natural science and agriculture, and the arts." In fact, the work of Kirby and Spence attracted many of the best known naturalists to insects. Among them was Charles Darwin, who cited the importance of the work by Kirby and Spence in hooking him, or at least, reinforcing his pre-existing curiosity.

By 1842, Robert Patterson, then the treasurer of the Natural History Society of Belfast, had published a detailed analysis titled, *Natural History of the Insects Mentioned in Shakespeare's Plays*. Title aside, his scrutiny of the literary uses made of insects extends well beyond Shakespeare. Moreover, Patterson, pointed out that many others, including writers, were already aware of the phenomenon of insects beguiling literary authors. He cited the label that the eighteenth century author and lexicographer, Samuel Johnson, also known as Dr. Johnson, applied to Shakespeare. It was, "the Poet of Nature."

In the early twentieth century, Harriette Wilbur (1919), and W. R. Walton (1922), took separate looks at the insects that pervade English poetry. Walton focuses on English works dated from Chaucer (1340–1400) forward. He identified

25 references to insects, belonging to six orders, in Chaucer's work.

Indeed, there may be no richer territory for finding insects in literature than in poetry. Walton suggested the reason when he wrote, "your true poet must of necessity ever be a naturalist in the broader sense." The tome, *Destructive and Useful Insects*, by Metcalf and Metcalf (1993 edition), includes an outline note that, "Insects have served as subject matter for hundreds of poems." No doubt the estimate of "hundreds" is low, but the point is made. W. John Tennent (2001), recently noted that he is compiling a compendium of insects in poetry, and in all likelihood the list will grow to the thousands, or more. Dependent upon allusions and the activities of the ancient gods to strengthen their metaphors and similes, writers would inevitably be drawn to the natural world, even if they were simply reading other writers and not wandering outdoors.

More than 2,500 years ago, Aesop launched many allegories built on the ways of insects. Among them are "Ant and the Grasshopper," which suggests a long-term reward for toiling instead of having fun, and "Bee and Jupiter," which illustrates that the empowerment rendered by a sting can also be a liability.

Psyche personified the soul to the late Greeks, even as she stirred Aphrodite's wrath and besotted Eros. Aristotle (384–322 B.C.), an early naturalist as well as a philosopher, assigned the name Psyche to butterflies.

Some mention of insects was made probably because the creatures annoyed writers so. Walton points to Edmund Spenser (1552–1599) as one that seemed to have a low tolerance for flies, and noted the *Faerie Queen*, had, "no less than eight references," to the disturbances they cause, from buzzing to filling chambers. From Austen to Spenser, it is not surprising that dipterans get attention. A writer need not look for flies. They make their presence known by alighting, biting or swarming. They are most often nuisances.

Yet even early writers that were living among flies and fleas, wonderfully nurtured by the dirty and crowded streets of pre-industrial London, found time to make careful observations of animal and plant interactions of a happier sort. Shakespeare's (1564–1616), play *The Tempest*, offers many acute insights into the cycles of the natural world, serving as an early, poetic treatise on ecology. It also includes some often cited and lovely lines about, "Where the bee sucks, there suck I/In a cowslip's bell I lie;... Merrily, merrily shall I live now/Under the blossom that hangs on the bough."

Entomologist, Writer, or A Little of Both?

In some cases, the boundary between the entomologist and the writer blurs. Novelist and poet Vladimir Nabokov (1899–1977), perhaps best known for *Lolita*, was also a serious student of butterflies. Smithsonian Institution entomologist Harrison Gray Dyar, who died in 1929, and is known for his biometric studies of immature insects, also wrote short fiction.

Contemporary author Margaret Atwood is the daughter of an entomologist, and insects often wriggle into her fiction. The father of Sylvia Plath (1932–1963), Otto Plath, was a Harvard University-based entomologist. Sylvia Plath committed suicide in a London dwelling once occupied by William Butler Yeats (1865–1939), a poet that had a great affinity for insects.

Yeats's poem, *Long-Legged Fly*, captures the essence of the movement of a water strider (Gerridae) on a stream. (His fly appellation probably derives from a Latin moniker applied to water striders, *tippula*, long before they had English common names.) French novelist Gustave Flaubert (1821–1880), also fretted about what to call striders, and settled on "long-legged insects."

Flaubert sought the help of correspondent and friend George Sand (1804–1876) in sorting out a lyrical name for what he described at one juncture as, "troublesome creatures," vexing to him because he did not like the sound of their available names. And, ultimately, he did not include striders in the novel for which they were destined. Correspondence between Flaubert and Sand indicate the former had no love of natural world, but the latter did.

Sand wrote of taking time for "botanizing" with her son, Maurice, whose entomological leanings were quite serious. Maurice produced a gilded volume, *Le Monde des Papillons*, published by Rothschild, in 1867.

Yet, one need not reach beyond a shelf of works by living writers to find insects. Mosquitoes, flies, crickets, locusts, wasps and bees get mentioned in Vikram Seth's *A Suitable Boy*, (1993). Even Hana, the lovesick caregiver in Michael Ondaatje's *The English Patient*, (1993), has time to notice the way, "bluebottles stumble in the air." Calliphorids wend their way into a great deal of fiction and poetry, probably because of their luster and ubiquity.

Read enough of a favorite author, and insects will emerge from the text in more instances than not, for two reasons. One, even the most reclusive writers sometimes cast a cursory look at nature and eventually see insects and write about them, or read writers that have done. Two, ideas and images are fortified by the introduction of insects, either as literal entities, or as figures of speech.

Significance

Entomologists and writers share common ground, and sometimes exploit it in a similar way. A search for solace sends both groups into the field, or into a book, seeking the same returns, comfort, context and common sense. Entomologists are more likely to quantify their experiences with insects than writers are, but to some extent, entomologists also allow themselves to make qualitative, or impressionistic judgments.

Insects make their way into prose and poetry through allegory, metaphor, simile, or simply by becoming central to the point of a story. Certainly, in some of the best-known tales involving insects, there are multiple uses in play.

A fly, or fly-man, takes a central role in Franz Kafka's (1883–1924), *The Metamorphosis*. The scarab beetle that is "The Gold-Bug" of Edgar Allan Poe (1809–1849), serves as a cipher and the key to a fortune. The eponymous heroine of A. S. Byatt's novella, *Morpho eugenia*, (1992), conceals as many secrets as any butterfly, and leaves the reader guessing throughout her transformation and amazed at its outcome.

Kafka, Poe and Byatt are just some of the many authors who have not been content to draw on insects for imagery alone. The authors also demonstrate knowledge of natural history and biology that is quite refined. Kafka taps the ancient mystery of complex life cycles, and anticipates DNA manipulation. Poe shows that mythology and beauty are melded in the ancient fascination with scarabs.

The history of exploration always plays itself out. The man that pursues Byatt's Morpho is a naturalist with a fondness for butterflies, freshly returned from the Amazon, where all serious nineteenth century naturalists trekked. Moreover, the man confronts a choice all naturalists make between comfort (the field) and context (the home).

C. P. Snow (1905–1980), wrote *The Two Cultures and the Revolution*, in part, as a lament over the gulf between the sciences and the humanities. Yet, thanks to the exceedingly large number of links between writers and entomologists, there are stepping-stones across the gap, making the reach across the divide so contiguous as to make Snow blush and reconsider.

Strong Images

When insects enter the picture, every stroke a writer makes seems to become stronger. For example, the most mundane and intangible thing, a rumor, can be made visible. Consider a simile Vikram Seth uses in *A Suitable Boy*. He wrote, "For every fact or imagined fact that appeared in print, there were ten rumors that hovered about like wasps over a rotting mango."

Or, focus on the nexus of beauty and horror, which is eternally in flux, and nevertheless can be portrayed. In *The Yachts*, William Carlos Williams (1883–1953), considered the way the ocean, when riled, can ravage sail bearing boats, and sink them, "pitilessly/mothlike in mists."

Thanks to insects, the reasoned, patterned ways of the world can be retold simply. Emily Dickinson (1830–1886) wrote, "To make a prairie it takes a clover and one bee."

Many writers transcribe their observations of the natural world in verse. In *The Sick Rose*, William Blake (1757–1827), speculated, "The invisible worm/that flies in the night/in the howling storm/has found out the bed."

Other writers try to sort out their place in the world by comparing natural entities. In *The Dancer* Philip Larkin (1922–1985), wonders, "Butterfly/Or falling leaf, Which ought I to imitate/In my dancing?"

Flaubert and Yeats are just two of the many writers captivated by water striders. Henry Wadsworth Longfellow (1807–1882), wrote in *Hiawatha* that, "Insects glistened in the sunshine, Insects skated on the water." In the same poem, "The mosquito, sang his war song." Walton (1922), saw the reference as prophetic, given it was published in 1855 and the role of mosquitoes as vectors for malarial parasites had not yet been established.

Trends

Over time, writers and entomologists have moved in roughly the same direction in the level of attention they give to the details of insect life. While the showiest, most common or most pestiferous insects got noticed early on, as time permitted a more leisurely approach to things, there has been a progression in literature that matches the one in science.

In general, there has been a trend away from observing more highly derived insects to observing less highly derived ones and from familiar to cryptic, nuisance to joy (or harbinger), destructive to helpful, and described to named. The shift in perspective was first cited by Walton (1922). As interest in the importance of insects in literature grows, the possible evolution in the precision of observation, or level of engagement, will be tested.

The change to more defining names is an easy trajectory to document. But, in certain instances, the correlation may reveal more about the author than the period of time. Yeats, who tapped insects in at least eight orders for his poems, also named tortoiseshell butterflies (*Nymphalis* sp.) and the peacock butterfly (*Inachis io*). As it happens, Yeats collected insects enthusiastically in his youth and anticipated at least once in writing that he would become an entomologist. He was also so fascinated by Alfred Russel Wallace, and he considered an homage to him.

There are other trends worth investigating as well. Across the centuries, simile has given way to metaphor, basic similitude to complex allegory, and comparative notes to central themes. To illustrate, and give a mention to arachnids, which also garner considerable interest from writers, look to *Mr. Edwards and the Spider*, by Robert Lowell (1917–1977). When Lowell, "saw the spiders marching through the air," he also saw a metaphor for humans without a purpose.

Finally, the reflection of insects in literature seems to mirror settings that are the major population centers. Thus, urban insects have lost some favor to rural ones, just as imaginary insects have been supplanted by real ones. The contemporary Irish poet Seamus Heaney describes a flirtation with the natural world that did not end well. In *Death of a Naturalist* (1966), he describes a, "flax-dam festered" where, "…bluebottles/Wove a strong gauze of sound around the smell."

A Full Circle

Sorting out the direction of influence when insects, entomologists and writers are linked is never easy, and is really just beginning to get the serious scholarship the subject area deserves. Almost every author has something to say about insects. In *Seven Pillars of Wisdom* (1926), T. E. Lawrence

(1888–1935), wrote that only, "bodily exhaustion," from marching across the Arab peninsula in hot sun was responsible for, "proofing me against the onslaught of lice and fleas."

The epigraph, a popular tool for nonfiction writers, entomologists among them, illustrates the ring writers and insects and entomologists tend to form. Choose a book of essays by any of the best known twentieth century entomologists from Howard Evans to E.O. Wilson, and see how skillfully the authors mined the rich territory of literature for nuggets.

An outstanding example of the integrative technique of the epigraph exists in *Wings in the Meadow* (1967). Author and amateur entomologist Jo Brewer taps Shakespeare, Lorenzo de Medici, Alfred Lord Tennyson, Walt Whitman, and others to find the perfect words to introduce and encapsulate the chapters on the life cycle of the monarch.

Alfred Russel Wallace's (1823–1913), influence on Yeats has already been mentioned. Wallace wrote in *My Life* (1905), his autobiography, about his father's fondness for the work of the poet William Cowper (1731–1800). His father read Cowper's work to him, which may have helped cement Wallace's interest in nature.

Cowper not only wrote about nature, he translated poems written by or credited to his schoolmaster Vincent Bourne, a scholar who wrote in Latin. Many of the poems, including *The Silk Worm*, provide good, basic descriptions of metamorphosis. He also did translations from Greek verses, such as *Of the Grasshopper*, which, interestingly, portrays the singing grasshopper as one that heralds spring. The match between the orthopteran and vernal days may signal the generic use of the name "grasshopper," and not a fondness for the humming.

There is much satire among Cowper's original verses, and, to be sure, much nature. On both counts, it is easy to understand why Cowper's work appealed to Wallace, a social critic as well as a preeminent naturalist.

Although this is very much an introductory word on the topic of insects in literature, and one heavily biased toward work written or available in English, someone must have the last word. The American satirical poet Thomas Hood (1799–1845), gets it. Hood nicely envisioned what the world would be like for entomologists and writers without insects. It would be like November, which Hood described in a poem titled, "*No*," for, among other absences, "No shade, no shine, no butterflies, no bees."

Litter

The uppermost layer of accumulated organic matter of the soil surface. Litter is mostly senescent leaf tissue material, and provides a rich source of food for decomposing fauna and flora. The arthropods associated with decomposition are mostly mesofauna, though large insects sometimes occur.

► Decomposer Insects

Little Bear Moths (Lepidoptera: Brachodidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Little bear moths, family Brachodidae, comprise 140 species, most being Old World tropical, particularly Indo-Australian; the family was formerly

Little Bear Moths (Lepidoptera: Brachodidae), Figure 51 Example of little bear moths (Brachodidae), *Nigilgia limata* (Diakonoff) from Taiwan.

known as Atychiidae. Some species are Neotropical but none are known from North America. There are three subfamilies: Pseudocossinae (only two species from Madagascar), Brachodinae, and Phycodinae. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults (Fig. 51) small to medium size (8–42 mm wingspan), with head usually rough scaled, but smooth heads in Phycodinae; haustellum naked; labial palpi usually porrect (sometimes upcurved); maxillary palpi 1 to 3-segmented; antennae usually thickened and often bipectinate. Forewings elongated and rounded on termens but hindwings often much enlarged and subtriangular. Bodies often robust; in one Neotropical genus the head is greatly reduced (*Hoplophractis*). Maculation very varied, but either subdued and darker, or colorful and with metallic-iridescent scaling; hindwings either mostly white or dark. Adults are diurnal. Larvae are root feeders of grasses (in the European *Brachodes*, Brachodinae), using silken tubes, or borers in palm trunks and leaf stems, or other plants; some are leaftiers (Phycodinae). Host plants are in Gramineae, and also Bromeliaceae, Melistomaceae, Moraceae, and Palmae. Few are economic on palms.

Lock and Key Hypothesis

Closely related insect species often have varied genitalia. The lock and key hypothesis purports that this complex anatomy is maintained to provide reproductive isolation through physical barriers to copulation.

Locomotion and Muscles

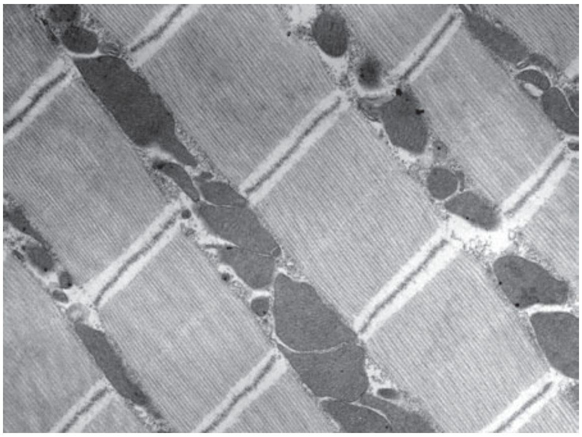
JAMES L. NATION
University of Florida, Gainesville, FL, USA

The capacity for movement is one of the most fundamental properties of animals. All insects are capable of locomotion at some stage in their life, including walking, running, swimming, crawling, or flying. Insects were the first animals to evolve flight, and today only insects, birds, and bats fly by flapping their wings. Insects evolved as wingless creatures about 400 million years ago but sometime between 300 and 400 million years ago insects with primitive extensions of cuticle from the thorax, presumably the beginning of wings, appeared in the fossil record. Several theories as to how insect wings might have evolved have been advanced, but none is universally supported. Flight no doubt gave insects a vast advantage over other terrestrial arthropods by allowing them to search widely for patchy food resources, escape predators, seek food, shelter, mates, find oviposition sites, and migrate in search of new habitats to escape limited food supply or other unfavorable environmental conditions. Locomotion has been highly important in the evolution of insects.

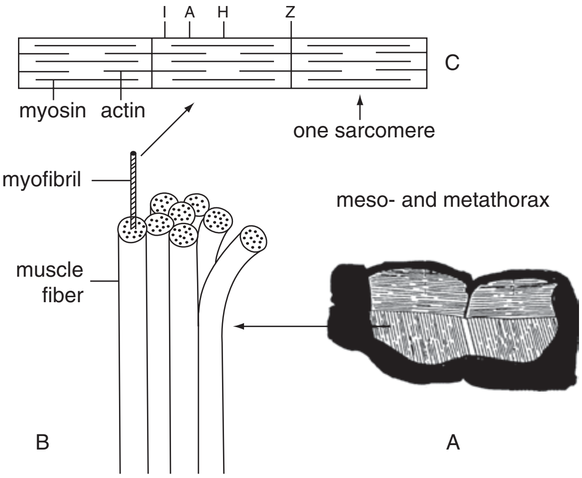
Movement in the animal kingdom is possible because of a series of linear protein molecules that shorten or contract when the appropriate chemical and physical conditions exist. These proteins will shorten when suspended in a cell-free buffer in a test tube, but of course in animals they are organized into a highly complex array in cells or fibers that form muscles. Although muscle proteins can shorten, they cannot lengthen by themselves. They must be stretched to their original length by an antagonistically arranged muscle or, in some cases, by the natural elasticity of a physical structure such as the insect cuticle. Antagonistic muscles are common in the appendages of insects and nearly all other animals. When an insect leg flexes (bends) because of contraction of one set of muscles, another set must contract to extend the leg, which then stretches the flexor muscles to their original length. Tymbal muscles that pull the thin cuticle of a cicada's sound-producing tymbal inward until it clicks into a new position are not arranged antagonistically, but when the muscle stops shortening, the elastic cuticle snaps back into its original position and stretches the muscle. Rapid repetition of tymbal muscle contraction followed by the elastic pull of the cuticle creates the high-pitched trilling sound we hear when cicadas call. Thus, in addition to enabling simple locomotion, contractile proteins created opportunities for insects (and other animals, too) to evolve chewing, digging, singing, oviposition, movements of the alimentary canal that aid digestion, and many complex behavioral displays of wing, antennal, and body movements during courtship displays and mating. The subject dealt with here, however, is limited to locomotion made possible by legs and wings and their associated muscles.

Skeletal Muscle Structure and Physiology

The skeletal muscles that enable leg and wing function are composed of relatively long muscle fibers composed of cells whose cell boundaries are no longer distinct. Still evident, however, are the nuclei from these cells, so muscle fibers appear to be multinucleate. In muscles of the alimentary canal, individual cells are short, cell boundaries are distinct, and the cells are uninucleate. Muscles are usually divided into broad categories such as skeletal-, flight-, heart-, alary- (associated with the heart), and gut muscles based on location within the body, structure, and function. Regardless of the type of muscle, the contracting units are called sarcomeres and each sarcomere is composed of several proteins including actin and myosin. The energy for muscle contraction is supplied by mitochondria. In flight muscles the mitochondria are abundant, and so large and irregularly shaped that they were first called sarcosomes, i.e., muscle bodies, because it was not certain that they should be considered the same as the much smaller mitochondria of many other cells (Fig. 52). After extensive physiological and biochemical research, sarcosomes were shown to have all the functions of other mitochondria. All mitochondria function aerobically, and oxygen is supplied to the large mitochondria of insect muscles by tracheoles that terminate only a few micrometers away from the mitochondria, after the tracheoles have indented the muscle cell membrane like a finger pushed against a soft balloon. Such tracheoles are called "intracellular tracheoles" although they are not really inside the muscle cell membrane. All insect muscle (and skeletal muscle of other animals) has a striated appearance in microscopic sections and the generally the striations or bands of adjacent myofibrils are aligned side by side (Figs. 53). The various bands or striations were designated by letters of the alphabet long before much was known about the chemical or physiological nature of the bands. Thus, there are A, H, I, M and Z bands. Z bands set (Figs. 52 and 53) the boundary of a sarcomere, and the other bands occur within the sarcomere. A skeletal muscle is composed of thousands of sarcomeres arranged end to end. A sarcomere typically is 2–3 μ m long in a muscle at rest, but longer sarcomeres occur in some very slow contracting muscles. Since the sarcomere is the contractile unit, the distance between Z bands decreases upon shortening. Shortening requires some finite time, and there is some relationship



Locomotion and Muscles, Figure 52 **A transmission electron microscope view of flight muscle showing periodic Z bands as dark lines across the muscle fibers and large sarcosomes (mitochondria) between the muscle fibers (photo courtesy of Jimmy Becnel and Alexandra Shapiro).**



Locomotion and Muscles, Figure 53 **Drawings to illustrate the subunits of muscle. (a) The large dorsal longitudinal and dorsoventral muscles in the meso- and metathorax that change the shape of the thorax and cause the down stroke and upstroke, respectively, of the wings; (b) Individual muscle fibers, with muscle fibrils (myofibrils) represented as black dots at the cut end of fibers, with one myofibril drawn as an illustration; (c) Three repeating sarcomere units among the thousands that occur along the length of a myofibril. Each sarcomere contains the linear proteins actin and myosin, as well as other proteins important in muscle function. I, A, H, and Z refer to the banding pattern that can usually be seen in muscle.**

between the length of sarcomeres and the speed of contraction. It is known now that the Z line is a plate-like sheet of protein to which actin and some other muscle proteins are attached. Actin filaments are about 5 nm in diameter, and extend from the Z line to about two-thirds to nearly the mid-point of a sarcomere. Myosin filaments, about 20 nm in diameter, lie between the actin filaments, across the middle of the sarcomere, but usually do not extend to the Z line. The various overlapping regions of myosin and actin filaments give muscle in thin histological sections its banded or striated appearance as light passes through regions of different density. The A band appears dark because light must pass through the overlapping regions of actin and myosin filaments, while the H zone in the middle of the sarcomere and the I band near the Z line transmit more light because those regions contain only myosin or actin filaments, respectively. The M line across the middle of the H zone is created by cross-links between myosin filaments that help hold the myosin filaments in place. The zones are of variable length in different muscles, depending upon the degree of overlapping of filaments. The width of the H zone bears some relationship to how much the sarcomere (and thus the whole muscle) will shorten upon stimulation and how fast it can accomplish its shortening. Muscles with very narrow H and I zones, such as fibrillar muscles that cause the wing movements in Diptera and Hymenoptera, shorten only a small amount upon contraction (2–3%), while some muscles may shorten much more. Each skeletal muscle is composed of multiple numbers of muscle fibers, although there may be only a few individual fibers in very small muscles. Muscle fibers can be separated into myofibrils, which are long linear arrays of sarcomeres containing actin, myosin, and other important proteins necessary for muscle function.

At the biochemical and molecular level the physiology and biochemistry of muscle contraction appears to be the same in insects as in other organisms. The sliding filament theory in which actin and myosin filaments slide over each other, drawing Z bands closer together, and thus shortening the entire muscle, adequately explains insect muscle contraction.

Muscle Attachments to the Exoskeleton

Skeletal and wing muscles are anchored to a relatively non-moveable part of the exoskeleton, and this anchor point is called the origin of the muscle. The other end of the muscle, called the insertion, is attached to a moveable part of the body, such as a wing hinge, an appendage, or a movable part of the exoskeleton. Skeletal muscle and wing muscles usually are anchored to the epicuticle layer of the exoskeleton. Recall that a single layer of epidermal cells lies just beneath the cuticle, so a skeletal muscle must attach first to the basal side of the epidermal cell. Recent research indicates that a protein encoded by the *dumpy* gene acts as the cement to attach the muscle cell membrane to the epidermal cell membrane. Bundles of intracellular microtubules arise at the muscle-epidermal cell contact point, extend through the epidermal cell to the apical membrane surface where they are cemented by dumpy protein to chitinous fibers called tonofibrillae in the cuticle. Tonofibrillae pass through the cuticle and anchor upon the epicuticle. Thus, although muscle cells do not themselves pass into the cuticle, they are nevertheless anchored to the epicuticle, the hard outer shell of the cuticle that provides a strong anchor for powerful muscles that power wing movements and jumping, running, swimming and digging legs. Tonofibrillae are very resistant to the action of molting fluid, and allow muscles to remain attached to the exoskeleton after apolysis and secretion of new cuticle begins. This is beneficial to many molting insects because apolysis occurs in some insects hours or even days before ecdysis, and movement during the interval between apolysis and ecdysis may be critical to feeding and predator escape. The final loosening of the tonofibrillae has not been elucidated, but once they detach, reattachment to the new epicuticle occurs rapidly. The old cuticle then is shed, and most insects rest quietly for some minutes or hours immediately after molting until the new cuticle has hardened, and can act as a strong support for the skeletal muscles.

Neural Control of Muscles

Because of the small size of insects, only a few neurons can be allocated to control each muscle. Muscles of very small insects are, of course, also small, and a muscle that moves a leg may be composed of only a few muscle fibers in some insects. Only two stimulatory neurons, commonly described as the slow neuron and the fast neuron, serve skeletal and other muscles in many cases. Large muscles, such as the jumping leg muscles in a large grasshopper or locust, may receive 4 or 5, or rarely a few more, stimulatory nerves. Both fast and slow axons break into a number of arborizations at the muscle surface and make multiple contacts with the muscle fiber. These multiple contacts ensure that the neural stimulus is rapidly communicated to the entire length of the muscle fiber. This is called multiterminal innervation, and it is common in invertebrates, but represents a major difference in muscle innervation between invertebrates and vertebrates. In vertebrates, a neuronal branch makes only one contact with a muscle fiber, and the muscle fiber itself conducts the electrical stimulus along its length. Although insect muscle fibers can be made to conduct an electrical stimulus like vertebrate fibers under certain experimental conditions, they seem not to do so in the living insect. Hence, the evolution of the multiple nerve contacts ensures that the neural stimulus is rapidly communicated to the entire muscle.

The fast axon sends multiple terminals to all or most of the muscle fibers in locust jumping leg muscle, but the slow axon makes junctional contacts with only 30–40% of the muscle fibers. This arrangement allows the locust (and similar insects) to make a maximal response (a jump) when the fast axon carries the nerve impulse to all the jumping muscle fibers, and a slower, graded walking response when the slow axon carries the nerve impulse. The routing of the nerve impulse through the fast or slow axon is controlled in the central nervous system of the insect. A third type of neuron, one that produces an inhibitory response, has been found in the jumping leg muscles of several insects. The overall effects of these three potential types of neurons feeding a muscle may be additive, and we might represent the fast and slow axons with a plus sign (+), and the inhibitory one with a minus sign (−). If the central nervous system of the insect specified some intermediate action between "jump" and "walk," it is conceivable that it might send 5 plus signals (+++++) and two minus signals (− −); the overall effect achieved in the muscle is a graded contraction, neither maximal response nor the slowest response. It may be worthwhile to point out that inhibitory nerve action is considered to be important, indeed necessary, in all higher nervous systems.

The stimulatory transmitter chemical released from fast and slow nerve junctions with the muscle fiber is the amino acid L-glutamic acid. At inhibitory junctions it is gamma amino butyric acid (GABA). Although vertebrates use GABA as an inhibitory transmitter, they use acetylcholine as the stimulatory transmitter at neuromuscular junctions in skeletal muscles. Insects also use acetylcholine as a stimulatory transmitter at nerve to nerve contacts within the central nervous system (CNS). Thus, organophosphate insecticides, which inhibit the enzyme acetylcholinesterase, are quite toxic to both insects and vertebrates, but the principal site of action in insects is within the CNS, while in vertebrates toxic action occurs at both CNS and skeletal muscle sites.

Insect Flight

Perhaps the most important act of locomotion that an insect makes is flight. Unlike birds, the muscles that flap the wings do not attach directly to the wing structure, except in a few groups of insects to be described later. In most insects the large wing muscles actually pull upon the thoracic wall and change the shape of the thorax, and thereby cause the up and down movement of the wings. The thorax, although heavily sclerotized to withstand the pull of the flight musculature, is not composed of one large sheet of cuticle, but rather consists of plates that come together at definite suture lines. The whole is flexible enough for some change in shape with the contraction of muscles inserting upon it. The wings are attached to the thorax by a number of small, hard sclerites, the wing hinges, at the junction where the top of the thorax, the tergum, laps over the side and meets the pleuron or side plate. The wings pivot up and down over a heavily sclerotized finger-like fulcrum of cuticle, the pleural process, that is part of the pleuron. Thus, the wings function much like a seesaw, except that the fulcrum is very close to one end, the junction point of the wings with the thorax. As every collector of insects knows, the wings of insects are only in a stable position when positioned either up or down. The horizontal position of the wings of butterflies and moths preserved in an insect collection can be achieved only by pinning the wings in this position until the thorax dries.

The wing down stroke in the majority of insects is produced by contraction of dorsal longitudinal muscles in response to a volley of nerve impulses. The dorsal longitudinal muscles do not attach directly to the wing hinges, but their origin and insertion are on the hard cuticular processes at the anterior and posterior, respectively, of each of the meso- and metathoracic segments. When they contract, they arch the tergum and slightly lift the attachment base of the wings at the tergopleural junction. The dorsal longitudinal muscles work against the elasticity of the thorax and the resistance of the air beneath the wings. Arching of the thorax causes the wings to begin to move downward, approaching the unstable horizontal position, and with continued contraction of the dorsal longitudinal muscles they suddenly pivot releases the dorsal longitudinal muscles from most of the load against which they were acting, and they stop contracting. It is a general characteristic of all muscle that there must be a load to work against or contraction ceases.

If now the dorsoventral muscles receive a volley of nerve impulses, they begin to contract. These dorsoventral muscles cause the upstroke of the wings in all insects. These powerful muscles have their origin or anchor on the heavily sclerotized ventral thoracic cuticle. They insert on the tergum, the top plate of the thorax. When they contract, they pull on the tergum and reduce the arching of the thorax that was caused by the dorsal longitudinal muscles. The wings now start to move upward, reach the unstable horizontal position, and suddenly pivot into the up position. This reduces the load on the dorsoventral muscles and they cease to shorten, but decreasing the arching of the thorax stretches the dorsal longitudinal muscles back to their original length. A sudden stretch acts on muscle (all muscle) like a nerve stimulus, and can cause the muscle to contract provided the muscle is still in an active biochemical state. Thus, the antagonistic sets of muscles, the dorsal longitudinal and the dorsoventral muscles, alternately contract against the resistance of the wings moving through the air. As one set contracts, it stretches the other set, inducing a subsequent contraction in that set. When the wings pivot up or down, the load or resistance of the wings against the air is released for one set of muscles and introduced to the other set. These wing muscles are capable of making several contractions in this antagonistic harness mechanism to one volley of nerve impulses to each set. This enables some insects to beat the wings at a rate of several hundred times per second - for example, 180 beats per second for honeybees, about 180 for a *Drosophila* fly, 150 for a housefly, and as many as 800 to more than 900 in a very small *Chironomus* species of fly. The important point is that these small insects with small wings must beat the wings very fast in order to produce enough lift to stay in the air. The smaller the wing surface, in general, the faster the wings must beat to generate sufficient lift for flight. Insects with much larger wings, such as a swallowtail butterfly

(5 beats per second) and the desert locust (17 beats per second) can get enough lift from the larger wings without beating them so fast. The evolution of this ability to beat the wings several hundred times per second depends upon successful operation of several anatomical and physiological factors: (i) the anatomical arrangement of the antagonistic wing muscles, (ii) the unstable horizontal position of the wings, (iii) the pleural process over which they pivot, (iv) the way the wings are hinged to the thorax, (v) the short distance over which both sets of muscles must contract to produce wing movement (shortening of the muscle by about 2% of its length is sufficient to produce a down stroke or upstroke), (vi) the elasticity of the thorax, and (vii) persistence of the biochemically active state of the muscle for about one second following a nerve impulse. A control center in the thorax sends out periodic nerve impulses to each set of muscles to keep a flight rhythm going.

The muscles enabling several hundred wing beats per second are called asynchronous muscles because they are not dependent upon a nerve impulse for each contraction. They also are called fibrillar muscles because the muscle fibrils that make up a fiber are so large and are loosely packed into the muscle fiber with thousands of very large, irregularly shaped mitochondria lying between muscle fibrils. These mitochondria, of course, supply the vast amount of energy needed for the rapid wing beats. Asynchronous wing muscles are found in the fast flying insects and smaller insects; achieving multiple muscle contractions for each nerve impulse enables fast flight and flight with a small wing airfoil.

Most slow flying insects beat the wings much slower than 100 times per second, and the muscles that cause the wing movements must get a nerve impulse for each contraction. These muscles are called synchronous muscles, because their contraction is synchronized with the rate of nerve firing. The muscles that move the wings are still the dorsal longitudinal muscle set and the dorsoventral set of muscles. Nerves that innervate the muscles are not able to carry repeated nerve transmissions faster than about 100 nerve impulses per second, a rate that allows only 10 ms for the repolarization interval in a neuron. There are important morphological and physiological differences in the structure of the synchronous muscles that make it more difficult for them to maintain the biochemically active state as long as the asynchronous muscles do after a nerve stimulus. The active state in synchronous muscles disappears so quickly, that a stretch is not a sufficient stimulus for them to contract again as in asynchronous muscles.

Flight in Dragonflies, Damselflies, and a Few Other Groups of Insects

The Odonata, representatives of an early group to evolve, and a few other groups of insects, depart from the description above about how wing down stroke occurs. In these few groups, the down stroke of the wings is produced by the basalar and subalar muscles that are attached directly to the wing hinges. The basalar muscles insert on the anterior part of one of the principal wing hinges, and contraction pulls the wings downward, with the leading edge twisted downward. This downward twisting of the leading edge of the wing during the down stroke is common in all insects and is called pronation of the wing. The subalars insert on the main wing hinge at the base of the wing posterior to the pleural wing process, also pull the posterior edge of the wing downward, with some twisting of the trailing edge. In dragonflies and damselflies, the basalar and subalar muscles are large, powerful muscles that have to act on the very short end of the lever to pivot the relatively long wings over the pleural wing process against the resistance of the air. They are anchored to parts of the heavily sclerotized ventral and pleural cuticle. The upstroke in odonates and all other insects is produced by the dorsoventral muscles that reduce the natural arching of the thorax, as described above.

Control of Pitch and Twisting of Wings

In addition to flapping the wings, insects control pitch and orientation of the wings with respect to the plane of the body. The principal muscles involved in controlling wing pitch and twisting in most insects are the basalar and subalar muscles that attach directly to the wing hinge sclerites. In most insects these muscles are not strong enough to pull the wings downward in rapid flapping flight, but they can change the pitch of the wings. During downward movement, the leading edge of the wing pronates or tips downward as the basalar muscles contract. During the upstroke, contraction of the subalars pull the posterior edge of the wing downward (supinates the wing), again tipping the leading edge of the wing upward. These changes in shape and angle of attack of the wings are important in generating lift forces.

In Diptera and Hymenoptera, the tergum of the thorax is divided by the scutal cleft into two plates, the scutum and the scutellum. Sclerites at the posterior of the wing base join to the posterior plate, the scutellum. When the scutellum is pulled slightly forward by the contraction of the dorsal longitudinal muscles, the wing tilts slightly forward, or pronates, as it pivots down over the pleural process. Relaxation of the dorsal longitudinal muscles at the end of the down stroke allows the tergal plates to move further apart, and the wing tilts slightly backward (supinates) as it is forced upward by the contraction of the dorsoventral muscles. The wing tip describes a figure eight during flight.

Lift Produced by the Motion of the Wings

In order to stay in flight, insects like airplanes have to have enough lift beneath the wings to overcome body weight. Contrary to the flight of fixed-wing aircraft operating under steady-state conditions, insect flight is characterized by unsteady-state conditions in which there are brief high lift forces followed by lower lift forces, or even negative lift conditions. One example of unsteady-state lift conditions occurs in very small chalcid wasps and has been described as a "clap" and "fling" wing motion. In this small insect the wings "clap together" at the top of the upstroke, and then twisting motions controlled by some of the small muscles inserting on the wing hinges fling the wings apart at the start of the down stroke. The flinging motion sets up air movements that increase the lift force of the down stroke, and may aid very small insects to generate enough lift for flight in spite of having tiny wings. Larger insects may also utilize discontinuous lift forces. For example, some workers have measured large, transient lift forces 15–20 times the body weight of tethered dragonflies, with time-averaged lift values equal to 2–3 times body weight created by the turbulent flow of air generated by the independent movement of the front and rear wings.

Tethered tobacco hornworm moths (*Manduca sexta*) generate unsteady lift forces during the down-stroke of the wings equal to at about 1.5 times the body weight. Coincident with the lift forces generated by the down stroke movement, intense leading-edge vortices of low pressure air above the wings are created by the pronation of the wing (tilting downward of the leading edge) during the down-stroke. The vortices form first over the leading edge of the wing, move out towards the wing tips, and finally extend behind the insect in a ring of turbulent air. These low pressure vortices increase the lift of the down stroke. The high angle of attack of the wing, a condition that rapidly creates stalling in a fixed wing aircraft, creates the vortices. This condition of dynamic or delayed stall can be tolerated in an insect for the brief interval of one down stroke (an interval of only a few milliseconds) or upstroke, at the end of which the stall conditions are eliminated as the wings stop and change direction. Measurements have shown that energy input to mechanical output is about 3% in a katydid singing muscle to as high as 10% in flight muscles of *Drosophila hydei* fruitflies. Flight clearly is a very energy-demanding activity.

Walking and Jumping

Walking and jumping depend upon muscles in the legs. In walking or running, insects must coordinate six legs. Like many other repetitive, rhythmical actions, walking is controlled by a motor program – a coordinated set of nerve impulses that repeats over and over as long as walking or running continues. In the American cockroach, *Periplaneta americana* L., two neural control centers are localized in each of the pro-, meso-, and metathoracic segmental ganglion. One center in each ganglion controls the leg on one side of the body. A small number of master command neurons provides control over the individual centers and ensures that legs are coordinated in movement. Neurons from the control centers go to the flexor muscles that bend a leg and swing it forward for the next step, while others supply the extensor muscles that straighten the leg and allow the tarsi to make contact with the substrate on which the cockroach is walking. Both positive and negative feedback loops in the neural circuitry are coordinated so as to allow inhibition of one set of muscles (say the extensors) while the other set (the flexors, for example) is stimulated. Similar neural motor programs allow humans to walk and swing the arms without any conscious thought; fortunately so, because if one does think about the process, it becomes much harder to do.

The ability of some insects to jump many times their body length and height might suggest that insect muscles are stronger than vertebrate muscles. Actual measurements of the force developed per unit cross sectional area for insect muscles reveal about the same force per unit cross sectional area as for other animals. It is anatomical arrangement of muscles and appendages, as well as physiology and lever systems, which enable some insects to jump so far. For example, the main muscle in the femur of the jumping (metathoracic) leg of a grasshopper or locust is composed of many short muscle fibers that insert on the cuticular apodeme extending the length of the femur. The muscle fibers are anchored to the epicuticle of the femur. Upon contraction, each muscle fiber shortens very little and pulls only slightly off the perpendicular to the long axis of the femur. The many muscle fibers along the length of the long femur exert large force rapidly upon the tendon that straightens the leg and propels the locust into the air in a jump. Furthermore, the long femur and tibia of the metathoracic leg (which is much longer than either of the pro- or mesothoracic legs) give the locust something of a "pole-vaulting" advantage, similar to a human who uses a long pole as an extension of the arms during pole vaulting.

Very massive muscles, with fibers that shorten only a small percentage of the muscle length, enable fleas to make extraordinary jumps. Although not all fleas are equipped for major jumping activity, those that do jump have an extraordinarily large coxa, in contrast to most insects. Inside the coxa is a large muscle with fibers that are anchored to the thorax. The coxal muscle fibers insert on the femur, which also is large and long. Overall, the jumping leg is about 80% of the length of the body of a cat flea, and contains large muscles inserting on the tibia. In preparation for a jump, a flea utilizes a cocking mechanism in which the femur is pulled up to overlap the large coxa. In this cocked position both coxa and femur are perpendicular to the body axis and to the substrate. The cocking action compresses an arch of resilin, a rubber-like protein, in the pleural arch near where the coxa is attached to the thorax. In addition, the cocking action clamps the three thoracic segments together by engaging a "catch" mechanisms between the three thoracic segments. The flea holds the sternum of the mesothorax tightly against the metathorax, and this allows the large muscles involved in raising the femur and locking the catches to relax, resisting tiring and reducing energy requirements. In this crouched position, a flea is poised for its leap with trochanter and tibiotarsal joint and most of the tarsi resting on the substrate. The flea propels itself into the air by relaxing the levator muscle holding the femur in the perpendicular position and relaxing the ventral longitudinal muscles holding the catches in the cocked position. The compressed resilin, like a compressed spring, forcefully drives the trochanter against the substrate to provide the initial leverage off the substrate. Powerful muscles extend the joint between the trochanter and the femur, and extend the leg providing further thrust as the terminal tarsal segments and tarsal claws press against the substrate. The long jumping legs aid the leap.

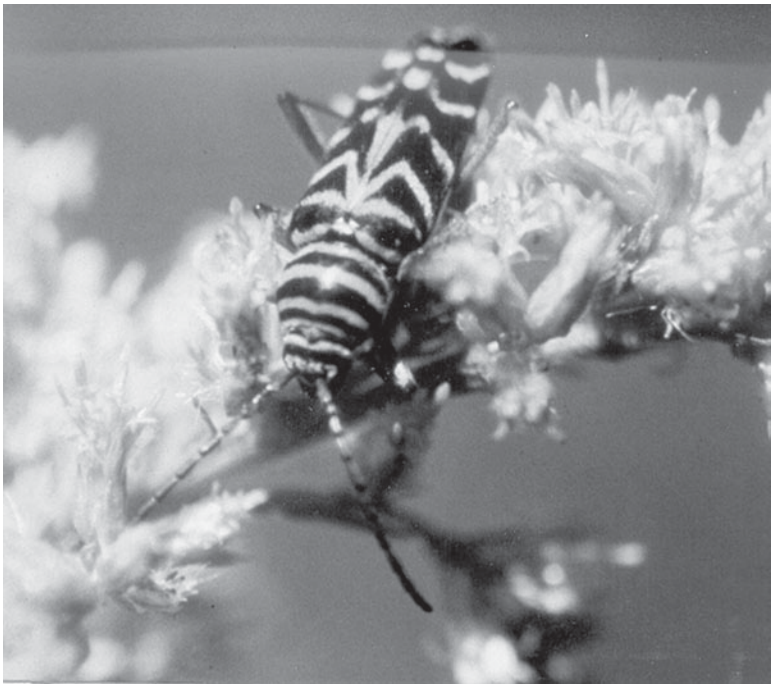
Locust Borer, *Megacyllene robiniae* (Forster) (Coleoptera: Cerambycidae)

DAN M. HARMAN
University of Maryland, Frostburg, MD, USA

The locust borer, *Megacyllene robiniae* Forster inflicts severe damage upon its host, the black locust tree, *Robinia pseudoacacia* L. Damage is encountered as the larva develops, tunneling first in sapwood and then in heartwood, in the host. The locust borer is monophagous, capable of developing on only one host, the black locust tree. Whereas the usual habit of longhorned beetles is to enter and destroy trees already weakened or dead, the locust borer invades only living trees, which are not normally killed, but suffer structural weakening and deformity, depending upon the numbers of borer tunnels in the trunks. The locust borer retains another habit of adults of the Cerambycidae; that of feeding on flowers. In this case, it feeds on goldenrod (*Solidago* spp.). Locust borer adults feed on (Fig. 54) pollen of goldenrod blossoms during August and September, where they are easily collected, and are frequent representatives in insect collections. As they occur on the goldenrod, intermingling with yellowjackets, wasps, and bees, they exhibit classic Batesian mimicry, with color patterns resembling the stinging hymenopterans, which may ward off predators.

Host, Range, and Impact

Aside from pollen-feeding by adults on bright summer flowers, the locust borer's main host is a valuable tree, native to the eastern United States. Researchers have determined that the original range of black locust was restricted to the Appalachian mountains form Pennsylvania to Georgia, and to portions of Arkansas and eastern Oklahoma. Best growth of black locust is reportedly the west slopes of the Allegheny ridge, in the mid-Atlantic region, and quality of growth recedes with distance eastward and westward from the ridge feature. However, humans expanded its range, beginning early in American history, because of certain properties of its wood, i.e., hardness, strength, and resistance to rotting. In addition, it is in the family Leguminosae, and has nitrogen-fixing properties. Thus, it survives when planted under adverse conditions, such as the exposed mineral soils from coal strip-mining, and depleted soils, where other species fail. Ecologically, it is termed a "pioneer" species, with thin crown allowing much light to the forest floor, being first to occupy openings and fringes, and later giving way to other tree species with thicker



Locust Borer, *Megacyllene robiniae* (Forster) (Coleoptera: Cerambycidae), Figure 54 Locust borer adult on goldenrod.

crowns. Farmers value it highly for posts, planks and structural material; shipwrights sought it for their trade. In New England, a local strain was named "shipmast locust" because of its straightness, height, and clearness of bole. The available trees were quickly cut, but the search was on for other sources of so-called "shipmast" locust. It was soon recognized that the supply of locusts with superior bole form was limited, but stands of reasonable quality could be found, and their seeds transported by settlers westward, northward, and across the seas. It now is common in the Pacific northwest, into British Columbia, and up the Atlantic seacoast to Nova Scotia, where it is seen planted along roadsides. It is now reported to be one of the most planted tree species in the world. The locust borer followed its host to its new areas in North America, but not in Europe, which is free of the insect and its damage.

The effect of the locust borer on the black locust tree is sustained and intense in most of its native localities. The larval tunnels typically start with a cavity, advance toward stem center through sapwood and into heartwood, and loop back in opposite direction 5–8 cm. Tunnels, with diameters of 5–8 mm, may heal over at their surfaces, but not in the inner wood, where they remain for the life of the tree. Numbers of tunnels per tree therefore accumulate with time, and vary in number per unit of trunk length. Among foresters and producers, the price per 6 ft (2 m) post is affected if more than 7 borer mines are present. Many trunk lengths sustain far more borer attacks than tolerable, and are deemed unacceptable. Where black locust is planted for coal strip-mine revegetation, devastating borer damage often renders the crop a loss for products, but the tree's ability to survive, fix nitrogen, and provide cover for other species keeps it in an important element in land reclamation; it survives where other species die.

Life Cycle

The locust borer is univoltine, having one generation per year. Adults are present from early

July until late September or early October, but disappear with onset of heavy frosts. They aggregate on blossoms of goldenrod, where they mate, and also feed on pollen from the flowers. Experiments have indicated they are not dependent on goldenrod pollen for survival, though it is normally present in the gut. They have been observed on other yellow flowers such as sunflowers, and in the absence of the goldenrod would probably feed on pollen from other species, but they nonetheless frequent the yellow goldenrod, which is usually found near black locust groves, and whose flowering period parallels the presence of locust borer adults. They may use the various goldenrod species, but the greatest numbers are found on the prominent *S. altissima* L. They are strong flyers, and fly back and forth from goldenrod to locust trees. Once on the trunks, females search out crevices on outer bark for egg deposition. Eggs are deposited singly, and hatch in about 10 days. The newly-hatched larvae then bore into the outer bark, where they overwinter. In milder seasons, some excavation at the cambium layer may occur in fall. In spring, the young larvae resume feeding activity, first (Fig. 55) hollowing out a cavity, then proceeding to tunnel inward toward stem center. Tunneling activity proceeds from May through most of June, at which time the fully-grown larvae pupate, behind a plug of shavings. The pupal stage lasts about 8–12 days. Prior to pupation, the larvae push excavated material back to the cavity and out to the trunk surface. The white boring dust, usually wet with sap, can be useful in finding active attacks. Because the new adult must exit through its larval tunnel, a proper-sized opening to exterior must be

Locust Borer, *Megacyllene robiniae* (Forster) (Coleoptera: Cerambycidae), Figure 55 **Locust borer larval tunnel, 3 to 4 yrs old, with wound surface healed over (*left*); locust boring dust on trunk, from active larval tunnels (*right*).**

maintained. In healthy trees, energy is expended to repair and seal over the wound entrances, which may be closed by the time of adult emergence, requiring that the adult chew its way out or die within the tunnel. Only a small percentage of those which have successfully pupated fail to exit the tunnels. With the onset of July, adults are again seen in the field, to begin the life cycle anew.

Control/Suppression

Although the tools are available, none of the artificial control measures against the locust borer are recommended. Researchers have experimented with a variety of approaches, including contact pesticides applied to tree surfaces, and systemic insecticides which can be absorbed within stem tissue. The dispersal of locust trees throughout the regional landscape renders most poisoning efforts costly, plus environmentally unacceptable. Parasites and predators have only slight effect, although ichneumonid wasps, garden spiders, woodpeckers, and others have been observed. The most commonly-suggested approach to damage reduction is to encourage growth of black locust on better sites, combined with sanitation removal of heavily-attacked trees. Some older trees, even on average or good sites, become weakened through aging, breakage, fungal attack, and similar causes, and assume the characteristics of "brood" trees for the locust borer. Managers normally seek out and remove such trees, promoting healthier growth, and conduct thinnings to avoid excessive crowding and establish desired stand composition. Unfortunately, some circumstances contribute to the problem, such as occur when black locust is planted for reclamation on stressed sites. In this situation, tree health and vigor are compromised, and borer populations increase. Better sites, and healthier trees, incur fewer borer tunnels. Deep soils with limestone outcrop may be seen supporting black locusts with improved stem form and reduced borer damage. An exaggerated view of the effect of site may be seen where heavily attacked black locusts occur on mineral soils of coal strip-mined lands, directly adjacent to lightly-attacked locusts on undisturbed soils nearby.

Ecological Overview

Tropically, the locust borer may be viewed as a consumer in reasonable balance with its host, in that its invasions do not result in (immediate) host mortality. Actual long-term damage varies with vulnerability of individual trees, and is influenced by many factors. Wound entrances become feeding sites for a group of organisms, including nitidulid beetles, dipterans, nematodes, mites, and others. The subcortical cavities at wound entrances shelter the sap-feeding guild, and many of these organisms, particularly mites, nematodes, and others, may be dispersed as winged borers depart the tunnels. The cavity organisms appear to progress with little effect on the borer larva or the tree. However, the sap-feeding organisms may also feed upon, and disperse, the fungus, *Fomes rimosus* (Berk.), which is present in the wood tissue of a vast percentage of black locust trees. The role of the fungus in relation to the locust tree and the borer is poorly known, but the fungus may be observed to cause a yellow heart rot in living tissue throughout the range of the tree, and perennial hard woody conks on the trunk surfaces of badly infected trees. The fungus likely reduces the tree's ability to overcome the invading borer larvae, and the hyphae and spores probably serve as food for the larvae within the tunnels. The locust borer is also labeled a disperser of *F. rimosus*, which infects a vast percentage of living black locust trees (it is also reported from mesquite, but from few if any others). The fungus, though an invader of living tree, also performs the essential function of decomposition of dead material on the forest floor. Other factors should also be mentioned. With their pollen feeding habit, locust borer adults perform cross-pollination in the forest ecosystem, an activity of increasing importance, due to loss of many native pollinating insects. In the present day of stressed environments, pest suppression tactics must be considered in terms of ecological impacts, as well as economic ones, and a balance must be sought which is not too costly to either.

Lodging

Toppling of crop plants, often in association with wind or rain, but ultimately due to destruction of roots by insects.

Loew, Hermann

Herman Loew was born in Weissenfels, Germany, on July 19, 1807. He is considered to be the "father of dipterology." He graduated from the University of Halle later and taught natural history, philosophy, and math at that institution as well as other schools and as a private tutor. He received recognition for publication of his "Horae anatomicae," a treatise on anatomy, particularly genial anatomy. Though participating in only one major international expedition, to the Orient, it proved to be a very important and productive trip. He described over 1,300 exotic species from this expedition. Over the course of his life, he described another 2,700 European species. In addition to his scientific studies, Loew was active in politics, serving in the parliament in Frankfurt. He became frustrated by politics, however, and in 1850 returned to teaching, which he continued until 1868. He then devoted his time to entomological research until 1873, when he returned to politics, accepting a seat in the Berlin legislature. Loew suffered a stroke in 1876, and though experiencing partial recovery, died April 21, 1879.

Logistic Growth

Population growth in which the growth rate initially is exponential, but as the ideal circumstances deteriorate due to competition for resources and the impact of natural enemies, the rate of population increase decreases. The curve describing this relationship (number of individuals and time) is S-shaped.

Logistic Model

A type of optimum growth model in which the growth is predicted from the overall function of population growth without specific consideration of specific elements such as mortality and recruitment.

Log-Normal Distribution

A frequency distribution of species abundances in which the log number of individuals represented in a sample is plotted on the X-axis, and the number of species is plotted on the Y-axis.

Loiasis

A disease cause by infection with *Loa loa*. These filarial worms develop in tabanid flies (Diptera: Tabanidae) and are passed to vertebrates when the flies feed on blood. It occurs only in forested areas of central Africa. The human form is vectored by *Chrysops silacea* and *C. dimidiata* deer flies. Another form occurs in monkeys. Years may pass before infection is evident. Diagnosis is accomplished by finding microfilariae in the blood. The worms are sizeable, with females attaining a length of up to 70 mm. They migrate under the skin, inducing inflammations called "Calabar swellings." The swellings, often on the wrists and ankles, are due to an immune response to the filariae. The filariae can also be seen in the cornea and conjunctiva of the eye, hence the term "eye worms." They may migrate to the brain as well, inducing encephalitis.

Lonchaeid Flies

Members of the family Lonchaeidae (order Diptera).

► Flies

Lonchaeidae

A family of flies (order Diptera). They commonly are known as lonchaeid flies.

► Flies

Lonchopteridae

A family of flies (order Diptera). They commonly are known as spear-winged flies.

Longhorned Fairy Moths (Lepidoptera: Adelidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Longhorned fairy moths, family Adelidae, comprise 295 species worldwide, but most are Palearctic (143 sp.); actual fauna probably exceeds 400 species. The family is in the superfamily Incurvarioidea, in the section Incurvariina, of division Monotrysia, infraorder Heteroneura. There are two subfamilies: Nematopogoninae and Adelinae. Adults minute to small (4–29 mm wingspan), with head very rough-scaled and with large eyes; haustellum reduced, scaled; labial palpi upcurved (sometimes strongly scaled); maxillary palpi 2 to 3-segmented (rarely 4 to 5-segmented); antennae extremely long (often 2× wing lengths) in males (Fig. 56), but of average length in females, although often thickened in both sexes toward bases. Maculation is often very colorful, with iridescent markings, and with wings rather elongated. Adults are usually diurnal but a few are crepuscular. Larvae are leafminers, but in later instars change to casebearers. Host plants include a number of different plant families.

Longhorned Fairy Moths (Lepidoptera: Adelidae), Figure 56 Example of longhorned fairy moths (Adelidae), *Nemophora polychorda* (Meyrick) from Taiwan.

Longhorned Grasshoppers

This term is sometimes applied to the katydids in the order Orthoptera: Tettigoniidae.

► Grasshoppers, Katydids and Crickets

Longicorn, Longhorned, or Round-Headed Beetles (Coleoptera: Cerambycidae)

QIAO WANG
Massey University, Palmerston North, New Zealand

The family Cerambycidae belongs to the suborder Polyphaga of the order Coleoptera. Classification of higher taxa such as subfamilies is still controversial but the most recent treatment (Lawrence and Newton 1995) is considered here.

Order: Coleoptera
Suborder: Polyphaga
Superfamily: Chrysomeloidea
Family: Cerambycidae

Thirteen subfamilies are included in the Cerambycidae: Vesperinae, Oxypeltinae, Disteniinae, Anoplodermatinae, Philinae, Paradrinae, Prioninae, Spondylidinae, Apatophyseinae, Necydalinae, Lepturinae, Cerambycinae, and Lamiinae. Lamiinae and Cerambycinae are the most speciose subfamilies.

External Morphology

Cerambycid adults range from 3 to 85 mm in length. Color varies greatly from very bright to dark gray or black. They are usually elongate and cylindrical with long antennae inserted on frontal prominences (Fig. 57). Antennae have 11 segments. Eyes are usually emarginated, surrounding the antennal insertions. Tarsi of most longicorn beetles appear 4-segmented with the third segment bilobed, but are actually 5-segmented with the fourth segment small and concealed in the notch of the third and not easy to see. Sexual dimorphism is most commonly reflected in greater ratio of antennal length vs. body length in male than in female.

The larvae are elongate, cylindrical and almost legless, and usually whitish or cream in color. The anterior end of the body is rounded. Therefore, they are called round-headed borers, to distinguish them from flat-headed borers (larvae of Buprestidae), whose anterior end of body is broadened and flattened.

Biodiversity and Life Cycle

Cerambycidae are one of the largest beetle families in the world, with over 35,000 described species in

Longicorn, Longhorned, or Round-Headed Beetles (Coleoptera: Cerambycidae), Figure 57 ***Epithora dorsalis*** **adult.**

about 4,000 genera worldwide. Its species are distributed in all biogeographic regions including Palaearctic, Oriental, Afrotropical, Australian, Neotropical, and Nearctic. However, the distribution pattern varies at subfamily level. For example, Cerambycinae, Lamiinae and Prioninae occur in all regions, but Lepturinae, Aseminae and Disteniinae are naturally absent from Australian region. More than 50% of cerambycid species are found in the tropics.

Eggs are usually laid in, or on, larval host plants and hatch in 6–25 days depending on species and temperature. Neonate larvae in the vast majority of species immediately bore into the hosts and make tunnels. Those of a few species start feeding on roots. Tunnels made by longicorn larvae are usually more or less circular in cross section and go straight for a short distance before turning. Length of the larval stage varies greatly depending on species and climates, being from 2 months to 3 years. They usually pupate in pupal cells inside the host plants (most) or in the soil (some). The adult, after eclosion, may remain in the pupal cell for days, or even months, before emergence from the host. Many longicorns do not hibernate, as their feeding stages are in quite stable environments (inside plant hosts or in the soil). In species with a lifecycle longer than a year, larvae may continue to feed all year round, but reduce feeding rate during cold months. Cerambycids can overwinter as larvae, pupae or adults.

Habitats and Food

Longicorn beetles occur almost anywhere the higher plants exist. Larvae of most species are borers, feeding on solid tissues of living, dying, dead or rotten plants. Most species are woodborers, such as *Anoplophora*, *Monochamus*, and *Phoracantha*; some are herbaceous plant feeders such as *Tetraopes*, *Phytoecia*, and *Paraglenea*; and a few are root feeders such as *Prionus* and *Dorysthenes*. Most woodborer (Fig. 58) species feed on subcortical tissues, at least initially. They may later burrow further into sapwood and even hardwood to continue feeding. Herbaceous feeders usually bore in host stems. Root feeders may bore in the roots, hollowing out and killing the roots of the host plants, or live in the soil and feed on the roots of grass and other small annual or perennial plants.

Each species has its range of host plants. In general, species feeding on dead or rotten plants have a very wide host range. Some of these species may be able to develop on wood of many plant families of both coniferous and nonconiferous origin (for example, most species from Parandrinae, Prioninae, Lepturinae, and some primitive Cerambycinae and Lamiinae). Most others are limited to families of either gymnosperm or angiosperm hosts (for example, Spondylinae, Aseminae and less specialized Cerambycinae are largely limited to gymnosperms while most Lamiinae and

Longicorn, Longhorned, or Round-Headed Beetles (Coleoptera: Cerambycidae), Figure 58 ***Oemona hirta*** **larva.**

Cerambycinae are restricted to angiosperms). Living or healthy plant feeders have much narrower host range, and dying or sickly plant feeders fall in between. Living plant attackers employ different strategies to consume the hosts. They may destroy the heartwood of a tree or branch but allow the living tissue to remain alive, such as *Pyrotrichus vitticollis*, or make tunnels in the (Figs. 58 and 59) cambium and heartwood in turn to avoid killing the host, such as *Oemona hirta*. The larvae of many living plant-feeders will die if the hosts are cut before they mature, such as *Saperda* and *Goes*. The host range of living- and stressed plant-feeders is usually quite stable in their natural and native habitats. However, these beetles can shift and expand their host range to attack introduced plant species, or once they are introduced to a new habitat they may attack plants there and establish new beetle-plant relationship. Furthermore, closely related longicorn species are usually sympatric with quite different host plants, but closely related allopatric species usually have identical or closely related host plants.

Longicorn, Longhorned, or Round-Headed Beetles (Coleoptera: Cerambycidae), Figure 59 **Citrus twigs damaged by *O. hirta*.**

Adults are free-living insects. All subfamilies have both diurnal and nocturnal species in adult stage. Adults of most species from Lamiinae, Paradrinae, Prioninae, Spondylidinae, and Aseminae are nocturnal while those of most species from Cerambycinae, Lepturinae, and Necydalinae are diurnal. Most nocturnal species are attracted to light. Diurnal species are usually bright in color and their eyes are finely faceted while nocturnal ones are usually dark in color and have coarsely faceted eyes. Most species can fly and some are flightless. Most flyers fly at dusk or night, but flower visitors are usually active during the day and are faster flyers.

Although some longicorn adults appear to require little or no food, most species need some feeding for egg maturation and oviposition. They feed on foliage, tender bark, shoots, flowers (including stamens, pollen and nectar), roots, coniferous cone, seeping sap or even fungi. Lack of feeding in the adult stage appears to be common among root and dead-wood feeders in larval stage. Adult feeding behavior usually plays an important role in sex location in longicorns. Adult feeding is usually insignificant to plants, but flower visitors help pollinations through feeding and other activities.

Host Finding and Selection

Location and selection of hosts for oviposition by adult longicorns are critical because the larvae are usually incapable of moving between hosts. Chemical cues appear to play an important role in host finding and selection by longicorn beetles. There is a definite succession of species which visit felled or wind-broken logs; the species which arrive a day or so after felling are quite different from those which appear a week or two later. Obviously the chemical changes in the logs have a selective effect on the beetles. For example, *Monochamus* species are attracted by pine terpenoids and ethanol; some *Phoracantha* species are attracted to newly felled or heavily stressed eucalyptus trees; and some *Arhopalus* species are attracted to newly burned pine forest for oviposition.

Baits for attraction of longicorn beetles exhibit similar selectivity in different stages of fermentation. Fermenting baits have been used as a means of attracting adults, as have natural sites of oozing saps. American entomologists reported the attraction of watermelon rinds of different fermenting stages to *Dendrobias* and *Eustromula* adults. Beers can also attract some cerambycid adults in the field.

Reproduction

Adults of longicorn beetles can usually live for weeks and a few can live for up to 8 months after emergence from larval hosts. During this time, main activities of adults are for reproduction. Males of a given species usually emerge earlier than the females and play the active role in mate location.

Sex pheromones are reported in many longicorn beetle species, but long-range sex pheromones appear to be associated only with a few species that do not feed in the adult stage. Most sex pheromones are operative either in short distance (~1 m), such as in the root-feeding *Migdolus fryanus* and the vine-boring *Xylotrechus pyrrhoderus*, or in contact, such as in the wood-boring *Anoplophora chinensis* and *Nadezhdiella cantori*. In some species such as *Phytoecia rufiventris*, no evidence of any kind of sex pheromones is found. Because long-range sex pheromones are not involved in mate location in most cerambycid species, other mechanisms must have evolved to bring both sexes together for mating, which may take place on the larval or adult hosts.

If both sexes visit the larval host for feeding, then mate location, mating and oviposition usually also occur on the same host. During their presence on the host, they may make a series of brief matings at intervals, with mating and oviposition taking place in turns, such as *Oemona hirta* and *Monochamus scutellatus*. In some species, however, mating and oviposition are two clear-cut phases and after mating the female oviposits either alone or with the attendance of her mate, such as *Anoplophora chinensis*. In many diurnal and flower visiting species (mainly in Lepturinae and diurnal Cerambycinae), mate location and mating occur on flowers of plants, either the same as or different from the larval hosts. Both males and females visit the flowers for feeding and sex. Females leave for the larval host for oviposition after mating, such as *Strangalia davidi* and *Zorion guttigerum*. Oozing saps from plants also bring sexes together in the species whose adults feed on oozing saps, such as *Dendorbias mandibularis*. When sex ratio is male-biased, male-male competition is common. They usually show strong territorial defense and/or mate-guarding behavior. In general, larger males are advantaged in fighting, but the size-dependent advantage may or may not translate into mating success.

Lamiine adults usually prepare the oviposition sites using mandibles, and lay eggs in slits cut by mandibles. Some genera from this subfamily even girdle the plants before making oviposition slits. For example, the parent beetles of *Oncideres* and their relatives completely girdle twigs and branches and then lay eggs beyond the girdle, thus providing freshly killed tissue in which their larvae can develop. Species of *Phytoecia* also girdle the twigs or shoots, but they lay eggs slightly below the girdled point and neonate larvae bore away from the killed part of the twigs or shoots. Most adults of other subfamilies lay eggs exclusively with the aid of the ovipositor. They deposit eggs on the bark or outer surface of the host such as *Spondylis*, in bark cracks or under bark scales such as most species that use the ovipositor only, in cracks and crevices in wood such as *Arhopalus* and *Hylotrupes*, in holes in plants made by other insects such as some lepturines and prionines, or in the soil such as many prionines.

Associations with Other Arthropods

Many arthropods are associated with longicorn beetles. Some of the most spectacular associations among arthropods occur between longicorns and mites. Many species of mites use longicorn beetles as vehicles for dispersal, and this phenomenon has been termed phoresy. Mites in longicorn larval galleries disperse with adult beetles to new, suitable habitats. In return, the longicorn may benefit as the mites they carry may help clean their larval galleries by feeding on fungi, nematodes and debris that may be harmful to the beetle larvae. In this way, commensalism or mutualism may be established. There is also the possibility that this might evolve further so that the mites become parasitic or even parasitoidal on longicorns.

Many insect parasites and predators are associated with longicorns. Ichneumonidae and Braconidae are among the most important parasitoids of longicorn larvae. Encyrtidae parasitize eggs. Clerid beetles prey on both eggs and larvae. There are also reports of longicorn parasites and predators in the orders Diptera and Hemiptera.

Economic and Ecological Importance

Cerambycidae are of high ecological and economic importance. They are responsible for the damage to forests, ornamental trees and tree crops. Heavy attacks usually occur in dense monoculture, and stressed/dying trees (such as fire damage, water stress, and lack of light due to high density). The genera *Monochamus* (on pines) and *Phoracantha* (on eucalyptus) contain some of the most important forest pests in the world. *Megacyllene robiniae* (on black locust), *Saperda tridenta* (on elm) and *A. glabripennis* (on poplar and willow) are among the most important pests of ornamental plants. Pests on tree crops seem more localized. For example, *A. chinensis* and *N. cantori* are important pests on citrus in Asia, and *S. candida* is an important pest on apple in North America.

Some longicorn species are candidates for the biological control of weeds by killing healthy weedy plants. For example, *Moneilema* spp. were used to control weedy cacti. Finally, most longicorn species feed on dead plants and are significant for renewal of forests by decomposing dead and sickly trees into humus.

Long-Legged Flies (Diptera: Dolichopodidae)

Marc A. A. Pollet[1,2], Scott E. Brooks[3]
[1]University of Ghent, Ghent, Belgium
[2]Royal Belgian Institute of Natural Sciences, Brussels, Belgium
[3]Agriculture and Agri-Food Canada, Ottawa, ON, Canada

The family Dolichopodidae is one of five major lineages within the superfamily Empidoidea of the infraorder Muscomorpha. The other four empidoid families that are currently recognized are the Empididae, Atelestidae, Hybotidae and Brachystomatidae. The Dolichopodidae are generally divided into 17 subfamilies (see classification below), including the recently added basal subfamilies Microphorinae and Parathalassiinae. This expanded concept of the family is referred to as Dolichopodidae *s.lat*. The other 15 subfamilies exclusive of Microphorinae and Parathalassiinae are referred to as Dolichopodidae *s.str*., which is equivalent to the traditional concept of the family.

Subper family: Empidoidea
- Family: Dolichopodidae *s.lat.*
  - Subfamily: Microphorinae
  - Subfamily: Parathalassiinae
- Family: Dolichopodidae *s.str.*
  - Subfamily: Achalcinae
  - Subfamily: Babindellinae
  - Subfamily: Diaphorinae
  - Subfamily: Dolichopodinae
  - Subfamily: Enliniinae
  - Subfamily: Hydrophorinae
  - Subfamily: Medeterinae
  - Subfamily: Neurigoninae
  - Subfamily: Plagioneurinae
  - Subfamily: Rhaphiinae
  - Subfamily: Sciapodinae
  - Subfamily: Stolidosomatinae
  - Subfamily: Sympycninae
  - Subfamily: Xanthochlorinae

Distinguishing Characters and Relationships

The Dolichopodidae *s.lat*., including the very species rich Dolichopodidae *s.str.* and the much smaller subfamilies Microphorinae and Parathalassiinae, are clearly a monophyletic lineage that is characterized by the following features: wing with vein Rs originating at or near the level of crossvein h, shortened basal cells (less than half the length of cell dm) with crossvein r-m in the basal fourth of the wing; male terminalia rotated and lateroflexed forward below the preceding abdominal segments with the pregenital segments partially twisted or rotated, and several characters of the male genitalia.

The Microphorinae and Parathalassiinae comprise the basal dolichopodids and are small (1–3 mm) non-metallic, greyish to dark colored flies, usually with wing cell dm emitting three branches. The Parathalassiinae forms a monophyletic group with the Dolichopodidae *s.str*. supported by several features of the wing venation, mouthparts and thorax. The Dolichopodidae *s.str*. are a well-supported monophyletic group and are readily separated from the Microphorinae, Parathalassiinae and the remaining Empidoidea by the combination of a metallic or yellow body color, and the generally narrow wings with the costal vein ending at M_1, vein Sc very short and ending in vein R_1, cell dm emitting two veins (instead of three), and cells bm and dm fused.

It has been hypothesized that the Dolichopodidae *s.str*. descended from marine coastal inhabitants, and that the common ancestor of the parathalassiines (which are almost exclusively marine littoral) and the Dolichopodidae *s.str*. invaded the sea coast from the ancestral terrestrial habitat of the microphorines. It has been further suggested that marine littoral habitats are still occupied by a basal grade of the Dolichopodidae *s. str*., which have traditionally been placed in the subfamily Hydrophorinae. The remaining Dolichopodidae *s.str*. abandoned the marine habitat in favor of a return to terrestrial and freshwater habitats, assuming independent reinvasions of the sea coast by several species in various subgroups. At present, phylogenetic relationships between subfamilies and between genera are not very clear, although some subfamilies like the Dolichopodinae and Sciapodinae seem more cohesive than others.

Fossil Record

Dolichopodids are well represented in the fossil record. Most dolichopodid fossils are amber inclusions which is unsurprising given that many groups of this family are associated with tree trunks and thus prone to becoming stuck in resins and fossilized. The earliest known representatives of the Dolichopodidae *s.lat*. (i.e., the microphorine genera *Microphorites* and *Avenaphora*) first appeared in Lebanese amber from the Lower Cretaceous (120–135 mya). The Dolichopodidae *s.str*. have also been reported from Lebanese amber (i.e., *Sympycnites primaevus*); however, the dating of this fossil is in question and is suspected to be from Baltic amber (40 mya). The earliest parathalassiines were found in Siberian amber from the Upper Cretaceous. The oldest definitive representative of Dolichopodidae *s.str*. is *Prosystenus zherikhini* in amber of Sakhalin Island, Far East Russia, from the Paleocene. Dolichopodids are very abundant in Baltic (Eocene/Oligocene) and Dominican (Miocene) ambers. The majority of fossil species of Dolichopodidae *s.str*. have been described from Baltic amber and assigned to extant genera. However, recent studies indicate that the majority of Baltic amber species cannot be included in extant genera based on synapomorphies and require separate fossil genera, suggesting that most recent genera of Dolichopodidae *s.str*. did not appear until after the Eocene/Oligocene.

Morphology

Adults (Figs. 60 and 61a–e) range from 0.8 to 9.0 mm in length. Most dolichopodids are metallic green, bronze to blue in body color, whereas some genera often feature yellow (*Achalcus*, *Neurigona*, *Xanthina*, *Xanthochlorus*), or – sometimes dull – brown to black, or greyish colors (*Aphrosylus*, *Micromorphus*, *Medetera*, *Microphor*, *Parathalassius*). Eyes are large and occupy most of the head, but are rarely holoptic on the frons (males of *Diaphorus*, *Microphor*, *Schistostoma*) or nearly continuous on the face (*Chrysotus*, *Allohercostomus*). The antenna is usually inserted rather high on the head and consists of a scape, pedicel, postpedicel (1st flagellomere) and arista-like stylus that usually consists of two articles (one article in Parathalassiinae and in some males with modified antennae). The stylus is basidorsal to apical, and the shape of the scape, pedicel and postpedicel is highly variable. In some genera the antenna is subject to strong sexual dimorphism which is mostly reflected in the shape and size of the antennal segments (e.g., arista-like stylus with terminal flag or binodate, postpedicel multilobate), but sometimes also in their color (Achalcinae). Palps are flat, usually with fine pubescence and one or more distinct apical bristles. In some genera, males possess palps that are greatly enlarged or elongated, silvery white or brilliantly metallic which are employed during courtship. The proboscis is equipped with a pair of flexible labellar lobes, each of which has six variously sclerotized narrow pseudotracheae on its inner surface. In *Melanderia*, these lobes are highly sclerotized and mandibuliform. The Dolichopodidae *s.str*. possess stout and sharply pointed epipharyngeal blades presumably utilized in tearing the bodies of their prey, and an elongated epipharyngeal apodeme that projects vertically into the head.

In most dolichopodid flies, the chaetotaxy of the scutum (thorax) is well differentiated and usually includes biserial acrostichal setae medially (sometimes uniserial or absent), a row of dorsocentral bristles laterad of the acrostichals, a row comprising one presutural, one sutural, two postsutural supraalar, and one postalar bristles laterally flanking the dorsocentrals, and one postpronotal, two posthumeral and two notopleural bristles near the lateral margin of the scutum. The chaetotaxy of the microphorine scutum is usually less differentiated than that of other dolichopodids, and in some species, the acrostichal and dorsocentral bristles are pluriserial and uniformly distributed over the scutum. The scutellum always has a strong medial pair of marginal bristles, and usually an outer pair of smaller bristles (absent, e.g., in some *Medetera* species groups). The proepisternum also bears one or more bristles, but the pleuron is usually devoid of bristles and hairs except in some genera (e.g., *Dolichopus*, *Ethiromyia*, *Gymnopternus*, *Thambemyia*, *Hydatostega*, *Syntormon*). Wings are mostly narrow but can be rather broad (*Diaphorus*, *Enlinia*). In general, the wing venation is reduced and most species entirely lack vein M_2, except for the Microphorinae, most Parathalassiinae, most Sciapodinae and some *Dolichopus* (with M_2 represented as a stub). In most species, vein M_1 is straight, gently curved, or distinctly bent towards R_{4+5}, whereas it is interrupted in *Asyndetus* and *Cryptophleps*, or divergent from R_{4+5} in Enliniinae and most Achalcinae. Two crossveins are present in the Dolichopodidae *s.str*., with the basal r-m very short and dm-cu usually situated in the centre or the apical half of the wing and connected to M_{1+2}. In most Microphorinae and Parathalassiinae an additional basal crossvein is present (bm-cu) and crossvein dm-cu is connected to the base of M_2. Micropterous (*Emperoptera*, some *Schoenophilus*), stenopterous (*Papallacta*) and apterous dolichopodids (*Apterachalcus*) occur, and males of the genus *Erebomyia* display directional asymmetry, with the left wing larger and of a different shape than the right wing.

The abdomen can be quite long and slender (*Neurigona*, Sciapodinae) or strongly shortened (*Hydrophorus*). Most females have five well-developed setose segments with the apical segments largely bare and retracted into segment 5, whereas others (e.g., some Microphorinae and Parathalassiinae) have the apical segments retracted into segment 6. Females of *Xanthochlorus* are unusual, with eight setose abdominal segments. Tergite 10 of females is usually partially or completely divided medially with each side bearing one to six stout spines arranged in a row. In some dolichopodids (e.g., *Microphor*, Neurigoninae, some Medeterinae, some Sciapodinae, *Xanthochlorus*), however, these spines are not developed. The female cerci are usually situated laterally and are partly or entirely divided into a longer, well-sclerotized dorsal lobe and smaller ventral lobe. The female terminalia of some genera are highly modified. In *Thrypticus*, the eighth segment and proctiger are fused into a strongly sclerotized lanceolate ovipositor. In the Taiwanese genus *Alishanimyia* the terminalia are greatly enlarged forming a rounded sclerotized cavity, the function of which is unknown.

The number of setose segments (at least tergites) varies from five to seven in males. The male hypopygium is either largely enclosed in an invagination formed by the sixth, and more rarely also the fifth abdominal sternite (many Sympycninae), free but sessile (many Hydrophorinae, Rhaphiinae) or pedunculate (Dolichopodinae, Medeterinae, Sciapodinae). In the pedunculate condition segment 7 is modified into a peduncle or external arm that supports the genital capsule. Segment 7 can be quite short to greatly elongated. The hypopygium itself is highly variable in structure and includes very important diagnostic features essential for identification.

The Dolichopodidae are best known for their legs which are usually long and slender (hence the common name of the family) and, in males, subject to an apparently endless variation in shape and vestiture. These specific ornamentations or Male Secondary Sexual Characters (MSSC) involve peculiarities in pubescence and chaetotaxy, and/or elongation, compression or deformation of tarsi, tibiae or femora. Extreme examples of these MSSCs on legs are found in *Campsicnemus* (e.g., *C. magius*). Although MSSCs are most commonly developed on the legs, they also occur on the head, wings and abdomen of males. Next to the detailed structure of the male hypopygium, these MSSCs are crucial diagnostic characters for identification. Males of a few genera largely lack these special structures (e.g., some *Medetera* species groups, *Micromorphus*), and examination of the male genitalia is usually required for species identification.

The larvae (Fig. 61f) are whitish cylindrical maggots with a slightly tapering anterior apex. The four-lobed head segment is usually short, lacks external sclerotization and has brown to black internal mouthparts. Each of the seven anterior abdominal segments shows a pair of creeping welts or swellings bearing spicules on its anterior margin, with those on the first segment being sometimes very large and resembling prolegs (*Systenus*). The terminal (12th) segment of the body is truncate and divided posteriorly by a horizontal and vertical furrow, producing four or more lobes that are usually elongate, but can be very short in some species (*Medetera*, *Neurigona*). Each of the dorsal lobes usually bears a posterodorsal spiracle.

Dolichopodid pupae are enclosed in a loose silky cocoon spun by the final instar larva which incorporates debris from the habitat. The pupae possess a pair of large respiratory horns that arise from the dorsal surface of the cephalothorax just behind the eyes. The tips of these horns are projected through a small aperture in the cocoon. The abdominal tergites are usually equipped with transverse rows of spines whereas the anal segment is bluntly rounded or ends in a pair of stout spines.

Diversity, Ecology and Distribution

With about 6,900 species in more than 220 genera worldwide, the Dolichopodidae represent over 5% of all described fly species, preceded only by the Tipulidae (approximately 11%) and Tachinidae (approximately 7%). Over one thousand species have been recorded in each zoogeographical region, except for the Afrotropical realm with about 700 species. These numbers, however, cannot be considered a reliable reflection of the real extant biodiversity: while certain areas in the Palaearctic and Nearctic regions have been sampled thoroughly, this is hardly the case for the tropics where the number of described species is likely only a fraction of the real diversity.

Long-legged flies occupy all semi-aquatic and terrestrial habitats in every zoogeographical realm, even on small islands amid the Pacific. Most species seem to prefer fairly humid to very humid habitats. They are most diverse and abundant in mangroves, salt marshes, reed marshes and swamps, humid deciduous forests and rainforests, humid heathlands and peat moors, and on banks of streams and stagnant water bodies. Drier habitats like coastal dunes and dry grasslands are characterized by lower diversities with only some xerophilous genera (*Chrysotus*, *Medetera*, *Sciapus*) being well represented. Most adult Dolichopodidae (Figs. 60 and 61a–e) are usually found on broad-leaved vegetation of low shrubs and trees and on humid or muddy soils, whereas others are confined to vertical structures like tree trunks, rock surfaces or fences. Larvae (Fig. 61f) occur in mud, damp soil, leaf litter, moss, algal mats, decaying seaweed, under bark and within plant tissues. Pupae have been found under bark of trees (*Medetera*) and in the muddy soil of riparian habitats (*Tachytrechus*). A number of microhabitats house a specialized dolichopodid fauna. Rotholes and sapruns on deciduous trees are inhabited by larvae of *Systenus* in all realms, and by *Australachalcus melanotrichus* and some *Hercostomus* species in the Palaearctic Region. Springs and waterfalls with water falling on, or seeping over, rocks show typical

hygropetric faunas with Hydrophorinae present in all realms. In contrast, other taxa associated with these hygropetric habitats differ between realms, with *Hercostomus* being more prominent in the Palaearctic Region, *Gymnopternus* in the Nearctic Region and Enliniinae in the Neotropical Region.

At present, ecological data on the habitat affinity of most dolichopodids is entirely lacking. Only the western European fauna has been fairly well documented in this respect. In what follows, distribution and ecology of the subfamilies are discussed primarily on the basis of the currently available data.

The Microphorinae are a small subfamily that includes the genera *Microphor* and *Schistostoma*. *Microphor* is primarily Holarctic, but also includes one species from Tasmania. Species of this genus occur in lowland shrubby habitats and forests. *Schistostoma* is known from the Holarctic and Afrotropical regions and is found in warm sandy habitats, and on dry river banks with sand and gravel.

The subfamily Parathalassiinae includes a relatively small group of dolichopodids that are primarily associated with sea coasts, with the exception of some *Microphorella* species known from inland sand and gravel river banks, or associated with mist of waterfalls. Parathalassiines are known from all realms.

At present, the strongly hygrophilous Achalcinae only account for about 1% of dolichopodid diversity with hotspots in the Neotropics and New Zealand. In the northern hemisphere, *Achalcus* prefers marshland habitats with a well developed vegetation layer, whereas *Australachalcus* species breed in rotholes of deciduous trees. The endemic Neotropical genus *Xanthina* is most diverse at low altitudes in contrast to *Achalcus*, *Australachalcus* and a number of yet undescribed genera.

The Babindellinae are endemic to the tropical and subtropical closed forests of Australia. The subfamily comprises two species in the genus *Babindella*.

The Diaphorinae are a diverse subfamily (approximately 12% of world fauna) with *Chrysotus*, *Diaphorus*, *Asyndetus* and *Argyra* as dominant genera. *Chrysotus* and *Diaphorus* are among the most species rich dolichopodid genera in the tropics with the former remarkably diverse in the Neotropics. They are both active on the soil and in the vegetation in dry to very wet places. *Asyndetus* is riparian with some species inhabiting crab holes. Many species of the primarily Holarctic genus *Argyra* are readily recognized by the silvery white pruinosity of the thorax and abdomen, which produces silver flashes while flying swiftly along forest paths and streams.

The Dolichopodinae are by far the most species rich subfamily in the Dolichopodidae *s.str*. with approximately 26% of the world fauna. The genus *Dolichopus*, which occurs in the Holarctic, Afrotropical, Oriental and Australasian regions, and also on the Hawaiian Islands, encompasses over 8% of all dolichopodid species. Other species rich genera include *Hercostomus*, *Tachytrechus*, *Gymnopternus*, *Paraclius* and *Pelastoneurus*. Although Dolichopodinae are found in very different habitats, ranging from salt marshes to humid forests, most species prefer humid conditions. *Tachytrechus* is often encountered on sandy beaches and on rocks in pools and along rivers, and like *Paraclius* and *Pelastoneurus*, is most diverse in the Neotropics.

The Enliniinae are a subfamily of microdolichopodid flies (most species less than 1.0 mm in length) that is endemic to the New World. Enliniines account for more than 1.4% of the world fauna but remain largely unstudied outside Mexico. They are mainly found at river runoffs or small waterfalls, hovering along wet vertical rock surfaces. They are sometimes very abundant in these habitats, with several species hovering together.

The subfamily Hydrophorinae includes approximately 8% of described species which are among the most hygrophilous dolichopodids. Many hydrophorines show strong habitat affinities. Some genera are restricted to rocky seashores (*Aphrosylus*, *Thambemyia*), whereas others prefer sandy to muddy beaches (*Thinophilus*, *Machaerium*), or mountain seeps (e.g., *Eucoryphus*, *Sphyrotarsus*). Species of the dominant genus *Hydrophorus* occur on beaches and along stagnant and running water, where they skate on the water surface in search of mates and prey.

The majority of Medeterinae (e.g., *Corindia*, *Medetera*, *Systenus*) are arboreal and usually encountered on tree trunks and other vertical surfaces. With over 300 species mostly described from the Palaearctic Region, *Medetera* is one of the largest genera in the family. This genus also appears to be very diverse in the Neotropics, but remains largely unstudied in this region. The larvae of many *Medetera* species live in the galleries of bark beetles (Curculionidae: Scolytinae) and are predaceous on the developing beetles. *Systenus* larvae develop in rotholes and sap runs of deciduous trees. The larvae of *Thrypticus* are unique among dolichopodids as leafminers in monocots. The Medeterinae represent approx. 8% of all described dolichopodid species.

The Neurigoninae are a rather small subfamily including approximately 3% of described species. Adults are typically slender, and long-legged. Neurigonines are most diverse in the Neotropical Region, and like many Medeterinae, are often encountered on tree trunks.

The Peloropeodinae are a small subfamily (approximately 3% of described species) comprised of several genera that were previously placed in Sympycninae. Its status as a separate subfamily remains in question. *Chrysotimus*, *Nepalomyia*, *Peloropeodes* and *Micromorphus* are the most species rich genera. *Chrysotimus* occurs in the canopy of deciduous trees, *Nepalomyia* is often found in dark, cool sites with running water, whereas *Peloropeodes* and *Micromorphus* are distinctly soil-dwelling.

The subfamily Plagioneurinae includes a single distinctive species, *Plagioneurus univittatus*, that is endemic to, but rather widespread in the New World.

About 94% of the species in the subfamily Rhaphiinae (approximately 3% of described species) belong to *Rhaphium* and *Nematoproctus* which are primarily Holarctic genera, with only few species in adjacent zoogeographical realms. Species of both genera show distinct sexual dimorphism. Many of the more than 180 *Rhaphium* species are among the first dolichopodid flies to appear in the spring and prefer very wet conditions, usually with open water.

The Sciapodinae account for about 19% of all described species and have been studied in greater detail than any other subfamily in the past two decades. Sciapodines are among the largest and most conspicuous dolichopodids in the tropics, and are frequently found sun-basking in the higher herb vegetation or the lower tree canopy. The widespread genera *Amblypsilopus*, *Condylostylus* and *Chrysosoma* include more than 200 species each. *Amblypsilopus* is most diverse in Australasia whereas most *Condylostylus* species are found in the Neotropics. Most species of *Chrysosoma* have been recorded from Afrotropical, Oriental and Australasian realms. *Sciapus* is primarily Palaearctic and comprises about 60 species with rather diverse habitat affinities. Some are stenotopic forest species that occur on tree trunks, whereas others prefer dry sandy habitats where they are found at soil surface level.

Most of the 29 species of the Stolidosomatinae are endemic to the Neotropics with a few species known from the Nearctic. *Stolidosoma* is found on tree trunks and on broad-leaved vegetation in rainforests.

The subfamily Sympycninae includes about 14% of the described species of the Dolichopodidae. Among the 40 described sympycnine genera, *Sympycnus*, *Campsicnemus*, *Teuchophorus* and *Syntormon* are the most species rich. *Sympycnus* and *Syntormon* are known from all realms, whereas *Campsicnemus* and *Teuchophorus* have not been recorded from the Neotropics. *Teuchophorus* is most diverse in the Oriental (Southeast Asia) and Australasian realms (New Guinea), whereas *Campsicnemus* has undergone a phenomenal radiation on the Hawaiian Islands similar to *Drosophila*, with nearly 160 or 70% of the world's species. Most Sympycninae are distinctly hygrophilous and occur in very wet places, from salt marshes to peat moors and high altitude mountain habitats. *Campsicnemus* is soil-dwelling and has been seen skating on water surfaces. Unlike most of the other Dolichopodidae, some *Sympycnus* species are considered dark-preferent.

The subfamily Xanthochlorinae includes the single genus *Xanthochlorus*, with one Nearctic species and 11 species in the Old World. The western Palaearctic species seem to prefer dry deciduous forests.

Feeding Ecology and Economic Importance

Both adults and larvae are predatory, with the exception of *Thrypticus* larvae which are phytophagous (see above). Adults seem to be generalists that feed on any suitable prey available. Soft-bodied arthropods such as mites, springtails, aphids, thrips, and the larvae and adults of Diptera are the most frequently recorded prey items. Predation by dolichopodids has also been recorded on annelids, cladocerans, amphipods, small myriapods, odonate eggs, termites, psocopterans, beetle larvae, early instar caterpillars, dead and wounded arthropods and amphibian embryos. Females of *Microphor* are known to be kleptoparasitic, feeding on insect prey in spider webs. The prey of dolichopodids is usually seized and held by the labella, cut open by the epipharyngeal blades and its liquid and liquefied contents sucked out. Honeydew is also used as a food source. Some Palaearctic species of *Hercostomus* (*H. germanus*, *H. chaerophylli*, *H. nigripennis*) and *Ortochile* appear to feed on nectar and pollen of flowers and possess elongated mouthparts.

Dolichopodids are important natural enemies of pests in a variety of habitats. Dolichopodid species with the greatest potential as biological control agents belong to the genus *Medetera*. Larvae of most *Medetera* species feed on developing bark beetles in their galleries under the bark. Adult *Medetera* use tree volatiles and/or pheromones released by the beetles to locate infested trees and oviposition sites. Predation on bark beetles by *Medetera aldrichii* has been investigated in detail in the Nearctic Region. Several Neotropical species of *Thrypticus* have been reared from the petioles and stems of water hyacinth (*Eichhornia crassipes*). As such, they have potential as biocontrol agents of this New World aquatic plant which is an invasive weed in the waterways of Africa, Asia and Australia. Several genera of Dolichopodidae have also been reported as predators of mosquito larvae.

Conservation

The Ko'Olau Spurwing Long-legged Fly (*Emperoptera mirabilis*, previously in *Campsicnemus*) from Hawaii is the only dolichopodid species that is currently included in the IUCN Red list of threatened species. This micropterous fly was discovered on a single occasion in 1900, but has not been seen since, and is currently regarded as extinct.

At present, little attention has been given to the conservation status of dolichopodids. However, during recent years Red Data Books (RDB) on the Dolichopodidae of Flanders (northern Belgium), Germany and Great Britain have been published. These RDBs, which are also available for water beetles, water bugs, butterflies, dragonflies, ground beetles and spiders, prove to be valuable tools for site quality assessment. Recent studies indicate that dolichopodids have very specific habitat requirements and appear to react quickly to environmental alterations. As more detailed ecological data become available and more revisionary studies are completed, dolichopodids show potential to be used as bioindicators for site quality assessment and conservation programs outside Europe.

Long-Tailed Burnet Moths (Lepidoptera: Himantopteridae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FLorida, USA

Long-tailed burnet moths, family Himantopteridae, include 56 species from Africa and tropical Asia; formerly included in Zygaenidae. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small to medium size (16–42 mm wingspan), with head scaling average; haustellum naked; labial palpi upcurved; maxillary palpi 1 to 2-segmented; antennae mostly bipectinate. Wings triangular; hindwings with extremely long tails (Fig. 62). Maculation usually colorful, with spots on the hindwing broader basal area; tails usually darker. Adults are diurnal but few are known biologically. Larvae are leaf skeletonizers, often communal; sometimes massing in the 1,000s as they move down the host trunk before pupating in soil; slug-like, with concealed head. Known host plants are in Dipterocarpaceae.

Long-Toed Water Beetles

Members of the family Dryopidae (order Coleoptera).
► Beetles

Looper

A caterpillar of the order Lepidoptera, family Noctuidae, subfamily Plusiinae (but sometimes others, especially the measuringworms, family Geometridae) that move with a pronounced looping motion. Such caterpillars are lacking most of the abdominal prolegs, and move by bringing the remaining prolegs (two to three pairs), located near the tip of the abdomen, up to the true legs before moving the anterior part of the body forward. (contrast with semilooper)

Lophocoronidae

A family of moths (order Lepidoptera). They also are known as Australian archaic sun moths.
► Australian Archaic Sun Moths
► Butterflies and Moths

Lophopidae

A family of bugs (order Hemiptera, suborder Fulgoromorpha). All members of the suborder are referred to as planthoppers.
► Bugs

Lorguin, Pierre Joseph Michel

Pierre Lorguin was born in Valenvicennes, France, on July 2, 1787. He graduated from the University of Douay and pursued a career in law. He was very successful, but with the outbreak of the French Revolution in 1848 he moved to Algiers. In 1850, Lorguin moved to California in response to discovery of gold in 1849. His family joined him in California in 1852, and he remained there until 1859. Lorguin collected Lepidoptera for J.A. Boisduval and contributed greatly to the California Academy of Science. In fact, nearly all of the Lepidoptera described by Boisduval from California were collected by Lorguin. In addition to California, he collected in the Philippine Islands, China, and in Southeast Asia. After contracting a disease he returned to France in 1865 where he died in Paris on February 8, 1873.

Lovebug, *Plecia nearctica* Hardy (Diptera: Bibionidae)

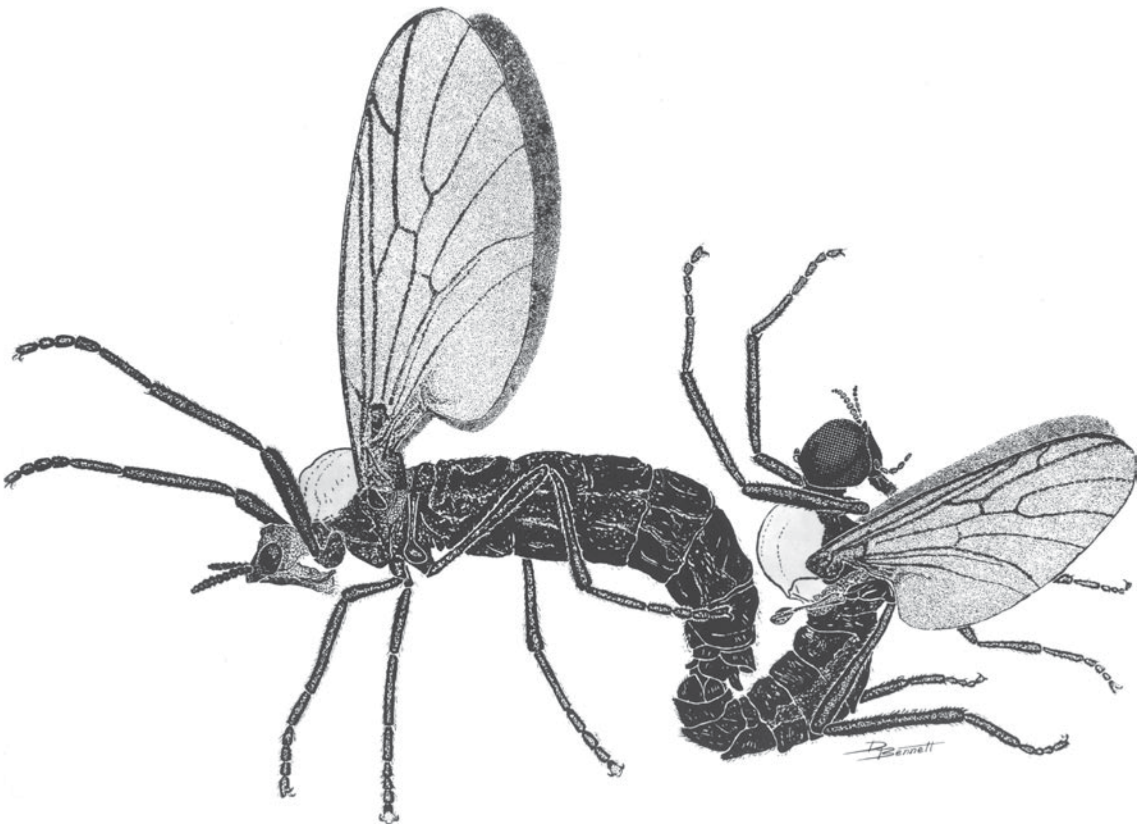
NORMAN C. LEPPLA
University of Florida, Gainesville, FL, USA

The lovebug is a seasonally abundant member of a generally unnoticed family of small flies related to gnats and mosquitoes. The males are about 6–7 mm and the females 6–9 mm in length, both entirely black except for red on the dorsum of their thorax. Other common names for this insect include March flies, double-headed bugs, honeymoon flies, and united bugs. Lovebugs characteristically appear in great abundance along the Gulf Coast of the USA as male-female pairs for only a few weeks every April-May and August-September. Although their range extends over a broad area, including south into Central America, their abundance varies greatly from place to place and from season to season. During the spring and autumn peak flight periods they can reach outbreak levels in some areas and yet be almost absent in others. Lovebugs are a nuisance pest, as opposed to destructive or dangerous, in areas where they accumulate in large numbers.

Lovebug Description and Biology

Lovebugs can be identified superficially as swarms of little black flies, each bearing a red thorax, that fly as pairs of males and females in tandem. Members of some related families contain pests of agriculture and vectors of pathogens that cause human and animal diseases (e.g., sand flies [Psychodidae], mosquitoes [Culicidae], biting midges [Ceratopogonidae], black flies [Simuliidae], fungus gnats [Mycetophilidae] and gall midges [Cecidomyiidae]) but bibionids are relatively harmless. Bibionids have antennae with seven to 12 segments and ocelli (simple eyes) on their heads. Their wings each have an undivided medial cell, a costal vein that ends at or before the wing tip, a large anal area and two basal cells. All members of the genus *Plecia* have an upper branch to the radial sector vein of the wing. The only two species of this genus in the U.S., *P. nearctica* and *P. americana* Hardy, are very similar in appearance. Males of both species are (Fig. 63) considerably smaller than females and have much larger compound eyes; *P. nearctica* males weigh 6–10 mg and females 15–25 mg. Both species and sexes have red dorsal thoraxes but *P. nearctica* has completely black pleura (sides of thorax) and a head with an oral margin distinctly extended forward. In contrast, the thorax of *P. americana* is almost completely red and rarely slightly brownish black on the metathoracic pleura (sides of third thoracic segment). The oral margin of the head does not extend forward but is evenly convex.

Other members of the family Bibionidae might be confused with the lovebug, particularly *Dilophus sayi* Hardy (= *Dilophus orbatus* Osten Sacken, = *Philia orbata* (Osten Sacken). However, *D. sayi* is clearly smaller than the *Plecia* species, completely black, much less abundant, and does not congregate noticeably on highways. Females are larger than males and have smoky brown rather than clear wings. The reproductive behavior of *D. sayi* is similar to that of the lovebug and in both species males and females can mate more than once. Unlike lovebugs, however, *D. sayi* adults do not disperse in pairs, instead males remain in the emergence areas while the females seek suitable oviposition sites. Females of *D. sayi* deposit 100–300 eggs that hatch in about 20 days. Under



Lovebug, *Plecia nearctica* Hardy (Diptera: Bibionidae), Figure 63 **Pair of mating lovebugs with larger female on left. Note the elongated female rostrum (snout-like prolongation of the head) and large circular male eyes (drawing by Dwight Bennett).**

laboratory conditions, females live for about 72 hours, whereas males survive for about 92. Adults of this species are periodically considered a nuisance pest in the southern USA from South Carolina to Florida and across the Gulf States into Texas, and also in California.

Although the lovebug has two distinct generations per year over much of its range, adults can be found during most months. Higher temperatures cause adult populations to peak slightly earlier in the southern areas of the state. As in all other flies, lovebugs exhibit complete metamorphosis, having egg, larva, pupa and adult stages. An individual female deposits an average of 350 eggs under (Fig. 64) decaying vegetation in a grassy or weedy area with adequate moisture. Conditions must not be too wet or dry, although the larvae soon emerge and can move short distances to locate the best habitats. Larvae develop more rapidly at higher temperatures, so the summer generation is shorter than the one in the winter. The larvae feed on decomposing leaves and grass until they pupate. The pupal stage lasts 7–9 days. In nature, the adults live just long enough to mate, feed, disperse and deposit a batch of eggs, about 3–4 days.

Lovebug reproductive behavior occurs within three general activity periods during the day. The first period (8 A.M.–2 P.M.) begins with the insects moving up onto the plants and feeding on nectar. Lovebug flight is initiated when the air temperature reaches about 20°C and illumination is 1500–2000 ft-c. Males and females that coupled and mated late during the previous day fly into the air to disperse. Unmated males and females first couple and mate before dispersing. Mating begins

Lovebug, *Plecia nearctica* Hardy (Diptera: Bibionidae), Figure 65 **Lovebug life cycle with the approximate duration and size of each stage (not drawn exactly to scale, adult pair 15.2 mm head to head). Drawings of the eggs, larva and pupa are from *P. plagiata* (Wiedemann) (Pinto 2002). In Florida, the lovebug has two generations each year, emerging as adults in April-May (winter generation, 240 days) and August-September (summer generation, 120 days).**

when swarms of 40 or more males form above the emergence sites, oscillating up and down rhythmically more than 6 m above the ground, even on windy days. These swarms last 10–30 min and end with the males eventually landing to rest or feed. Swarming peaks at 10–11 A.M. and again at 6–8 P.M. Larger males prefer positions at the bottom of a swarm. Individual females fly into a swarm and are grasped almost immediately by a male, after which the pair lands on vegetation to mate. Males prefer larger and heavier females, often grasping them before they fly into swarms or displacing attached males. In this competition for (Fig. 65) females, larger males are able to displace smaller ones about 20% of the time but success diminishes if the original male has been attached for a long time. Even if undisturbed, however, males and females often will disengage and mate a second time. After coupling, the male faces the opposite direction from the female within 1.5–10 min and the pair begins copulating. Insemination involves discharging the contents of the spermatophore into the spermatheca of the female.

During the second activity period (2–5 P.M.), single males and females are considerably less mobile but pairs continue to disperse. As in the morning, males swarm and grasp incoming females during the third period (5–8 P.M.) but at this point the pairs remain on vegetation throughout the night. Pairs that have been dispersing during the day also settle on vegetation when illumination falls below the 1500–2000 ft-c threshold, even though the temperature remains above 20°C. Lovebugs do not fly during the night. After a pair disperses, the male perishes and the female deposits as many as 600 eggs under decaying leaves or grass before also dying. Groups of about 300 larvae have been found on or near the surface of the soil among the roots of grasses.

Lovebug Myths

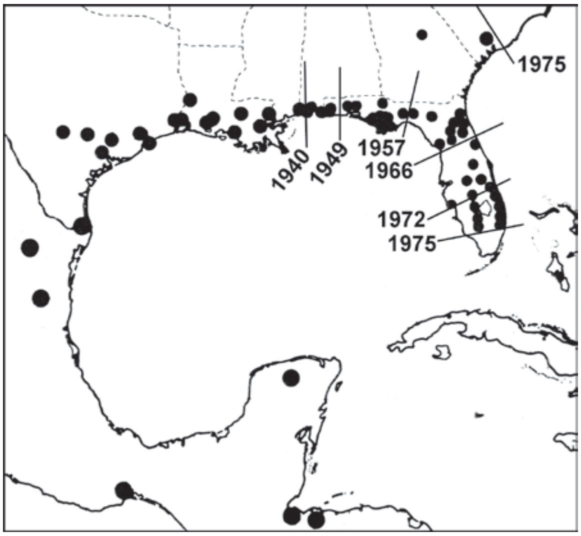
The invasion of the USA by the lovebug prompted development of much erroneous information about the origin and behavior of this species. This problem is exacerbated by the lack of research on this nuisance species. Following are some of the most common myths:

Lovebugs Escaped After University of Florida Researchers Brought Them Into Florida

Lovebugs are not native to most of the southern United States. Since 1940, *P. nearctica* has extended its range from Mississippi and Louisiana across the Gulf States, reaching Florida in 1949. In the late 1960s, it became established entirely across north Florida. During the 1970s, explosive populations occurred progressively southward nearly to the end of peninsular Florida and northward into South Carolina. Its movement may have been accelerated by prevailing winds, vehicle (Fig. 66) traffic, sod transport, increased habitat along highways and expansion of pastures - but not by university researchers.

University of Florida Researchers Genetically Engineered Lovebugs to Kill Mosquitoes

Lovebugs are small, slow herbivorous insects that feed on the pollen and nectar found in flowers. Thus, they lack the mandibles (jaws), grasping legs,



Lovebug, *Plecia nearctica* Hardy (Diptera: Bibionidae), Figure 66 **Pattern of migration of *Plecia nearctica* from Central America to the southeastern U.S. (from Buschman 1976).**

speed and other characteristics of predatory insects, such as dragonflies. Lovebugs are active during the day, whereas most mosquitoes are crepuscular (active at twilight) or nocturnal, and they are only adults for a few weeks each year. For these and many other reasons, the lovebug would be a poor candidate to genetically engineer as a mosquito predator, even if it were possible.

Lovebugs are Attracted to Automobiles

After mating, lovebugs disperse as coupled pairs, presumably flying in search of nectar on which to feed and suitable oviposition sites. Mated females are attracted to sandy sites with adequate moisture, dead leaves, grass clippings, cow manure and other decomposing organic debris. Lovebugs are attracted to anethole, an essential oil found in plants that also attracts bees. Female lovebugs are also attracted to UV-irradiated aldehydes, a major component of automobile exhaust fumes. They may confuse these chemicals with the odors emitted from decaying organic matter at typical oviposition sites. Heat has also been shown to attract lovebugs and contribute to their abundance on highways. Additionally, lovebugs seem to collect on light-colored buildings, especially when freshly painted. Many kinds of flies are attracted to light-colored and shiny surfaces, although the physiological or behavioral mechanisms are unknown. Thus, lovebugs apparently accumulate in relatively warm, humid, sunny areas with chemicals in the atmosphere that mimic feeding and oviposition sites.

Dispersing Lovebugs Move Great Distances and are Attracted to Homes

Lovebug pairs are not strong fliers, so tend to remain within a few hundred meters of emergence sites when there is little or no wind. They are able to move across the wind when it is 8–12 kph and search for sources of nectar and suitable oviposition sites. Stronger winds blow them as high as 450 m in the air and concentrate them against downwind objects. Coupled females initiate and control flight but males assist if they are able to obtain food. Locations within 30–50 km can have quite different levels of lovebug emergence and dispersal and this variable distribution can lead to naturally occurring “hotspots” in different places from year to year. Lovebugs are most abundant in moist grassy habitats. People who live near these habitats, or are exposed to winds that deposit the insects at their homes, can perceive erroneously that they are attracting these pests.

Lovebugs Mate the Entire Time They are Coupled

The general pattern of mating in lovebugs begins with males forming swarms above emergence areas each day in the morning and afternoon. Females emerge from the soil later than males, crawl on to vegetation, and fly into the swarms. A male may grasp a female before or after she flies into a swarm. In either case, the pair couples on vegetation and the male transfers sperm to the female. Sperm transfer requires an average of 12.5 hours but the pair usually remains coupled for several days during which they feed and disperse. The male ejects a depleted spermatophore after separating from the female and both sexes may mate again. Pairs formed during the morning hours begin dispersal flights, whereas those that couple in the evening remain in place on vegetation until taking flight the following day.

The Body Fluids of Lovebugs are Acidic and Immediately Dissolve Automobile Paint

When numerous lovebugs are smashed on the front of a vehicle, the contents of their bodies, especially eggs, coat the painted surface. No permanent damage is caused, however, if the surface is cleaned before the coating is baked by the sun for several days. Lovebugs are about neutral, with a pH of 6.5, but become acidic at 4.25 within 24 h. Yet, automobile paint may not be damaged after being coated with macerated lovebugs and held in a humid indoor environment for 21 days. A lovebug-coated surface exposed to the sun for an extended period of time, however, may be damaged by the insects and their removal. The front of a vehicle can be protected by coating it with wax and removing the lovebugs within 24 h.

Lovebugs Have no Significant Natural Enemies

No parasites have emerged from lovebug larvae or adults held in the laboratory and few cases of predation have been observed in nature over the years. Apparently lovebugs adults are avoided by red imported fire ants, *Solenopsis invicta* Buren and most other predators but periodically are eaten by spiders, dragonflies and birds. They have aposematic coloration that implies defensive mimicry but have not been chemically analyzed or tested as food for predators. Beekeepers report anecdotally that honeybees do not visit flowers infested with lovebugs. Fungal pathogens have been identified, six from larvae and one from adults, that could limit lovebug populations. These fungi include the well-known insect pathogenic genera, *Metarhizium*, *Beauveria* and *Conidiobolus*. Although not yet studied, lovebug eggs may be subject to predation or parasitism.

Insecticides are Effective in Controlling Lovebugs

Insecticides available to the public for controlling houseflies, mosquitoes and other flies will also kill adult lovebugs. However, there are risks associated with using these products around humans and pets, and the lovebugs will likely reinvade almost immediately. Other insects are often misidentified as being lovebugs, some of which are innocuous or beneficial and therefore should not be killed. It is important to preserve lady beetles, lacewings, honeybees and other insects that help to protect or pollinate plants. Thus, insecticides are expensive, potentially harmful and of no value in controlling lovebugs. It is best to avoid lovebugs if they become a nuisance during their brief appearances each year.

Lovebugs and People

It is possible but usually not necessary to avoid lovebugs and the problems they cause. Unlike some of their close relatives, lovebugs do not bite, sting or transmit diseases, and are not poisonous. Lovebugs are only active in the daylight and are much less mobile during the early and late daytime hours. Typically, the pairs fly across the wind during their dispersal flights and are blown against obstacles, especially vehicles traveling at high speeds. Their remains can be removed from surfaces easily if not left to bake in the sun. Lovebugs are poor fliers that can be kept out of a building by creating positive pressure with an air-conditioning fan. If a few lovebugs enter, a vacuum cleaner can be used to remove them. Screens can be added to windows and doors, particularly on the prevailing windward side of a building, and placed over decks and swimming pools. A fan can be used outside near work or recreational areas to keep lovebugs away. Due to their abundance and mobility, lovebugs cannot be controlled effectively with poisons or repellents.

People consider the lovebug to be among the peskiest alien invasive species to become established in the Gulf States. On the contrary, these potentially annoying flies are actually beneficial as larvae because they help to decompose dead plant material. People would also appreciate esthetic aspects of the adults, if these insects were not such a nuisance. Like migratory birds, lovebugs signal changes in the seasons from spring to summer and again from summer to fall. Moreover, if they were larger, people could easily see and admire their delicate features, particularly the big round eyes of the males. Wilhelm Rudolph Wiedemann named the genus *Plecia* for the lovebug and its relatives in 1828, so his concept for the term may never be known. A reasonable guess, however, is that he applied the Greek verb "pleo" intending to mean "to sail." Lovebugs sail from flower to flower much like butterflies, and in smaller numbers they could be perceived as beautiful. They have become less abundant over the past 30 years and people living in the Gulf States are beginning to accept them as a normal part of nature. However, newcomers tend to be intolerant of lovebugs until they learn that these pests are not dangerous. Because lovebug populations tend to rebound unpredictably, it is fortunate that these creatures create only minor inconveniences rather than threaten human health and the environment.

Lugger, Otto

Otto Lugger was born at Hagen, Westphalia, Germany, on September 16, 1844. In 1865, after service in the military, he and his family moved to the United States. Initially he worked as an engineer, surveying the Great Lakes region. He always was interested in entomology, however, and became acquainted with C. V. Riley. When Riley became state entomologist of Missouri, he appointed Lugger to be his assistant. There he labored for several years, but in 1875 moved to Maryland to serve as curator of the Maryland Academy of Sciences. In 1885 he was appointed to the Division of Entomology of the United States Department of Agriculture, and in 1888 was appointed entomologist to the Minnesota Agricultural Experiment Station. The first challenge he faced in Minnesota was invasion of the area by the Rocky Mountain locust, but with the governor's backing the insects were destroyed and damage averted. Lugger published numerous articles on economic entomology, but also a detailed series on the insects of Minnesota. This important series of publications was unfortunately interrupted by his death on May 21, 1910.

Lyme Borreliosis

DOUGLAS E. NORRIS
Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Lyme borreliosis and the clinical syndrome, Lyme disease, are currently epidemic throughout much of the northern hemisphere and are reported sporadically world-wide. Lyme disease is the most frequently reported vector-borne infection in the United States. This tick-borne bacterial zoonosis is maintained in rodent populations by hard ticks of the subgenus *Ixodes*. Human cases resulting from infection with the gram-negative spirochete, *Borrelia burgdorferi s.l.,* are largely a consequence of human encroachment into areas where the enzootic cycle is naturally maintained. The ticks that transmit this spirochete are largely opportunistic and will feed on a wide variety of hosts including mammals, birds and reptiles.

Clinical Manifestation

Clinical Lyme disease is remarkably variable, especially in the manifestations of chronic syndromes. Onset of "flu-like" symptoms occurs after a one to three week incubation period following transmission via tick bite. These symptoms are generally characterized by headache, fever, lymphadenopathy, myalgias, arthralgias, sore throat and stiffneck. Less frequent symptoms are malaise, fatigue, nausea and vomiting. Approximately 60–80% of people also exhibit a circular rash at the bite site, called erythema migrans (EM). The EM lesion generally expands in size and clears in the center giving the characteristic "bullseye" appearance. In addition, atypical or multiple lesions may appear away from the bite site. Without treatment, the EM and flu-like symptoms will resolve in several days or weeks. In some patients the disease appears to be self-limiting and no further symptoms appear. In other patients, chronic syndromes may start to appear within weeks or months. Chronic syndromes may range from mild to severe, involving neurologic, cardiac or arthritic manifestations. Treatment of early disease with 2–3 weeks of oral antibiotics (most commonly doxycycline or amoxicillin) will usually prevent onset of chronic symptoms. Treatment of chronic manifestations is much more complicated and controversial, and may involve multiple organ systems.

Etiology

Borrelia burgdorferi s.l. is a member of the Family Spriochaetaceae. These bacteria are Gram-negative, flagellated microaerophiles and have the typical helical shape of spirochetes. Considerable genetic variation is recognized in these spirochetes and has resulted in the recognition of at least three species in North America (*B. burgdorferi s.s.*, *B. bissettii*, *B. andersoni*), 5 species recognized in Europe (*B. burgdorferi s.s.*, *B. afzelii*, *B. garinii*, *B. lusitaniae*, *B. valaisiana*) and six species recognized in Asia (*B. japonica*, *B. turdae*, *B. afzelii*, *B. garinii*, *B. valaisiana*, *B. sinica*). In addition, application of a variety of molecular techniques is revealing that a considerable amount of genetic variation also occurs at the microgeographic scale. The high polymorphism of many of the protein encoding genes evaluated in these studies is not surprising in terms of the pathogen's ability to evade host immune response. In fact, differential correlation of variant genotypes with clinical Lyme disease may assist in the explanation for the broad variability in clinical manifestations of this disease.

In culture (in BSK growth media), these bacteria replicate by binary fission with a doubling time of 18–26 h at 33°C. However, pathogenicity appears to be lost during multiple passages and prolonged cultivation. It is hypothesized that this phenomenon is attributable to alterations or loss of plasmids known to contain genes that encode outer envelope proteins. In contrast to the logarithmic growth rate in culture, growth in the vector tick appears programmed. Following ingestion of the bacteria in a bloodmeal, spirochetes quickly multiply, adhere to the tick midgut wall and become dormant. The tick then completes digestion of the bloodmeal and molts to the next life stage (i.e., larva to nymph or nymph to adult). Maintenance of infection throughout this process is referred to as transstadial transmission. Dormant spirochetes become active soon after initiation of the next bloodmeal. The active bacteria traverse the midgut wall, enter the hemocoel and can be visualized near the salivary glands within 48 hours. Due to this feeding initiated activation step, the process of transmission is slow. Laboratory experiments have illustrated that transmission of the spirochete from infected tick to host does not occur within the first 48 hours of feeding following attachment.

Vectors, Hosts and Ecology

As is the case with many vector-borne diseases with a broad geographic distribution, the tick and vertebrate species involved in the maintenance of *B. burgdorferi s.l.* in enzootic cycles are geographically dependent. For example, *Ixodes scapularis* is the primary vector in the eastern United States, *I. pacificus* in the western US, and *I. ricinus* and *I. persulcatus* serve as the primary vectors in Europe and Asia, respectively. Despite this variability, these enzootic cycles exist nearly worldwide, even where clinical Lyme disease does not occur. The stability of these enzootic cycles is attributable to several ecological and biological factors. The primary factor responsible for the distribution of Lyme disease is the presence of a competent vector.

All recognized vectors of *B. burgdorferi s.l.* to humans are 3-host ticks. The significance of this observation is that all these ticks spend the majority of their existence off-host and exposed to environmental factors. Therefore, distributions of the vectors involved in the transmission *B. burgdorferi s.l.* have ecological limitations, which may include humidity, vegetative cover and/or soil composition. Ixodid, or hard ticks, have four life stages, the egg, larva, nymph and adult, with each stage other than the egg requiring a single blood meal before molting to the next stage. Sexual differentiation, in terms of morphology and behavior, only occurs in the adult stage. Females will take an enormous blood meal to produce a single batch of eggs. In the northeastern United States, this entire life cycle is generally completed in 2 years. In cooler climates, the life cycle may be extended, and in warmer climates the entire life cycle may be completed in as little as one year. The temporal distribution of these life stages is important in the intensity and maintenance of *B. burgdorferi* in an enzootic cycle. Larval ticks are rarely infective, with transovarial transmission rates (from female tick to her eggs) less than 1% in most vector species. Nymphal *Ixodes* ticks (1.0–1.5 mm long), having had the opportunity to become exposed to the spirochete during the first feeding as larvae, are widely considered to be responsible for the majority of human transmission. Their small size allows them to attach to the host and feed without being noticed for the 48 hours required for transmission. In addition, larval and nymphal (immature) *Ixodes* have the preference for the same hosts. In endemic regions in the United States, nymphal Ixodes may have infection rates of 40% or higher and precede larval ticks in the spring and early summer. This temporal stagger allows the small mammal hosts to be infected with *B. burgdorferi* from the nymphal ticks, and in turn become infective to the larval ticks that will subsequently feed. Adult ticks, although having had twice the opportunity to become infected as nymphal ticks, are relatively large and easily seen and felt by human hosts. Therefore, adult *Ixodes* are often discovered and removed from a human host within the first few hours of feeding and although capable, are rarely implicated in *Borrelia* transmission.

Where competent vectors are distributed, animal hosts play an enormous role in the intensity of transmission to man. Animal hosts tend to serve as either source of infection or as amplifying hosts resulting in high tick densities. Rodents (primarily *Peromyscus* in North America) become infected with *B. burgdorferi s.l.* while serving as hosts for ticks that have become infected from an earlier blood meal taken from an infective host. There is no evidence for animal-to-animal or tick-to-tick transmission. Infected rodents become important in the exacerbation of infection as they may support life-long infections of the pathogen and may therefore serve as the source of infection, or reservoir, for several generations of ticks. These small mammals however, usually only serve as hosts for the immature stages of the ticks. As adults, most tick species within the subgenus *Ixodes* will seek medium to large mammals as hosts. In eastern North America, white-tailed deer are notoriously involved in the maintenance of Lyme disease as each of these large mammals may serve as a host for hundreds if not thousands of female ticks, each of which will produce 3,000–6,000 eggs. Although egg batches and the resulting immature ticks may incur significant amounts of mortality due to desiccation, exposure or predation, if hosts are available tick populations have a tendency to explode. Host reduction or exclusion, primarily of deer, has been shown to significantly reduce tick densities within control areas.

Emergence, Expansion and Control of Lyme Disease

Lyme disease is recognized as an emerging disease, in particular with relation to range expansion. In the United States, this expansion is primarily recognized in the upper Midwest where the geographic range of the vector, *I. scapularis*, appears to be growing. This phenomenon is probably due, at least in part, to the transport of ticks on highly mobile hosts such as deer and birds. These ticks are rapidly relocated to new suitable habitats where they found populations that locally expand. Improved diagnosis and increased recognition of the clinical manifestations of this disease also contribute to the growing number of cases reported.

Control of Lyme disease is perhaps most effective at the level of the individual, by reducing exposure and evading tick bite. This is accomplished by either avoiding seasonal tick habitats or by following personal protection practices such as wearing long sleeves and pants, tucking pants into boots, and the use of acaricides and repellents, such as pyrethroid-based products that are readily available. Frequent tick checks and careful removal of attached ticks, to be kept for identification should symptoms occur, are appropriate preventative practices for individuals living or traveling through endemic regions. Timely treatment is salient to the prevention of chronic manifestations. Some success with area control has been illustrated with the use of barrier acaricides and host (i.e., deer) exclusion. Acaricide-treated bedding material for rodents has also proven effective at reducing ectoparasite loads on these hosts, theoretically reducing vector densities within control areas. In addition to vector reduction strategies, both canine and human vaccines are currently available. However, these prophylactics are still new and controversial, as the actual cause of the chronic syndromes associated with Lyme disease remain elusive. Although there is no human mortality directly associated with Lyme disease, the debilitation and loss of productivity associated with the chronic manifestations can be significant and deserve further scientific investigation.

Lyonet Moths (Lepidoptera: Lyonetiidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Lyonet moths, family Lyonetiidae, total 264 species, mostly Holarctic; actual fauna probably exceeds 600 species. There are three subfamilies: Cemiostominae, Lyonetiinae, and Bedelliinae. The family is part of the superfamily Yponomeutoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults are minute to small (4–12 mm wingspan), with head roughened; haustellum naked; labial palpi short, slightly porrect; maxillary palpi 1-segmented (rarely vestigial); antennae with eye-caps. Wings elongated and hindwings linear with long fringes. Maculation typically white with a black, silvery or golden tornal spot. Adults mostly crepuscular and nocturnal. Larvae are blotch leafminers; rarely mining stems. Many plant groups are recorded as hosts. A few species are economic. The family and nominate genus Lyonetia are named after the French entomologist, Pierre Lyonet (1706–1789).

Macleay (Sir) William John

GEORGE HANGAY
Carrabeen, NSW, Australia

William John Macleay was born on June 13, 1820, in Wick, Scotland. His parents died early and he had to discontinue his medical studies at Edinburgh University, and in 1839 he migrated to Australia. He accompanied his cousin, William Sharp Macleay (a son of Alexander Macleay, the founder of the greatest Australian natural history collection at the time, which later became known as the Macleay Collection and consequently the Macleay Museum). For about 16 years he lived in the rural Murrumbidge area of New South Wales, chiefly as a pastoralist and woolgrower. His interest in natural history was evident from an early age and he collected insects, many of which he described later on as new species. He also assisted his cousin in various curatorial tasks at the Macleay Collection, then housed in Elizabeth Bay House, in Sydney's Elizabeth Bay. When William Sharp Macleay died in 1865, the collection was entrusted to the care of William John, who left the Murrumbidge property and moved into Elizabeth Bay House. By then he took a very active part in politics, eventually serving seven successive parliaments over a period of 20 years. However, his main interest was natural history and within that entomology with coleopterology the focus. He became the main patron and benefactor of science of his time, amounting to about 100,000 pounds (a very large sum at that time), mainly spent on expanding and curating the collections, which contained more than a million specimens. In 1874 he and his friends laid the foundations of the Linnean Society of New South Wales. Several collectors hired by him worked the field, channeling a constant stream of specimens to the collections. George Masters was appointed as Curator, although Macleay himself described most species new to science. In 1875, he purchased the barque "Chevert" and organized a major expedition to New Guinea. In 1889 he was knighted, and two years later, on December 7, 1891 he passed away.

Macquart, Pierre Justin Marie

P. J. M. Macquart was born at Hazebrouck, France, in 1776. Much of the family was interested in natural history, so it is not surprising that Macquart became interested in insects. He served in the military starting at the age of 21, visiting Germany, Switzerland, and Austria, which provided an opportunity to collect specimens and books. Upon his return home in 1798 he devoted himself to his studies, and came to know the great French entomologist Latreille. He came to specialize in Diptera, publishing "Diptères du nord de la France" (1828–1833). He then was invited by Latreille to participate in a group effort, with Macquart handling the Diptera, which became known as "Histoire naturelle des Insectes Diptères." (1834, 1935). Macquart acquired the holdings of Meigen, and tackled the job of describing all the new species acquired by French naturalists from around the globe. In this monumental effort, he described 1,800 new species. He continued to publish updates of his work until his death in 1855.

Macrofauna

A term used to describe the larger of the soil invertebrates, usually in the body width size range of 2–20 mm. (contrast with microfauna and megafauna)

Macropsyllidae

A family of fleas (order Siphonaptera).

► Fleas

Macropterous

Having long wings. (contrast with brachypterous)

Macroveliidae

A family of bugs (order Hemiptera).

► Bugs

Maculate

This describes an object that is marked with irregular spots.

Maggot

An elongate, legless larva that lacks a well-developed head. This term usually is reserved for larvae of flies (Diptera).

► Flies

Maggot Therapy

SUSAN V. GRUNER
University of Florida, Gainesville, FL, USA

Maggot therapy, or maggot debridement therapy, is the medicinal use (biotherapy) of live fly larvae (maggots) for cleaning non-healing wounds and osteomyelitis (bone infection). Maggots debride, or clean, wounds by eating necrotic (dead) tissue. They secrete therapeutic chemicals such as ammonia and calcium carbonate, which disinfect wounds and promote healing. Only larvae that eat dead tissue (usually calliphorids from the genus *Lucilia*) can be used for medicinal purposes (Table 1). Obviously they must display no invasive behavior to living tissue.

For centuries, maggots have been used to help heal wounds. Historically, it has been military surgeons who noticed the benefits of maggot-infested wounds. One of Napoleon's surgeons noticed that maggots consumed only putrefying tissue and that they seemed to promote wound healing. The surgeon, Baron Dominic Larrey, stated that "during the progress of suppuration, the patients were only troubled by worms or larvae of the blue flies common in Syria although these insects were troublesome, they expedited the healing of the wounds by shortening the work of nature, and causing the sloughs to fall off." During the American Civil War, military surgeon W. W. Keen noted that "maggots were very common in summer – the resulting maggots were certainly disgusting but so far as I ever observed they did no harm." J. F. Zacharias of Cumberland, Maryland, USAMD, a surgeon for the Confederate Army, wrote, "I first used maggots to remove the decayed tissue in hospital gangrene and with eminent satisfaction. In a single day they would clean a wound much better than any agents we had at our command".

Maggot Therapy, Table 1 The species of flies used in maggot therapy (adapted from Sherman et al. 2000)

Family	Species
Calliphoridae	*Calliphora vicina*
	Chrysomya rufifacies
	Lucilia caesar
	Lucilia cuprina
	Lucilia illustris
	Lucilia sericata
	Phormia regina
	Protophormia terraenovae
Sarcophagidae	*Wohlfahrtia nuba*
Muscidae	*Musca domestica*

During World War I, soldiers with compound femur fractures and abdominal wounds, with the best of medical care, had only a 75% chance of survival. Those that had maggots in their wounds were more likely to survive. William Baer, an orthopedic surgeon at Johns Hopkins University, was the first physician in the USA to promote maggot therapy. His research and results were published posthumously by his colleagues in the *Journal of Bone and Joint Surgery* in 1931. By 1932, approximately 300 hospitals in Canada and the US were using maggot therapy to heal deep tissue wounds. Hospitals stopped using maggots in the 1940s as better antibiotics became available.

Though still useful, maggot therapy has been marginalized by the medical community, as has use of leaches and some other medical procedures, but occasionally these approaches remain very useful. Renewed interest in maggot therapy has been generated in response to an increase of chronic wound infections that are resistant to antibiotics. Chronic wound infection is a problem that costs billions of dollars worldwide. Wound tissue provides a perfect environment for proliferation of bacteria. Wound infection is compounded by the widespread occurrence of antibiotic-resistant "superbugs." Maggots secrete antibacterial activity against a range of these superbugs which include Gram-positive *Staphylococcus aureus*, both methicillin-resistant *S. aureus* (MRSA), and methicillin-sensitive *S. aureus* (MSSA), and *S. pyogenes*. Additionally, larval secretory products can withstand lyophilization (freeze drying) and long-term storage. These secretions may be a potential source of antibiotic-like compounds for treatment of MRSA.

Before use, medicinal maggots are sterilized internally and externally. Eggs from adult flies are sterilized in solutions containing formalin or mercuric chloride, alcohol, hydrochloric acid, dilute sodium hypochlorite or prolonged immersion in hydrogen peroxide. Hatched larvae are placed on a sterile food source and are ready to be used medicinally after two days of growth. Sterile maggots are placed on wounds within a cage-like structure or a sealed pouch for 2–4 days. The maggots are removed and new ones are applied as needed. Most patients, after an initial period of adjustment (as would be expected), adapt well to the presence of maggots.

Maggot therapy is generally limited to non-acute external wounds that have failed conventional treatment. Treatment is protracted, so if the ailment is life threatening, surgery is normally recommended rather than maggot therapy. Medicinal maggots provide three forms of benefit: debridement or elimination of dead tissue, disinfection of the wound by elimination of microbes, and promotion of wound healing. Elimination of necrotic tissue is easy to imagine, but the antimicrobial maggot exudates are more important in eliminating infection and in promoting wound repair. The species that have been used in maggot therapy are shown in Table 1. Interestingly, the species most commonly used, *Lucilia sericata*, is a pest to the sheep industry in some regions of the world. *Lucilia cuprina* must be used with care as it has a tendency to cause myiasis.

The actual application of maggots to a wound is rather simple. Prior to application, a hole matching the shape and size of the wound is cut out of a hydrocolloid pad, which prevents wound drainage from further contamination of surrounding healthy skin. Next, Dacron® chiffon is placed over the hole in the hydrocolloid pad, which creates a cage-like structure that prevents the maggots from crawling away. The dressing is further covered with a layer of gauze, which absorbs necrotic drainage from the wound. Sterile maggots, at a density of approximately 5–8 per cm^2, are placed on the wound for one 48 h cycle per week.

According the BioTherapeutics Education and Research Foundation, current use of maggots for wound therapy involves approximately 3,000 doctors, clinics and hospitals in over 20 countries, including Germany, Britain, Israel, Australia and Japan. In 2004, "medical maggots" were approved by the FDA as a medical device; however, only a single laboratory in California has been approved for production and distribution of medicinal maggots in the USA.

Mahogany Pests and Their Management

F. W. HOWARD
University of Florida, Fort Lauderdale, FL, USA

Mahoganies are the source of an exceptionally valuable cabinet wood, and are widely considered the most economically important tropical timber trees in the world. Thus, the insects that attack mahoganies are of considerable economic importance. True mahoganies include three species of

Swietenia (family Meliaceae) that are native to the American Tropics. These are West Indies mahogany (*S. mahagoni* Jacquin), Honduras, or big-leaf, mahogany (*S. macrophylla* King), and Pacific mahogany (*S. humilis* Zuccarini).

West Indies mahogany is native to the Greater Antilles except Puerto Rico, with its native range extending north of the tropics proper to southern Florida and some islands of the Bahamas. Exploitation of West Indies mahogany began early in the European colonial period, especially in Cuba, Hispaniola, and Jamaica, and by the twentieth century the species was greatly depleted from natural areas by excessive logging. It remains a popular shade tree in urban areas of southern Florida, the Antilles, Bermuda, and other areas with a tropical climate, and potentially could be restored as a plantation or forest tree.

By the twentieth century, mahogany logging had largely shifted to Honduras mahogany, which is native to mainland Tropical America. This species occurs in lowland humid regions from about 23°N latitude on the Atlantic side of Mexico though Central and South America to about 18°S latitude in Bolivia. Currently, Honduras mahogany is the commercial source of almost all mahogany wood. It is being severely depleted in many areas, and research and conservation are greatly needed to conserve this species. Pacific mahogany is distributed in a narrow zone along the relatively dry Pacific.

Khaya is a genus closely related to *Swietenia* with about seven species distributed in Africa. These species are collectively known as African mahoganies. There are many similarities between *Swietenia* and *Khaya* in structure, utilization, and ecology including relationships with insects.

The family Meliaceae contains several additional genera and species of large tropical timber trees, notably *Cedrela* spp., known as cedros or tropical-cedars, an important local wood source throughout Tropical America, and *Toona* spp., which is widely distributed in Australia and East Asia. Some of these are hosts of the same or similar insects that attack mahoganies.

Hypsipyla spp. (Lepidoptera: Pyralidae: Phycitinae)

The most important pests of mahoganies are moths in the genus *Hypsipyla* (Lepidoptera: Pyralidae: Phycitinae), whose larvae bore into the shoots and seed capsules of mahoganies and their relatives. The genus includes one species in Tropical America and several in the tropics of the Eastern Hemisphere. The American species, *Hypsipyla grandella* (Zeller), is known as the mahogany shoot borer. It is considered the most important pest of mahoganies in the Americas because its damage can reduce growth in height and cause distorted growth of the main stem. Damage by this shoot borer is a major impediment to establishing and growing mahoganies in plantations. It is also a serious pest of mahoganies grown in nurseries for use as ornamentals. *Hypsipyla grandella* is distributed in southern Florida, the West Indies, northern Mexico southward through Central America, and South America except Chile. This distribution coincides with that of its host plant species, i.e., mahoganies and other tropical meliaceous trees.

Hypsipyla robusta (Moore) plays a similar role as an important shoot borer of African mahoganies and other meliaceous trees in the tropics of the Eastern Hemisphere. The distribution of *H. robusta* was formerly reported as extending from Africa to Tropical Asia, Australia, and some Pacific islands, but *H. robusta* as currently understood is a species complex and its taxonomy is being resolved. *Hypsipyla robusta* and perhaps other species of this complex have been variously referred to as the toona fruit and shoot borer, cedar tip moth, cedar shoot caterpillar, and also in some countries as the mahogany shoot borer. *Hypsipyla grandella* and *H. robusta* have been the subject of considerable research. Since the various species of *Hypsipyla* are very similar insects in appearance, biology, economic impact, and in the approaches to managing them as pests, this discussion will focus on *H. grandella*, which is the better known of the two species (Fig. 1).

The adults of *H. grandella* are grayish–brown in color with a wingspan measuring about 23–45 mm.

Mahogany Pests and Their Management, Figure 1 **Mahogany insects: (a) The larva of the mahogany shoot borer, *Hypsipyla grandella*; (b) A shoot of West Indies mahogany, *Swietenia mahagoni*, damaged by the mahogany shoot borer, *Hypsipyla grandella*; (c) A seed capsule of West Indies mahogany, *Swietenia mahagoni*, with boring damage of the mahogany shoot borer, *Hypsipyla grandella*; (d) The mahogany webworm, *Macalla thyrsisalis*; (e) The abaxial surface of a leaflet with the larva of the mahogany leaf miner, *Phyllocnistis meliacella* within the mine; (f) Leaf mines of the mahogany leaf miner, *Phyllocnistis meliacella*, in leaflets of West Indies mahogany, *Swietenia mahagoni* (photos by F.W. Howard).**

They are nocturnal and oviposit during the early morning hours on leaf scars, new shoots, leaf veins and fruits (seed capsules). The eggs hatch in several days. Recently emerged first instar larvae may begin feeding on the surfaces of the leaves or other plant parts, then bore into new shoots or seed capsules. The total development time including the larval, prepupal, and pupal stages, is usually one to two months and may be extended if the larvae undergo diapause.

Larvae that bore in shoots produce a tunnel of several centimeters in length and expel frass from the tunnel entrance as a reddish–brown mass which becomes intertwined with the insect's silk. The hollowed out portion of the shoot dies and the shoot buckles.

In southern Florida, where the rainy season usually begins in May or June, and the flush of West Indies mahogany takes place from April to June, *H. grandella* attacks shoots from early spring to mid-summer, with pronounced peaks in May. Population surges in spring, i.e., at the beginning of the rainy season, also have been observed in some studies in the tropics. But generally in the tropics, *H. grandella* is active all year with high shoot borer activity typically coinciding with flushes of mahoganies subsequent to periods of high rainfall.

Hypsipyla grandella also attacks seed capsules of mahoganies and cedros, penetrating between the valves of the capsules when they have dehisced. There they bore into seeds and hollow them out, after which they bore into the core of capsules. The pupal stage takes place inside the hollowed portions of the twig or seed capsule, or in the leaf litter or soil beneath host trees.

Damage. Mahogany trees are susceptible to attack beginning when they reach a height of about 0.5 m. The shoot borers may attack both the terminals of side branches and the leader (central terminal). Boring of the leader causes the more serious damage to the form of the tree, because this breaks apical dominance, resulting in excessive side-branching, and more importantly, in the replacement of the leader with one or more lateral branches and thus the formation of a crooked main stem. Small trees whose terminal shoots are attacked repeatedly in successive years become extremely deformed. Because attacks ultimately result in a reduction in the number and length of straight, clear logs, *H. grandella is* a major pest of mahoganies, cedros, and some other meliaceous tropical trees grown as timber. Mahogany shoot borer attack reduces the grade and thus the monetary value of young mahoganies grown in nurseries for use as shade trees, their chief use in southern Florida and urban areas in various tropical countries.

Damage to seeds by *H. grandella* has usually been regarded as unimportant or second in importance to the damage to the shoots, as seeds are thought to be produced abundantly enough to compensate for losses to the shoot borer. However, in a study in southern Florida, *H. grandella* attacked up to 100% of the seed capsules of West Indies mahogany trees and consumed 50–96% of the seeds per capsule. During the same period, only 14–22% of new shoots on the same trees were attacked. The impact of this insect on regeneration should be investigated further, especially in natural areas and managed plantations.

Management. Considerable research has been conducted to develop methods of managing *Hypsipyla* shoot borers. This insect is notoriously difficult to control, primarily because although some methods reduce the pest population considerably, even light populations can cause significant damage. In fact, destruction of the leader, which is the most critical damage, is caused by a single larva.

A review of published information on chemical control of *Hypsipyla* spp. shoot borers reported that after more than eight decades of research in 23 tropical countries there is still no reliable, cost-effective, and environmentally sound chemical control method available to prevent economic damage by these insects. However, chemical control of these pests might be appropriate in nursery situations.

About 40 species of insects have been identified as natural enemies of *H. grandella* in the Americas. As a natural enemy complex, they undoubtedly are important in regulating populations of this insect, but their effect is generally insufficient to prevent economic damage.

Mahoganies growing at low densities in mixed forests are generally less frequently attacked by *H. grandella* than mahoganies in pure plantations. This and other ecological principles have been applied in silvicultural techniques to reduce shoot borer damage, with varying degrees of success.

In testing different provenances of mahoganies and cedros, less damage has been seen in some selections. Research to identify genetic strains of these trees that are resistant or that can overcome shoot borer attack has progressed well.

An international workshop on *Hypsipyla* shoot borers held in 1996 (online at http://aciar.gov.au/web.nsf/doc/JFRN-5J472Q), in which 36 papers were presented, concluded that the strategies most promising for management of these pests involved identification and use of resistant genotypes, and silvicultural methods, viz., growing mahogany and cedro trees in mixed rather than pure stands and under an established canopy. It was also emphasized that vigorous growth of young trees should be promoted by cultural methods in the nursery and in young plantations. Chemical control was seen as a tool for temporarily reducing shoot borer populations in limited areas.

In addition to *Hypsipyla* species, several other insect species that are specific feeders on mahoganies and close relatives sometimes cause significant damage. In the Americas, these include a defoliator, a leaf miner, a bark weevil, and a scale insect (Fig. 2).

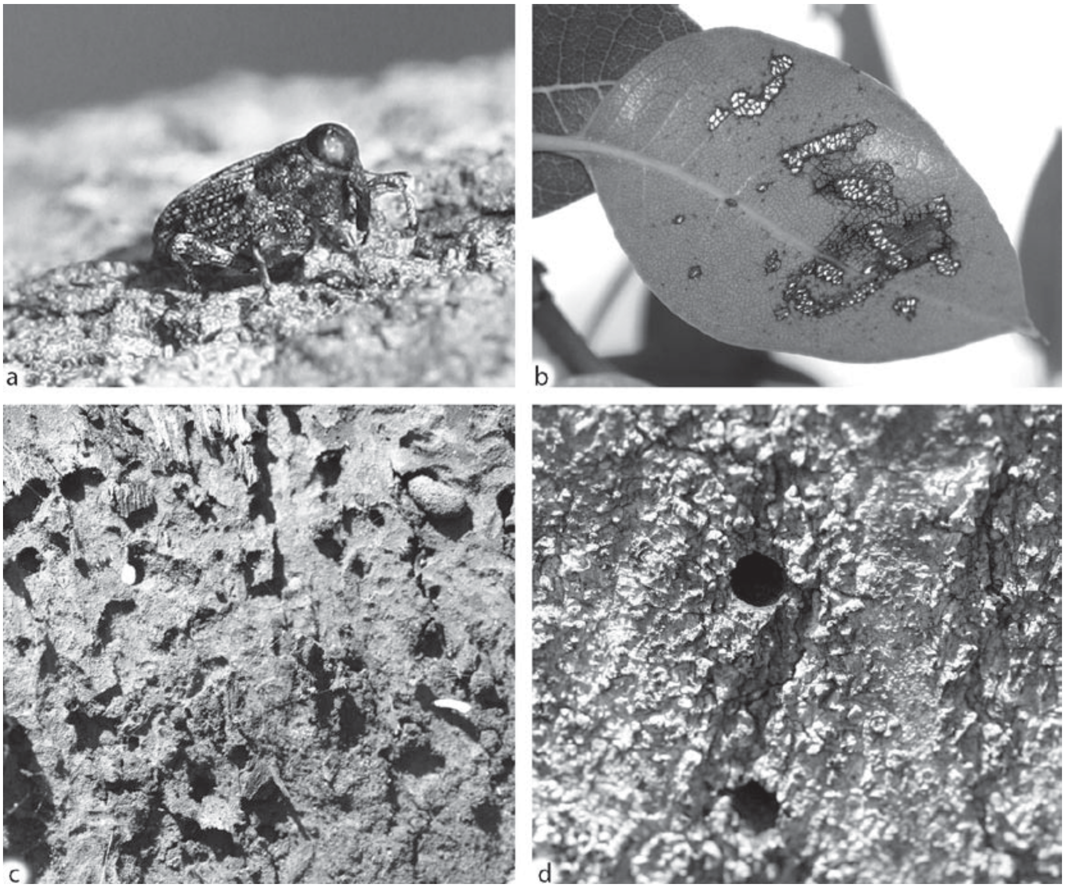
Mahogany Webworm, *Macalla thyrsisalis* Walker (Lepidoptera: Pyralidae: Epipaschiinae)

The mahogany webworm is a defoliator of mahoganies reported from throughout most of the range of mahoganies in the Americas. Nearly all records in Tropical America are based on trap catches of the adult, with no data on the larva and its hosts. It has not been reported as a pest except in southern Florida, and the biology of this species has been studied only in that locality.

The adult is a small gray–brown moth with whitish hindwings. They are probably nocturnal. Their peak flight period is in late winter or early spring prior to the annual flush of mahoganies. The eggs have not been observed in nature, and possibly are eaten by the recently hatched larvae, as is known in many Lepidoptera. The larva has a vivid yellow ground-color and lateral bands that consist of three narrow black stripes alternating with two white stripes. Each larva spins a web to pull several leaves together, and remains partially hidden in the resulting leaf cluster, consuming laminar tissue from the margins of leaflets inward, leaving the midveins intact. The larval stage is completed in about 10 days, and multiple generations may be produced during the spring season, so that by mid-spring webworm populations may consist of larvae in early and late instars. As with the mahogany shoot borer, their presence on their host trees coincides with the period of spring flush and leaf expansion of mahogany. The webworm larvae feed on young leaves before they have matured and hardened off. Dense populations of these caterpillars may entirely strip a tree of foliage.

In southern Florida, several years of annual spring outbreaks of mahogany webworms have alternated with periods of years in which populations are diminished, but there has been no long-term monitoring to record the patterns of outbreaks. Possibly, outbreak cycles of mahogany webworm are related to cycles of their parasitoid populations. In southern Florida and presumably throughout its native range, the mahogany webworm is under natural control. A fly, *Lespesia* n. sp. (Diptera: Tachinidae) and two species of wasps, *Habrobracon* sp. and *Apanteles* sp. (Hymenoptera: Braconidae), are parasitoids of mahogany webworm in southern Florida.

When parasitoids and other natural control factors fail to adequately control mahogany webworms, landscape or nursery managers may resort to chemical control. In the interest of discovering a safe treatment with minimal negative environmental effects, a study was conducted involving foliar applications of a neem product. It was



Mahogany Pests and Their Management, Figure 2 **More mahogany insects: (a) The mahogany bark weevil, *Copturus floridanus*, resting on bark of the West Indies mahogany, *Swietenia mahagoni*; (b) A leaflet of West Indies mahogany, *Swietenia mahagoni*, with feeding damage of the adult mahogany bark weevil, *Copturus floridanus*; (c) Galleries of the mahogany bark weevil, *Copturus floridanus*, beneath the bark of West Indies mahogany, *Swietenia mahagoni*. A cocoon is at upper right in photograph; (d) Exit holes of the mahogany bark weevil, *Copturus floridanus*, in the bark of West Indies mahogany, *Swietenia mahagoni* (photos by F. W. Howard).**

determined that the product acted as an antifeedant against this pest, and when applied early in the development of an infestation, it prevented mahogany webworm attack on the treated trees.

Mahogany Leafminer, *Phyllocnistis meliacella* Becker (Lepidoptera: Gracillariidae)

The mahogany leafminer attacks foliage of Honduras and West Indies mahogany, cedro, and probably some other meliaceous trees. It was described from specimens from Honduras mahogany in Costa Rica, and during certain years is common on West Indies mahogany in southern Florida. More recently this species was listed as an insect on cedro in Tamaulipas, Mexico. Although not reported elsewhere, it is probably widely distributed throughout the range of mahoganies in the Americas, but seldom noticed. In fact, an unidentified leaf mine identical to that of *P. meliacella* is visible in a photo of leaves of *Cedrela odorata* in Venezuela in a paper on mahogany shoot borer published 12 years prior to the publication of the taxonomic description of *P. meliacella*.

The adult of the mahogany leafminer is a minute white moth about 2 mm long from the apex of the head to the folded-back wings. The apodous, wormlike, white larva consumes leaf mesophyll, creating a winding gallery in the leaflet (mahoganies leaves are compound, with 5–7 leaflets) that eventually terminates in the leaflet margin, which the larva rolls. Pupation takes place within the rolled margin. Several hymenopterous species are parasitoids of the mahogany leafminer in Florida.

The mahogany leafminer is generally considered a minor pest at most, and has received little study. In observations in a research planting in Florida during spring 1993, which was a year when mahogany leafminer damage was relatively extensive, 62% of the leaves of young West Indies mahoganies had at least one leaf mine made by this insect, and 8.8–12.4% of the leaflets were mined. The amount of leaf tissue consumed by one larva is undoubtedly very small, but mined leaflets become distorted and stunted and may be shed early. Nevertheless, the effects on tree vigor of mahogany leafminer damage, even when populations are high, are presumably negligible. In a test of a neem product to control mahogany shoot borer, the treatment suppressed shoot borer attack and also acted as a preventative against mahogany leaf miner damage, but treatments applied specifically to control the leafminer would probably seldom be economically justifiable.

Mahogany Bark Weevil, *Copturus floridanus* (Fall) (Coleoptera: Curculionidae)

The mahogany bark weevil is reported in the Bahamas, Cuba, and southern Florida. The adult weevils are about 4–6 mm long and 3 mm in width, and dark grey–brown, with patches of fine whitish speckling on the elytra. Their coloring and texture blend well with the bark of mahogany, upon which they rest for long periods during the day, flying quickly when disturbed. They are often seen feeding on the leaf lamina, leaving closely grouped small feeding holes, which eventually become surrounded by brown necrotic leaf tissue. The females bore similarly small holes through the bark to the cambium, then turn around and oviposit in them.

The larva is small, apodous, ivory colored, and has the typical c-shape of weevil larvae. They feed in the cambium of mahoganies, producing winding galleries, and construct a cell in which they pupate. Development is completed in three to six months. Adults and larvae are present all year in Florida.

The feeding damage of the adult weevils on the leaves of a mahogany tree serves as an indicator that the mahogany bark weevil adults are present in the area, but does not necessarily imply that the same tree is infested with bark beetle larvae. A mahogany bark beetle infestation may result in the formation of drops of a reddish–brown resinous exudate on the bark, although these may be a result of almost any kind of injury to mahogany stems. The presence of round exit holes of about 3 mm in diameter in the bark is a stronger indicator that a tree is infested with the larvae. The holes indicate that weevils have completed development in the tree and it can ordinarily be assumed that additional weevils are still in the larval stage beneath the bark. In Florida, mature mahogany bark weevils are commonly seen in low numbers on the bark of mahoganies in plantings where there is no visible borer damage to mahogany trees except for exit holes in or near dead branches. Extensive damage to the main stem appears to occur mostly on stressed trees, as when trees are severely damaged by hurricanes or growing under excessively wet conditions. Mahogany saplings transplanted during drought periods are said to be highly susceptible to attack. Thus, like stem borers in general, the mahogany bark weevil is regarded as a secondary pest which can be managed by horticultural or silvicultural techniques.

West Indies Mahogany Scale, *Conchaspis cordiae* Mamet (Hemiptera: Conchaspididae)

Mahoganies tend to be relatively free of scale insects, but West Indies mahoganies were recently found to be highly infested with West Indies mahogany scale, over a broad area of southern Florida, where this scale insect was apparently accidentally introduced. This species, which is in the small and relatively unstudied tropical scale insect family Conchaspididae, is native to several islands of the Caribbean, where it is apparently under natural control factors. In Florida, 5–8% of scale coverings of *C. cordiae* had parasitoid exit holes, and a parasitoid, *Marietta* sp., was reared from this scale insect.

Although this scale insect has been reported on mahoganies, *Cordia* sp. and seagrape (*Coccoloba uvifera* L.) in its native range, it has been observed only on mahoganies in Florida, and shows a strong preference for West Indies mahogany as compared to Honduras mahogany and *Khaya nyasica* (Stapf.). Heavy infestations occur on twigs and branches of up to about 6 cm in diameter, but no more than light infestations have been seen on larger branches and main stems. Although it has become widely disseminated in southeastern Florida, it has not yet caused serious damage to mahoganies.

Other Insects

In addition to the above insects, which are specific to mahoganies and their close relatives, some insect pests of mahoganies are polyphagous species whose host ranges include mahoganies. These include various species of ambrosia beetles (Coleoptera: Curculionidae: Scolytinae) that bore the twigs or main stems, and species of Scarabaeidae whose adult beetles feed on the leaves.

Although mahoganies are acknowledged as the most important tropical timber trees in the world and there has been much interest in their genetics and breeding, there is almost nothing known concerning their pollination, except for results of some observations in southern Florida indicating that the pollen of West Indies mahogany is adapted to entomophily, and various species of thrips (Thysanoptera) are abundant in mahogany flowers and apparently transfer the pollen between flowers. No other insects have been implicated as potential pollinators of mahoganies in southern Florida. However, southern Florida is where the West Indies mahogany is isolated at the northern extreme of its natural range, and can be considered a recent arrival in the context of geological time. Possibly, within the principal range of mahoganies in the tropics, pollination of mahoganies is accomplished by other insects. That there is an effective pollination system present in Florida is evident in that mahoganies here are typically highly productive of fruits, i.e., seed capsules.

Research on insects associated with mahoganies has focused almost entirely on *Hypsipyla* spp., with far less attention to the other pests noted in this discussion. In the natural habitats of mahoganies, there are undoubtedly many additional species of insects associated with them that have not been studied.

Maize (Corn) Pests and Their Management

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

In some English speaking countries, principally USA, Canada and Australia, maize is known as corn. Maize, *Zea mays*, is one of the world's most important cereal grains. More maize is produced than wheat or rice, though because much of the maize is fed to livestock or used for industrial purposes, more people are directly dependent on these other grains. Nevertheless, maize is a tremendously important crop, particularly in the Americas, China, and parts of Africa.

Maize was domesticated in Mesoamerica, probably in Mexico, sometime between 7,500 and 12,000 years ago. Its origin is obscure, but seems to be derived from a small-seeded wild *Z. mays* subspecies known as teotsinte. Small teosinte-like cobs have been found in caves that date back to about 2750 B.C., but later, beginning about 1500 B.C., this grain began to be dispersed widely in the Americas. It became a staple of the indigenous peoples not only in Mesoamerica, but also in North and South America and the Caribbean. When Europeans (starting with Christopher Columbus) made contact with the Americas they quickly recognized the value of maize, and it became introduced to many areas of the world, where it is grown in all but the coldest and driest regions. In 2002, for example, over 70 countries harvested at least 100,000 ha of maize. The major maize producers (2005 data) were USA, China, Brazil, Mexico, Argentina, and Indonesia, which accounted for 40.5, 18.9, 5.0, 3.0, 2.9, and 2.2% of the world's production, respectively. Thus, though some maize is grown almost everywhere, most of the production is concentrated in a few countries. Note that a considerable amount of maize is grown in southern Europe, but it is easy to underestimate its significance in this region because many small countries are involved in its production.

Maize is a productive plant, and is rich in many of the nutrients needed by humans and livestock. However, alone it does not provide completely balanced nutrition. Early Americans supplemented their maize consumption with beans, fish, meat, and other grains to obtain a complete range of amino acids. They also liberated the niacin found in maize through the addition of wood ash or lime. Failure to take the steps to provide balanced nutrition in maize-dependent diets results in severe nutrient deficiency.

Maize is a tall grass, and some varieties surpass 7 m in height. Male flowers are found at the apex of the stem, in a structure called the "tassel." Pollen from the tassel falls or blows to the "silk," which are elongated stigmas that protrude from the female inflorescence, or "ear." Once on the silk, the pollen produce pollen tubes that grows the length of the silk, resulting in pollination. Pollination results in expansion of the individual fruits or "kernels" on the ear. They are attached to a pithy core called a "cob," and generally occur in rows. Ears usually contain 200–400 kernels. Different varieties produce varying sizes and numbers of ears and kernels, and kernels with differing properties, allowing the grain to be used for several purposes. Maize has long been used to feed livestock (as grain corn which uses the kernels, or silage corn which also uses the stalk and foliage), as corn flour for baking, as popcorn, and as a sweet vegetable called "sweet corn." Increasingly, however, it is being used as a source of fructose for sweetening, or fermented and distilled as ethanol for production of liquor or as a gasoline additive.

Maize removes a considerable amount of nutrients from the soil, and is often grown as part of a crop rotation with a soil-replenishing legume crop such as alfalfa or soybean, and with a small grain crop such as wheat or barley. Nitrogen fertilization is normally required. Maize is not tolerant of cold weather, so in temperate areas it is planted after all danger of frost is past. It is tolerant of drought, but must have adequate moisture during the pollination period. Sugar-rich maize varieties harvested as sweet corn are harvested soon after kernel formation, before starch has begun to form. For silage, the maize may be harvested any time before it dries. For grain production, the ears and kernels are allowed to remain on the plant until they are very dry, which is late fall or even winter.

As one would expect of a crop grown on extensive acreage and in most regions of the world, many pests have adapted to the crop. Some of the most important are shown in Table 2.

Although there are numerous pest species, for an overview of the pests and their management, most can be grouped together with similar species based on their feeding behavior. The principal groups are stem borers; rootworms; earworms; armyworms; cutworms; aphid, leafhopper, delphacid plant disease vectors; and mites.

Stem Borers

Stem borers are the most important pests of maize wherever it is grown. Most are in the order Lepidoptera, and usually in the families Noctuidae or

Maize (Corn) Pests and Their Management, Table 2 Some important arthropod pests of maize (corn) and places where they are damaging

Feeding behavior	Primary taxon	Common name	Scientific name	Location
Foliage (leaf), chewing	Lepidoptera	Fall armyworm	*Spodoptera frugiperda*	Americas
		African armyworm	*Spodoptera exempta*	Asia, Africa
		Common armyworm	*Pseudaletia unipuncta*	Asia, Europe, Africa, America
		Maize webworm	*Marasamia trapezalis*	Africa
	Coleoptera	Grey weevils	*Tanymecus* spp.	Asia, Europe
Foliage, piercing-sucking	Hemiptera	Corn leaf aphid	*Rhopalosiphum maidis*	Asia, Europe, Africa, America
		Corn delphacid	*Peregrinus maidis*	Americas
		Corn leafhopper	*Dalbulus maidis*	Americas
		African leafhopper	*Cicadulina* spp.	Africa
		Chinch bug	*Blissus leucopterus*	N. America
	Acarina	Twospotted spider mite	*Tetranychus urticae*	Asia, Europe, Africa, America
		Banks grass mite	*Oligonychus pratensis*	C., N. America
Stalk, chewing	Lepidoptera	European corn borer	*Ostrinia nubilalis*	Asia, Europe, Africa, N. America
		Asian corn borer	*Ostrinia furnacalis*	Asia
		Lesser cornstalk borer	*Elasmopalpus lignosellus*	Americas

Maize (Corn) Pests and Their Management, Table 2 Some important arthropod pests of maize (corn) and places where they are damaging (Continued)

Feeding behavior	Primary taxon	Common name	Scientific name	Location
		Southwestern corn borer	*Diatrea grandsiosella*	N., C. America
		Neotropical corn borer	*Diatrea lineolata*	C., S. America
		Sugarcane borer	*Diatrea saccharalis*	Americas
		Asiatic rice borer	*Chilo suppresalis*	Asia
		Spotted stem borer	*Chilo partellus*	Asia, Africa
		Pink stem borer	*Sesamia cretica*	Africa
		African pink stem borer	*Sesamia calamistis*	Africa
		Mediterranean corn borer	*Sesamia nonagroides*	Europe
		Asiatic pink stem borer	*Sesamia inferens*	Asia
		African maize stalk borer	*Busseola fusca*	Africa
		African sugarcane borer	*Eldana saccharina*	Africa
		Potato stem borer	*Hydraecia micacea*	Asia, Europe, N. America

		Northern corn rootworm	*Diabrotica barberi*	N. America
		Wireworms	Various	Asia, Africa, Europe, Americas
		White grubs, chafers	*Phyllophaga, Cyclocephala, Melolontha* spp.	Asia, Europe, Americas

Maize (Corn) Pests and Their Management, Table 2 Some important arthropod pests of maize (corn) and places where they are damaging (Continued)

Feeding behavior	Primary taxon	Common name	Scientific name	Location
		Seedcorn beetle	*Stenolophus* spp.	N. America
		Flea beetles	*Chaetocnema* spp.	N. America
	Diptera	Seed fly	*Delia platura*	N. America. Europe, Asia

Pyralidae. Initially they feed on the foliage, but then move into the stems and affect movement of water and nutrients. Fungi, particularly *Fusarium* spp., gain access to the plants through the openings created by borers, leading to various rots and the occurrence of mycotoxins. When they bore into the base of the ear they can cause ear drop. In North America and Europe, the most important stalk borer is European corn borer, though some European countries also suffer from Mediterranean corn borer. Similarly, portions of North and Central America are affected by southwestern corn borer. In South America, the sugarcane borer and the lesser cornstalk borer predominate. In Africa, the African stalk borer and spotted stem borer are most important, but pink stem borer and sugarcane borer also can be important. In Asia, the most important species are Asian corn borer, Asiatic rice borer, Asiatic pink stem borer, and spotted stem borer.

Rootworms

Corn rootworm larvae feed on the roots and base of the stem. They disrupt water and nutrient uptake, and cause plants to lodge (fall over), making harvest difficult. Adults also feed on foliage and silks, sometimes interfering with pollination, but this generally is not very important. Historically, the *Diabrotica* rootworm problem was mostly a North American issue, though causing some damage in Central and South America. However, western corn rootworm was discovered in Yugoslavia in 1992, and has since spread through several countries in Europe. More insecticide is used in North America for suppression of corn rootworms than is used for control of any other insect pest on any crop, and 80% of the insecticides used in North America on corn is directed to corn rootworms, so the effect on Europe of the establishment of western corn rootworm is potentially great. In the USA, other corn rootworm species can inflict damage, but none are as important as western corn rootworm.

Corn Earworms

The corn earworm found in the Americas, *Helicoverpa zea*, can be a extremely damaging insect on sweet corn, though it is of lesser significance on field corn. In the old world, *Helicoverpa armigera* is the corn earworm of importance. These insects feed on both silk and within the ears, with the latter being of importance. Due to their feeding habits, sweet corn has a low tolerance threshold, so a great deal of insecticide is used against these insects during sweet corn production. Damage by these insects also facilitates entry of plant pathogens. These are not the only earworms, of course, but other ear feeders such as western bean cutworm are not nearly as important.

Armyworms

Most armyworms, *Spodoptera* and *Pseudaletia* spp., attack maize at intermediate stages in the growth of the plant, during the whorl stage. They can cause extensive defoliation and occasionally affect the ear. In tropical and subtropical areas of the Americas they can be the most severe problem, and often cause injury annually.

Cutworms

These insects affect mostly the seedling stage, severing the shoot at the soil surface, and often killing the young plant. A large number of noctuids possess this feeding habit, but the most important is black cutworm, *Agrotis ipsilon*. This species overwinters in subtropical areas throughout the world, but disperses to more temperate areas early each spring, causing considerable damage to young corn plantings.

Aphids, Leafhoppers and Delphacids

Alone, aphids (Hemiptera: Aphididae), leafhoppers (Hemiptera: Cicadellidae), and delphacids (Hemiptera: Delphacidae) are not usually very damaging to maize. However, because they can vector plant viruses, they can become quite important. For example, although corn leafhopper, *Dalbulus maidis*, can cause plant wilting due to direct feeding injury, its principal effect is to vector disease such as maize rayado fino virus, maize bushy plant mycoplasma, and corn stunt spiroplasma. Likewise, an African species of Delphacidae, *Peregrinus maidis*, that has become redistributed around the world in tropical and subtropical areas transmits maize mosaic virus and maize stripe virus.

Mites

Mites are severe pests of maize mostly in arid areas or under dry conditions. However, dry land production is common with maize, and mites can become the dominant pest in such situations. Also, under irrigated conditions in dry environments, mite problems develop when the weather is unusually dry or dust is abundant. Along unpaved roadways, for example, the large amounts of dust produced by vehicles can be lethal to predatory insects while mites harbored beneath a layer of silk on the foliage are protected from the desiccating effects of dust. Mites are often resistant to chemical insecticides, and there is risk of their populations flaring up when insecticides are applied against caterpillars or other pests, resulting in the inadvertent destruction of the mite's natural enemies.

Other Pests

Locally, other pests can be quite important due to ecological situations favoring their abundance, or because the crop is especially susceptible. For example, wireworms tend to be more troublesome following rotations of other grasses or when grass weeds are abundant in the previous crops. Moisture conditions can also favor the occurrence of wireworms in low-lying areas of fields; corn wireworm, *Melanotus communis* (Coleoptera: Elateridae), is commonly associated with more moist areas of fields. Grasshopper and locust (Orthoptera: Acrididae) outbreaks can occur intermittently, or occur where weeds or weedy crops are not managed properly, resulting in dispersal of these insects into maize fields and causing extensive damage, especially along the margins of the field.

The high value and low threshold for damage associated with sweet corn can create special conditions favoring the occurrence of pests. Sap beetles such as *Carpophilus lugubris* (Coleoptera: Nitidulidae), and cornsilk fly, *Euxesta* spp. (Diptera: Otididae), are very damaging to sweet corn in some areas, but they are not considered to be pests of grain corn. Even the earworms, which are devastating pests of sweet corn, because consumers are repulsed by the presence of insects or insect parts in their food, have little impact on grain corn production.

Pest Management in Maize

The effect of arthropod pests on corn production is considerable, though quite variable from location to location. Data in Table 3 suggests that the potential level of damage in maize is about 14–17% worldwide. In contrast, the actual level of arthropod-caused losses is about 10–12%. The approximately 5% difference is due to the plant protection efforts of producers. The different areas of the world vary considerably in the effectiveness at protecting maize from damage. Most effective, it seems, are producers in North America and the Near East, which incur only about 6 and 9% loss, respectively. In contrast, areas of Africa and Asia derive little benefit from protection efforts, or make little effort to reduce losses. Virtually all the African countries (also Mexico and Brazil) have high levels of pest pressure (infestation) on maize, whereas most of the rest of the world has moderate levels of infestation.

Maize (Corn) Pests and Their Management, Table 3
Estimated actual and potential losses due to maize pests in the major maize-producing regions of the world (adapted from CABI Crop Protection Compendium, 2002)

	Actual % loss with controls	Potential % loss without controls
Africa	14	17
Eastern	17	18

Andean	10	14
North America	6	15
Central America	13	14
Europe	9	14

Cultural or environmental management. A number of approaches are used to manage maize pests. Cultural practices such as early planting or harvest, crop rotation, and effective weed suppression can be used to advantage in many cases. For example, rotation of maize with a non-grass crop can usually be used effectively in North America to manage corn rootworm because they overwinter as eggs. Upon hatching in the spring, young corn rootworm larvae will perish if they cannot reach the roots of suitable grass crops such as corn. So simply rotating corn with soybeans was a successful technique for many years, though in recent years a strain of rootworm has begun to evolve that diapauses for two seasons, necessitating a longer crop rotation period or other management approaches. Sometimes growers prefer not to rotate crops, instead growing maize continuously. Under these conditions, some benefit can be acquired by planting the new crop between the rows of the previous crop, rather than in the same location as the previous crop. Moving the crop planting even a few centimeters requires that the rootworm larvae must disperse to find the roots of the young plants, and many die while searching for food.

Insecticides. Insecticides (including bioinsecticides such as *Bacillus thuringinsis*) are a principal approach to avoid loss in maize. In the Americas, where rootworms are a problem, most of the insecticide is applied to the soil to protect roots. The rootworms hatch several weeks after the maize is planted, and if the insecticide is to be applied at planting, this requires the use of a persistent insecticide. Post planting applications are possible, but it is difficult to attain good root protection with post-plant applications, and it is more costly. Lesser amounts of insecticide are sprayed onto foliage to protect against defoliation and ear damage, and only a small amount is expended via seed treatment to protect the seed and young seedling from injury by seed-feeding insects. The insecticide used on maize in North America is estimated at over 50% for rootworm suppression, 11% for the stalk borers (European corn borer and southwestern corn borer), and 12% for corn earworm. In other areas of the world, however, proportionally more insecticide is used as a foliar protectant and seed treatment because soil pests are not as important. About 70% of the insecticide used on maize is used in the Americas, and of the insecticide used in the Americas, about 2/3 is used in North America. This pattern is not surprising considering the preponderance of maize production in North America, and the propensity to maximize yield in corporate-type farming operations. In less well financed or subsistence agriculture, insecticide purchase is a much more difficult option.

Genetically engineered germplasm. The soil bacterium *Bacillus thuringiensis* has long been recognized for its ability to control caterpillars, and in more recent times strains have been identified that affect lower flies (e.g., mosquitoes, blackflies) and beetles. With the advances in genetic engineering, it has proved possible to incorporate components of the *B. thuringiensis* bacterium into plants (usually called transgenic plants), thereby conferring a degree of resistance against lepidopterous insects. In maize, the caterpillar-specific elements of *B. thuringiensis* (cry1Ab gene), which affect stalk borers, have been rather widely deployed via genetically modified maize germplasm. The beetle-specific elements (cry3B1), which are active against rootworms, are less well known but are beginning to gain acceptance, at least in the Americas. When farmers plant maize that is engineered to resist herbivory by Lepidoptera and Coleoptera, they effectively eliminate much of the potential damage that they might incur. Such practices do not eliminate all problems, of course, as there are other taxa that can be damaging. Also, expression of the *Bacillus thuringiensis* toxin is not uniform throughout the plant, and not all pests are affected. Nevertheless, yield gains in the USA are attributable to maize containing *Bacillus thuringiensis* genetic elements (Bt corn) is estimated at 5%. In areas of the world where insecticide use is less prevalent, Bt corn confers higher yield gains, often 10% or more. The detrimental effects of Bt corn are somewhat obvious, principally higher cost of seed and the risk of widespread resistance to Bt. On the other hand, there are certainly economic, health, and environmental benefits associated with decreased use of insecticides in Bt corn. Overall, the benefits of genetically engineered maize will only be known with additional time.

Malaria

EUGENE J. GERBERG
University of Florida, Gainesville, FL, USA

Malaria is a debilitating disease caused by an infection of one or more protozoan parasites belonging to the subphylum Sporozoa, family Plasmodiidae, genus *Plasmodium*. These parasites are found in the blood of mammals, birds and reptiles. Human malaria is transmitted by the bite of female anopheline mosquitoes of the genus *Anopheles* (Diptera: Culicidae).

Malaria is a major endemic tropical disease characterized by severe chills and fever, anemia, and splenic enlargement. The disease has a wide geographical range, occurring from the temperate zones to the sub-tropics and tropics. It has been estimated that there are 150–400 million malaria cases a year, with five million deaths.

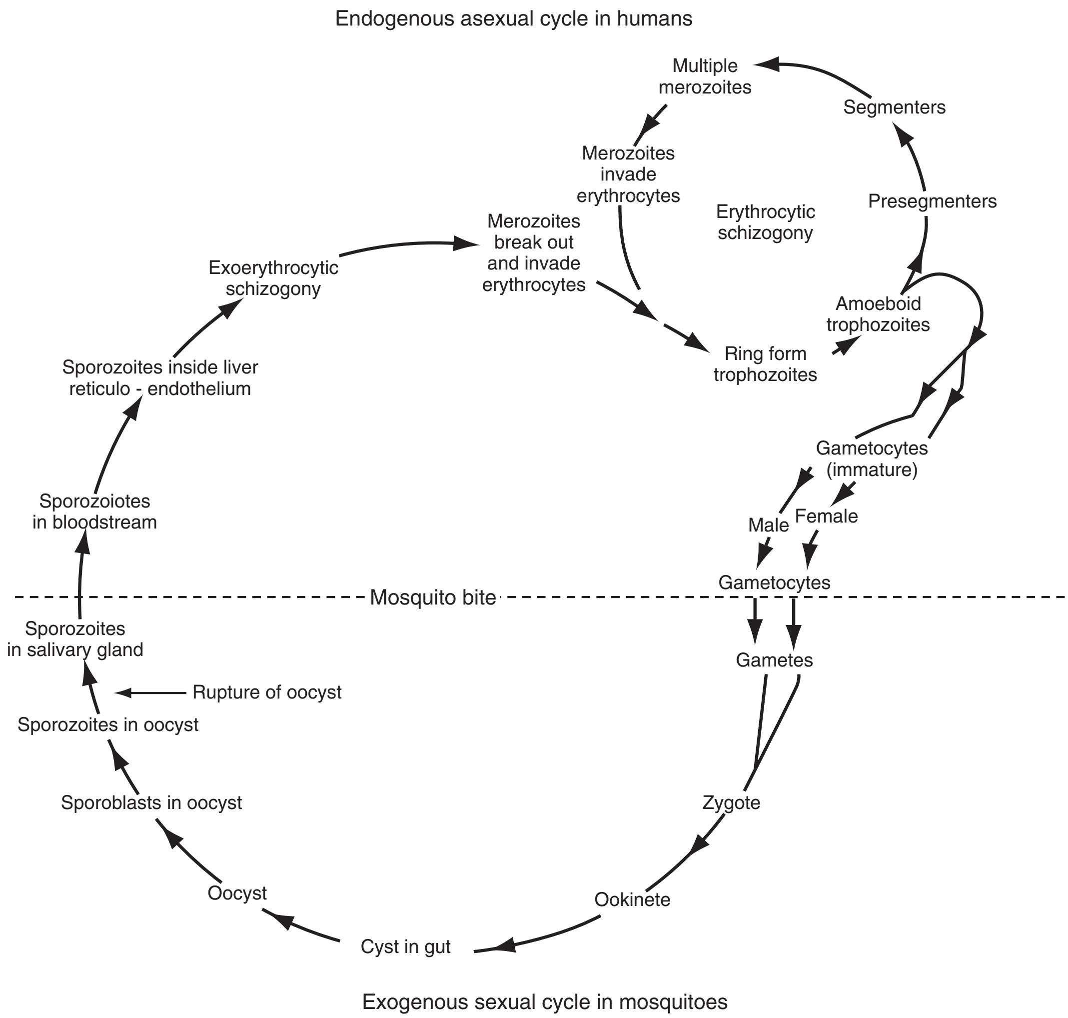
Malaria once was thought to be caused by vapors arising from swampy areas, and thus in the eighteenth century the Italians called it malaria, or bad air. It wasn't until 1880 that Charles Laveran, a French army surgeon, described malaria parasites in the red blood cells of humans. In 1897, Ronald Ross found a form of a malaria parasite in a mosquito. In 1898, Battista Grassi, Amico Bignami and Giuseppe Bastianelli, in Italy, described the malaria cycle in humans and mosquitoes.

Plasmodium undergo two types of multiplication by an endogenous asexual division (erythrocytic schizogony, and exo-erythrocytic schizogony) in the vertebrate host, and an exogenous sexual multiplication (sporogony) in the mosquito host.

The life cycle may start with the ingestion of blood by a female *Anopheles* mosquito from a malarious person (Fig. 3). The female mosquito requires a blood meal for subsistence and for egg production. The ingested blood may contain sexual cells (gametocytes). In the stomach of the mosquito, the male gamete (microgametocyte) exflagellates, producing microgametes which seek out and fertilize the female gamete (macrogamete) to form a globular zygote. Within 18–24 h it becomes elongate and motile, and is known as an oökinete. The oökinete forces its way into the epithelial lining of the stomach wall of the mosquito, and is now called an oöcyst. The mosquito stomach may contain several hundred globular oöcysts. The oöcyst increases in size, and the nuclei divide to form many spindle-shaped motile sporozoites. The oöcyst reaches maturity in 4–15 days, bursts, and liberates thousands of the sporozoites into the body cavity (hemocoel) of the mosquito. Many then migrate to the salivary glands. The mosquito is now infective. Malaria infection is initiated when sporozoites are introduced into the new host following the bite of the infective mosquito.

The sporozoites now enter the parenchymal cells of the liver where they develop and multiply in what is known as pre-erythrocytic schizogony. As the parasite (schizont) divides, it forms many thousands of merozoites. After about 6–16 days, the schizont bursts and releases the merozoites into the tissue and into the blood circulation. The time between the date of infection and the appearance of the parasites in the peripheral blood is known as the pre-patent period.

After a period of growth, the parasite multiplies in the red blood cell by asexual division, called schizogony, in which a mature schizont divides into a number of small merozoites. When the red blood cell bursts, the merozoites are released into the bloodstream. This is the stage that is responsible for the morbidity and mortality associated with malaria. The merozoites then invade fresh red blood cells (erythrocytes) and



Malaria, Figure 3 Life cycle of the malaria parasite, *Plasmodium falciparum* (adapted from Scott and Rice 1966).

grow at the expense of the host cell. A vacuole is formed, surrounded by a thin ring of cytoplasm. A small round or oval nucleus lies within the ring. This stage of the parasite is called the ring form. Within a few hours, the cytoplasm becomes somewhat ameboid and is in the trophozoite stage. After a number of nuclear divisions, the mature schizont may contain 16 merozoites. The blood cell ruptures and the merozoites enter the bloodstream where they may invade new blood corpuscles. This process of erythrocytic schizogony is repeated over and over again. After several generations of merozoites having been produced, sexually differentiated forms or gametocytes are produced. These are taken up when the mosquito bites, and thus the circle is completed.

There are four types of human malaria, *Plasmodium vivax*, *P. falciparum*, *P. malariae* and *P. ovale*. Based on the length of time of the erythrocytic cycle of schizogony or schizogonic periodicity, the species may differ. Thus *P. malariae* is 72 h and is known as quartan malaria. The other species of *Plasmodium* last 48 h, and are called tertian malaria. *P. falciparum* is the most dangerous type of malaria, and is called malignant tertian malaria, and is also the cause of a condition known as blackwater fever. *P. vivax* is known as benign tertian malaria. These names have become obsolete, and the various forms of malaria are now known by their specific name, unitalicized, i.e., vivax malaria.

There are approximately 400 species of *Anopheles* mosquitoes throughout the world. Of these, approximately 75 are considered to be important vectors of malaria. Resting or feeding adult *Anopheles* usually have their abdomen at an oblique angle, compared to other genera of mosquitoes whose abdomen is usually parallel to the resting surface. The palpi of both sexes of *Anopheles* are as long as the proboscis. The eggs are boat-shaped with floats. They are laid on the surface of the water. The larvae that hatch from the eggs do not have a prominent air tube, and have float or palmate hairs on the abdominal segments. The Anopheline larvae lie parallel to the surface of the water, in contrast to Culicine larvae which hang head down from the surface of the water. The aquatic habitats of the larvae may be temporary or permanent, natural or made by humans. Anopheline species vary in their oviposition requirements. Some species may prefer sunlit pools, while others may prefer a shady slow-moving stream. Some species prefer brackish water while others may prefer fresh water along the grassy margins of lakes. Breeding sites inadvertently created by human activity are often troublesome. Roadside ditches, badly maintained irrigation ditches, gem mining pits and other water collecting structures can be the source of large numbers of anophelines. The flight range of adult anopheline mosquitoes is usually about 2 km, though they have been known to be carried by wind for much greater distances.

Over the past half century, vector control and chemotherapy have reduced, and in some cases eradicated, malaria in many countries. Malaria control has been based on a number of measures to prevent mosquitoes from feeding on humans: by environmental control modifications, by residual spraying of habitations to destroy the adult mosquitoes, or larvaciding to destroy the larvae. Chemotherapy has been used to eliminate or control the parasite in humans. Insecticide resistance by the vector mosquito and drug resistance by the parasite has now made malaria control more difficult, and in some countries malaria incidence has increased. In many areas, indoor spraying of residual insecticides is still the main control measure. Malaria vaccine research has been extensive, but to date a truly effective vaccine has yet to be developed. One of the goals of the World Health Organization is to use primary health care as a means to deliver malaria control services, whether it be the use of insecticide treated bed nets, distribution of drugs, or limited vector control.

Mallis, Arnold

Arnold Mallis was born at New York, New York, USA, on October 15, 1910. He and his family relocated to California in 1927 and he entered the University of Southern California with the intent of becoming a dentist. The Great Depression intervened and Mallis had to leave college to work. He then became interested in natural history and enrolled at Pasadena Junior College and the University of California, Berkeley. He was awarded a B.S. degree in 1934 and an M.S. degree in 1939, both in entomology. Mallis worked for several years as an entomologist with the building and grounds department of the University of California, Los Angeles. During World War II, he worked on malaria control, and from 1945 to 1968 he was employed by Gulf Oil Company, where he worked on screening and formulating insecticides. In 1968 he joined Pennsylvania State University as an extension entomologist, where he worked until he retired in 1975. Mallis is best remembered as the author of "the bible of the structural pest control industry," also known as the "Handbook of pest control" (1945 and subsequent editions). In retrospect, Mallis' varied positions prepared him well for authoring this tome, which treats most of the pests associated with buildings and the immediate environs. It is a remarkably complete and interestingly written treatment of pest control, and anyone who examines it critically is not surprised that it has persisted as the favorite reference manual for the pest control industry for over 50 years. Mallis died on January 16, 1984.

Management of Insect-Vectored Pathogens of Plants

SUSAN E. HALBERT
Florida Department of Agriculture and Consumer Services, Division of Plant Industry, Gainesville, FL, USA

Epidemiology of vectored plant pathogens involves the plant, the pathogens, the vectors, and the environment, all interacting in various ways. Often, an understanding is needed of seasonal cycles of host plants, pathogens, and vectors. For example, pathogens and vectors important to an annual crop may have non-crop reservoirs between harvest and re-planting. Vectors may overwinter in the crop, or on alternate host plants. The host range of the pathogen may determine whether inoculum control is feasible or not. Some pathogens are transmitted via plant propagation, and others are not. The epidemiology of vectored plant pathogens often is complex, and an integrated approach to management is needed. Often, no single approach will achieve adequate control. This section is organized according to the concept of integrated pest management, including chemical control, biological control, host plant resistance, cultural control, and regulatory measures. Each of these categories will be considered in terms of the vectors and the pathogens.

Chemical Control

Chemical control of vectors will limit spread of vectored plant pathogens if two conditions are met. First, the vector being controlled must be a colonizer of the crop being treated. Some plant viruses are transmitted by transient flying insects. In these cases, chemical control has a poor record. Second, most of the spread must come from within the treated area (secondary spread). For the most part, insecticides simply prevent the buildup of populations of insects within a treated area. Most pesticides will not kill an immigrant insect before it has a chance to transmit a pathogen. Thus, if there is an infected field nearby with a high population of vectors, pesticide treatment may not be very effective in preventing infection from primary spread. Pesticide treatment has a good track record for control of certain luteovirus diseases such as potato leafroll and barley yellow dwarf, spread by colonizing aphids. Even if the above conditions are met, dependence on chemical control of vectored pathogens in perennial crops may be risky, because a single missed spray application or insecticide failure could result in infection and demise of the crop.

Another variation on chemical control is the use of stylet oil. Certain horticultural oils can reduce transmission of viruses by aphids. This methodology can reduce transmission of pathogens carried by transient insects, something that is not usually possible with standard insecticides. There is also potential for use of insect repellents for vector management. Some work has been done with visual repellents (mulches, paints, colored netting), but little has been done with chemical repellents.

There is no known chemical control of plant viruses, but some fastidious bacteria in perennial tree crops can be controlled with injected antibiotics. Remission of symptoms usually is temporary.

Biological Control

The use of biological control for management of vectored pathogens has a mixed review. Obviously, fewer vectors is better; however, sometimes the economic threshold for vectors is so low that it is not achievable through biological control. Sometimes, the presence of natural enemies evokes scatter responses in vector prey. This can actually cause an increase in pathogen transmission.

Total dependence on biological control for a vectored pathogen in a perennial crop is risky. Biological control inherently fluctuates between high populations of pests and high populations of natural enemies. If pests are not vectors, the crop often can stand temporary high pest populations, but if the main concern is pathogen transmission, the entire crop can be lost if populations fluctuate in favor of the pest. Similarly, often a grower will have to spray for another pest. The pesticide may kill the natural enemies of the vector, resulting in an increase in transmission of the pathogen and destruction of the crop.

Biological control in simpler island ecosystems may have a better chance to work than in more complex settings. For example, the introduction of psyllid parasitoids into RÉunion Island dramatically reduced the transmission of the bacteria that cause citrus greening disease. However, the same parasitoids are present in Viet Nam, and citrus greening disease is a major limiting factor in citrus production there.

Sometimes disruption of existing biological control can result in an increase in transmission of a plant pathogen. Increased spraying for late blight (caused by a fungus) in potatoes was linked to a major increase in numbers of green peach aphids. Evidently, populations had been controlled by an aphid pathogenic fungus that was killed by the fungicide applications for late blight. The result was a big increase in incidence of potato leafroll virus (PLRV), transmitted by the aphids.

Biological control of the pathogen is another option. Usually this is done by means of cross protection - infecting a crop with a mild strain of a pathogen that prevents symptom expression of a more severe strain that may be transmitted by an insect later on. Cross protection has worked very well for control of citrus tristeza virus, an aphid transmitted closterovirus, in several parts of the world.

Host Plant Resistance

The efficacy of plant resistance to vectors depends on the means of resistance and the mode of transmission. Resistance that prevents feeding or repels the insects can prevent transmission of pathogens spread by feeding. If the resistance merely prevents or slows population growth, it cannot prevent primary spread. It can, however, have some effect on secondary spread.

Resistance to the pathogen probably is the most effective means of controlling vectored plant pathogens. If plant resistance to the pathogen is available, it should be the first line of defense. Complications with host plant resistance can occur if the pathogen evolves strains that can break down the resistance. Also, some crops are notoriously difficult to breed due to difficult genetics or longevity.

Resistance to the pathogen may be the only means of management in some cases. An example is sugarcane mosaic virus. Sugar cane is propagated vegetatively, so the virus is propagated with the crop. Once planted, a crop remains in the same field for several years of production, and planting is staggered throughout the production area. Thus, even if clean planting stock could be found, there is no possibility for an area-wide crop-free (and virus-free) period. The virus is transmitted by transient winged aphids, including species that do not necessarily colonize the sugar cane crop, so pesticide application is not effective. Fortunately, there has been success with mosaic resistant cultivars.

Cultural Control

Many of the effective management practices for diseases caused by vectored plant pathogens involve some sort of cultural control such as adjusted planting date, pruning, roguing, and removal of volunteer crop plants and other non-crop reservoir hosts of vectors or pathogens.

Adjusting planting dates can minimize crop exposure to vectored pathogens. In the Pacific Northwest, several vectored pathogens, transmitted by eriophyid mites and aphids, can damage early-planted fall cereals. The mite transmitted viruses are particularly serious because they cause severe yield loss, resulting in total crop failure in some cases. These viruses infect newly seeded winter wheat that is planted near a maturing crop from the previous season, or near infected volunteer grain. These viruses are most troublesome in years when the old crop is slow to mature, and there is overlap between late-maturing cereal crops from the previous season and emergence of newly sown winter wheat. The infective mites are blown from the old crop to the new one. After landing on the new crop, they apparently stay put, because there is little secondary spread in the fall. The mites cannot survive very long off a host plant, so any break in the "green bridge" between old and new crops will prevent infection. As little as 10 days delay in planting can make the difference between crop failure and negligible incidence. Similarly, the aphid-transmitted barley yellow dwarf virus complex largely can be prevented by delay in planting. Other viruses are managed on an area-wide basis by maintaining a crop-free period at some time during the year. For such a policy to work, all growers in the area must cooperate in field clean-up and coordination of planting dates.

Pruning and roguing often are used as a means of management of vectored plant pathogens, especially in perennial crops. The efficacy depends on whether latent infections remain, and if so, whether plants with latent infections are suitable source plants for vectors. In the early stages of an epidemic, there usually will be more plants with latent infections than with visible symptoms. If plants with latent infections can serve as source plants for vectors to acquire the pathogens, and vectors are present, pruning and roguing will not be very effective.

In some cases, pruning actually can eliminate disease. Pierce's disease of grape vines is caused by a xylem limited bacteria called *Xylella fastidiosa*. It moves slowly in the plants. If Pierce's disease is transmitted by small leafhoppers that feed on twigs, winter pruning can eliminate most of the infection. However, if the disease is transmitted by the much larger glassy-winged sharpshooter (*Homalodisca coagulata*), which feeds on larger branches and trunks, pruning is much less effective.

Control of volunteer crop plants may limit or eliminate primary inoculum for newly planted crops. Volunteer potatoes are important sources of virus inoculum in Idaho potato seed production areas. Similarly, volunteer grain can be an important reservoir for aphids and barley yellow dwarf at planting time for winter wheat. The volunteer wheat provides a "green bridge" for the viruses and their vectors between harvest of one crop and emergence of the next one.

Other cultural control measures include elimination of weed hosts of vectors or pathogens, use of reflective mulches and paints to repel vectors, and various protective row covers. Quite a bit of work also has been done on the use of windbreaks and barrier crops to protect susceptible plantings.

Regulatory Measures

Regulatory measures for control of vectored plant pathogens are a very important aspect of management, especially for those pathogens that are transmitted through propagation. Strict sanitation measures for propagative material are common. Other kinds of regulatory measures include crop-free periods, quarantines, and required virus testing.

One of the best ways to prevent vector-borne disease in plants is to keep the disease and the vector out. Many plant diseases and vectors that occur elsewhere in the world do not occur in the United States. Some of these are listed as quarantine or actionable pests/diseases. If they are found at U.S. ports of entry, the shipment is rejected. If a pest or disease has a limited distribution in the U.S., there may be a state quarantine for certain items. For example, if a pest is found in Florida but not in

California, California may reject shipments from Florida that contain the pest.

Production of healthy propagation materials involves regulatory agreements. Potato tubers grown for seed are subject to winter testing for a variety of vector-borne viruses. Standards are much stricter for early generation seed. Citrus trees are propagated vegetatively by grafting, in order to ensure varietal uniformity. Citrus trees used for budwood in Florida are required to be tested for citrus tristeza virus every year. Those found to contain severe strains are no longer allowed to be used for propagation purposes. Lettuce mosaic virus and bean common mosaic virus are transmitted by seed as well as by aphid vectors. Some states have regulations in place requiring that seed used commercially in the state be tested and meet standards for virus incidence.

In warm climates where crops are grown year around, control of diseases caused by vectored pathogens can be particularly challenging. Sometimes an agreement is made to adhere to a crop-free period to break the disease cycle. State regulatory agencies may be involved to ensure that there are consequences for any growers that do not comply.

Other regulations are tailor-made for a given situation. Green peach aphids (*Myzus persicae* (Sulzer)) transmit potato leafroll virus (PLRV), which causes an important disease in potatoes. The aphids overwinter in peach and apricot trees. In the spring, they leave the trees and infest potatoes and other plants. In parts of Idaho where seed potatoes are grown, it is illegal to grow peach and apricot trees. If the trees are found, the state can require their removal. Guy Bishop, University of Idaho, discovered that another source of green peach aphids was greenhouse grown bedding plants. These infested seedlings were purchased by home gardeners, who often also grew potatoes. Frequently, the home grown potatoes either were grown from seed saved from previous years, or from unregistered seed. Thus, the PLRV infection rate in home gardens was high. Bishop found that the closer a seed potato field was to a town with home gardens, the more likely it was that the seed farmer had unacceptably high levels of PLRV. Regulations were made to prevent sale of infested bedding plants. Additionally, the local growers provided home gardeners with clean potato seed tubers. Incidence of PLRV in seed potatoes decreased dramatically in the region after the regulations were implemented.

Integrated Management

Most often control of vectored pathogens of plants will involve an integrated approach. A good example is potato production. Some popular varieties of potatoes develop internal discoloration as a result of infection with PLRV that results in rejection by potato processors. In order to prevent PLRV infection there are regulatory measures to ensure clean propagation material. Additionally, commercial ware potato growers employ scouts to survey for green peach aphids. If numbers reach an economic threshold the crop is treated with insecticide to prevent secondary spread of PLRV. Cultural controls include removal of volunteer potatoes, and in some cases, removal of peach and apricot trees that are overwintering sites for vectors. Department of Agriculture inspectors make the rounds of retail vendors of bedding plants, preventing sale of infested ones. Finally, there is work at the federal and state levels to breed potato varieties that are more tolerant to PLRV infection, but that also retain the taste, baking and processing qualities of the popular susceptible cultivars.

Epidemiology of vectored pathogens affecting crops is a complex and very interesting field of study. Many more puzzles remain to be solved that will make even more effective management a possibility.

Mandibulate Archaic Moths (Lepidoptera: Micropterigidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Mandibulate archaic moths, family Micropterigidae, comprise 130 sp. known worldwide, in 2 subfamilies: Micropteriginae and Sabatincinae. The actual fauna likely exceeds 175 species. The family is in the monobasic superfamily Micropterigoidea, the only representative group of the most primitive extant Lepidoptera, the suborder Zeugloptera. The family includes small lepidopterans that have retained chewing mouthparts as adults, yet have lepidopteran scales and other adult and larval features that exclude them from Trichoptera. Adults small (5–12 mm wingspan), with very roughened head scales, and prominent five-segmented folded maxillary palpi; labial palpi short, one to three-segmented; haustellum absent (chewing mouthparts). All species are diurnally active as far as is known and most species have some iridescent scales on the forewings. Larvae are small, slug-like in shape, feeding mostly on mosses, liverworts, or detritus, as far as is known.

Mango Mealybug, *Rastrococcus invadens* Williams (Hemiptera: Pseudococcidae)

PETER NEUENSCHWANDER
International Institute of Tropical Agriculture,
Cotonou, Bénin, West Africa

This is one of many insects that came to the attention of science only after it had been inadvertently transported and established on a new continent, where it became an important pest. To date, most field data concerning this species are therefore from West Africa. In the 1980s, mealybug infestations suddenly devastated mango, but also many ornamental and shade trees, around Lomé, Togo, and Cotonou, Bénin. From there, this new plague rapidly spread along the coast, west to Ghana and Côte d' Ivoire and east to Nigeria. At the turn of the millennium, it had invaded most of West and Central Africa (from Senegal to R. D. Congo). In Benin, for instance, it was observed most often in and around large cities, being less abundant in commercial orchards and even less so on local mango varieties in farmers' fields.

In 1986, it was described as *Rastrococcus invadens* Williams (Hemiptera: Pseudoccocidae) from India, where several cryptic species of Rastrococcus infest mango, a native of this sub-continent. Among them, only *R. invadens* had made it to West and Central Africa; but interestingly, the species is still absent from East Africa. It is also known from all over India, Bangladesh, Malaysia, Sri Lanka, Indonesia, where it seems to be of minor or no economic importance, and it has been intercepted by quarantine authorities in Hawaii.

Morphology and Biology

This is a typical white mealybug. It is covered with waxy dust, oval in shape (3–4 mm length) with no wings, weak legs, and long sucking mouth parts on the ventral side. It has characteristic waxy lateral filaments (anterior up to 6 mm, posterior up to 8 mm long). Females produce up to 200 first instar larvae, which disperse and develop through three nymphal instars, which resemble each other and the adult, except for the size increase. Males are typical winged adults with long caudal filaments and milky wings. They emerge from a characteristic resting stage ("pupa") and are short-lived.

The life cycle (egg to first egg) is completed within one month. The females are long-lived (up to 225 days) and the mealybug reproduces throughout the year. Dispersal is probably mostly through humans, particularly on fruits and cuttings from nurseries. Population densities were usually higher on young than on old leaves and differed markedly between individual mango trees, indicating the importance of plant genotype on mealybug reproduction and survival. Population peaks were irregular, but mostly in the wet season. Population dynamics were highly influenced by the parasitoids introduced in a classical biological control project.

Damage

Wherever *R. invadens* turned up in Africa, it infested a wide variety of trees from many families (over 100 hundred plant species were listed as hosts), being noticeable primarily on shade trees, like *Terminalia catappa*. The abundant honeydew ejected by the mealybug, and the resulting sooty mold and leaf drop, led to wide-spread cutting of ornamental trees and economic damage, mainly on mango and citrus. In the early 1990s, mango production along the Benin and Togo coast was almost completely jeopardized.

Control Options

Wherever this mealybug appeared for the first time, extension services tried to combat it with pesticides. As the mealybug is often hidden in the buds and the large mango trees are difficult to cover, insecticides are generally inefficient. Indigenous natural enemies, like coccinellids, are sometimes abundant, but fail to reduce mealybug populations to acceptable levels.

Mango varieties vary a lot in their susceptibility, but generally it is the wild type mangos ("mangotiers") that are least affected, but also least productive. It is clear that resistant/tolerant varieties alone are not a satisfactory solution. Similarly, cutting infested branches or entire trees gave only temporary relief.

The Solution: Biological Control

Mango, *Mangifera indica* L. (Anacardiaceae) has been cultivated in India for about 4,000 years. It was brought to East Africa in the tenth century A.D. and from there by the Portuguese to West Africa. It was therefore surmised that this new mealybug came from India and that classical biological control, i.e., the transfer of natural enemies that keep this mealybug under control in its original home, could bring the solution. Foreign exploration to find natural enemies was therefore undertaken by CABI Bioscience in Southeast Asia. This led to the discovery of two specific parasitic wasps *Gyranusoidea tebygi* Noyes and *Anagyrus mangicola* Noyes (Hymenoptera, Encyrtidae).

They were shipped to CABI Bioscience in the United Kingdom for quarantine. There, the insects were reared and checked as described for the biological control project against the cassava mealybug. With the necessary import permits and under the umbrella approval of the Inter-African Phytosanitary Council of the Organisation for African Unity, *G. tebygi* was then sent to an FAO-supported GTZ project in Lomé, Togo, and from there to IITA in Cotonou, Bénin, whereas *A. mangicola* was sent directly to IITA. Further studies, mass rearing, and releases followed, first in Togo in 1987 (six releases of *G. tebygi*), and from IITA in another ten countries, from 1988 to 2001 (48 releases/deliveries of *G. tebygi* and 57 releases/deliveries of *A. mangicola*). This was always done on request by the local quarantine authorities and in close collaboration with national scientists.

Laboratory studies revealed that mated females lay their eggs into mealybugs, where a larva develops freely floating in the coelom of the mealybug. The larva pupates in the sausage-shaped dry remains of the mealybug, called a "mummy," from where the adults emerge after a total life cycle of about 2–4 weeks, depending on the host stage attacked. The tiny *G. tebygi* attacks first to third instars, where as the larger A. *mangicola* prefers older instars, including adult mealybugs that cannot be attacked by *G. tebygi*. As a consequence the two wasp species do not strongly compete with each other, but are complementary.

By the end-1990s, *G. tebygi* was established everywhere in Africa where *R. invadens* occurred, having dispersed sometimes long distances from the release sites. *A. mangicola* was more difficult to establish; but is now well represented mainly in large towns. Both species were never found on any other mealybug.

Both parasitoids are attacked by indigenous hyperparasitoids and compete with several species of indigenous coccinellids, which have now become uncommon on mango. As biological control took hold in Africa, the original wide host spectrum collapsed and today (2002) *R. invadens* is confined almost exclusively to mango. Overall, good biological control was achieved, particularly in the more humid areas of West and Central Africa. In the northern savannas, equilibrium might not yet have been reached or this equilibrium might not lead to complete control.

Economic and sociological studies demonstrated that homeowners and farmers are well aware of this biological control and that returns are similar to those found for the biological control project against cassava mealybug, with yearly gains for southern Benin of $50 million and a benefit-cost ratio of $145 for each $1 invested, again for Benin alone.

Manitoba Trap

A trap for capturing horse flies and deer flies (Diptera: Tabanidae). It consists of a dark sphere suspended from a tripod, with a canopy suspen-ded above, and topped by a collection apparatus. The flies are attracted to the dark color and movement of the sphere and fly upward where they are directed by the canopy into the collection apparatus, usually a jar. Traps for Capturing Insects.

Mann, William M

William M. Mann was born at Helena, Montana, on July 1, 1886. He was interested in animals beginning in his childhood, and he earned a B.S. degree at Stanford University in 1911, and a Sc.D. at Harvard University in 1915. The latter degree was earned under the guidance of William Morton Wheeler, so it is not surprising that Mann became an authority on ants. He was appointed to the United States Department of Agriculture, where he worked as a specialist on ants, from 1917 to 1925. In 1925 he became director of the National Zoological Park of the Smithsonian Institution, and served in this capacity until his retirement in 1956. In this capacity he traveled over much of the world, and became renowned as a collector of wild animals. He discovered many new species, and was featured many times in National Geographic Magazine. He is remembered as a creative and progressive zoo director, and received many awards from zoological park organizations. He died October 10, 1960, in Washington, DC.

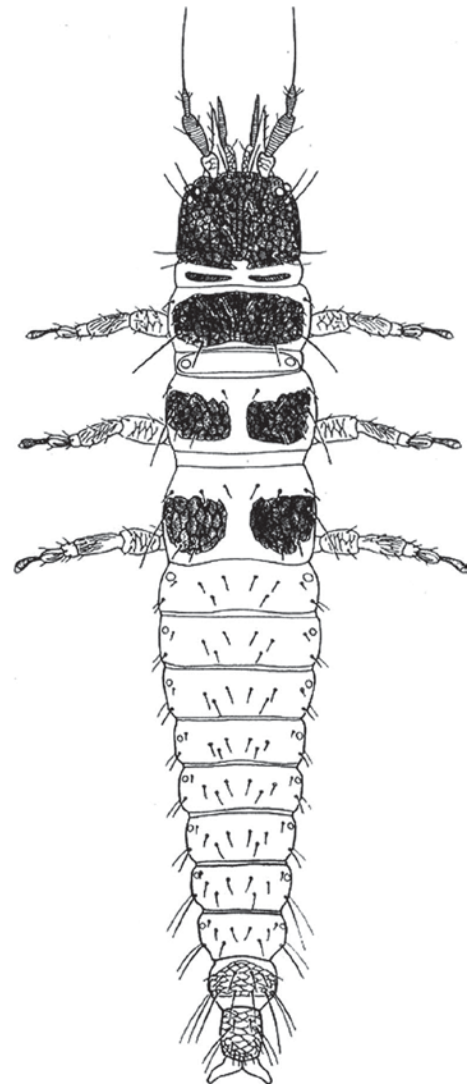
Mantidflies (Neuroptera: Mantispidae)

KURT REDBORG
Coe College, Cedar Rapids, IA, USA

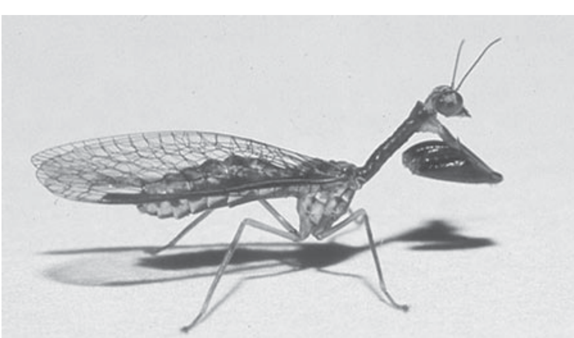
The family Mantispidae belongs to the suborder Planipennia of the order Neuroptera. The group receives its name from the remarkable resemblance of the adults to praying mantids. Like mantids, adult mantispids, or mantidflies as they are sometime called, have an elongate prothorax, a freely movable head with prominent eyes, and raptorial forelegs composed of a lengthened coxa and a spined femur, which fits against the tibia to immobilize prey (Fig. 5). Of course, the two groups are not closely related, instead providing an excellent example of convergent evolution. Unlike the mantids, mantispids have membranous wings, no cerci, and are holometabolous.

Features that mantispids share in the larval stage with other Planipennia include three instars (with the exception of the Coniopterygidae), grooved mandibles and maxillae that fit together to form a piercing/sucking tube, a blind-ended midgut that accumulates wastes that are then voided as a meconial pellet or fluid when the gut becomes complete at maturity, and Malpighian tubules modified for cocoon silk production in the last larval instar (Figs. 6 and 7).

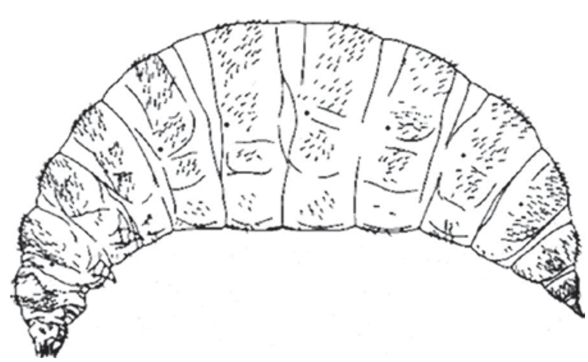
There are four recognized subfamilies: Symphrasinae (*Anchieta, Trichoscelia, Plega*),



Mantidflies (Neuroptera: Mantispidae), Figure 6 ***Mantispa uhleri*** **Banks, unfed first instar.**



Mantidflies (Neuroptera: Mantispidae), Figure 5 ***Mantispa uhleri*** **Banks, adult male.**



Mantidflies (Neuroptera: Mantispidae), Figure 7 ***Mantispa uhleri*** **Banks, mature third instar.**

Drepanicinae (*Drepanicus, Ditaxis, Theristria, Gerstaeckerella*), Calomantispinae (*Calomantispa, Nolima*), and Mantispinae (all other genera).

While adult mantispids are general predators, larval feeding is more specialized. Our knowledge of the developmental biology of the first three subfamilies is sketchy. The larval stages of some members of the Symphrasinae have been linked with immature Hymenoptera, Lepidoptera, Coleoptera, and Diptera. It is possible that larvae of some members of these three subfamilies may simply be generalist predators feeding on a wide variety of sedentary arthropod foods.

In contrast, the biology of the Mantispinae is far better known. Mantispine mantispids develop within the egg sacs of spiders. This association has sometimes been referred to as parasitic, but the feeding ecology of mantispines is more appropriately termed spider-egg predation because the first instar larvae are responsible for finding a source of spider eggs. Adult mantispines lay large clutches of stalked eggs containing from a few hundred to several thousand eggs, depending on the size of the ovipositing female, which can vary greatly. Extreme size variation in both males and females occurs because larvae are locked into their supply and there can be great variation in the quantity of food contained within a spider egg sac. There is no compelling evidence indicating where females lay their eggs. The stalk (produced from the female colleterial gland) on the egg is quite short and it is difficult to see how it could serve as the kind of protective device that longer stalks afford the eggs of Chrysopids. The eggs hatch in about ten days. Newly hatched larvae are campoediform and less than a millimeter in length. They aggregate for unknown reasons around the empty egg cases for a day or so before they disperse. After entering an egg sac, they pierce the eggs with their short, straight, modified mandibles and maxillae and drain the eggs of yolk. There are two subsequent larval instars with a quiescent period of about a day separating the first and second and second and third stadia. The second and third instars are physogastric, with reduced legs that are consistent with their limited need for locomotion. Mantispids have been described as hypermetamorphic, but this is not really true. The three larval instars are not uniquely different from each other and utilize the same basic feeding mechanism. The abdominal tip of the third instar is modified into a spinneret. When all of the eggs within the sac have been consumed, the third instar spins a cocoon with silk from the Malpighian tubules. Pupation occurs within the cocoon. The pharate adult chews its way out both the cocoon and egg sac. Since the egg sac may have been constructed in a constricted area, such as under tree bark, the pharate adult crawls some distance away before undergoing the final ecdysis.

There are two basic strategies for spider egg location by larval mantispids - direct penetration of egg sacs that have already been produced and deposited in the environment versus the boarding of female spiders with entry into the sac occurring during, or closely associated with, its construction. *Mantispa viridis* Walker, a green mantispid common in the southern United States, is an example of an obligate egg sac penetrator. Larvae are attracted to spider silk and adept at burrowing through it but they display no interest in the spiders themselves. Once inside the egg sac, *M. viridis* larvae are tolerant of other larvae and will commence feeding immediately. It is not uncommon in this species for more than one adult to emerge from the same spider egg sac. Although *Mantispa viridis* will enter the egg sacs of a wide variety of spiders, it is particularly adept at entering the sacs of web-building spiders that tend to be relatively immune from attack from spider-boarding mantispids. Spiders utilized by *M. viridis* include the cob-web weaver, *Achearanea tepidariorum*, the orb-builder, *Argiope aurantia*, as well as several species of funnel-web spiders belonging to the genus *Agelenopsis*. *Mantispa viridis* overwinters inside the spider egg sac where cool temperatures arrest its development; it does not seem to have a specific diapausing stage. Thus, severe winter temperature can kill it, which probably explains its more southern distribution.

Climaciella brunnea (Say) is probably the mantispid most familiar to naturalists. Adults are diurnal, often frequent flowers, and are excellent Batesian mimics of *Polistes* wasps. *Climaciella* larvae are obligate spider boarders. First instar larvae exhibit a unique phoretic behavior in which they rear up on caudal suckers and sway back and forth with legs outstretched awaiting a passing spider that they can board. Larvae enter the egg sac as it is being constructed. Larvae are unable to directly penetrate the silk of an egg sac. In fact, if they arrive at the eggs after the eggs have been partially enveloped with silk, they can be spun into the fabric of the sac and become permanently trapped. *Climaciella brunnea* specializes on the egg sacs of wolf spiders of the family Lycosidae, especially the genus *Schizocosa*. Larvae adopt positions around the edge of the spider's carapace. Multiple boardings of more than one larva per spider do occur. Larvae pass the winter aboard the spider. *Mantispa pulchella* Banks is also an obligate spider boarder. In this species, there is always only one larva to each spider; the larva is always found loosely draped over the spider's pedicel. *Mantispa pulchella* specializes on boarding small, foliage-inhabiting spiders, particularly spiders of the family Anyphaenidae.

Some mantispids facultatively utilize either egg location strategy. In the laboratory, first-instar *Mantispa uhleri* Banks will penetrate egg sacs and can also be found extensively in the field aboard a variety of spiders. After penetrating an egg sac, *uhleri* larvae can halt the development of the spider eggs within the sac with an aggressive allomone, although the manner by which the mantispid uses this chemical is not yet known. If more than one larva enters the sac, each larva will attempt to kill the other and refrain from engorging on eggs until they are the only larva left alive in the egg sac. If the sac contains hatching spiderlings, the larva will board one of the spiderlings and attempt to follow the spiderling through to its adult stage. Larvae wrap themselves tightly around the spider's pedicel after they board. Larvae can easily negotiate the spider's molts during which they either remain on the pedicel or enter one of the spider's book-lungs. More than one *M. uhleri* larva may initially board a spider but as the spider progresses through molts, the number of larvae is usually winnowed down to one. Analogous to the behavior within an egg sac, a larva attempts to kill or dislodge any competing larvae on the spider. While aboard the spider, larvae maintain themselves by piercing the spider's cuticle and ingesting blood. Other spider-boarding mantispids probably do this also. Thus, in this phase of its life cycle, *M. uhleri* is actually a spider parasite after all. Larvae will board male as well as female spiders even though only females will provide them with a direct source of spider eggs. This situation is not as "dead end" as it sounds. Larvae of *M. uhleri* will transfer from males to females when they are cannibalized after mating. Larvae of *Mantispa pulchella* and *Climaciella brunnea* will actually make the transfer during copulation by their spider hosts.

The major spider host for *M. uhleri* in the Midwest is the philodromid spider *Philodromus vulgaris* Hentz. Infestation levels on this spider often exceed 50% Selection pressure is so great on this spider that it has evolved an anti-mantispid mechanism. Without any additional feeding, female *P. vulgaris* produce a second, smaller egg sac a few days after the first sac. The two sacs are constructed next to each other and the female guards both sacs. If a mantispid successfully enters the first egg sac, all the eggs within it are consumed. But, the second egg sac escapes predation, at least from mantispids.

Many-Plumed Moths (Lepidoptera: Alucitidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Many-plumed moths, family Alucitidae, total about 184 species worldwide. The family is part of the superfamily Copromorphoidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (7–28 mm wingspan), with head smooth-scaled; haustellum naked; labial palpi porrect, mostly with long second segment; maxillary palpi 3–5-segmented (rarely vestigial). Wings with rounded shape (hindwing merges with forewing margin) and all veins as separate wing clefts to near the wing bases, and fringed (at least one Neotropical species has the clefts split only half way in from the termen). Maculation shades of gray, with various bands or spots, but a few with shades of brown or yellow, or white, and both forewings and hindwings with matching or merging patterns. Adults active in deep shade, or may be crepuscular. Larvae are borers or gall makers as far as is known. The few plant records are in Bignoniaceae, Caprifoliaceae, Compositae, Dipsaceae, Labiatae, and Rubiaceae.

Marine Insects and the Sea-Skater *Halobates* (Hemiptera: Gerridae)

LANNA CHENG
Scripps Institution of Oceanography, University of California-San Diego, La Jolla, CA, USA

Although insects originated in swampy areas some 300 millions years ago, they then moved toward a terrestrial existence, evolving various physiological adaptations which allowed them to become independent of water or damp places, and to achieve dispersal though the air.

Some of the most important adaptations of many insects living on land include the following:

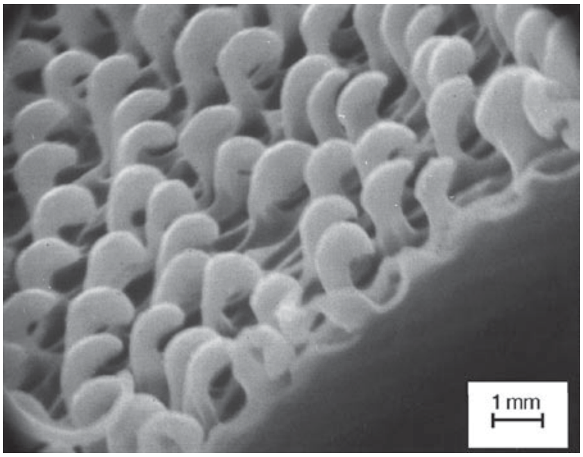
- Hardened, impermeable cuticle often impregnated with lipids to cut down on water loss.
- Tracheal breathing system for efficient distribution of oxygen by diffusion.
- Wings for long-range aerial dispersal.
- Complete metamorphosis, which may allow adults and young to exploit completely different habitats.

Surviving the Marine Environment

In order to return to the sea they have had to solve a number of ecological, physiological as well as physical problems. Some of these problems, e.g., osmotic regulation, they have succeeded in solving, while others, e.g., underwater respiration, are perhaps insurmountable, hence the rarity of insects at sea. Although, several thousand insect species are known to live in various marine environments, the five oceanic *Halobates* species are the only ones known to spend all their lives at sea, but even they are confined to the air-sea interface. Because they do not fly, nor do they normally dive, *Halobates* must face certain challenges in order to live in such an unusual habitat. Some of these challenges are:

- Avoidance of drowning – This is probably the foremost problem they have to solve. Storms at sea can be fierce, and it is highly likely that these tiny insects would then be pushed underwater. They solve this by surrounding their bodies with a layer of tiny hairs that trap air and form an air-bubble around them (Fig. 8). This not only allows them to bob up to the surface rapidly if they are pushed underwater, it also acts as a mechanical gill in that when the oxygen level in the bubble is low, more oxygen diffuses into the bubble from surrounding sea water.

- Solar irradiation – On sunny days, *Halobates* are totally exposed to the tropical sun because there is no shade to be found anywhere in the open ocean. They have, therefore, evolved a sort of sunscreen in the form of a UV-absorbing layer in the cuticle to protect them from radiation damage (Fig. 9). Although the chemical composition of this substance is unknown, it is able to absorb almost all of the UV rays at the potentially damaging wavelength of 280nm, allowing less than 0.01% to pass through the cuticle to reach reproductive and other soft tissues underneath.
- Starvation – Prey animals may be found only sporadically at the sea surface, thus *Halobates* must have the ability to withstand short-term starvation. They do this by storing triglycerides in their fat bodies, which provide a ready energy source.
- Mate location – It is not known how adult *Halobates* find mates of the opposite sex at sea. Even if individuals are brought within meters of one another by winds and waves, it is still necessary for the sexes to come into contact. They may use surface-dispersible pheromones for aggregation or as sex attractants. Although no such chemicals have yet been detected in *Halobates*, they have been demonstrated in a coastal relative, *Trochopus plumbeus* (Veliidae) (Fig. 8).



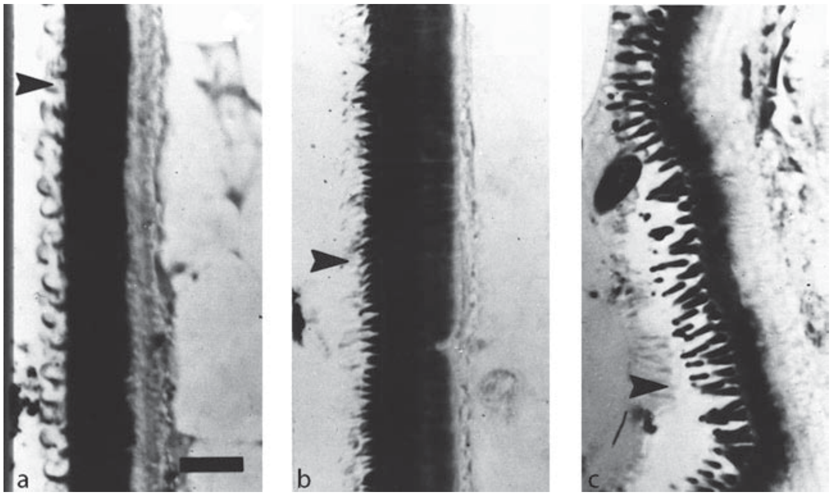
Marine Insects and the Sea-Skater *Halobates* (Hemiptera: Gerridae), Figure 8 **Section of cuticle of *Halobates germanus* showing micro-hairs layer in side view (scale = 1 μm, from Cheng, 1973; Nature 242: 132–133).**

Sea-skaters, *Halobates* spp

The sea-skater *Halobates* is undoubtedly one of the most remarkable members of the class Insecta. It is the only insect that has succeeded in living in the open sea. It is a member of the Family Gerridae, commonly known as pond-skaters or water striders. The gerrids are some of the most common aquatic bugs in the order Heteroptera and can be found in a great variety of fresh water as well as brackish and marine habitats. The genus *Halobates* is almost exclusively marine. All but one of its known species occur in the sea. Of the 45 described species, only five are found in the open ocean, miles away from land. The others occur near the coast and, under ordinary circumstances, do not venture out to the open ocean (Fig. 10).

Sea-skaters are found only in warm waters where the winter temperature is above 20°C. Coastal species are common around tropical islands fringed with mangroves or other trees, but are normally absent from coral atolls or islands devoid of fringing vegetation. They feed on terrestrial insects that have fallen or are trapped at the sea surface, and carry out their life cycle very much like those of their fresh water cousins. Oceanic *Halobates*, however, have evolved many special adaptations necessary for their survival at sea.

The air-sea interface where these insects live is unique in many ways. This is where the ocean meets the atmosphere, where air-borne particles accumulate when they fall, where nutrients are brought up to the surface from deep water by air bubbles and where various chemical and physical interactions take place. Although scientists have been measuring seawater temperature, salinity, current flow, wind velocity, etc., for decades, almost all of the measurements were taken in a water column. Physical and chemical measurements of the surface film have proved to be more difficult until



Marine Insects and the Sea-Skater *Halobates* (Hemiptera: Gerridae), Figure 9 **UV photomicrography taken at 280 nm of thin sections of *Halobates* cuticle showing dark UV-absorbent layer (from Cheng et al. 1978; Limnology and Oceanography 23:554–556).**

the last 10 years, when special sensing devices were developed. Attempts to correlate the occurrences of oceanic *Halobates* with physical or chemical features of the sea surface are thus still in their infancy. We do, however, know quite a lot about their distributions, biology and special adaptations.

All five pelagic (i.e., open ocean) *Halobates* species occur in the Pacific Ocean, two are found in the Indian Ocean and only one occurs in the Atlantic Ocean. Each species has a rather well defined distribution pattern, but we still do not understand fully what determines such patterns. We do know, however, that these patterns are controlled to a large extent by seawater temperatures and currents.

General Biology

The eggs of oceanic *Halobates* are laid on flotsam: seeds, plastic, wood, mollusk shells, sea bird feathers and even tar lumps. There are five larval stages. The young resemble adults in general morphology although they are smaller. The sexes are not distinguishable until the final larval stage. The general body plan of *Halobates* is similar to those of other gerrids (Fig. 11), but *Halobates* are totally wingless at all stages of their life cycle. Adults measure 5–6 mm in body length and the sexes are easily distinguished by the presence in the males of external genital processes that are characteristic for each species. They are predators, feeding on animals trapped at the sea surface. Adults and older nymphs are also cannibalistic. They are, in turn, preyed upon by sea birds (by far their most important predators), surface-feeding fishes, and occasionally turtles.

Mariner

A transposable element that has been engineered for transforming insects other than *Drosophila. mariner* elements are widely found in most arthropods and in insect-parasitic nematodes, other nematodes, flatworms, hydras, humans, mouse, rat, Chinese hamster, sheep and cow. *mariner* has been used to transform chicken, zebrafish and a protozoan.

Marker (DNA Marker)

A DNA fragment of known size used to calibrate an electrophoretic gel.

Marker (Genetic)

A trait that can be observed to occur (or not) in an organism. Marker genes include genes conferring resistance to antibiotics, expression of green fluorescent protein, eye color, etc.

Marking Insects for Studying Ecology and Behavior

ALLAN T. SHOWLER
USDA-ARS SARC, Weslaco, TX, USA

Insect ecology and behavior studies often occur in conditions that preclude visual observations. To assess insect dispersal, subterranean habits, feeding, and complex ecological relationships among diversified taxa, efficient markers (synonymous with labels and tags) are useful. An effective and versatile marker should have the following characteristics: easy to apply to large populations, minimal manipulation and trauma to the test insect(s), detectable without destroying or killing the insect sample, persist in the insect or community, and no adverse effects on the physical functions or behavior of the labeled organisms. A number of marking techniques have been used for insect tagging in behavior and ecology studies.

Visually Detected Markers

Visually detected markers include wire ties, paints, dyes, inks, powders, pollen, and spores that are fixed to the insects at least until sampling for tagged insects is completed. These methods, however, commonly suffer limitations. One study evaluated the use of wire ties, paint, and excised legs as markers for ants (*Solenopsis* sp.). The wire ties stayed on, but attaching them was laborious and required anesthetization of the ants. Workers with excised legs were killed by their nestmates, and painted labels were scraped off. In another study, a ground sprayer and an airplane were used to spray cotton fields with a blue enamel paint, and it was estimated that about one-third of the boll weevils received the marker. However, this method was reported as being messy, hard on the spray equipment and the cotton plants, and it had unknown effects on boll weevil behavior.

In one study where fluorescent dye was applied to hornflies, *Haemotobia irritans* L., only 26–60%; of the dye was detected, and the dye was also lethal to the hornflies. Individually applied external labels often inflict trauma upon the insect and are impractical in lieu of other options. Dusts (including pollen) and dyes have been used to label large numbers of insects. Pollen can be used to determine the origin of insects in dispersal studies by passive marking (the insects' natural interaction with flora in the area) but these labels may be lost, are suitable only between molts, and are not reliable for monitoring species with cryptic habits. Therefore, external markers are usually of little value for studying insect behavior over long periods of time, for researching trophallaxis and food webs. Visual labels can affect insect behaviors by abrasion, added mass, altered appearance, and health related side effects. Some researchers have suggested that external visual markers might make labeled insects more visible to predators.

Dyes were ingested by imported fire ants, *Solenopsis invicta* Buren, in an experiment to monitor the intracolony exchange of various foods; however, detection of the label required the destruction of the insects for dye extraction, partitioning and drying before light wavelength absorbance was measured. In another study, imported fire ants were labeled with ingested dyes which were detected visually after the ants were crushed on white paper. Ants have also been dissected in order to detect ingested dyes, however, it is difficult to detect dyes and vital stain indicators in small quantities.

Ingestion of pollen and spores can also be used to mark insects but the labeled insects must be dissected to determine the presence or absence of these markers. In spite of the limitations and assumptions required for many applications of visual markers, a large number of studies, especially on dispersal (mark-recapture studies), have been conducted with varying degrees of success.

Rubidium

Rubidium (Rb) markers can be ingested from labeled artificial diet, tagged solutions sprayed onto host plants, and host plants raised from Rb-treated seeds. For example, pea aphids, *Acyrthosiphon pisum* Harris, have been labeled after feeding on bean, *Phaseolus* sp., plants cultured in Rb-tagged nutrient solutions. Rubidium can be detected using atomic absorption spectroscopy in pea aphids for up to 4 days (77% was eliminated in 2 days) after marking, and for up to 34 days after marking in the adult Mexican bean beetle, *Epilachna varivestris* Mulsant. Unlike most visually detectable markers, ingested Rb can be retained from larval to adult stages as has been demonstrated in the corn earworm, *Heliothis zea* Boddie; tobacco budworm, *Heliothis virescens* F.; fall armyworm, *Spodoptera frugiperda* J. E. Smith; pink bollworm, *Pectinophora gossypiella* Saunders; cabbage looper, *Trichoplusia ni* Hübner; and the imported cabbage worm, *Pieris rapae* L., and other insects with no observed toxic effects. Cabbage looper fecundity, fertility, longevity, mating behavior, and responses to sex pheromones were not influenced by ingested Rb concentrations of as much as 28,000 ppm. Rubidium labels have been useful for studying the dispersal patterns of the flights of various insects, including the corn earworm, fall armyworm, and pink bollworm. Food chains to the primary predator level in crop systems (e.g., cotton and grain sorghum) have been studied using Rb tags. Despite these advantages, researchers have reported equivocal results because of variation and detectable levels of naturally occurring Rb in their samples. Quantification of Rb also requires the physical destruction of samples for the use of atomic absorption spectroscopy or flame emission spectrophotometry.

Radiotracers

A desirable marker (i) provides analogs for biologically essential elements, (ii) does not require the destruction of labeled samples, (iii) persists in readily detectable quantities for longer periods of time, (iv) is easily applied to large numbers of insects with minimal manipulation of the populations, and (v) may permit detection in the field, even when tagged insects are located underground or within plant material. Unlike Rb, radioactive isotopes (radiotracers) provide analogs of biologically essential elements such as P-32, C-14, H-3, I-125, S-35, and Ca-45 that can be applied to study physiological phenomena including reaction rates, metabolic pathways, and the distribution and incorporation of elements or molecular compounds in biological systems. Radioactive analog or non-analog nuclides can also be administered to monitor the behavioral and ecological dynamics of individuals, populations, and biotic communities. The sensitivity of radiation detection exceeds that of most chemical and physical methods. To illustrate, carrier-free tritium at 30 Ci per mmole can be diluted by a factor of 10^{12} without hindering detection. In one study, 200 μ Ci Zn-65 in 20 ml molasses was used to label an entire imported fire ant colony. The tracer was easily detectable in the ants six months after the tagged bait was removed. Radiolabels can be detected while the tagged insect is living or dead, after being ingested by a predator or while the insect is functioning in the environment.

More than 44 different radionuclides have been used in entomological studies. To select a radiotracer for labeling insects, several factors must be considered: (i) the effective half-life of the isotope in the organism, (ii) possible toxic effects to the insect, (iii) the type of radiation emitted, (iv) the energy of the radiation, (v) the form or valence of the radionuclide, and (vi) the ease of handling and detecting the label.

The amount of a radioisotope retained by an insect after administration of a single internalized dose can decrease exponentially through time because of biological elimination and radioactive decay. The time required for the amount of a particular internalized radiotracer to decrease by one-half in a given insect is termed the "effective half-life." Effective half-lives of radiotracers decrease in response to excretion, oviposition, length of exposure to labeled bait, life stage, or caste of the insect, and the nature of the labeled food ingested (e.g., oil, protein, carbohydrate). Radioactivity can, however, be unequivocally detected long after the isotope's effective half-life has elapsed. To minimize loss of radiotracers in individuals over time, isotopes may be delivered to insects in a continuous infusion through a constant supply of radiolabeled food or water, or by using large, but nontoxic, single pulse doses of radionuclides.

A radiolabel might be detrimental to the inoculated system (and researcher) because of the nature of the emitted radiation. The biological hazards of radiation, although negligible in most studies, have been emphasized by the media, thus the decline in radioecology studies after the early 1960s. Radiotracers have received wide application in insect biochemistry and physiology experiments; various isotopes are selectively distributed within insect bodies. Female *Aedes aegypti* L. mosquitoes were twice as radioactive as males. Depending on the isotope, the dose of radionuclide, the type of radiation, the insect species and life stage exposed, and the method of administration, radiation levels that cause toxic effects may differ. Toxicity can also result from a species-dependent overdose of the element itself. Toxic levels of isotopes such as Ca-45, Fe-59, Ag-110, Cd-115, and I-131 in certain insect species have been documented.

White pine weevils, *Pissodes strobi* (Peck), painted with 500 μ Ci Co-60 per individual did not suffer increased mortality for at least two months, whereas in boll weevils, *Anthonomus grandis grandis* Boheman, mortality increased when P-32 concentrations exceeded 9.9 μ Ci per gram of labeled diet. Mortality studies on termites, *Reticulitermes flavipes* Kollar, revealed that although equivalent amounts of Mn-54, Sr-85, and Sr-85 + Co-60 produced lethal effects, Co-60, Cs-137, Sb-125, Mn-54 + Zn-65, Mn-54 + Se-75, Co-60 + Cs-137, and Cs-137 + Se-75 were not toxic to the termites. The wasp *Habrobracon juglandis* Ashmead developed "radioresistance"; P-32-treated adults survived as long or longer than controls. In some cases, sublethal doses of radiation have been shown to reduce insect fecundity. *Habrobracon juglandis* adults fed on less than 50 μ Ci P-32 per gram of labeled food showed no ill-effects, 50–200 μ Ci resulted in decreased (26%) egg production, and 200 μ Ci halted the egg production process. Eggs produced from radiolabeled adults may also show increased mortality and offspring hatched from labeled eggs may be deformed or die soon after eclosion. Boll weevil larvae raised on P-32-labeled diet had reduced longevity, fecundity, and pre-oviposition and oviposition periods compared to adults fed on P-32-labeled diet. On the other hand, radiotracers in other insects, such as the screwworm fly, *Cochliomyia hominivorax* Coquerel, did not affect longevity, fecundity, fertility or egg eclosion. Therefore, the use of a fixed radionuclide dose may be suitable for one species or life stage within the same species, but impractical for another species or intraspecies life stage.

Nuclides that release energy as gamma photons have advantages peculiar to the nature of gamma radiation. Gamma-emitting isotopes produce characteristic spectral emission' signatures' such that confusion between different radionuclides in the same insect or community is eliminated. Additionally, because gamma rays have negligible mass and are highly energetic, gamma-emitting isotopes have been employed to locate cryptic insects through several cm of soil and up to 14 cm of wood.

There are several methods for administering radiotracers to insects. Radiotracers can be applied as components of biologically essential compounds for biochemical research and radiolabeled mosquito sperm has been developed for mating studies. The following methods have been implemented to tag individual insects, populations, or biotic communities.

Dipping and Painting

Dipping insects in radioactive solutions, including I-131, Se-46, Ir-192, and Co-60, has been used to mark individual arthropods such as white pine weevils, and Co-60 dips for labeling boll weevils. The addition of a detergent allowed a P-32-labeled water dip to penetrate the cuticle of the ant *Lasius flavus* F. for a detectable retention time of 10 days. Dipping might not work in some instances, such as when the plum curculio, *Conotrachelus nenuphar* Herbst., was dipped in P-32 solution despite supplementation with wetting and sticking agents. However, P-32-glycerin suspensions painted onto the southern pine beetle, *Dendroctonus frontalis* Zimmermann, enabled the location of the tagged beetles after dispersal by the presence of radiotag on host tree pitch tubes. Southern pine beetle adults were also labeled as they emerged from tree boles painted with P-32. Painted radiolabels, like many visual markers, can be chipped or washed off, and thus might give false indications of radioactivity in the environment.

Disc and Wire Attachments

The movements of various subterranean beetle larvae have been monitored with external attachments labeled with Ra-226, Ta-182, and Co-60. Similarly, Ta-182 wire glued to coccinellid larvae was used to investigate crawling behavior on foliage. Discs and wires glued or tied to the insect exoskeleton or inserted within the insect's body have the disadvantages of some visually detected markers.

Ingestion

Isotopes can be transferred to insects by ingestion of radiolabeled food; in this way, large numbers of marked insects can be reared simultaneously. Tagged sugar and honey solutions, artificial diets, royal jelly, milk, raw meat, and living plants smeared or sprayed with radiotracers have produced desired results in a variety of insects. Labeled wood, blood, and living insect prey have been employed to tag termites, mosquitoes, and mantids, respectively. A more refined radionuclide delivery technique involves rearing insects on plants cultured in radiotagged nutrient solutions or plants injected with radioisotopes. Insect food webs on the thistle, *Cursium undulatum* Nutt., balsam fir, *Abies balsamea* L., and other plants were determined by injecting the plants with P-32. Similarly, P-32 injected into living rats, rabbits, goats, sheep, and hamsters resulted in the tagging of insects including *A. aegypti*, screwworm flies, and Oriental rat fleas, *Xenopsylla cheopis* Rothschild. Food interaction studies have been conducted in the White Oak Lake bed, an area in South Carolina contaminated by Cs-137 and Sr-90 wastes that were subsequently translocated by the terrestrial plant community. Naturally occurring U-238 and Th-232 fission products bismuth-214 and actinium-228 were similarly used in a stream ecosystem.

Water Culture

Large quantities of aquatic insects such as mosquitoes and blackflies have been labeled through adulthood when the larvae were raised in P-32-tagged water. In a large scale application of this technique, Zn-65 was sprayed onto a lake, and P-32 was systematically dripped into a stream to examine the trophic structure of each system.

Trans-life Stage Transmission

Radiotracers can be passed from one life stage of an insect to other life stages, and in a sense, this can be viewed as being a delivery system if an earlier life stage is more effectively tagged for studying a subsequent life stage. This can be accomplished when the initially labeled insect stage obtains the tag by injection, ingestion, or water culture. Grasshoppers, *Melanoplus mexicanus* Sauss and *Camnula pellucida* Scudder, were shown to retain ingested P-32 from nymphs to adults. Similarly, radioisotopes ingested by larvae of imported cabbageworm (Ca-45 and P-32), *Panaxia* sp. and *Arctia caja* L. (S-35), and boll weevil (P-32) were retained to adulthood. Screwworm fly larvae raised on P-32-injected goats and sheep had detectable levels as pupae, adults, and eggs and larvae of the next generation. Examples of insects that had ingested radiotagged food and transferred the label to their eggs include *Habrobracon juglandis*, (Sr-89), the walnut husk fly, *Rhagoletes completa* Cresson, and the velvetbean caterpillar, *Anticarsia gemmatalis* Hübner (P-32). P-32 was transmitted from tobacco budworm adults to eggs to larvae. Larval mosquitoes and blackflies raised in P-32-labeled water cultures retained the tag into adulthood, and egg batches of *Culex pipiens* L. mosquitoes retained P-32 from adults raised as larvae in a labeled water culture.

There are a number of different ways of detecting radioactive decay. The choice of detector depends upon the type of radiation, the physical state of the sample, and where detection will occur (e.g., in the laboratory or the field). The Gieger–Müller tube, liquid scintillation and solid detectors, autoradiography, and portable rate meters have received the greatest application in insect ecology and behavior studies.

Representative insect ecology and ethology radiotracer include population measurements, dispersal and movement, territoriality, feeding behavior (including trophallaxis), vector-parasite relationships, and food chains and webs.

Neutron Activation Analysis

Because of public concern regarding the potentially hazardous effects of ionizing radiation, some scientists have used neutron activation analysis (NAA) as an alternative. Rare earth elements, such as Sm and Dy, are good tracers but are not analogous to biochemically essential elements. Because NAA markers are made radioactive by exposing samples to specific thermal neutron fluxes in a nuclear reactor, the thermal neutron capture cross-section of the nuclide should be large (≥ 0.1 barn). The natural abundance of the stable tracer in the experimental system should be less than 10% of the applied dose to avoid equivocal results such as those encountered with Rb labels. The NAA tracer for insect studies should be selected for a short half-life and readily detected radiations (preferably gamma rays) after the nuclide has been activated. NAA methods provide radio-safety in the environment, a diversity of nuclides from which to choose, and sensitivity of detection. The techniques also permit long-term experiments without decay of the tracer, nondestructive sample analysis such that the same sample can be repeatedly activated and measured, and quantification of the label in each sample based upon the amount of radiation emitted. Drawbacks to NAA techniques include (i) relatively long (≥ 1 d) analyses of the samples, (ii) persistence of the stable tracer in the environment which may render future experiments in the same area unreliable, and (iii) "loss" of the tracer in the experimental system until NAA is performed. The activated nuclide can be detected and quantified using the same diversity of methods available for conventional radiotracers.

Toxicity to the insect may result from stable-activable tracers, but detectable nontoxic levels may be determined by experimentation. Application of these elements to insects has been achieved through ingestion and by exposure to the insect's cuticle. Some plant species, such as white mustard, Brassica hirta Moench, and hairy vetch, *Vicia villosa* Roth., have been shown to translocate Dy and Eu from soil to leaves; thus certain herbivorous insects may be labeled on tagged host plants, and by extension, food webs could be examined using NAA methods.

Rare earth tags have been detected in medically and agriculturally important insects, including the tsetse fly, *Glossina morsitans* Westwood (from Eu-, Dy-, Au-, and Ir-labeled nutrient solutions), and the Mediterranean fruit fly, *Ceratitis* *capitata* Wied. (Mn-labeled nutrient solutions). NAA has been used in some insect ecology and ethology studies, including dispersal of *Drosophila* spp. and effects of vegetative cover on the sizes of imported fire ant territorial areas.

Other activation analysis methods have been conducted with trace elements and compounds such as zirconium oxide, Bi, Pb, cerium oxide, Sn, and Se sprayed on mosquitoes then bombarded with alpha particles in a cyclotron to produce X-ray emissions.

Carbohydrate Profiling

Gas-liquid chromatograph profiles of cuticular lipids extracted from the surface of insects is a form of "passive" marking in that the marker was naturally acquired by the insect during its lifetime. This technique has received limited use, including application for determining differences in age, sex, and geographical origin of screwworm flies. One preliminary study showed that overwintered boll weevils could be distinguished from other individuals, and that geographic origins of boll weevils may be determined with 90% certainty.

Immunoglobulin

Various immunoglobulins (Ig) can be applied to insects and later detected using enzyme-linked immunosorbent assays (ELISA). Applications of this marking method have been few and the primary limitation has been relatively rapid loss of unequivocally detectable levels of the Ig (generally measurable loss occurs within a week). The following examples, however, illustrate how Ig methods can be used in different ways. Convergent lady beetles, *Hippodamia convergens* Guérin–Meneville, were marked and recaptured after as long as 30 d using rabbit Ig, and chicken Ig was 75% effective after 11 d. *Lygus hesperus* Knight were marked for 8 d by submersion in rabbit Ig. *Anaphes iole* Girault, a parasitoid of *Lygus* spp. eggs were marked by feeding them with rabbit Ig-tagged honey solution, and others were marked externally tagged by contact exposure or topical mist. The Ig marker was retained by the parasitoid throughout the entire adult lifespan (<2.5 d) regardless of the application method.

Marking Pheromones

RONALD J. PROKOPY
University of Massachusetts, Amherst, MA, USA

A marking pheromone is a chemical compound (or mixture of compounds) emitted by an insect that advertises the past or current presence of the insect or its progeny at or in association with a valued resource. The type of resource may be food, an egglaying site, or a site of shelter.

Some kinds of insects foraging for food save valuable time and energy and improve foraging efficiency by following a trail of marking pheromone deposited by conspecifics that have discovered a quality food resource. Other kinds of insects foraging for food or egglaying sites avoid investing time, energy, or progeny at depleted or overcrowded resources by rejecting locales scented with marking pheromone. A few kinds of insects use pheromone to mark territories around nests that serve as sites of shelter.

Marking pheromones may be released from a variety of endocrine or exocrine glands of insects as well as from other structures associated with digestive, reproductive and locomotory systems. Most marking pheromones are non-volatile and can be detected only when touched by antennae, mouthparts, tarsi, or the ovipositor. Some, however, are volatile and can be detected via antennae at distances of several centimeters.

Ants and tent caterpillars are good examples of insects that follow a trail of marking pheromone to enhance food-foraging efficiency. After finding food, fire ant workers and tent caterpillar larvae deposit marking pheromone on their return to the nest. The pheromone signals the discovery of food to conspecifics, which then proceed to follow the trail to its source. The greater the amount or quality of the food, the greater the amount of pheromone deposited. Trail marking ceases when the food supply is exhausted.

Honeybees and bumblebees are good examples of insects that use information from marking pheromone as a cue to cease foraging (at least temporarily) for food at marked sites. Bees may visit a variety of flowers to obtain nectar. When doing so, they temporarily deplete the nectar supply of florets, which may not be renewed for an hour or more. If a bee were to invest time and energy probing for nectar in florets whose supply was not yet renewed, it could jeopardize its ability to acquire a full complement of nectar. Marking pheromone deposited on a floret by a previous forager signals the arriver that the supply of nectar has been exhausted, or at least is not yet fully renewed. Interestingly, honeybees and some species of bumblebees can detect each other's marking pheromone. Moreover, the time required for nectar replenishment appears to correspond closely to the duration of activity of marking pheromone.

Among insects foraging for egglaying sites, hymenopterous parasitoids that oviposit in host eggs, larvae, or pupae, fruit flies (family Tephritidae) that oviposit in the flesh of host fruit, and beetles that oviposit on or in seeds illustrate the role of marking pheromone in preventing overcrowding of larval food resources. Often, the host of a parasitoid, tephritid fly, or seed beetle can support only a single larva to maturity. Pheromone released during or after egg deposition signals occupancy by a conspecific. In a few cases, host-foraging females may be able to detect host occupancy and associated marking pheromone of a close or distant relative.

Sometimes, a host is sufficiently large enough to support several larvae to maturity, though never an unlimited number. In such cases, marking pheromone may allow a female to assess not merely the presence versus the absence of an occupant, but also to assess the level of occupancy, as determined by the amount of pheromone present relative to the size of the host.

Some predatory insects, such as neuropteran lacewing females and coleopteran ladybird females, use marking pheromone as a cue for avoiding overcrowding food resources (particularly colonies of aphids) that will serve as prey for larval progeny. Although aphids may be numerous at the time of predator oviposition, they are unlikely to remain so in the face of the voracious appetites of lacewing and ladybird larvae. Several members of these groups are known to refrain from ovipositing in the presence of conspecific larvae. The most frequently encountered cue indicating larval presence is the marking pheromone associated with the footprints of conspecific larvae.

The physiological and informational state of an insect, along with the state of the environment, may have a strong effect on the degree to which an individual in search of a resource responds to the presence of marking pheromone. If prior experience informs an insect that a desired resource is plentiful in the local habitat, then the insect may almost always respond strongly to marking pheromone and, except in cases of trail-marking pheromone, leave the marked locale and search elsewhere. On the other hand, if prior experience informs the insect that a desired resource is scarce and the insect is highly motivated to acquire the resource, then the insect may respond weakly to the marking pheromone, or even ignore it, and proceed to attempt to use the depleted or occupied resource at hand.

Numerous species of ants deposit marking pheromone in the vicinity of their nests. Such pheromone may serve not only as a home-range marker that circumscribes the territory within which colony members forage, but also may serve as a signal to alien ants from other colonies that the nest itself is occupied.

Some marking pheromones have been exploited for managing pest insects. For example, the European cherry fruit fly, *Rhagoletis cerasi* L., deposits marking pheromone on the surface of host fruit after laying eggs. The pheromone has been identified, synthesized and sprayed on cherry trees in Switzerland to protect cherries against fly oviposition. Formulation with adjuvants helps protect the water-soluble pheromone against the degrading effects of rainfall. It is anticipated that enhanced knowledge of the identity of marking pheromones will be accompanied by the increasing use of such pheromones in pest management.

Marlatt, Charles Lester

Charles Marlatt was born in 1863. He attended Kansas State University, where he received a B.S. in 1884 and an M.S. in 1886. He joined the staff at Kansas State in 1887, but in 1889 C. V. Riley hired him to work in Washington, DC, as an assistant entomologist and artist. Riley became first assistant entomologist and assistant chief of the Division of Entomology in 1894, a position he held until 1925. It is largely through Marlatt's persistent efforts that the Plant Quarantine Act of 1912, important legislation that helped curb the unregulated movement of plants (and insects) into the United States, was passed. In 1927 he was named chief of the Bureau of Entomology, a job he held in addition to the position as Chief of the Plant Quarantine and Control Administration. He administered the Plant Quarantine Act until 1929. Marlatt was an authority on both sawflies and scale insects, and in 1900 assumed responsibility for the government's collection of scales. He played an important role in identifying the homeland (northeastern China) of the San Jose scale, and of establishing biological control in the United States through importation of a predator. Under his leadership two successful eradication campaigns were conducted: the Mediterranean fruit fly in Florida and the date scale in California. Marlatt received a number of honors during his career, and served as president of the Entomological Society of Washington and the American Association of Economic Entomologists. He died on March 3, 1954.

Marx, George

George Marx was born in Hess, Germany, on June 22, 1838. He is known as an illustrator of renown. Marx completed pharmaceutical studies in Germany before moving to the United States in 1860. There, he served in the Union army during the American Civil War. After working as a pharmacist in Philadelphia, Marx accepted a position as a natural history illustrator with the United States Department of Agriculture in 1878. He received a M.D. degree in 1885. In 1889 he was made chief of the Division of Illustrations. Although acknowledged as an expert on spiders and scorpions, he is remembered primarily for his excellent illustrations. He died in Washington, DC, on January 3, 1895.

Mass Provisioning

The act of storing all the food required for the development of an immature insect at the time of egg laying. (contrast with progressive provisioning)

Mass Rearing of Natural Enemies

JOSE ROBERTO POSTALI PARRA
Esalq/USP,
Piracicaba, Brazil

Mass rearing involves the production of millions of insects, with the objectives of controlling pests and supporting Integrated Pest Management (IPM) programs. Several definitions have been proposed for mass rearing, including:

- Mass rearing is the economic production of millions of beneficial insects, as if in an assembly line, in order to produce the maximum number of fertile females, with the least number of men/hours and space, in the shortest time possible, at low cost;
- Insect production that can accomplish goals at an acceptable cost/benefit ratio, in numbers exceeding from 10 thousand to 1 million times the average productivity of a population of native females;
- Systematic, automated activity conducted in integrated facilities, in order to produce a relatively large supply of insects for distribution.

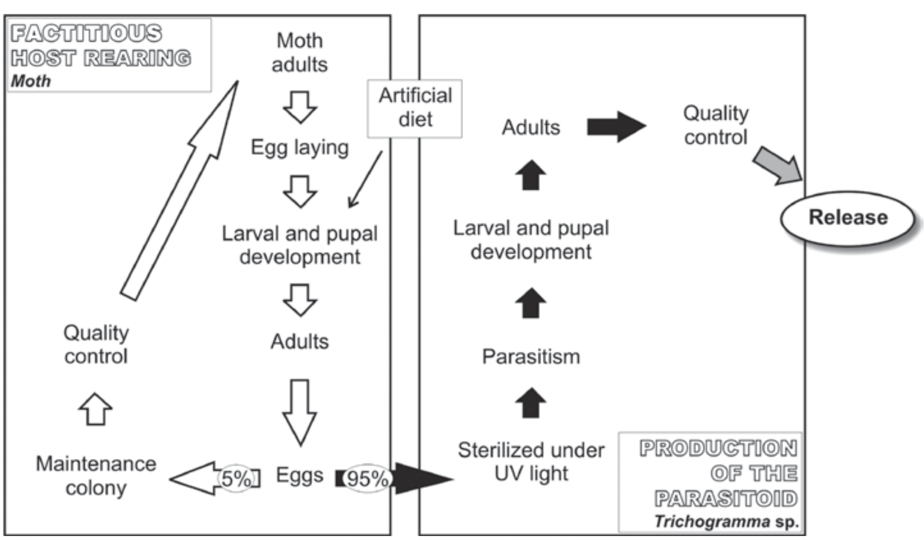
Therefore, mass rearings are truly factories, in which cost is highly important, particularly with respect to labor, since it represents 70–80% of total production cost. To achieve this goal, the personnel involved in rearing must be highly qualified in the field of insect rearing techniques. Often such personnel are not readily available. Consequently, it becomes necessary to automate the process for the production of natural enemies, especially in countries where labor is more costly.

Mass rearings are started from smaller-scale or research rearings (conducted by one or two people), or intermediate-sized rearings, upon which basic research about the target (often an agricultural pest) and the natural enemy (parasitoid or predator) are conducted. Therefore, in order to produce natural enemies, two species have to be reared, the pest and the natural enemy (Figs. 12 and 13). The potential for rearing a large number of natural enemies increased as artificial diets began to be developed since the 1960s, with emphasis on artificial diets for Lepidoptera, Coleoptera, and Diptera.

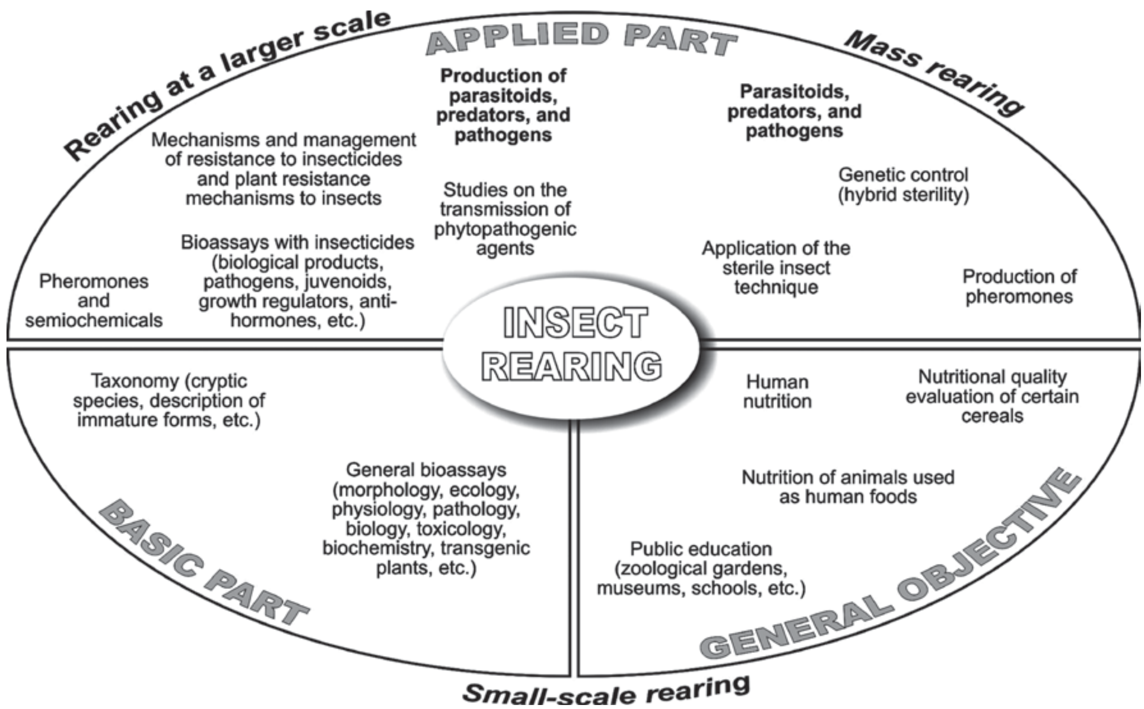
Considering the fundamental approaches to implementing biological control, i.e., introduction (classical biological control), conservation (natural biological control), and multiplication (applied biological control), mass rearings assume greater importance in the latter because, in this case, inundative releases are made with a similar effect as conventional insecticides, because they decrease pest populations more rapidly and are well accepted by growers because of their similarity with conventional agrochemicals.

Although many government-sponsored programs exist worldwide involving mass rearings of fruit flies, boll weevil and the egg parasitoid *Trichogramma* spp., most rearings are commercial. These are companies that sell natural enemies.

Although the first mass production by a private company took place in 1926 (Fillmore Citrus



Mass Rearing of Natural Enemies, Figure 12 **Rearing schematics of *Trichogramma* spp. on a factitious host.**



Mass Rearing of Natural Enemies, Figure 13 **Relationships between insect rearings and various areas of entomology.**

Protective District) in the USA, insect trading was initiated in the 1960s, with ladybugs and mantids sold to control garden and nursery pests. Beginning in the 1980s, the number of companies that supplied insects significantly increased. In 1992, 95 suppliers (twice as many as in 1977) made 106 species available in the market; in 1997, there were 142 suppliers and 130 beneficial insect species for sale. In Europe, there was also a great increase in this type of trade from the 1970s.

A principal impetus to the use of insectary production of natural enemies was the successful use of the predatory mite *Phytoseiulus persimilis* to control mite pests. Today, several natural enemy species, produced by many companies, are available for the grower, especially against protected-cultivation pests. *Encarsia formosa* is the most frequently sold parasitoid on the European continent to control whiteflies in protected cultivations. As a result, today many companies worldwide sell biological control agents packed in a similar manner as agrochemicals at market prices.

In South America, Colombia is the industry leader, with about 20 companies, particularly in the Cauca Valley, a region with a well-developed, technical agriculture. Brazil already has a similar number of companies, with emphasis on the production of *Cotesia flavipes*, which is currently released into 1.7 million ha annually to control *Diatraea saccharalis*, the sugarcane borer. *Trichogramma* spp. is released in about 200,000 ha of sugarcane, corn, and vegetables, while *Trissolcus basalis* is released in about 20,000 ha of soybean to control bugs. India, the Philippines, the Canary Islands, Venezuela, and Chile, among others, are players in this industry. New Zealand and Australia have a tradition in rearing natural enemies. China, Russia, and Cuba, in turn, have government-supported rearings. At present, between 15 and 20 million hectares are treated worldwide with such agents. *Trichogramma* is still the most widely used.

More than 125 natural enemy species are available in the market, with hundreds of producing companies. Currently, a US$50 million annual market exists for biological products; even though this represents 0.5% of the agrochemicals market, this figure is expected to double or triple in the first part of this century.

As the number of insects produced in any rearing increases, problems related to facilities, costs, microorganisms (contaminants), and insect quality control also increase. In addition to a necessity for automation, problems with employees may arise due to allergies, such as those caused by moth handling, in *Trichogramma* rearings, for example.

As previously commented, two insect species have to be reared; this requires basic knowledge about the pest and the natural enemy (biology, ecology, biochemistry, behavior, physiology, nutrition, etc.). Knowledge about temperature requirements (in degree-days) is essential for production planning.

Another problem in mass rearings relates to the fact that the insect will be used during one season of the year only. When it is not being used, it must be stored. These techniques, still incipient, are used with *Trichogramma* by inducing diapause and subsequently stopping it when demand for the insect arises. Liquid nitrogen has also been used to store eggs. Quality of the insects produced is one of the greatest concerns today. Loss of genetic variability in mass-reared insects may lead to the loss of wild-insect traits, preventing laboratory-reared insects from being as competitive as those found in nature. There are two types of processes that may result in genetic deterioration: random and non-random or adaptive processes. Among these deterioration mechanisms, genetic drift (or founder effect), inbreeding, and selection are the most relevant. Therefore, monitoring the production, the process, and the product over successive laboratory generations is essential for the production of laboratory insects that are as competitive as those that occur in nature. The International Organization for Biological Control has already established standards that take into account biological characteristics and molecular analyses, which must be followed up and regulated by law to prevent ethical problems that may discredit the reputation of biological control.

An ideal situation in mass rearing would occur if the insect host could be eliminated and the parasitoid or predator reared on artificial (*in vitro*) diets. Although the Chinese demonstrated *in vitro* advancements to the world in 1982 by rearing *Trichogramma dendrolimi* on artificial diet, the expected developments in this area did not occur, frustrating the scientific community, which had high expectations for this new technology.

Further studies are required, since the diets used today are based on those developed in the 1960s. The search for better diets must include greater knowledge of the nutritional requirements of insects, but also must take into account the technology and equipment used in this food processing industry for large-scale production. More refined bioassays, using microscopic, nanotechnological, molecular, and biochemical and fermentation techniques may provide advancements in this field. More sophisticated bioassays may improve microorganism control in large rearings and elucidate the role of symbionts (*Wolbachia*, *Buchnera*, etc.) in insect nutrition. Together with these, it is essential to foster those that work in the insect-rearing sector, training them at both the undergraduate and graduate levels. The process of using natural-enemy agents to control pests is a cultural as well as an economic process that requires high-quality employees, in order to assure acceptance by agricultural producers.

Masters, George

GEORGE HANGAY
Narrabeen, NSW, Australia

George Masters was born in July 1837 in Kent, England. Not much is known of his early years, except that he was a horticulturist and when he migrated to Australia, he lived in Tasmania. Later, the amateur entomologist A.W. Howitt in Melbourne employed him. Consequently, many of the specimens which he collected are now in the Howitt Collection in the Museum of Victoria (Melbourne). In 1864 he became Assistant Curator and Collector of the Australian Museum in Sydney. In 1874 William John Macleay employed him as curator of his zoological collections. Masters remained in this position even after the collections (by then Museum) were transferred to the University of Sydney. He was a very good field worker, not only with insects but also with most vertebrate animals, especially birds. It was said that at time more than half of the natural history specimens in the Australian Museum were of his taking. As Curator of the Macleay Collections he participated in the "Chevert" New Guinea expedition. Apart from his collecting and curating activities, his Coleoptera catalogues are his main contributions to Australian entomology (Catalogue of the described Coleoptera of Australia, 1871–1886; Catalogue of the known Coleoptera of New Guinea, 1888). Later in life he suffered from nervous complaints and his eyesight became very poor. He died in a cab accident on July 23, 1912.

Mastotermitidae

A family of termites (order Isoptera) presently containing only one species, Giant Northern Australia termite.

► Termites

Maternally Inherited

Characters that are transmitted primarily by cytoplasmic genetic factors, including mitochondria, viruses, etc., derived from the maternal parent. This is also known as cytoplasmic inheritance or extranuclear heredity.

Matheson, Robert

Robert Matheson was born at West River, Nova Scotia, Canada, on December 20, 1881. He received all his degrees in entomology at Cornell University, attaining his Ph.D. in 1911. He worked for South Dakota State University, Nova Scotia Agricultural College, and Cornell as a medical entomologist. His expertise was on mosquitoes and malaria, and he helped in the elimination of malaria from the east-central United States. He trained many students in medical entomology, and published "Handbook of mosquitoes of North America" (1929), "Medical entomology" (1932), and "Entomology for introductory courses" (1944). He died on December 14, 1958, at Princeton, New Jersey.

Mating Disruption

Use of pheromones to interfere with mating and reproduction, resulting in pest population suppression.

Matsumura, Shonen

Shonen Matsumura was born on March 5, 1872, and is considered to be the "father of Japanese entomology." He was interested in insects from an early age, and studied entomology at Sapporo Agricultural College (now Hokkaido University). He was appointed to the faculty there in 1896 and in 1898 published "Nippon Konchugaku" (Entomology of Japan). In 1899 he moved to Europe to advance his knowledge and in 1902 returned to Japan as professor. Much of his work was on Lepidoptera and Hemiptera, but he published on most orders. He authored about 240 papers and 35 books during his career. The illustrated 12-volume "Thousand insects of Japan" published between 1904 and 1921 was especially noteworthy. He also accumulated Japan's largest insect collection. He died on November 7, 1960.

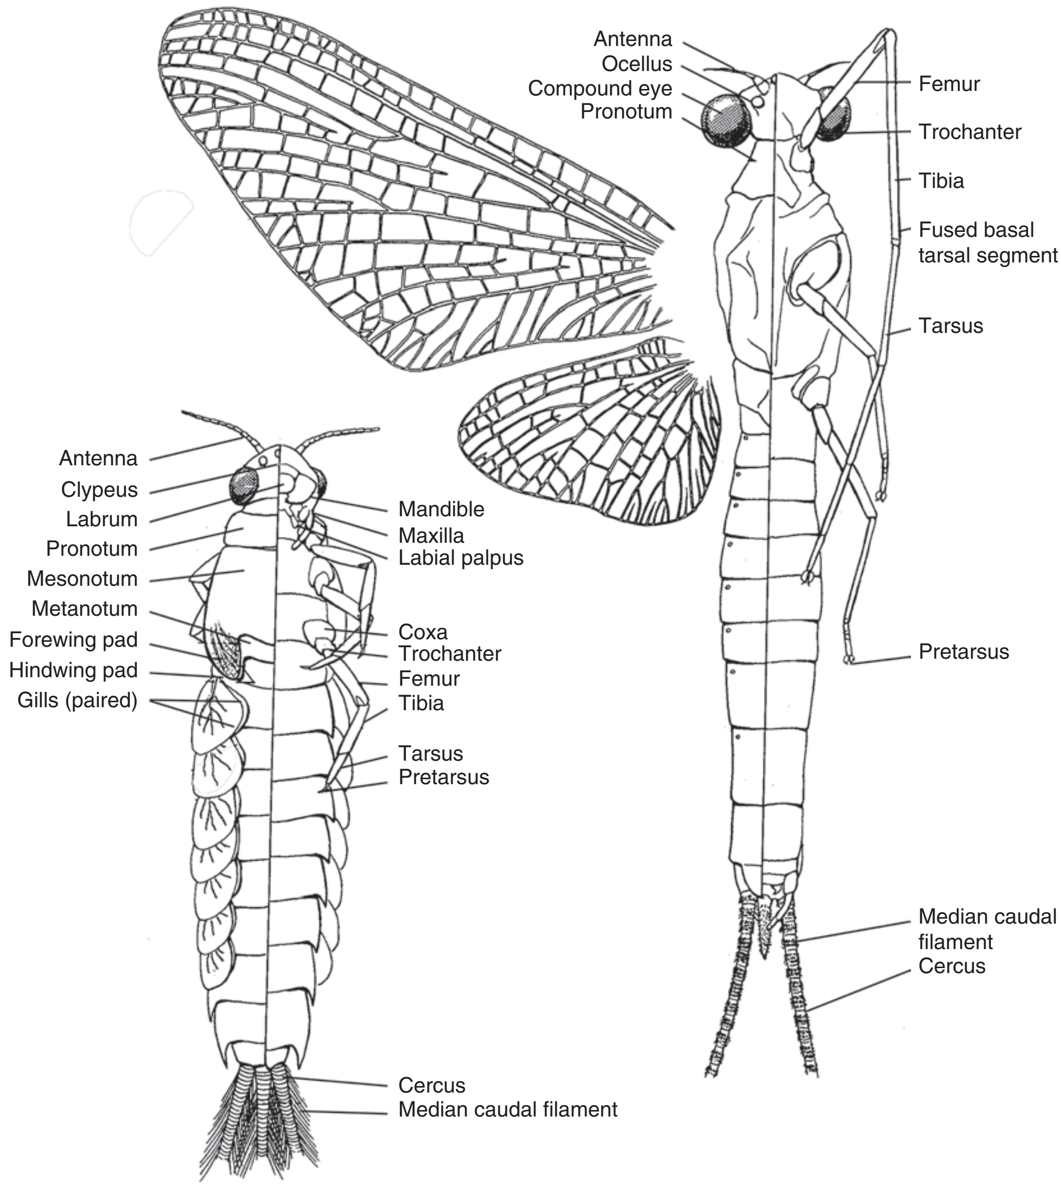
Mayflies (Ephemeroptera)

BORIS KONDRATIEFF
Colorado State University, Fort Collins, CO, USA

The Ephemeroptera or mayflies, are a primitive order of aquatic insects that, as adults, are easily distinguished by the presence of two pairs of membranous wings, the front wings larger and triangular in shape, with the hind wings much smaller (and sometimes absent). The antennae are bristle-like, and two or three long segmented caudal filaments or "tails" extend at the end of the abdomen. Additionally, adults are usually found at or near bodies of water (Fig. 16).

Most mayfly adults have two winged stages, one termed the subimago and the other the imago. The subimago, the winged stage after the molt from the nymphal stage (many entomologists prefer the term larvae for all immature insects) after a period of time that varies from an hour to days, will molt to the imago or adult stage. The angler or fly fisherman terms the subimago the "dun" and the imago the "spinner." The imago stage is ready to reproduce and disperse, the only biological functions of this stage. Some mayflies remain as a subimago and still can reproduce. In fact some subimagoes have vestigial or nonfunctional legs, and can only fly and mate, then die! Adult mayflies often form enormous nuptial flights, during which mating takes place. Swarming behavior can take place over the water, or sometimes remote from a body of water, and at various times of the day from dawn to dusk, or at night. The eyes of the male imago are modified, apparently for better acuity for aerial mating. Mated females return to the stream or pond to oviposit. Eggs of most mayflies are modified for different aquatic environments, usually with specialized attachment structures.

Mayfly immatures or nymphs can be distinguished from other aquatic insects with hemimetabolous or incomplete metamorphosis by the



Mayflies (Ephemeroptera), Figure 16 Diagram of mayflies: adult (*right*) and immature (*left*). Note that each is divided into dorsal (*left portion*) and ventral (*right portion*) perspectives.

presence of two or three caudal filaments or tails at the end of the abdomen, and usually one claw on each leg (absent in Behningiidae). Additionally, gills are attached to various segments on the side of the abdomen, either as flattened plates or filaments. Gills can also occur on the base of the legs or mouthparts. The body length can range from 2 to almost 35 mm, not including the caudal filaments.

Immature mayflies occur in many different habitats, both lotic (flowing waters, streams, rivers) and lentic (standing waters, ponds, lakes, reservoirs). However, the greatest diversity of mayflies is found in lotic habitats, especially those of higher elevations. Some species of Baetidae can be found in tide pools and alkaline desert pools. Some groups such as members of the family Heptageniidae (flatheaded mayflies) have flattened bodies, and are adapted to cling to instream rocks or other firm substrates in fast-flowing streams, whereas others such as members of the Baetidae (small minnow mayflies), Ameletidae (ameletid minnow mayflies), and Siphlonuridae (primitive minnow mayflies) are well adapted for swimming. Members of the Ephemeridae (common burrower mayflies) are burrowers in soft sediments of lakes, ponds and large rivers.

The higher classification of the Ephemeroptera is in part provisional. Researchers have presented much significant work towards a phylogenetic classification of the order. Currently, about 631 species are recognized from North America in twenty-three families of the forty-one extant families known in the world. A comprehensive index to North American mayfly species is provided at the website http://www.entm.purdue.edu/entomology/research/mayfly/mayfly.html.

The majority of mayflies reside in running waters, but unlike another group of aquatic insects, the stoneflies (Plecoptera), they attain maximum diversity in warm lotic habitats. Most mayfly nymphs are collector-gatherers or scrapers. A few species are specialized filter-feeders or carnivores. Shredders are very poorly represented. Most mayflies of temperate regions have a one-year life cycle (univoltine), the vast majority of which is spent as an aquatic nymph. In fact, it is the ephemeral nature of the aerial adult stage that is responsible for the Greek name of the order. Adults live from one hour to several days, depending on weather conditions and the species in question. The gills of mayflies are highly variable. In most species gills are present only on the abdomen. Gills often occur on the first seven abdominal segments, although one or more pairs may be absent, depending on the species. A few species also possess gills on the legs and head. Most mayflies possess three caudal filaments; a few have two caudal filaments. Microhabitat occurrence is reflected more distinctly in the body form of nymphs than in that of any other order. Some species have a fusiform body shape that enables them to move about on the tops of rocks in rapid water, whereas others are flattened dorsoventrally to hug rock surfaces. Other groups construct burrows in the substrate with their mandibles, and use their gills to create respiratory and feeding currents. Yet others are adapted for creeping and climbing among accumulations of organic material, or in silty backwaters, or in plant beds.

A brief synopsis of the more common families is provided.

Family Ameletidae (Ameletid Minnow Mayflies)

The nymphs are usually found in small fast-flowing streams among rocks. Some species are confined to very small brooks, often congregating in pool areas. Nymphs are strong swimmers, but often seek quieter waters. Nymphs are scrapers, using the pectinate comb of spines (the diatom rake) on part of the mouthparts to feed on periphyton or algae. There is usually only one generation per year. Some species of *Ameletus* apparently are parthenogenetic, reproducing without the presence of males.

Family Baetidae (Small Minnow Mayflies)

Nymphs are found in a wide variety of aquatic habitats. They may be the only mayflies present in extreme environments such as high-elevation streams, the sources of springs, or mildly polluted waters. They are considered good swimmers, darting in short spurts from one spot to another. Often they are, in terms of numbers, the most important mayflies of many North American streams. The species of *Baetis* collectively occupy an extremely wide range of flowing water habitats. *Callibaetis* is primarily a standing water genus, some species of which occur in the backwaters or quiet margins of running waters. Most members of the family are collector-gatherers or scrapers. Most of the species found in flowing water habitats apparently have two generations per year, others only one.

Family Caenidae (Small Squaregill Mayflies)

The small nymphs are usually found in standing water, and are often abundant in ponds, lakes and wetlands. They are considered sprawlers in silty bottoms in the zones of rooted vegetation. Nymphs feed usually on decaying plant material. Some species have several generations per year, especially in the more southern areas. *Caenis* is the common genus.

Family Ephemeridae (Common Burrower Mayflies)

Nymphs of this family construct a U-shaped tunnel in bottom sediments with openings at both ends. They use their feathery gills to maintain a current within the burrows for obtaining dissolved oxygen. Additionally, they filter out small particles of organic material brought in by the current. Some species ingest sediments mixed with organic material. The nymphs are often abundant in lakes, ponds, large rivers, and reservoirs. Mass emergence of the large-sized adults, especially in the Mississippi River Valley region, attracts attention, and at times is considered a nuisance. Depending on location, species of common burrowers complete their life cycle in 1–2 years. The two genera, *Ephemera* and *Hexagenia* are widespread throughout North America.

Family Ephemerellidae (Spiny Crawler Mayflies)

Nymphs occur in almost all types of flowing water. Some species occur in steep gradient segments of streams in high elevations to silty microhabitats in lower elevations. Some groups also are found in standing waters of lakes and wetlands. Nymphs crawl about and are well camouflaged. Most species are considered collector-gatherers or scrapers, but some *Drunella* species have been reported to be partially predaceous. Nymphs have the peculiar defensive behavior of raising its three tails in a posture called the "scorpion posture." Most species have one generation per year.

Family Heptageniidae (Flatheaded Mayflies)

Heptageniids are perhaps the most typical of all mayfly families found in flowing water. The nymphs are flattened and generally adapted to life in high-gradient mountain streams. Most species are restricted to running waters; a few also inhabit wave-swept shores of lakes. Species of *Heptagenia* generally occupy warmer and siltier running waters than other genera such as *Epeorus*, and *Rhithrogena* are restricted usually to cool, fast mountain streams. Most heptageniids are scrapers, removing attached microscopic plants and other particles from rock surfaces; a few are collector-gathers and predators. The numerous North American species have one to two generations per year.

Family Isonychiidae (Brushlegged Mayflies)

Nymphs of this family can be abundant in a variety of flowing waters, and especially abundant in shallow riffle reaches of streams of eastern North America. Nymphs are strong swimmers, and use hair fringes on the forelegs for filtering organic particles from the water column. Most species have one generation a year, but in more southern areas they may have two generations per year. The genus *Isonychia* occurs over most of North America, and adults are easily distinguished by their reddish coloration.

Family Leptohyphidae (Little Stout Crawler Mayflies)

Nymphs are often associated with beds of aquatic plants or other habitats where silt accumulates. The opercular gill plates protect the remaining gills from silt deposition. Members of this genus are slow-moving sprawlers that feed on sedimentary organic material. The genus *Tricorythodes* is a common North American genus.

Family Leptophlebiidae (Pronggilled Mayflies)

The poor-swimming nymphs of this family are commonly found in shallow streams of all sizes. Some groups are associated with accumulations of leaves and debris in overflow areas or flood plains. Nymphs of some species are filter-feeders in rapid sections of large silty rivers of western North America, while others feed on accumulated decomposing plant material or scrape algae of various substrates. Nymphs of some species are known for their migratory habits of moving in spring from streams to pools associated with the floodplain. One to two generations per year are common with most species. Emergence of some species occurs as early as February.

Family Siphlonuridae (Primitive Minnow Mayflies)

Nymphs occur both in lotic and lentic habitats, usually associated with accumulations of silt or the presence of vegetation. Nymphs often congregate in pools or overflow areas of streams. Nymphs are good swimmers but prefer quieter areas of streams or edges of pools and ponds. They feed on organic debris, but also engulf small aquatic organisms. Most species have only one generation per year. The genus *Siphlonurus* is widespread throughout North America (Fig. 16).

McDunnough, James Halliday

James McDunnough was born at Toronto, Canada, on May 10, 1877, and studied music before switching to entomology and becoming an authority on the systematics of Lepidoptera and Ephemeroptera. His zoological education commenced at Kaiser Wilhelm Institute in Berlin, Germany, followed by a M.S. from Queen's University in Kingston, Ontario, Canada, and then back to Kaiser Wilhelm for a doctorate. From 1910 to 1919 he worked as a curator at William Barnes' private museum in Decatur, Illinois. In 1919 he left to head the Division of Systematic Entomology at the Canadian National Collection in Ottawa. He served in this capacity for 28 years, accumulating one of the finest collections in North America. McDunnough published over 200 papers on Lepidoptera, 38 on Ephemeroptera, and several on other orders. Important works include "Check list of the Lepidoptera of Canada and the United States of America," and "Saturniidae of North America." Over the course of his career he named about 1,500 species. McDunnough died at Halifax, Nova Scotia, on February 23, 1962.

McGlashan, Charles Fayette

Charles McGlashen was born August 12, 1847. After obtaining seminary education in California and Massachusetts he became a high school principal in Placerville, California, and also was an accomplished lawyer, editor, and astronomer. He is also remembered, however, as an ardent amateur entomologist. He contributed numerous specimens to Henry Edwards' Lepidoptera studies and collection and developed an all-glass display case for his moths and butterflies. Interestingly, he also established a butterfly farm at Truckee, California, offered a correspondence course for amateur entomologists, and started a short-lived monthly magazine, "The butterfly farmer." He died in 1931.

McPhail Trap

The McPhail trap is a glass or plastic liquid-containing trap that uses protein solutions as bait. Ammonia given off by the trap is attractive to fruit flies, which enter the trap from below. As they instinctively attempt to move upward, they are restrained from escaping by the solid top.

► Traps for Capturing Insects

Meadow and Coneheaded Grasshoppers

Mechanical Control

Control techniques that are based on the operation of machinery or manual operations to destroy insects. Examples of mechanical control techniques include vacuum machines and black-light traps.

Mechanical Protection of Humans from Arthropod Attacks and Bites

IGOR USPENSKY
The Hebrew University of Jerusalem, Jerusalem, Israel

In addition to chemical repellents for arthropod vectors or annoyers, human protection from their attacks and bites can be provided by numerous mechanical methods. Mechanical protection is based on the creation of a barrier that prevents the penetration by arthropods to the target humans. Such a barrier can protect either a group of people or an individual person.

Environmental Design

A very simple and effective technique to protect a human locality from malarial mosquitoes is so-called "zooprophylaxis." This technique is based on rational planning of localities. The technique was tested at the end of the 1930s in several areas of the then U.S.S.R. and was later successfully applied in antimalarial campaigns in rural areas with developed animal husbandry. Thus, if a cattle-ranch is located between a mosquito breeding site(s) and a village, mosquitoes flying towards the village attack the cattle and only a few specimens reach the human dwellings. The distance between a large ranch and a village should be from 200–500 m, and between an individual cattle stall and the nearest dwelling, about 25–35 m. To protect a human locality from flies which develop on cattle ranches, it is recommended to separate these two sites by creating a brush and tree belt between them of not less than 100 m in width.

Several measures should be taken to protect dwellings from insect penetration. All windows should be fitted with screens of metal netting. The mesh size to prevent penetration of mosquitoes and most flies is 1.5–2 mm, but in the cases of such small insects as midges or sandflies the mesh should be as fine as 0.75 mm. Also, it is desirable to construct a porch before the entrance into the house, which should be fitted with appropriate screen and the entrance should be closed with a net fixed at the upper jamb and freely hanging down to the floor. Entrances to the animal housing also should be closed with screens.

Protective Clothing and Bed Nets

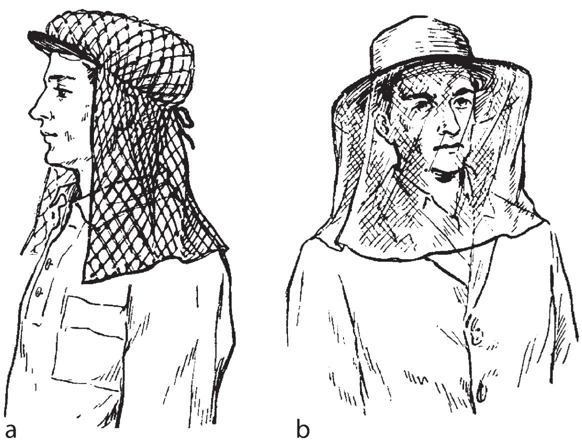
The easiest method of individual protection is proper clothing to create a barrier between attacking arthropods and the human body. In general, the more the human body is covered by clothing, the lower the probability of arthropod bites. A head veil made from a single- or double-layered net (impregnated by repellents, if possible) put over or under a head-dress, as well as a hood on a shirt or a jacket, provide additional protection from insect bites. A veil made from a fine mesh net covering the whole head and tightly fixed to clothing (similar to that used by beekeepers) provides nearly complete protection from insect bites without any necessity of repellents (Fig. 17). There are many things specific to various groups of arthropods that must be taken into account to provide a better barrier between them and the human skin. Blackflies that are active during the day prefer darker clothing rather than lighter fabric when selecting a landing site. To bite, blackflies must penetrate under the clothing and contact the body, using any minute openings for this purpose. Thin and delicate materials only partly protect from bites by horse flies or stable flies, whereas mosquitoes can pierce even fabrics with rough texture using their long proboscis (Fig. 19). For protection of people from night-biting arthropods during sleep, bed nets have been used for many centuries both inside and outside human dwellings. They can be of different shape and made from various materials. If a bed net is properly organized, it may provide nearly complete protection of the person using it. Correct maintenance of the bed net during the day prevents it from being used by mosquitoes as a resting site (Fig. 18). The development of bed nets impregnated with pyrethroid insecticides has supplemented their exclusively protective role by the suppressive effect on mosquito populations and their capacity as malaria vectors. Though the efficacy of impregnated bed nets differs for different mosquito species and in different areas, they have become an important tool in human protection from mosquitoes and malaria. An important factor to remember with nets for both head veils and bed nets is the necessity of good ventilation, a condition not always fulfilled.

Development of pyrethroid resistance in mosquito vectors may threaten the sustainability of impregnated bed nets, though the real impact of this phenomenon on the efficacy of bed nets is controversial. Meanwhile, various combinations of pyrethroid and non-pyrethroid insecticides for impregnation of bed nets have been tested. However, operational difficulties are more critical for effective application of impregnated bed nets, e.g., the necessity for regular retreatment of bed nets to maintain their high efficacy against mosquitoes. Most users do not impregnate their nets in time and properly, and the limited impact of such bed nets on mosquito population decreases the motivation of people to use this technique. This stimulated the development of "long-lasting insecticidal wash-resistant mosquito net" which should maintain its activity for 3–5 years, the average life expectancy of the net.

Arthropod Behavior and Protection

Protection from the bites of ixodid ticks is based on the specificity of their behavior. After adhering to human clothes, ticks usually move upwards, trying to penetrate under the clothes and to contact the body. To make tick penetration onto the body more difficult, people should seal all possible routes for tick penetration under the clothes. Trouser legs should be tucked into boots or socks, the shirt into trousers, and the head should be covered by a hood. Some researchers have recommended making two repellent strips, about 2 cm in width and 5–7 cm from each other, around each trouser leg above the knees. Such strips prevent ticks, most of which adhere to the clothes at a lower level, from moving upwards. Another pair of strips may be made around the collar to protect the head. People at risk of tick attack must regularly carry out self- and/or cross-inspections followed by tick removal. The frequency of such inspections depends on the tick abundance; they should be carried out at least several times per day, but in heavily infested areas, every hour or half hour.

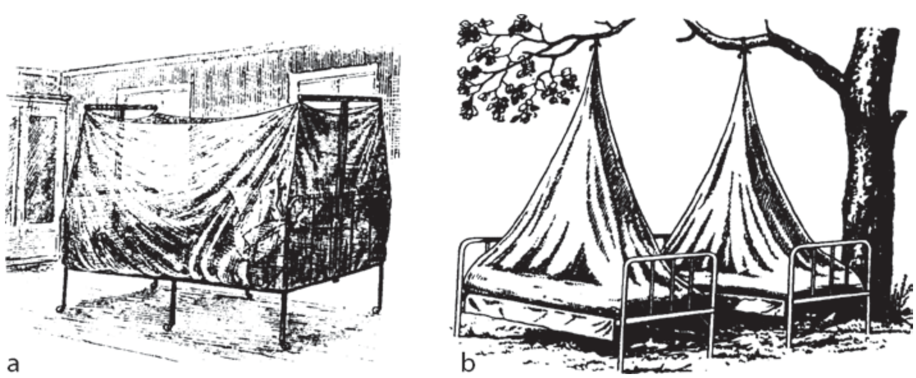
Many areas are populated by both ticks and blood-feeding insects. The necessity of simultaneous protection from both groups of arthropods has always been on the agenda. A protective suit developed by Russian scientists provides mechanical protection from both ticks and insects. Two shirts, which are worn one over the other, are the key part of this suit. The inner shirt is made from a thickened wide-mesh cotton netting, whereas the outer shirt is made from a fine-mesh net material. The outer shirt has elastic cuffs and a hood with an elastic band border. The suit also includes wide trousers with elastic cuffs and a belt, both made from a durable material. A mosquito able to penetrate through the material of the outer shirt cannot reach the human body with its proboscis; the thickness of the fabric of the inner shirt net material is about 2 mm, which is close to the maximal length of the proboscis. Other bloodsucking insects have a shorter proboscis. At the same time, the mesh size of the outer shirt is smaller than the size of the scutum of nymphal ticks. The net shirts made from cotton provide good ventilation so that the suit may be used during hot summer weather even by workers such as lumbermen. Depending on conditions, the suit may be used either for combined protection, or only as an anti-insect or anti-tick device. In the first case, the shirt has no hood but is supplemented by a head net impregnated with repellents. In the second case, only the outer shirt with the hood is used (Fig. 20).



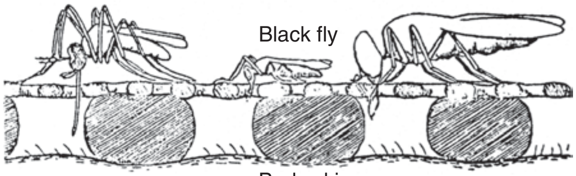
Mechanical Protection of Humans from Arthropod Attacks and Bites, Figure 17 **Head veils of different types: (a) Head is partly protected; (b) Head is completely protected.**

Human Motivation

An important consideration in using different protective techniques is human motivation. The



Mechanical Protection of Humans from Arthropod Attacks and Bites, Figure 18 **Bed nets of different types: (a) Rectangular bed net inside human dwelling; (b) Conical bed nets outside dwelling.**



Mechanical Protection of Humans from Arthropod Attacks and Bites, Figure 19 **Thickness of two net shirts compared with proboscis length of bloodsucking insects from different families.**

Mechanical Protection of Humans from Arthropod Attacks and Bites, Figure 20 **Combined protective suit consisting of two shirts made from net material of different meshes (man shows the inner shirt).**

latter depends to a higher degree on the level of discomfort than on the real danger created by arthropods. In areas where the abundance of bloodsucking insects is enormous, people have willingly applied protective clothes even if the insects are not vectors but just annoyers. On the other hand, even in areas where severe tick-borne diseases are endemic but the tick abundance is moderate, people are reluctant to apply any protective measures creating even minor discomfort. Another aspect concerning human motivation is connected with the purpose for which humans are in areas where they may be attacked and bitten by arthropods. If they work in such an area and have been well instructed, they usually protect themselves properly. However, people at leisure, even when specially instructed, do not like any discomfort and use protective measures rather unwillingly, if at all. In some cases, when people are vaccinated against a disease endemic in the area they are habiting, they believe the use of other protective measures is unnecessary. However, the area may also be endemic for other diseases, which is quite realistic since new cases of mixed infection have been discovered. From all these data presented above, one can see that the problem of human protection from arthropod attacks and bites has two aspects: the development of more efficient and comfortable techniques of protection, as well as the necessity of convincing people to apply them.

Mediterranean Burnet Moths (Lepidoptera: Heterogynidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Mediterranean burnet moths, family Heterogynidae, include only seven species, with three species from the Mediterranean region of southern Europe and northern Africa (genus *Heterogynis*) and four species from South Africa (genus *Janseola*). The family is in the superfamily Zygaenoidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small (9 to 29 mm wingspan), with head rough-scaled; haustellum absent or vestigial; labial palpi reduced, 3-segmented; maxillary palpi absent; antennae bipectinate. Wings rather rounded. Maculation mostly gray, with similar hindwings. Adults are diurnal, but females are apterous and larviform. Many of the species resemble bagworms and were originally described as Psychidae. Larvae, upon hatching inside the female cocoon, feed on the dead female and then become external leaf feeders. Host plants are in Leguminosae.

Mediterranean Flannel Moths (Lepidoptera: Somabrachyidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods, Gainesville, FL, USA

Mediterranean flannel moths, family Somabrachyidae, include only five species, with three species from Southern Europe and North Africa (genus *Somabrachys*) and two species from South Africa (genus *Psycharium*). The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Sometimes the group is included in Megalopygidae. Adults small (18–22 mm wingspan), with head scaling average; haustellum absent; labial palpi absent; maxillary palpi absent; antennae bipectinate. Wings very broadly rounded and body robust. Maculation gray or brown on wing margins, with most of wings hyaline. Adults are diurnal, but females are larviform and wingless (females of the South African species are unknown). Larvae are leaf feeders (eggs laid on leaves, not in the female cocoon), somewhat slug-like, with concealed head. Hosts are grasses (Gramineae) and Compositae.

Mediterranean Fruit Fly, *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae)

NIKOS T. PAPADOPOULOS
Aristotle University of Thessaloniki, Thessaloniki, Greece

The Mediterranean fruit fly (medfly) belongs to the tribe Ceratitidini of the sub-family Dacinae, and is the most well-known of the 65 species of the genus *Ceratitis*. It is highly polyphagous, very widespread (both in tropical and temperate areas), and it is considered one of the most important pests for world fruit production.

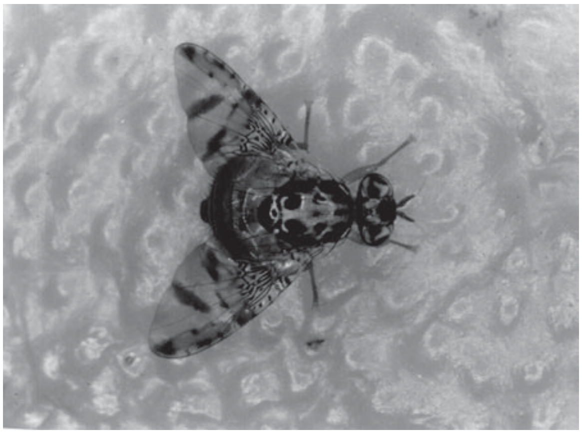
Origin and Geographical Distribution

The Mediterranean fruit fly was first described in 1824 by Wiedemann, when he analyzed a specimen collected aboard a ship in the Indian Ocean that was transporting fruits from Africa. Most of the studies suggest that this insect is native to tropical Africa, originating from areas south of the Sahara desert. This suggestion is supported by recent genetic studies. It is believed that the fly invaded first the Mediterranean basin either by dispersing along the valley of the Nile and then following the Middle East coastline, or by reaching Spain from the North Western coast of Africa and Gibraltar. From Spain, where it was first detected in 1850, it probably dispersed to the New World (Latin America). The fly usually disperses to neighboring orchards by flying. Invasions of new areas are achieved through the national, international and intercontinental transport of infected fruits. In general, suitable areas for the development of medfly lay between 45° north and 45° south geographical latitude. In the Northern Hemisphere, the fly is endemic in areas located below 41° latitude. The fly has been reported in many parts of Africa, in the Middle East, in Western Australia, in most of the Central and South America countries and in islands of the Atlantic, Pacific and Indian Oceans. It has invaded North America many times and is believed to be established in California, USA. In Europe, medfly occurs in all the Mediterranean countries and in Portugal.

Morphology

The adult medfly measures 4–6 mm in length, and 1.2–2 mm in width. It has quite a colorful appearance, owing to the yellow, brown, black, white and whitish stripes on its thorax, abdomen and wings. Compound eyes, which are iridescent royal purple to blue-greenish, occupy most of the head, which is yellowish in color. The antennae have a general brown color and several small black setae. The two base segments of the antennae are red-brown, while the aristae are almost black. The males are easily distinguished from females and from other species of the family by a pair of stalky, cornea like, pointed, black-gray expansions at the apex of the anterior part of their head. The wings (measuring about 4.5 mm in length) are transparent with yellow, brown, and red stripes. In resting or walking adults the wings are semi-open, sloping towards the posterior part of the body resembling a roof. The notum of the thorax is shiny black with discrete whitish stripes, whereas that of the sternum is yellow. The apical half of the scutellum is completely black. The abdomen is orange yellow with two red brown transverse stripes. The ovipositor is 0.9–1.3 mm in length. The legs are yellow red with several rather long, yellow setae on the back part of the tibiae (Fig. 21).

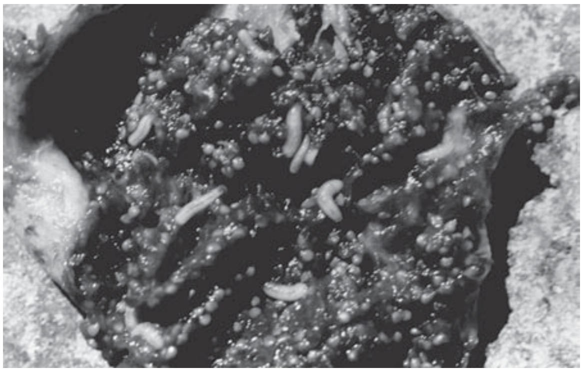
Eggs are oblong, elliptical, glossy white and measure around 0.9–1.1 mm in length and 0.2–0.3 mm in diameter.



Mediterranean Fruit Fly *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae), Figure 21 Mediterranean fruit fly, *Ceratitis capitata*, adult female.

Larvae are white or cream-white, oblong without legs, with the anterior part being narrower than the posterior. There are three instars that can be differentiated from each other by the shape, size and color of their mouthhooks. In general, the first instar measures 0.17–2.2 mm, the second instar 2.3–5 mm and the third 6–10 mm.

The puparium is elliptical barrel-like, and measures 4.4–4.5 mm in length and 2–2.5 mm in diameter. The color depends mostly on the larval food and ranges from almost white to dark brown.



Mediterranean Fruit Fly *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae), Figure 22 **Ripe fig infested by medfly larvae.**

Hosts and Economic Importance

The medfly is the most polyphagous tephritid and infests fruits of plants belonging to more than 67 families. Of the 353 hosts reported (although some lack confirmed field infestation), 40% belong to the families Myrtaceae (6%), Rosaceae (10%), Rutaceae (9%), Sapotaceae (9%), and Solanaceae (6%). Medfly develops in many fruits of tropical, sub-tropical, and temperate fruit trees. In the tropics and sub-tropics, it is a serious pest of coffee (*Coffea arabica*), mango (*Manifera indica*), papaya (*Carica papaya*), avocado (*Persea americana*), guava (*Psidium guajava*), carambola (*Averrhoa carambola*), sweet orange (*Citrus sinensis*), sour orange (*Citrus aurantium*), fig (*Ficus carica*), grapefruit (*Citrus x paradisi*), prickly pear (*Opuntia vulgaris*), loquat (*Eriobotrya japonica*), and oriental persimmon (*Diospyros kaki*). In temperate regions, it also infests stone and pome fruits such as apricot (*Prunus armeniaca*), peach (*Prunus persicae*), apple (*Malus domestica*), pear (*Pyrus communis*) and other fruits (Fig. 22).

Ceratitus capitata is one of the most serious pests worldwide, with infestation levels reaching 100% in some of its hosts. It is a quarantine pest in countries such as the United States of America and Japan. Intensive control programs have been carried out, coordinated by national and international organizations, with the aim of restricting the expansion of the distribution of medfly or of erradicating it from invaded areas.

Biology

Medfly is a multivoltine, non-diapausing species that usually completes between 3 and 7 generations per year. The number of generations is determined mostly by geographic area, climatic conditions (mostly temperature), host species and host availability. In the tropics and subtropics, as well as in the southern Mediterranean areas, this species develops continuously all year round with slower developmental rates in response to low temperatures. However, in the northern Mediterranean coasts only larvae inside infested fruits can survive and maintain the populations throughout winter.

Adults need to feed on carbohydrates and nitrogen after their emergence in order to reach sexual and reproductive maturity. The mating system of this insect is mainly based on receptive female attraction to "calling" males emitting a sex pheromone. Seven to 10 day-old females begin to lay eggs just after mating, in ripe or semi-ripe fruits. They open a small hole a few millimeters deep into the fruit using their ovipositor, and insert a batch of up to nine eggs in the flesh of the fruit. The oviposition sting is only visible in some hosts. Hatching larvae feed on the flesh of the fruits and, after completing their development, they leave the fruits to pupate at a small depth (up to 5 cm) in the ground beneath host trees. The direct damage of the larvae to fruits is usually accompanied, and magnified by, secondary infections of fungi and bacteria. The mean generation time under constant conditions in the laboratory (25°C) is estimated at one to two months depending on the host in which the fly developed. Throughout her life span each female lays from 250 to 1,000 eggs.

Control

The conventional control of *C. capitata* is based on population monitoring using adult traps and the application of bait or cover insecticide sprays. Of the many adult traps used, two are the most acceptable, the McPhail trap with various food baits, and the Jackson trap baited with the male lure trimedlure. A McPhail trap with the food attractants ammonium acetate, putrescine and trimethylamine, loaded in dispensers lacking a month, constitutes a very effective, female-targeted and medfly-selective trapping system that outperforms most of the other trapping systems. Several insecticides, used in cover or bait sprays, have been proved effective to control medfly. For example, malathion is very effective and is less toxic for invertebrates, and has been used extensively in several, large, area-wide control programs (Fig. 23).

Besides chemical control, several other pre-harvest and post-harvest methods have been developed and deployed for controlling medfly. There is also a set of cultural measures effective for the suppression of the fly. The most important of them are fruit bagging, sanitation (destruction of infested fruits), destruction of all wild host over a vast area, or stripping and destroying fruit over a large area. Satisfactory control has been achieved in some cases (mostly under low population densities) by biological control and mass trapping. The sterile insect release technique (SIT) has been used with success, the aim being in most cases the eradication of the fly from an area. More recently, this method has also been used to suppress the pest. There are several cases of successful combination of SIT with other methods such as bait sprays and/or augmentative releases of parasitoids. The control of this pest is most successful on an area-wide basis. Succesful implementation of an area-wide control programme can lead to the establishment of pest free zones within a country and also to the eradication of the pest from a state or country.

Mediterranean Fruit Fly *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae), Figure 23 **Jackson trap.**

In addition to direct control measures, there are other strategies to control this fly. The most important of these are the legislative measures. Very often, strict quarantine regulations are set up to prevent the entry of the fly into an uninfested area. Several markets accept only those fruits and/or vegetables that have undergone a commodity treatment that secures a mortality of at least 99.9968% (Probit 9) that is generally acceptable as zero infestation. The best-known of the commodity treatments is the exposure of the fruits to lethal low or high temperatures, and to fumigant insecticides.

Meigen, Johann Wilhelm

J. W. Meigen was born at Solingen, Germany on May 3, 1764. He became interested in insects at an early age, but had little opportunity for formal education. By various circumstances, he acquired knowledge of math and French, and eventually gained access to books. Thus, he became qualified to serve as a tutor in 1784, and moved away from home. He made the acquaintance of Mathias Baumhauer, an ardent collector of insects, and became extremely interested in insects. About 1778 he came to realize that Linnaeus had not described everything, and that the Linnean genera were too inclusive. He began a reclassification of Diptera based on wing venation, which eventually was expanded to include other body parts. Meigen taught himself enough Latin to read the works of Fabricius. In 1796 he took a teaching position in Stolberg. Meigen's approach to classification, using many body parts, did not find favor at the time, especially with Fabricius. Due to the political turmoil of the era, Meigen found difficulty with employment, but always maintained his interest in Diptera, and eventually became renowned as a pioneer in dipterology. He published several volumes on Diptera, but also on Lepidoptera. Meigen sold his collection and drawings to P.J.M. Macquart in 1839 and retired. He died July 11, 1845 (Fig. 24).

Meiosis

The sequence of events occurring during two cell divisions to convert diploid cells into haploid cells.

Meiotic Drive in Insects

MARJORIE A. HOY
University of Florida, Gainesville, FL, USA

Mendel's law of segregation proposes that equal numbers of alleles (variants of the same gene) derived from the paternally and maternally-derived chromosomes are distributed to eggs and sperm during meiosis (the reductional division that results in haploid eggs or sperm having only one copy of each type of chromosome). However, this law is sometimes violated due to a phenomenon called meiotic drive. Meiotic drive has been studied in insects and has been proposed to be a future tool for suppressing pest populations.

Meiotic drive alters the equal assortment of chromosomes during meiosis so that certain chromosomes are inherited by the progeny more frequently than expected (greater than 50% of the time). Meiotic drive most frequently is observed affecting sex chromosomes (chromosomes that are different in males and females). In most insects, females are XX and males are XY (or heterogametic, with half the sperm receiving the X and half the Y chromosome) and the ratio of male and female progeny is 1:1. If changes in distribution of the X and Y chromosome occur through meiotic drive, it is detected because more females or males are produced than expected. Whether meiotic drive mechanisms actually affect the sex chromosomes more frequently, or whether meiotic drive is more frequently discovered because it is relatively easy to detect due sex ratio changes, is unknown.

Meiotic drive has been found most often in Diptera, including *Drosophila obscura*, *D. melanica*, *D. tripunctata*, *D. testacea*, *D. melanogaster* and *D. quinaria* groups, mosquitoes (*Aedes* and *Culex*), sciarid flies and stalk-eyed flies (Diopsidae). Whether meiotic drive is common in other insect orders is controversial.

Three examples of sex chromosome meiotic drive are described below, including Segregation Distorter (SD) in *Drosophila*, male drive (MD) in the mosquitoes *Aedes aegypti* and *Culex quinquefasciatus*, and meiotic drive in stalk-eyed flies.

Segregation Distorter (SD) In *Drosophila melanogaster* the SD phenotype is present at low, but stable, frequencies in most field populations. *D. melanogaster* males containing one SD chromosome and one normal (SD^+) chromosome may produce only progeny with the SD chromosome, instead of half with SD and half with SD^+, due to the failure of sperm with the SD^+ chromosome to mature. Segregation distortion occurs because the nuclei of the sperm with the normal SD^+ chromosome fail to condense at sperm maturation. The Enhancer locus of SD, E(SD), is required for the full expression of this type of meiotic drive.

The SD phenotype actually involves two overlapping genes, one called HS2ST and the second called RanGAP. RanGAP is an essential component of a system that transports proteins and RNA molecules into and out of the cell's nucleus. Both HS2ST and RanGAP are present twice on the SD, as opposed to once on the SD^+, chromosome. This tandem duplication is necessary for segregation distortion. Both genes appear normal in the right hand copy, but the

RanGAP gene on the left lacks the last 234 amino acids. It is possible that the truncated RanGAP protein functions incorrectly and is mislocalized within the cell.

Distorter Gene Meiotic drive also has been described in the mosquitoes *Aedes aegypti* and *Culex quinquefasciatus*. In both species, a Y-linked gene results in excess males. Excess males are produced because X chromosomes are broken during meiosis in males. As a result, fewer X than Y chromosomes are transmitted, leading to the production of fewer female embryos. The *Distorter gene* (D) is linked closely to the sex-determining locus m/M and causes the chromosome breakage.

Additional genes are involved in the sex ratio distortion; sensitivity to *Distorter* is controlled by m, the female-determining locus. In some strains, sensitivity is influenced by a second sex-linked gene t. Yet another sex-linked gene A enhances the effect of *Distorter*. *Distorter* has been found in mosquito populations from Africa, America, Australia and Sri Lanka, but resistance to it is widespread.

Female-biased Sex Ratios in Stalk-eyed Flies Extreme female-biased sex ratios are found in two sister stalk-eyed flies, *Cyrtodiopsis dalmanni* and *C. whitei* (Diopsidae), due to a meiotic drive element on the X chromosome. Eye stalks are more exaggerated in males than in females in these species and females prefer to mate with males with a longer eye span. The longer eye stalks may be an indicator that the male either lacks meiotic drive or can suppress the meiotic drive. Thus, females prefer to mate with males with longer eye stalks because it should increase the female's fitness by avoiding a biased sex ratio in her progeny. Apparently, there are both autosomal- and Y-linked genes involved in resistance to the meiotic drive.

Meiotic Drive as a Pest Management Tool?

Meiotic drive operates as an evolutionary force which can cause an increase in the population frequency of the allele or chromosome which is favored in transmission, even if it confers a disadvantage on its carriers. It has been proposed that meiotic drive might be used to introduce new genes (such as cold-sensitive lethal genes, insecticide-susceptibility genes, or behavior-altering genes that would reduce the impact of pest populations on humans) into natural populations as a method to achieve control of pest insects. However, much remains to be learned about the stability of such drive mechanisms and the conditions under which they might function in pest management programs. Furthermore, as noted above, resistance to meiotic drive mechanisms can evolve in some species or populations; such resistance mechanisms, if developed rapidly, could reduce the effectiveness of the drive mechanism in the pest management program.

Hybrid Sterility and Meiotic Drive

It is sometimes possible to cross different insect species, and the progeny sometimes show altered sex ratios, with one sex absent, rare, or sterile. The missing or sterile sex is usually the heterogametic sex (XY). This phenomenon is known as Haldane's Rule. However, Haldane's Rule appears to occur only in taxa with sex chromosome-based meiotic drive, such as the Lepidoptera and Diptera. Haldane's rule may be occurring if suppression of sex ratio distorters is lost in the novel nuclear cytotype of the hybrid.

Melander, Axel Leonard

A.L. Melander was born at Chicago, Illinois, USA, on June 3, 1878. He became interested in insects while in high school, and studied with William Morton Wheeler at the University of Chicago and the University of Texas. He received his M.S. in 1902. Melander taught at Washington State University from 1904 to 1926, and was head of the department for 20 years. He completed his Sc.D. at Harvard University in 1914. He left Washington State in 1926 and moved to the City College of New York where he served as professor of biology and head of the department, and retired in 1943. Melander worked on many insect problems, and among his accomplishments was the first documentation of declining effectiveness of an insecticide. He collaborated with C.T. Brues on authorship of "Key to families of North American insects" (1915), and "Classification of insects" (1932). He served as president of the Entomological Society of America in 1938. Melander also accumulated one of the world's largest collections of flies, which is now incorporated in the Smithsonian Institution. Melander died at Riverside, California, on August 14, 1962.

Mellanby, Kenneth

Kenneth Mellanby was born in 1908 and was educated at King's College, Cambridge, England, and the London School of Tropical Medicine, but his studies were interrupted by World War II. At the time, scabies was widespread in the military, and Mellanby deduced that the purported means of spread were erroneous and quickly demonstrated effective control. This work effectively released the equivalent of an additional two divisions of soldiers from the hospital to aid in the war effort. This work also resulted in publication of two books, "Scabies" (1943) and "Human guinea pigs" (1945). After the war he moved to Nigeria to start a college, and in a few years had a program operational. Mellanby returned to England in 1953, worked on various projects, and eventually assumed the position of Head of Entomology at Rothamsted Experimental Station. However, it was not until 1961, when he was appointed Director of the Nature Conservancy's Experimental Station at Monk's Wood did his career again flourish. He quickly assembled the largest research station in Britain devoted to studying conservation of wildlife. Work done here included the effects of pesticides on wildlife, habitat management, monitoring changes in distributional status, and establishment of a records center. Mellanby was the founding editor of the journal "Environmental pollution," and he wrote several books related to environmental causes, including "Pesticides and pollution" (1967), "Farming and pollution" (1991), and "The DDT story" (1992). Mellanby was active in several scientific societies and received numerous honors, including several honorary doctorates. He died in 1993.

Melon Aphid, *Aphis gossypii* (Hemiptera: Aphididae)

TIMOTHY A. EBERT
The Ohio State University, Wooster, OH, USA

The melon aphid is a polyphagous species capable of feeding and reproducing on plants in over 90 plant families. There are over 72 crops in over 32 plant families worldwide that require some kind of human intervention for managing this aphid. This aphid is considered a pest in crops produced both in the field and in the greenhouse. Host plant damage includes direct feeding and transmission of plant pathogenic viruses. Reproduction in this aphid is entirely asexual in warmer climates, but includes a sexual phase in colder climates. Aphids of any given clonal line do not have the ability to utilize the entire host range reported for this species. Indirect damage by this aphid may also occur through the production of honeydew. Honeydew is a sugary liquid excreted by aphids to eliminate excess carbon and water. Honeydew coats plant surfaces below the aphid colony. Fungi able to utilize honeydew as a food source then cover the plant surface, thereby reducing the light reaching the chloroplasts.

Systematics and Biology

Common Names

The most popular English common names are the cotton aphid, or the melon aphid. These are the Entomological Society of America approved common names. However, there are at least 40 "common" names which are older, of more regional importance, or not English.

Description

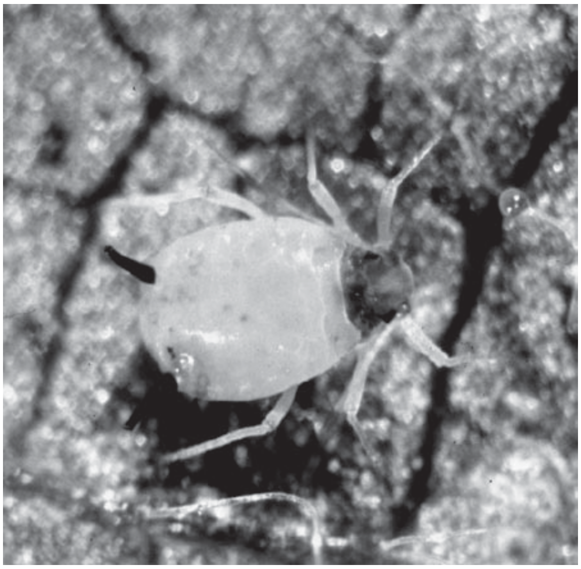
Apterous, mature, viviparous, yellow females can be <0.83 mm long and weigh <5.8 mg, while green females can be over 1.8 mm long and weigh over 66 mg. The body is generally rounded. Antennae have 5–6 segments. Cornicles (also known as siphunculi, and located between the fifth and sixth abdominal tergites) are dark, slightly conicle with the proximal end slightly larger in diameter than the distal end, and the length up to five times the diameter. Cornical length ranges from 0.13 to 0.35 mm. The cauda is pale to dark with two or three pairs of lateral setae.

The following stages have been observed: fundatrix (first parthenogenic generation from fertilized egg), fundatrigeniae (viviparous females on the primary host), alienicola (viviparous females on a secondary host), gynoparae (viviparous females are born on a secondary host and then migrate to the primary host to produce sexual females), oviparous female (egg laying female), alate and apterous male, hibernating viviparae (viviparous female), androparae (viviparous females that exclusively produce males), heteroparae and androgynoparae.

In addition to the specific life stages, this aphid displays considerable variability within clones. Adult individuals may have wings that fail to develop fully and range in size from little stubs to nearly functional. Furthermore, this aphid has a wide range in color variation, from yellow to a "green that is almost black," and individuals can be found anywhere along a gradient within this range. Additionally, some individuals may appear to be part yellow and part green. The yellow (and smaller) form occurs during warmer summer conditions. The green (and larger) form occurs during cooler spring (Fig. 25) and fall temperatures, with uncrowded conditions. Color is not a host race trait because color morphs are able to produce progeny of the other color morph. Host plant also influences aphid color, presumably due to stress – where the yellow form predominates under stressful conditions. The mechanism for color morph development is unknown. Some insecticides can cause a reverse stress response: e.g., LC_{10} doses of sulprofos (an insecticide).

Genetics

2n = 8, with chromosome lengths of about 2.3–3.65, 3.4–5.42, 3.8–6.24, and 5.0–7.64 μm.



Melon Aphid, *Aphis gossypii* (Hemiptera: Aphididae), Figure 25 **Melon aphid (cotton aphid), *Aphis gossypii*.**

Chromosomes are believed to be holokinetic (chromosomes lack a centromere), which could simplify genetic rearrangement and permit more rapid adaptation to new conditions: from adapting to new host plants to developing pesticide resistance.

Host Range and Utilization

The worldwide distribution of *A. gossypii* is partly due to its broad host range and its ability to switch hosts. One study reported *A. gossypii* surviving at least 15 days following transfer from plants in the Scrophulariaceae, Brassicaceae, Asteraceae, Lamiaceae, Rosaceae and Malvaceae to plants in the Asteraceae, Solanaceae, Cucurbitaceae, Liliaceae, Portulacaceae, Commelinaceae and Araceae. The broad host range increases survival under unfavorable conditions (e.g., when the original host plant species is unavailable), and aids in the transfer of viruses from reservoir plants to crop plants.

Reproduction in *A. gossypii* is mostly asexual with either alate (winged) or apterous (wingless) females. In warmer environments, this aphid has an anholocyclic life cycle (reproduction only through parthenogenesis), while in cooler areas, the aphid exhibits either a heteroecious or autoecious holocyclic life cycle. The heteroecious cycle involves a migration from a primary host to a secondary host in the spring and a return to a primary host in the fall for laying eggs. The primary host for the aphid is considered to be the ancestral host upon which the aphid evolved, and therefore, it is where the sexual phases of the life cycle are completed. The primary host for this aphid is unknown because there is the possibility that the aphid has secondarily acquired new "primary" hosts. The ancestral host is probably one of the following: *Citrus* (Rutaceae), *Hibiscus syriacus* L. (Malvaceae), *Rhamnus dahuricus* Pall. (Rhamnaceae), *Celastrus orbiculatus* Thunb. (Celastraceae), *Rubia cordifolia* L. (Rubiaceae), *Catalpa bignonioides* Walter (Bignoniaceae), *Zanthoxylum simulans* Hance (Rutaceae), or *Punica granatum* L. (Lythraceae). Aphids that remain on the primary host for both sexual and parthenogenic reproduction are described as "autoecious".

Population Growth

Population growth is a function of survival, time to reproduction and nymphs produced per day. A recent study examined the stage-specific influence of temperature on the population growth rate for this aphid on cotton. Temperatures examined were from 10 to 35°C. Individual life table parameters were optimized at slightly different temperatures; e.g., total fecundity of 28.3 nymphs per female was highest at 25°C, while development was fastest at 30°C where it took only 4.6 days from birth to time of first reproduction. The development threshold was estimated for the first through fourth instar, and the adult, to be 8.2, 8.0, 7.2, 6.2 and 7.9°C, respectively. Overall, the maximum intrinsic rate of increase (0.386 per day) was achieved at 25°C, which results in a population doubling time of only 1.8 days. While other studies have reported specific values that would lead (if combined) to a faster population growth rate, in total, this is probably close to the upper limit for the population growth rate for this aphid.

Nutrition

The nutritional requirements of aphids are modified due to endosymbionts that produce some nutrients the aphid is unable to make without them. Typically, nutritional quality for aphids is measured by reproductive rate, or growth rate. Diet pH is best between 7.4 and 7.8. Sugars in the diet serve as nutrition and to stimulate feeding. Optimal sucrose concentrations in artificial diets are between 20 and 30%, and diets with other sugars are less suitable, although 20% sucrose with 10% maltose came close to equaling a sucrose-only diet. Experiments on identifying amino acid requirements have shown that cystine and methionine in the diet improve growth rate, but above 30 mg/ml, they are toxic. While not essential, improved growth was observed with tyrosine, phenylalanine and tryptophan in the diet.

Abiotic Environment

One of the most important abiotic factors affecting the life cycle of this aphid is temperature. A lower developmental threshold for this aphid was estimated at 7.34°C on squash. Development thresholds have also been estimated for the aphid on cucumber at 5.8°C from birth to age of first reproduction, but the development threshold for the nymphal stages was 6.9°C. A study of this aphid on speedwell, Veronica persica, estimated a developmental threshold of 10.47°C for the preflight period. An upper limit of survival at 35°C was reported on squash in Saudi Arabia, but the authors pointed out that the aphid survives in okra fields where the daytime temperature exceeds 45°C. Temperature is also thought to be responsible for some strains of *A. gossypii* being holocyclic while others are anholocyclic.

Light intensity and day length are also important abiotic factors in the reproductive capacity of this aphid. Increasing day length increases the intrinsic rate of increase, decreases population doubling time and decreases generation time. However, there is some indication that at 18-h daylengths, population growth rates decline slightly. The effects of light intensity have been studied, but with conflicting results; sometimes light intensity increases reproduction, and sometimes it decreases reproduction. In the field, increased light intensity may decrease reproduction. Reflective mulch can decrease aphid populations, and a suggested mechanism was increased light intensity on abaxial leaf surfaces.

Production of Winged Aphids (Alates)

There are two proposed triggers for production of winged aphids in *A. gossypii*: nutritional factors (physiological stress), and crowding. Aphid-aphid contact has been proposed as a mechanism for triggering alate production, but it is possible that the aphid has a chemical means of identifying the number of neighbors. It is not known if the trigger for production of alates is continuous, discrete, or a combination of the two. As a continuous process, increased numbers of aphids changes plant nutrition and brings about a corresponding change in alate production. However, it would appear that production of alates is partly a discrete process where crowding gets to some threshold level and suddenly alates are produced.

Crowding effects have been conclusively demonstrated for alate production on cotton. One study examined crowding using leaf disks with a single, apterous aphid that was removed following reproduction. The resulting colonies contained from one to seven nymphs. From 52 colonies with one or two nymphs, no alates were produced. From 41 colonies with three or four nymphs, <10% of the colony became alate. However, of 29 colonies with five to seven nymphs, over 30% of the total number of aphids became alate. The observation that colonies with one to two individuals never produce alates has beed reported several times.

Nutritional factors from other sources also play a role in production of alates. One of the more interesting hypotheses is the possible role of aphid-borne plant viruses. The survival of the virus is dependent on having an efficient aphid vector, and the most efficient vector is alate. Therefore, one might expect that a virus would promote conditions favoring alate production in the aphid. Indeed, zucchini plants infected with the zucchini yellow mosaic virus increased alate production in the melon aphid.

The parentage and physiological state of the parent influence production of alates. Starved nymphs from apterous parents resulted in 13% alates versus 0.4% from unstarved nymphs, but the starvation of nymphs from alate parents resulted in no increase in formation of alates. A similar result was also reported for starved parents, where starved, apterous parents produced more alate progeny than well-fed, apterous parents (23% and 2%, respectively), and there was no increase in alate formation by starved, alate parents.

Behavior

Flight

Flight is the beginning of the dispersal or sexual reproductive phase in the life cycle of the melon aphid. It begins with the preflight period (from molt to flight), which lasts from 1 to 70+ hours depending on host plant and temperature. Adult flight activity is most common from about sunrise to early afternoon, with little or no activity after dark. Alates typically fly within 1 m of the ground.

In laboratory colonies, the flight period lasted from 1 to 4 days. Older colonies produced fewer alates that flew for 1 day and more that flew for 2 days. Aphids flew from one to several (about five) times each day, with the first flight always longer than the others. Alates larviposited after flight, and flew again when the number of embryos with pigmented eyes per ovariole decreased. Alates that flew longer had a shorter reproductive period and produced fewer total progeny. Alates that land on previously colonized plants have a decreased probability of larvipositing.

Light

The melon aphid is sensitive to different wavelengths and intensities of light, but the nature of the effect is not clearly understood. Aphids were attracted to Auclair's artificial diet illuminated at 570–595 nm, while diets illuminated at 420–485 nm were repellent. This contradicts other findings where newly molted, alate adults preferred shorter wavelengths down to 357 nm. Adults of mixed age also preferred this short wavelength, though some preference was also shown for wavelengths of 550 nm. Furthermore, there is a stage-dependent response to light, the adults being more sensitive to different wavelengths than the nymphs.

Host Plant

Orientation to host plants begins at 6 h after wing development, but has a maximal response after about 24 h. In addition to the type of host present in a field, the arrangement of hosts within the field is also important. An experiment was done using soybean, dwarf sorghum and tall sorghum planted in monoculture or interplanted. At the sorghum canopy level, landing rates were highest on monocultures of dwarf sorghum, then monocultures of tall sorghum, and lowest in mixed plantings.

Feeding

In one set of experiments, alates were placed on squash, *Cucurbita pepo*, plants and watched under a microscope. Given that probing occurs when aphids pressed their labium to the surface and placed their antennae flush with the body, the aphid took 6–9 min following contact with the plant before probing. However, this is the same time it took newly emerged alates, and may not be characteristic of alates after migration.

Egg Laying

Egg laying on *Hibiscus syriacus* occurred mostly between the leaf scar and the twig near where the buds would emerge in the spring. Some eggs were also laid at the branching point of twigs. However, from the wandering behavior of the oviparous females, it appears that females searched for protected places to lay eggs rather than for specific parts of the plant.

Biotic Interactions

Virus Transmission

The ability of the melon aphid to transmit plant pathogenic viruses increases its ability to damage a wide range of crops. This ability is influenced by the biochemistry of all three participants: plant host, virus and aphid. Some examples are: Citrus Tristeza virus acquisition rates are affected by citrus cultivar. Transmission of the virus is influenced by virus strain, but not by the aphid strain nor the rearing host for the aphid. Cucumber mosaic virus (CMV) transmission is governed by virus RNA strands 1, 2 and 3, but not strand 4. Transmission of CMV is influenced by the previous aphid host, and aphid clones differ in their ability to transmit the virus. The relationship between aphid and virus is very specific in that changes in amino acids 129, 162 and 168 of the coat protein significantly alter the ability of the aphid to transmit the virus. The interaction between this aphid and other plant pathogenic viruses can be equally specific at a biochemical level. While some viruses like CMV have specific locations on the coat protein, which mediate aphid transmission, other viruses produce helper components, which mediate transmission: e.g., *Aphis gossypii* transmission of tobacco etch potyvirus (TEV) and turnip mosaic potyvirus (TuMV).

Mortality

This aphid is an important food resource for many organisms. These include many insect predators (ladybugs: *Coccinella septempunctata* L., *Hippodamia convergens* Guérin-Méneville, *Menochilus sexmaculatus* (Fabricius), *Scymnus louisianae* Chapin; lacewings: *Chrysopa carnea* Stephens, *Chrysoperla rufilabris* (Burmeister), *Chrysopa sinica* Tjeder; hoverflies: *Syrphus* sp.; Hemiptera: *Orius insidiosus* (Say), *Geocoris* spp., *Nabis* spp., *Zelus* spp.), hymenopteran parasitoids (*Trioxys* spp., *Aphelinus* spp., *Lysiphlebus testaceipes* (Cresson), *Aphidius colemani* Viereck, *Lipolexis scutellaris* Mackauer), and some parasitic mites (*Allothrombium ovatum, Allothrombium pulvinum* Ewing). Several fungi are also able to cause aphid mortality (e.g., *Paecilomyces fumosoroseus*, *Neozygites fresenii*, *Cephalosporium lecanii*, *Verticillum lecanii*, *Erynia neoaphidis*, *Beauveria bassiana*), as well as some bacteria. These lists of names are provided as an indication of the melon aphid's importance in the food chain and are far from complete.

This aphid has also been associated with ants, which both protect the aphid and feed off the aphid. The association is opportunistic rather than obligate. The ants, which have been found with this aphid, include: *Camponotus japonicus* Mayr, *Camponotus compressus* Fabricius, *Anoplolepis* spp. and *Solenopsis invicta* Buren, among others.

Melon Fly, *Bactrocera cucurbitae* (Coquillett) (Diptera: Tephritidae)

JOHN L. CAPINERA
University of Florida Gainesville, FL, USA

Melon fly is found in the tropical regions of Asia, a portion of east Africa, and on some Pacific islands, including Hawaii, USA. Melon fly has been recovered on several occasions in California, and although it has not become established in the western hemisphere, the tropical and subtropical regions would be suitable habitat.

Life History

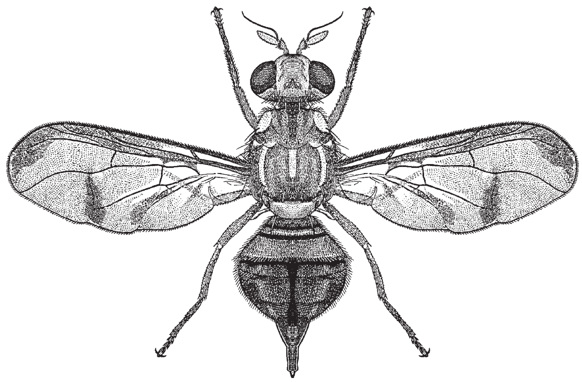
A life cycle can be completed in about 5 weeks in warm climates, but may require 3–4 months in cool climates. The adults (Fig. 26) can survive for months, and will continue to reproduce if fruit is available. In tropical climates such as Hawaii they are present throughout the year. Their abundance is determined mostly by availability of suitable host plant material, but they tend to be most common in summer and autumn.

Females deposit eggs in small batches, usually 5–20 eggs each. Females may produce 800–900 eggs over their life span. The white eggs are about 1.3 mm long and 0.25 mm wide, and are deposited in the fruit or vegetative parts of plants. The lower and upper developmental thresholds for egg development are about 10 and 40°C, respectively. Eggs hatch, on average, in 1.3 days.

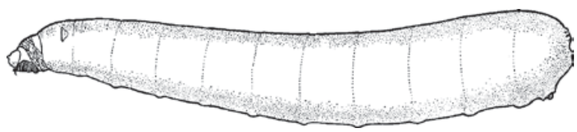
The larvae (Fig. 27) are white, and when they hatch they are about the length of the egg. Larvae immediately begin to grow, and attain a length of about 2.5, 5.5, and 11.0 mm in length during instars 1–3, respectively. The mouth hooks are pale in the first instar, but thereafter are darkened and easily observed. Larvae complete their development in 5–8 days, with instars 1–3 requiring about 1, 1–2, and 2–3 days, respectively, in soft hosts such as papaya. The lower and upper developmental thresholds for larvae are about 12 and 34°C, respectively.

When mature, larvae leave the host, burrow into the soil up to a depth of 10 cm, and pupate. The adults emerge from the tan or yellow-brown puparium after about 10 days (range of 7–14 days), and dig to the soil surface.

Newly emerged adults crawl to a sheltered location where they rest for 2–3 h before taking flight. Adults are yellow or yellow-brown in color, with yellow wings marked with brown bands. They measure about 6–9 mm in length. Dark markings resembling a "T" occur on the abdomen, and two lateral and a medial yellow stripe are found on the thorax. The presence of wing bands and the dark abdominal markings can be used to differentiate melon fly from oriental fruit fly and Mediterranean fruit fly, respectively. The preoviposition period of adults is about 7.4 days, and they are capable of depositing eggs for about 3 months.



Melon Fly, *Bactrocera cucurbitae* (Coquillett) (Diptera: Tephritidae), Figure 26 **Adult of melon fly, *Bactrocera cucurbitae* (Coquillett).**



Melon Fly, *Bactrocera cucurbitae* (Coquillett) (Diptera: Tephritidae), Figure 27 **Mature larva of melon fly, *Bactrocera cucurbitae* (Coquillett).**

Adults spend most of their time associated with the adult host plants, seeking vegetable crops or other prospective larval hosts intermittently for oviposition. Fly activity in crop fields peaks in the afternoon hours. At dusk, males form aggregations called leks, and by making wing vibrations and releasing sex pheromone, attract and copulate with females.

Melon fly prefers such cucurbits as watermelon, cantaloupe, pumpkin, squash, and cucumber, but infests other vegetables including tomato, pepper, green bean, and cowpea. Wild hosts, particularly bitter melon, *Mormordica charantia*, can be important. Passion fruit, papaya, grape, and citrus also are suitable larval hosts, but it is the availability of vegetable crops that generally determines melon fly abundance.

The adult often is found associated with plants that are not larval food sources, but rather provide sustenance for the adults. Honeydew produced by such insects as aphids and scale insects, and secretions of extrafloral nectaries, attract flies to plants such as corn; castor bean, *Ricinus communis*; spiny amaranth, *Amaranthus spinosus*; rattlepod, *Crotolaria incana* and *C. mucronata;* and other cultivated and wild plants.

Extensive research has been conducted around the world to identify effective natural enemies of this serious pest. The wasp *Psytallia fletcheri* (Silvestri) (Hymenoptera: Braconidae), a larval parasitoid, is the most effective biological control agent located. Although *P. fletcheri* is effective at parasitizing melon fly larvae infesting wild cucurbits, it is relatively ineffective in crops. Therefore, its use is limited to reduction of background populations only.

Damage

In the absence of biological or chemical control, melon fly is extremely damaging. Melon fly larvae develop in blossoms, fruits, and some vegetative portions of plants. Among vegetative plant material, newly emerged seedlings and terminal shoots are preferred. Similarly, among fruits, immature fruit is usually selected. Larval feeding also opens the plant tissue to secondary invaders, both microbial and insect. Damage can also occur from egg laying even when larvae cannot survive because oviposition allows entry of microorganisms or causes deformities in the growing fruit. Some differences in damage among cucurbits exists. Seedling and stem damage is more common in watermelon and cantaloupe than in squash, cucumbers, and pumpkin. Blossom damage is serious among all cucurbits except cucumber.

Management

Fruit may be sampled for eggs and larvae, and soil for pupae, but this is not done routinely because of the high labor requirements and expense. A natural chemical constituent of some plants, raspberry ketone, is highly attractive to male melon flies, and a synthetic analog called cue-lure is equally or more attractive; the latter is useful with traps for sampling. Fluorescent yellow sticky traps can also be used to sample adult densities, and odor and visual stimuli are sometimes combined in a single trap design. However, the most widely used trap is the McPhail trap, a liquid-baited trap.

Melon fly adults, unlike many insect pests, do not remain in contact with larval host plants for extended periods of time. Instead, they spend a great deal of time in weedy vegetation surrounding crop fields. A program of treating the surrounding vegetation, rather than the crops, is often recommended. Treatment of border vegetation can be much more effective than treatment of crops. Bait sprays containing insecticide also can be used effectively for adult suppression. Sugar or protein hydrolysate is mixed with various insecticides to produce bait sprays. Insecticide and bait treatments have been combined with mass release of sterile male insects to eradicate melon fly from some Pacific islands. Cue-lure can also be mixed with insecticide to attract and kill flies, but it is only effective against males.

Field sanitation is the most important element of cultural management. High melon fly populations result from continuous availability of larval food, which may be due either to continuous cropping or failure to dispose of crop residues. Destruction of infested or unmarketable vegetables in a timely manner is essential. Trap crops have not been effective at protecting vegetables, probably due to the relatively wide host range and vagility of the insects.

Protective coverings have long been used to deter oviposition by melon fly. Paper bags and newspapers are used to wrap individual fruit in the case of large produce such as cantaloupe and watermelon. This is effective but tedious, and not useful for small-fruited vegetables. Also, it does not protect vines and flower buds. Row covers provide more complete protection, but pollination may be interrupted.

Melon Thrips, *Thrips palmi* Karny (Thysanoptera: Thripidae)

JOHN L. CAPINERA
University of Florida, Gainesville, FL, USA

Until the mid 1970s, the distribution of melon thrips was limited to Southeast Asia. In recent years it has spread throughout Asia, and to many Pacific Ocean islands, North Africa, Australia, Central and South America, the Caribbean region and southernmost mainland USA (Florida). It has the potential to infest greenhouse crops widely, but under field conditions likely will be limited to tropical and subtropical areas.

Life History

A complete generation may be completed in about 20 days at 30°C, but it is lengthened to 80 days when the insects are cultured at 15°C. Melon thrips are able to multiply during any season that crops are cultivated but are favored by warm weather and suppressed by senescent crops. In southern Florida, they are damaging on both autumn and spring vegetables. In Hawaii, where vegetables are grown during the summer months, they also become numerous during the summer growing season.

Eggs are deposited in leaf tissue, in a slit cut by the female. One end of the egg protrudes slightly. The egg is colorless to pale white in color, and bean-shaped in form. Duration of the egg stage is about 16 days at 15°C, 7.5 days at 26°C, and 4.3 days at 32°C.

The larvae (sometimes called nymphs) resemble the adults in form except for the lack of wings and smaller body size (Figs. 28 and 29). There are two instars during the "larval" period. Larvae feed gregariously, particularly along the leaf midrib and veins, and usually on older leaves. Larval development time is determined principally by the suitability of temperature, but host plant quality also has an influence. Larvae require about 14, 5, and 4 days to complete their development at 15, 26, and 32°C, respectively. At the completion of the larval instars the insect usually descends to the soil or leaf litter where it constructs a small earthen chamber for a pupation site.

There are two instars during the "pupal" period. The prepupal and pupal instars are inactive, nonfeeding stages, although the insect changes slightly in form at each molt. The prepupae and pupae resemble the adults and larvae in form, except that they possess wing pads. The wing pads of the pupae are longer than that of the prepupae. The combined prepupal and pupal development time is about 12, 4, and 3 days at 15, 26, and 32°C, respectively.

Adults are pale yellow or whitish in color, lacking blotches of dark pigmentation but with numerous dark setae on the body. The population is heavily weighted toward females. The slender fringed wings are pale. The hairs or fringe on the anterior edge of the wing are considerably shorter that those on the posterior edge. Adults measure 0.8–1.0 mm in body length, with females averaging slightly larger than males. Unlike the larvae, the adults tend to feed on young growth, and so are found on new leaves. Adult longevity is 10–30 days for females and 7–20 days for males. Development time varies with temperature, with mean values of about 20, 17, and 12 days at 15, 26, and 32°C. Females produce up to about 200 eggs, but average about 50 per female, which they deposit in leaf tissues in an incision made with the ovipositor. Both mated and virgin females deposit eggs.

Damage

Melon thrips is a polyphagous species, but is best known as a pest of Cucurbitaceae and Solanaceae. Among vegetables injured are bean, cabbage, cantaloupe, chili, Chinese cabbage, cowpea, cucumber, bean, eggplant, lettuce, melon, okra, onion, pea, pepper, potato, pumpkin, squash, tomato and watermelon. Other crops infested include avocado, carnation, chrysanthemum, citrus, cotton, hibiscus, mango, peach, plum, soybean, tobacco, and others.

Melon thrips cause severe injury to infested plants. Leaves become yellow, white or brown, and then crinkle and die. Terminal growth may be discolored, stunted, and deformed. Densities from 1 to 10 per cucumber leaf have been considered to be the threshold for economic damage in some Japanese studies. However, studies in Hawaii suggested a damage threshold of 94 thrips per leaf early in the growth of the plant. Feeding usually occurs on foliage, but on pepper, a less suitable host, flowers are preferred to foliage. Because melon thrips prefer foliage, they are reported to be less damaging to cucumber fruit than western flower thrips, *Frankliniella occidentalis* (Pergande). Nevertheless, fruits may also be damaged; scars, deformities, and abortion are reported. In Hawaii, thrips were observed to attain higher densities on cucumber plants infected with watermelon mosaic virus, but it was not determined whether the plants were more attractive to adults or suitable for survival and reproduction.

In addition to direct injury, melon thrips are capable of inflicting indirect injury by transmitting some strains of tomato spotted wilt virus and bud necrosis virus.

Management

To assess population density, nymphs and adults are collected from foliage. Adults tend to move toward young foliage, with nymphs tending to be clustered on foliage inhabited by adults several days earlier. Adults can also be sampled with sticky and water pan traps. Blue and white are attractive colors for thrips, and have been used to trap melon thrips. However, yellow has also been suggested to be an attractive color.

Foliar insecticides are frequently applied for thrips suppression, but at times it has been difficult to attain effective suppression. Various foliar and drench treatments, alone or combined with oil, have achieved some success. The eggs, being in the foliar tissue, and the pupae, which reside in the soil, are relatively insensitive to insecticide application.

Several cultural practices apparently affect melon thrips abundance. Physical barriers such as fine mesh and row cover material can be used to restrict entry by thrips into greenhouses, and to reduce the rate of thrips settling on plants in the field. Organic mulch is thought to interfere with the colonization of crops by winged thrips. Plastic mulch also is reported to limit population growth, but it is uncertain whether this is due to reduced rates of invasion or denial of suitable pupation sites. Crop stubble is not an effective deterrent. The effects of intercropping potato with onion are variable. Although aphid and aphid-borne disease incidence was decreased in such potato plantings, the density of thrips on potatoes was increased. Thus, the benefits of such cropping practices are largely a function of which pests are likely to be most important in an area. Heavy rainfall is thought to decrease thrips numbers. However, there seems to be no evidence that overhead irrigation is an important factor in survival.

Predation is often considered to be important in population regulation, and misuse of insecticides exacerbates thrips problems by killing predators. The predatory mite *Neoseiulus cucumeris* (Oudemans) has been investigated for suppression of melon thrips. Mite density is correlated with thrips density, but within-plant distribution differs among the two species, suggesting that although the mites may increase in numerical abundance they are unlikely to drive the thrips to extinction.

Melonworm, *Diaphania hyalinata* Linnaeus (Lepidoptera: Pyralidae)

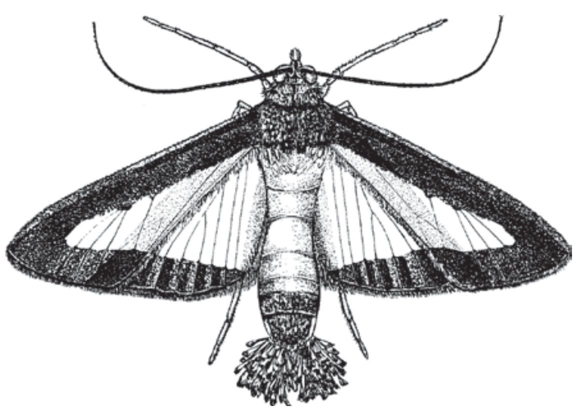
Melonworm is a tropical insect, and occurs throughout most of Central and South America and the Caribbean. It also occurs in some subtropical locations, such as the southernmost United States. Melonworm disperses readily, invading areas where it cannot overwinter, so occurrence in the cooler portions of its range is variable, depending on wind and favorable weather.

Life History

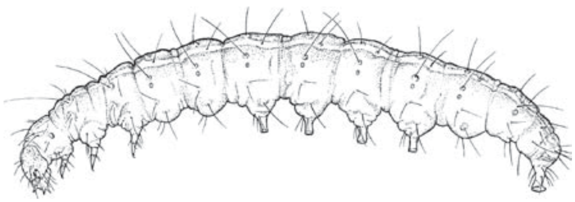
The melonworm can complete its life cycle in about 30 days. It is present throughout the year in warm locations, undergoing numerous generations annually, but has as few as one generation in peripheral, invaded areas.

Melonworm moths (Fig. 28) deposit oval, flattened eggs in small clusters, averaging 2–6 eggs per egg mass. Apparently they are deposited at night on buds, stems, and the underside of leaves. Initially they are white, but soon become yellow in color. They measure about 0.7 mm long and 0.6 mm wide. Hatching occurs after 3–4 days.

There are five instars. Total larval development time is about 14 days, with mean (range) duration the instars about 2.2 (2–3), 2.2 (2–3), 2.0 (1–3), 2.0 (1–3), and 5.0 (3–8) days, respectively. Head capsule widths are about 0.22, 0.37, 0.62, 1.04, and 1.64 mm, respectively. Larvae attain lengths of about 1.5, 2.6, 4.5, 10, and 16 mm in instars 1–5, respectively. Neonate larvae are colorless, but by the second instar larvae assume a pale yellow-green color. They construct a loose silken structure under leaves that serve to shelter them



Melonworm, *Diaphania hyalinata* Linnaeus (Lepidoptera: Pyralidae), Figure 28 Adult melonworm, *Diaphania hyalinata* Linnaeus.



Melonworm, *Diaphania hyalinata* Linnaeus (Lepidoptera: Pyralidae), Figure 29 Mature larva of melonworm, *Diaphania hyalinata* Linnaeus.

during the daylight hours. In the fifth instar, larvae have two subdorsal white stripes extending the length of the body. The stripes fade or disappear just prior to pupation, but they are the most distinctive characteristic of the larvae (Fig. 29).

Prior to pupation, larvae spin a loose cocoon on the host plant, often folding a section of the leaf for added shelter. The melonworm cocoon is much better formed than the cocoon of the co-occurring pickleworm, *Diaphania nitidalis* (Stoll), and the melonworm's preference for green foliage as a pupation site also serves to differentiate these insects. The pupa is 12–15 mm in length, about 3–4 mm in width, and fairly pointed at each end. It is light to dark brown in color. The pupal stage persists for 9–10 days.

The moth's wingspan is about 2.5 cm. The wings are pearly white centrally, and slightly iridescent, but are edged with a broad band of dark brown. Moths frequently display brushy hairpencils at the tip of the abdomen when at rest. Melonworm moths differ from pickleworm in that they remain in the crop during the daylight hours. While they are generally inactive during the day, they will fly short distances when disturbed.

Melonworm is restricted to feeding on cucurbits; both wild and cultivated cucurbits may be attacked. Summer squash and the winter squash species are good hosts. Pumpkin is of variable quality as a host, probably because pumpkins have been bred from several *Cucurbita* species. The *Cucumis* species, cucumber, gherkin, and cantaloupe, are attacked but not preferred. Watermelon is almost never eaten.

Natural enemies of melonworm are nearly the same as those of pickleworm, and the parasitoids attacking pickleworm also attack melonworm: *Apanteles* sp., *Hypomicrogaster diaphaniae* (Muesebeck), *Pristomerus spinator* (Fabricius) (all Hymenoptera: Braconidae), *Casinaria infesta* (Cresson), *Temelucha* sp. (both Hymenoptera: Ichneumonidae), and undetermined trichogrammatids (Hymenoptera: Trichogrammatidae). However, additional species parasitize melonworm, including *Gambrus ultimus* (Cresson), *Agathis texana* (Cresson) (both Hymenoptera: Ichneumonidae) and an undetermined fly (Hymenoptera: Tachinidae). The tachinids known from melonworm are *Nemorilla pyste* (Walker) and *Stomatodexia cothurnata* (Wiedemann). Studies conducted in Puerto Rico reported levels of parasitism reaching 24%. Generalist predators such as *Calosoma* spp. and *Harpalus* (both Coleoptera: Carabidae), the soldier beetle *Chauliognathus pennsylvanicus* DeGeer (Coleoptera: Cantharidae), and the red imported fire ant *Solanopsis invicta* Buren (Hymenoptera: Formicidae) have also been reported to be mortality factors.

Damage

Melonworm feeds principally on leaf tissue, especially if foliage of a favored host plant such as summer or winter squash is available. Usually the leaf veins are left intact, resulting in lace-like plant remains. However, if the available foliage is exhausted, or the plant is a less preferred species such as cantaloupe, then the larva may feed on the surface of the fruit, or even burrow into the fruit. As is the case with pickleworm, growers sometimes refer to these insects as "rindworms" because they cause scars on the surface of melons. In a study of melonworm damage potential to summer squash conducted in south Florida, melonworm caused a 23% yield loss due to foliage damage (indirect loss) and a 9–10% yield reduction due to fruit damage (direct loss).

Historically, melonworm was considered to be a very damaging pest, but because it feeds preferentially on foliage it is easy to control with a variety of insecticides. In tropical areas it often is considered more damaging than pickleworm. In temperate areas, and especially in commercial vegetable production areas, it is treated as only a minor pest. In insecticide-free cucurbit production and in home gardens, melonworm can cause serious damage.

Management

Monitoring the population of moths is difficult. The sex pheromone has been identified but is not available commercially. Moths are not attracted to light traps. Thus, larval populations normally are monitored.

Melonworm is easily suppressed with insecticides. Pollinators, particularly honeybees, are very important in cucurbit production, and insecticide application can interfere with pollination by killing honeybees. If insecticides are to be applied when blossoms are present, it is advisable to use insecticides with little residual activity, and to apply insecticides late in the day, when honeybee activity is minimal. In addition to chemical insecticides, *Bacillus thuringiensis* is commonly recommended for suppression, and this product does not kill bees.

Row covers can be used effectively to exclude melonworm adults. Intercropping of corn and beans with squash was shown to reduce damage by melonworm. Since melonworm prefers squash to most other cucurbits, trap cropping has been suggested, and of course destruction of crop residue which may contain melonworm pupae is recommended. Early plantings, except in tropical areas where melonworm overwinters, often escape serious damage.

Melsheimer, Frederick Valentine

Frederick Melsheimer was born on September 25, 1749 at Regenborn, in the Duchy of Brunswick, Germany. He attended the University of Helmstadt until 1776 when he was ordained and became a chaplain with a regiment of Hessian dragoons. Soon afterwards he and his regiment were shipped to Quebec, Canada, and captured by American troops during the War of Independence. He remained in the United States after the war, and served as a Lutheran clergyman among the German settlers of Pennsylvania. Melsheimer became a professor of languages at Franklin and Marshall College, and also served as its president. Melsheimer pursued an interest in insects throughout his life, a source of amusement to his parishioners, who considered it an eccentricity. Nevertheless, Melsheimer made the first important collections and wrote the first important entomological work in the United States, "A catalogue of the insects of Pennsylvania" (1806). It remained the only publication available on American insects for 25 years, until Thomas Say's "American Entomology" was published. The "catalogue" considered only beetles, and Melsheimer intended to publish additional tomes to treat other groups, but illness intervened. He died on June 30, 1824. Interestingly, two of Melsheimer's children, John F. and Frederick Ernst, shared their father's interest in insects and were avid collectors, with F.E. Melsheimer gaining prominence as a coleopterist.

Messenger RNA (mRNA)

RNA molecules which code for proteins and which are translated on the ribosomes.

Metabolism of Insect Cuticular Lipids

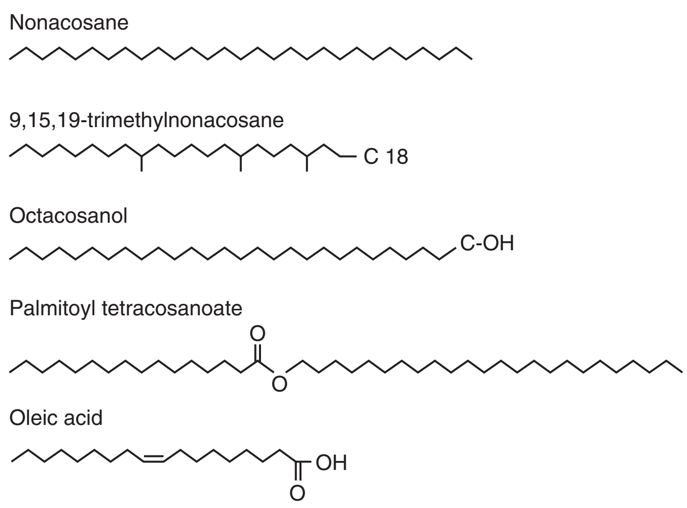
M. PATRICIA JUÁREZ
University of La Plata, La Plata, Argentina

Insect cuticular lipids, also called cuticular waxes, consist of a complex mixture of very long chain compounds with low reactivity and rather high melting point. They provide a variety of functions ranging from water-proofing properties to chemical cues (sexual attractants, deterrents, defensive secretions, kairomones), as well as barrier against microbial or chemical penetration. Among the most usual and major lipid components of the epicuticle are hydrocarbons, fatty alcohols, wax esters, and free fatty acids. They have been reported for more than a hundred species. Minor components include ketones, aldehydes, acetate esters, sterol esters, and less frequently, acylglycerols. Different chain length, branching pattern, substitution, and or unsaturation, determine characteristic blends for different orders, although their relative amounts depend on a variety of internal and external factors: developmental stage, sex, feeding status, reproduction cycle, etc (Fig. 32).

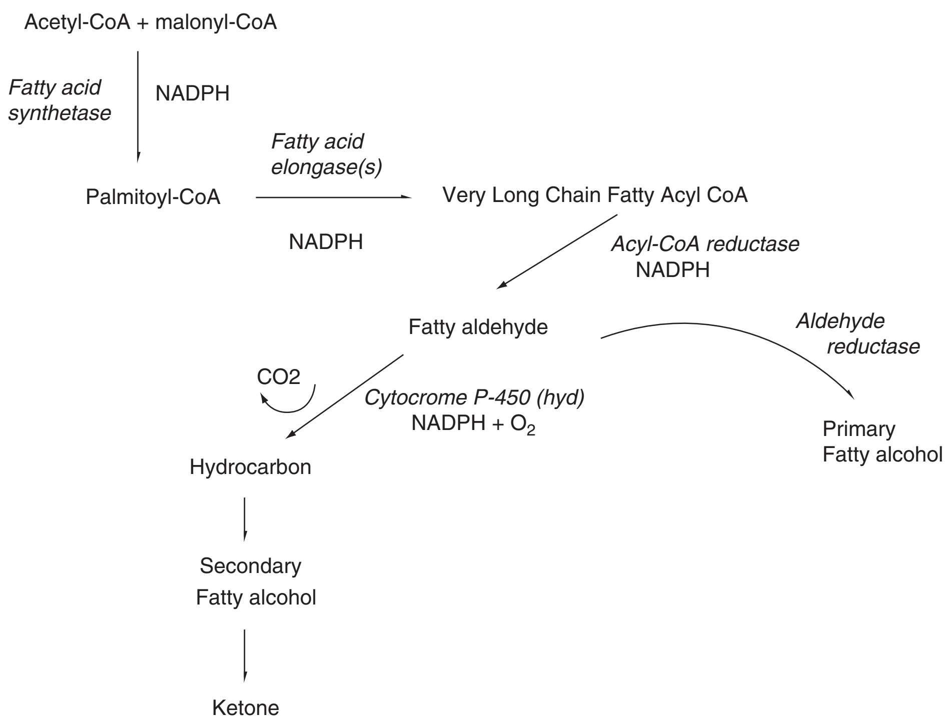
Unique metabolic pathways for the epicuticular lipids have been disclosed in the last 20 years, mostly by Blomquist and co-workers. Depending on the diet, a short chain amino acid, glucose, or fatty acids will be converted to acetate – the building block of two-carbon units – in order to initiate *de novo* straight chain fatty acid biosynthesis which occurs at two different steps. The first one involves condensation with coenzyme A (CoA) to provide acetyl-CoA units, which are then converted to malonyl-CoA by the multienzyme system called acetyl-CoA carboxylase. At the second step, both acetyl-CoA and malonyl-CoA are required for long chain fatty acid synthesis through the multienzyme system of the cytosolic fatty acid synthetase (FAS) from the integument. Reaction will usually proceed until a 16- or 17-carbon fatty acid is released as the end product, remaining as free fatty acid or incorporated into acylglycerols (Fig. 33). Aphids are unusual in this regard, with C14:0 as the major fatty acid due to the presence of an active thioesterase. Exogenous fatty acids of 16 and 18 carbons are incorporated into acylglycerols and phospholipids. Most of the cuticular lipids are biosynthetically related.

One or more malonyl-CoA units might be replaced by methylmalonyl-CoA during fatty acid formation, leading to the formation of methyl-branched fatty acyl precursors. An integumental microsomal FAS is involved in these reactions, as shown in the German cockroach *Blatella germanica*, the housefly *Musca domestica*, and the assassin bug *Triatoma infestans*. Endogenously produced fatty acids serve as primers for microsomal elongation and or desaturation reactions, prior activation as the fatty acyl-CoA derivative by the action of fatty acyl-CoA synthetases, as shown in the cockroaches *B. germanica* and *Periplaneta americana*. There is now overwhelming evidence that insects synthesize hydrocarbons and other cuticular wax components from fatty acids, in a pathway similar to that postulated by Kolattukudy and co-workers in plants in 1976. The reaction occurs through chain elongation by the action of fatty acyl-CoA elongases producing very long chain fatty acyl (VLCFA) moieties that are finally converted to hydrocarbons one carbon shorter, rendering mostly odd-numbered straight chain hydrocarbons.

The major endogenous mono-unsaturated or di-unsaturated fatty acids, rather than newly synthesized unsaturated chains, were suggested



Metabolism of Insect Cuticular Lipids, Figure 32 **Representative straight and methyl-branched insect cuticular lipids.**



Metabolism of Insect Cuticular Lipids, Figure 33 **Biosynthesis of insect cuticular lipids.**

to be the precursor for multi-methylene interrupted alkadiene, and no reports on desaturase activity in the integument are available. Afterwards, chain elongation reactions will proceed as described above. The VLCFA precursors are converted into aldehyde intermediates by a fatty acyl-CoA reductase. Finally, a microsomal cytochrome P-450 type enzyme releases CO_2 to yield odd-chained alkanes. This step was shown in *M. domestica*, the house cricket *Acheta domesticus*, the dampwood termite *Zootermopsis nevadensis*, and *B. germanica*, among others.

Methyl-branched hydrocarbons are abundant in a large number of insect species. They arise through a modification of the straight-chain pathway described above. Methyl branches located on carbon 3 or greater originate from propionate in the form of methylmalonyl-CoA, which replaces one or more malonyl-CoA units during early fatty acid synthesis leading to the formation of internally-branched methyl-alkanes, multiple-methyl-branched alkanes and 3-methylalkanes. An integumental microsomal FAS is the major enzyme responsible for methyl-branched fatty acid formation, whereas the cytosolic integumental FAS shows less activity. Alkanes can then undergo sequential oxidations by cytochrome P-450 oxidation to form secondary alcohols and ketones, as shown by the conversion of 3,11-dimethylnonacosane into 3,11-dimethylnonacosan-2-one, the contact sexual pheromone in *B. germanica*.

Fatty alcohol biosynthesis has been scarcely addressed, but the action of an aldehyde reductase was proposed in *Manduca sexta* for the conversion of the appropriate very long chain aldehyde into the corresponding even-chain primary fatty alcohol. Primary alcohols can then be combined with free fatty acids to form wax esters. Cell fractionation studies have shown that many of the enzyme activities of wax biosynthesis are located in the microsomal fraction. Other than FASs, the wax biosynthetic pathway is composed of various enzyme activities; fatty acid elongase, acyl-CoA reductase, aldehyde reductase and wax synthase. The relative activities of the enzymes determine the chain lengths of the waxes found in the cuticle. However, very little is known about the enzymes of these biosynthetic pathways, the regulation of wax production, and the secretion of wax components onto the surface of the insect.

Methodology

How can these reactions be followed up, the enzymes involved, and metabolite production determined? One of the most powerful and worldwide accepted methodologies is to employ radioactive (labeled) tracer molecules of the same or similar structure than the putative precursor, containing labeled isotopes, usually ^{13}C-, ^{2}H-, ^{3}H-, ^{14}C-or ^{32}P with the label located at specific positions helps to follow the biosynthetic pathways both by *in vivo* and *in vitro* techniques. The most simple *in vivo* experiments are performed by injecting an appropriate fatty acid precursor (i.e., labeled acetate) to a certain number of insects of the target species, following the transport of labeled lipids into the cuticle at selected time intervals. Then, lipids might be washed off from the epicuticular surface (or those from the whole integument by a previous dissection) by solvent extraction. After concentration and preliminary fractionation, information on the total amount and classes of lipids formed is usually obtained employing various kinds of radioactive detectors and methods, i.e., by liquid scintillation counting (LSC) to determine the total amount of metabolites produced in the experimental conditions of an assay, and by radio-thin layer chromatography (radio-TLC) to determine the kind of lipid classes produced. After fractionation, and sometimes derivatization in order to facilitate detector response, radio-high performance liquid chromatography (radio-HPLC) and radio-gas chromatography (radio-GC) are widely used to provide a preliminary identification of the intermediates and end products of the biosynthetic process under study. Final identification and structure assignment require the use of more sophisticated techniques such as capillary gas chromatography-mass spectrometry (CGC/MS), HPLC/MS, and nuclear magnetic resonance (NMR). Enzyme studies might be carried out employing appropriate label tracers and/or by spectrophotometric measurements for preliminary characterization. Studies on enzyme location, purification, cofactors required, kinetic parameters and, regulation are carried out by more complex studies including HPLC purification, molecular mass determination, amino acid sequence, electronic microscopy, immunofluorescent assays, protein purification and characterization in addition to the previously mentioned techniques. Furthermore, if isolation of genes encoding the target enzyme and insertion in an appropriate vector are feasible, the overexpression of such enzyme in an appropriate system can increase the quantity of intermediate precursors, i.e., very long chain fatty acids, and thus increase the substrates available to study wax formation (Figs. 32 and 33).

Metalmark Butterflies (Lepidoptera: Riodinidae)

JASON P. W. HALL
National Museum of Natural History, Smithsonian Institution, Washington, DC, USA

This is one of the five families of "true" butterflies (in the superfamily Papilionoidea). Recent morphological and molecular evidence, for the first time based on sufficient taxon sampling, indicates the Riodinidae to be the sister group to the Lycaenidae (blues, coppers and hairstreaks). Based on the only confirmed riodinid fossils, of *Napaeina* and *Nymphidiini* species in Dominican amber, the family is at least 25 million years old. The higher classification of the Riodinidae is now relatively well resolved, and the group is currently divided into three subfamilies, twelve tribes and six subtribes, with only one *incertae sedis* section of unplaced riodinine genera still remaining. However, intertribal relationships in the largest subfamily, the Riodininae, are poorly understood.

Morphology

The Riodinidae present perhaps the most kaleidoscopic array of colors, patterns, shapes and sizes of any butterfly family. Many have metallic silver or gold markings, hence their common name of metalmarks. They are generally rather small and range in size from about 12–60 mm. The only distinguishing characteristic of the Riodinidae that is visible to the naked eye is their greatly shortened male forelegs, which are no longer used for walking. Although the Nymphalidae share this character, Riodinidae additionally have a coxa on the male foreleg that extends as a spine-like projection below the trochanter (a character only weakly developed in the two species of Corrachiini, and also quite well developed in various poritiine and curetine lycaenids), trichoid sensilla on the female foretarsal segments that are clustered into single instead of medially divided patches, and no posterior apophyses extending anteriorly from the ovipositor lobes of the female genitalia.

Although their external morphology is comparatively uniform (Fig. 34), the male and female genitalia exhibit a remarkable diversity of form given the relatively small size of the family. The most comprehensive set of drawings of venation, palpi, legs and genitalia is still that of Stichel (1910–1911). Although androconia, specialized male secondary-sexual scales, have historically been thought to be rare in the Riodinidae, especially, for example, compared to the Lycaenidae, a recent comprehensive study found that at least 25% of riodinid species possess a wide morphological array of them. Because the Riodinidae are now known to have abdominal coremata (similar to those of danaine nymphalids), concealed internal and visible external abdominal androconia, genital brush organs and hind leg hairpencils (unique within the Papilionoidea), as well as the more obvious alar organs, the family can reasonably be described as exhibiting among the greatest morphological diversity of androconial organs in the butterflies.

Diversity and Biogeography

The Riodinidae contain about 1,350 species, only a few of which remain undescribed. The family has a worldwide distribution, but it is unique among the butterflies in being almost exclusively confined to a single biogeographic region, the Neotropics, where approximately 95% of the familial diversity occurs. Riodinid diversity peaks in the lowlands of the Amazon basin, where as many as 400 species can be found in a single heterogeneous locality, constituting more than 20% of the local butterfly fauna (including Hesperiidae). Species richness in Central America is roughly half that of Amazonia, and only two dozen species extend northwards into North America. Species richness also tapers off gradually with increasing elevation, and very few species occur above 2,000 m.

On average, riodinids have smaller geographic ranges than their close relatives the lycaenids, and this makes them ideal subjects for biogeographic study. *Detritivora* Hall & Harvey, a genus of small, drab, forest-dwelling riodinines, provides perhaps the most extreme example in the Lepidoptera of a continuously distributed lowland group with highly fragmented species ranges. The *D. cleonus* group is divided into an incredible nineteen parapatrically distributed species across Amazonia, each occupying a variably small area of endemism. A cladogram of these riodinids, superimposed over a map of their distributions, led to the most detailed hypothesis yet of Amazonian area relationships.

Adult Ecology

Riodinids are found in a wide variety of primary and secondary habitats, from dry *Acacia* scrub to pluvial forest, but most are exclusive denizens of

primary rainforest. Most species are very localized in time and space. Years of observations in an area usually result in finding only one or two places where a particular species occurs and even then the species will most likely only be present for a couple of hours a day, and perhaps only during certain months of the year. It is not surprising then that so many riodinids are very rare in collections. Intergeneric and interspecific differences in male riodinid perching behavior, involving variably sized groups of males resting at characteristic sites and investigating passing butterflies in search of conspecific females, can be explained these differences in the context of premating isolating mechanisms. Such perching behavior, better known in birds, is known as lekking, a word derived from the Swedish verb "leka," meaning "to play." Male riodinids most frequently lek along forest edges, streamsides, and especially on ridgetops and hilltops, where they may use the same patch of vegetation year after year, arriving from the surrounding forest and departing at roughly the same time every day, and always resting on leaves or tree trunks at about the same height above the ground.

Mimicry is perhaps more rampant in the Riodinidae, especially in females, than in any other butterfly family in terms of the diversity of taxa that its species mimic. There are tiger striped riodinids that resemble papilionids, pierids and various nymphalid subfamilies, clear-winged species that seem to mimic ithomiine nymphalids and dioptine and arctiine moths, and gaudy blue, red, orange, or yellow patterned species that seem to be mimicking dioptine, arctiine, geometrid and tortricid moths. Such riodinids also mimic the same flight behavior of the presumed model(s), often even holding the antennae at the same angle. Most of these mimetic relationships are probably Batesian, with moths generally being the unpalatable models, but we know essentially nothing about the palatability of mimetic riodinids.

Like other butterflies, riodinids can be found feeding on flowers, or imbibing nutrients and ions from damp sand or mud (known as puddling). However, carrion is the most frequently recorded food source, both in terms of number of individuals and taxa. This behavior is common elsewhere in butterflies only in certain subfamilies of the Nymphalidae and Lycaenidae. There is also a correlation between food substrate choice and wing area to thoracic volume ratio in male riodinids, with puddlers and carrion feeders having lower such ratios (i.e., relatively larger thoraces for their overall size). These feeding behaviors are believed to supplement nutrient stores from larval feeding to increase reproductive success and provide the necessary nutrients to maintain high metabolic rates during rapid flight.

Immature Stages and Myrmecophily

The early stages of the Riodinidae remain probably the most poorly known of all the butterfly families and only a small fraction of the genera have been reared, making the immatures a fertile field for further study. Riodinid eggs are generally laid singly, but in certain groups, such as the Euselasiinae, they are often laid in clusters, resulting in gregarious groups of often aposematic larvae. Riodinid eggs are remarkably diverse in form compared to those of the Lycaenidae, in anthropomorphic terms resembling crowns, pies, cakes, cones, footballs, automobile tires and more. Those larvae that have symbiotic relationships with ants tend to be smooth, whereas those that are non-myrmecophilous are generally hairy. Riodinid pupae are generally smoothly cylindrical, girdled, and best distinguished from those of other butterflies by their broadly flattened cremaster. Some pupae have spines, others are moth-like cocoons made from the shed larval setae, and those of *Eurybia* Illiger are extraordinary in having an elongate spine-like posterior projection almost as long as the remainder of the pupa to enclose the very long proboscis.

Myrmecophily, or the ability of butterfly caterpillars to form symbioses with ants by providing food secretions in exchange primarily for protection from arthropod predators, is almost entirely confined to the Lycaenidae and Riodinidae. Although this phenomenon is very widespread in the Lycaenidae, only about one quarter of the Riodinidae are myrmecophilous, encompassing the tribes Eurybiini and Nymphidiini. Myrmecophilous larvae possess a suite of "ant-organs" that facilitate their interactions with ants. Tube-like paired tentacle nectary organs (TNOs) on abdominal segment eight, which secrete nutritionally rich droplets to be harvested by ants, are present in both tribes, but a further two "ant-organs" are restricted to the Nymphidiini. Setose paired anterior tentacle organs (ATOs) on thoracic segment three appear to influence ant behavior through the use of semiochemicals, and a pair of stridulatory rod-like appendages on the first thoracic segment, termed vibratory papillae, grate against granulations on the head as it moves in and out to produce an acoustical call that is thought to function in attracting ants. The function of bladder or balloon setae, a corona of inflated setae on the first thoracic segment which also occur in the non-myrmecophilous Helicopini and *incertae sedis* section, is still unclear, but, at least in the Nymphidiini, they may release an ant alarm pheromone analogue, when squeezed by an ant, to confer protection on the caterpillar.

Riodinids are known to feed on over forty families of flowering plants, using leaves, extrafloral nectaries and, more rarely, flower parts, but are of little economic importance. Certain members of the Euselasiinae feed on harvested myrtaceous plants such as guava, and some Napaeina species can be pests on ornamental Neotropical bromeliads and orchids. Aphytophagy, or feeding on non-plant material such as ants or their regurgitations, or on hemipterans and their secretions, is rare in the Lepidoptera and in butterflies also present only in the Lycaenidae (e.g., Liphyrinae, Polyommatinae and Miletinae) and "Riodinidae (Eurybiini and Nymphidiini). Although aphytophagy has only been unequivocally documented for two riodinid species, there is evidence to suggest that this phenomenon is significantly more common in the family.

Metalmark Moths (Lepidoptera: Choreutidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Metalmark moths, family Choreutidae, comprise 418 species worldwide, in three subfamilies (in the past incorrectly included in Glyphipterigidae); actual world fauna probably exceeds 800 species. There are three subfamilies: Millieriinae, Brenthiinae, and Choreutinae. The family is in the superfamily Sesioidea in the section Tineina, subsection Sesiina, of the division Ditrysia. Adults small (7–24 mm wingspan), with head mostly smooth-scaled; haustellum scaled; labial palpi often with a scale tuft on second segment; maxillary palpi 1 to 2-segmented. Forewings somewhat elongate or more triangular (Fig. 35). Maculation variable but usually with brilliant metallic-iridescent spots or marks; sometimes more colorful markings, or subdued in a few species. Hindwings colorful or dark, and often with a light band near termen; sometimes pale. Adults are diurnal; usually near their host plants and tend to hop about on leaves. Larvae mostly leaf skeletonizers, but some are budworms; rarely leafminers (Millieriinae). Cocoons are white and spindle-shaped. Numerous hostplant families are recorded, but many in Compositae and Moraceae. The subfamily Millieriinae and nominate genus *Millieria* are named after the French lepidopterist Pierre Millière (1811–1887).

Metamorphosis

JUDITH H. WILLIS, JOHN S. WILLIS
University of Georgia, Athens, GA, USA

Insects are the only invertebrates that fly. The development of a winged form is the culmination of metamorphosis that converts a larva capable only of moving by squirming, crawling or swimming into a flying machine.

Issues of interest in insect metamorphosis include its evolutionary origin, the source of adult structures, hormonal control, and the identity of genes that regulate metamorphosis and code for proteins that form the structures of the different metamorphic stages.

Evolution

Among the orders of insects, patterns of cellular participation in metamorphosis vary from the simplest case, adults only slightly different from larvae, their structures having arisen from the same cells, to the most advanced in which differentiated larval cells in effect commit suicide and are replaced by new cells arising from undifferentiated precursors. By examining insects in different orders we can get an idea of how metamorphosis may have evolved from simple to complex.

A few "primitive" insects do not undergo metamorphosis (are ametabolous) and hence are flightless. Thysanura (silverfish), for example, hatch from the egg looking much like the adult, and only undergo subtle anatomical changes between molts. They never develop wings and continue to molt as sexually mature adults (Fig. 37).

Incomplete metamorphosis (or hemimetabolous development) is found in Blattodea (cockroaches), Orthoptera (grasshoppers), Hemiptera (bugs) and others. Here the larval and adult forms are also similar. After several molts from one larval stage (called instar) to the next, major changes appear at the final molt from larva to adult. These include the development of functional wings, genitalia and internal changes that accompany sexual maturation. These insects have larval wings, which though small and non-functional, are visible as pads on the thorax. Such insects are called exopterygotes because of these external wings.

In insects with complete metamorphosis (holometabolous development), there is a dramatic change in appearance, physiology and behavior between larvae and adults, and a physiologically and morphologically distinct stage, the pupa, has been inserted between the final larval instar and the adult. Available evidence indicates that there was a common ancestor for all of the holometabolous insects. These include the orders, Diptera (flies), Hymenoptera (bees and wasps), Coleoptera (beetles) and Lepidoptera (butterflies and moths). Such holometabolous insects account for about 90% of all insect species. Their success is due presumably to their ability to exploit radically different environmental resources at different stages in their lives.

Morphology and Physiology

The morphological changes in an individual that accompany metamorphosis can be created in one of two ways: First, a single lineage of cells can form larval, then pupal and finally adult structures. Second, change may involve the death of most of the cells of the larva and their replacement by the proliferation and differentiation of clusters of "stem cells". An example of the first type, persistence of cells throughout the life of an insect, is the abdominal epidermis of lepidopteran larvae. Here a single row of epithelial cells secretes first the cuticle of each larval stage, then switches and forms a pupal cuticle, and finally, accompanied by special differentiative cell divisions forms the scales and sockets and background cuticle of the adult.

The second type of change involves groups of cells that contribute little or nothing to larvae, but are used to build the pupa and adult. An example of the second type is seen in wing development. The cells that will contribute to the wings of holometabolous insects are present as imaginal discs in larvae. Imaginal discs are infoldings of the single layer of cells that constitute the surface epithelium. Once formed, they do not contribute to the external structure of the larva but evaginate to the surface at pupation, forming first pupal and then adult cuticle. Insects with such hidden, undifferentiated larval wings are also called endopterygotes, a synonym for holometabolous insects.

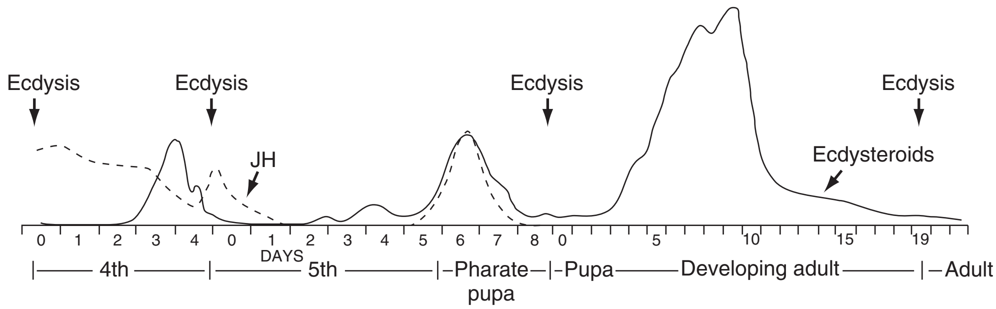
Imaginal discs are found in all holometabola, but arise in various ways. They first appear during late embryonic development of some insects like the higher Diptera, and only shortly before pupation in others like some Coleoptera. In the former case, they are attached to the surface epithelium by a thin stalk; in the latter they are no more than a thickening of the epidermis. In some insects, imaginal discs are only used as the source of a few adult structures, in others there are discs for all of the adult structures. In some cases, a few cells at the base of a larval structure, legs, antennae etc. may proliferate at pupation and be the exclusive source of the corresponding pupal and adult structures. In the *Drosophila* abdomen, there are small clusters of diploid cells, histoblasts that lie amidst the polyploid larval cells. Both types of cells secrete larval and pupal cuticles. Then larval cells die, the histoblasts proliferate and spread to form the adult abdomen.

In addition to the creation of these morphological structures definitive for the pupa and adult, complex changes also occur in the internal organs in the transition from larva to adult. As the food source changes in many cases from leaves to nectar, changes occur in the mouthparts from munching via strong mandibles to sipping via an extensible proboscis. Accompanying these changes in food source are changes in appearance and physiology of the digestive system. Different enzymes are needed to handle different food sources. In lepidopterans, the abdominal prolegs and their muscles, useful in walking, are lost. Flight muscles develop and the nervous system is rewired to accommodate this. Some neurons die; others develop from neuroblasts; while others change their outgrowths, (axons and dendrites) to connect with new targets.

Hormonal Control

There is far less variation in the hormonal control of metamorphosis than in the morphological changes themselves and the cellular events that underlie them. Essentially two classes of hormones (ecdysteroids and juvenoids) are involved, and the same mechanisms of metamorphic controls apply to both hemi- and holo-metabolous insects (Fig. 36). Briefly, ecdysteroids make insects molt. Juvenoids determine what they molt into. When juvenoids are absent at a critical period early in a molt cycle, the cells respond to ecdysteroids by forming the structures of the next metamorphic stage instead of making another larval instar. In this case, unimpeded by juvenoids, ecdysteroids also cause metamorphosis. Final instar hemipteran or lepidopteran larvae that receive an extra dose of juvenoids by injection or by implanting active corpora allata (the glands that make juvenoids) will molt into a giant extra instar larva rather than undergoing a metamorphic molt (to adult in the hemipteran or to pupa in the lepidopteran). If a lepidopteran pupa receives excess juvenoids, it will molt into another pupa, something not seen in nature. This action of juvenoids results in their being recognized as "status quo" hormones, for they direct the repetition of the pattern of syntheses necessary to reform the characteristics of the previous stage.

In the hornworm *Manduca sexta*, when a critical larval size is reached, it has a metamorphic molt. Thus size is in some sense the signal that the time has come for metamorphosis. The signal to undergo metamorphosis causes the corpora allata to cease making juvenoids and other tissues to synthesize enzymes that metabolize and inactive



Metamorphosis, Figure 36 **Diagram of the titers of ecdysteroids and juvenoids (JH) in *Manduca* during the final two larval instars, the pharate pupa, pupa, and developing (pharate) adult. The time at which ecdysis to the next stage occurs is also shown. (Adapted from Riddiford in "Metamorphosis/post-embryonic reprogramming of gene expression in amphibian and insect cells." Reprinted with permission of Cambridge University Press.)**

juvenoids. The mechanism of how size is measured and the nature of the metamorphic signal in other insects remain unknown.

There are exceptions to these findings. *Drosophila* larval tissues, except for the histoblasts, are insensitive to the antimetamorphic actions of juvenoids. Some larvae continue to grow rather than have an extra larval instar in the presence of excess juvenoids, and not all pupae or all pupal tissues can be induced to molt again to a pupa.

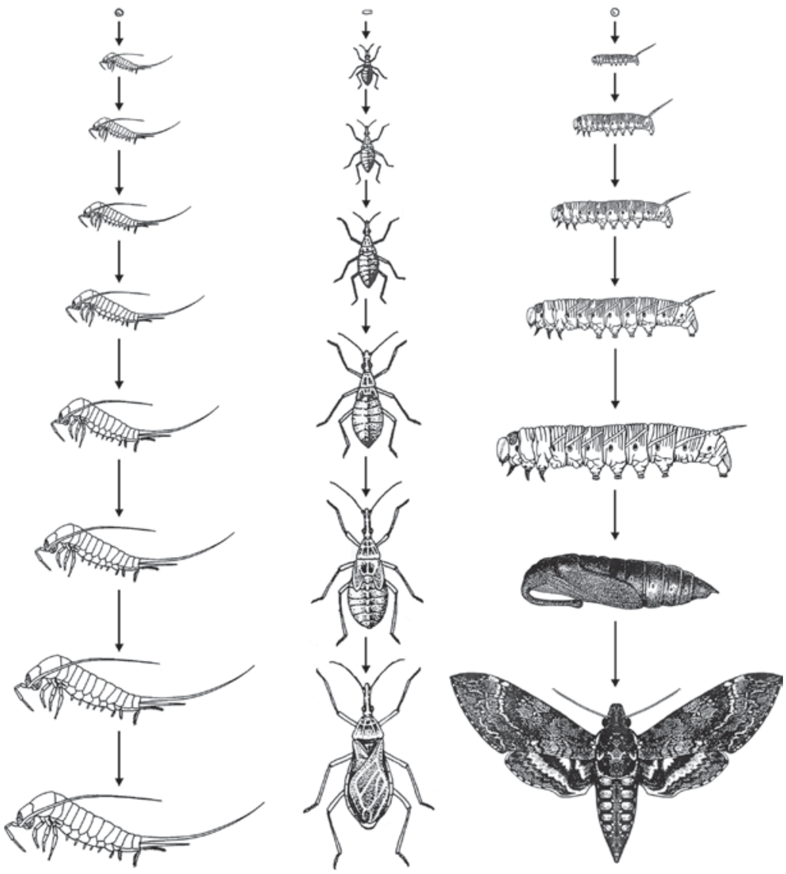
Genes and Metamorphosis

Regulatory Genes

Ecdysteroids initiate a cascade of gene activity that involves both early and late genes. Most of these genes code for transcription factors that activate a series of genes for the proteins that build the structures of the various stages. Thus flies, mosquitoes, beetles and moths have homologous genes that are activated in the same order in response to ecdysteroids, although the culmination of their action is to build very different kinds of insects. One goal has been to identify early ecdysteroid-response genes whose activities differ between larval and metamorphic molts. One such gene, named *broad*, has been found. It was first discovered in *Drosophila* where it is expressed in response to ecdysteroids as they initiate the larval/pupal molt, but it is not expressed at larval/larval molts. A gene with a similar sequence is expressed in *Manduca* larvae in the same manner, at the larva/pupal molt, but not at larval/larval molts. In *Manduca*, juvenoids prevent the activation of broad, in keeping with their status quo action.

Effector Genes

Also of interest are the genes that code for proteins that contribute directly to the form and function of the morphologically distinct metamorphic stages of the holometabolous insects. These can be structural proteins, such as cuticular proteins, or enzymes that participate in physiological activities such as digestion and intermediary metabolism, or even enzymes necessary for the formation of pigments found in different stages. Analyses of cuticular proteins and their genes revealed that quite different structures could be built from the same cuticular components. Thus, the hard structures found in lepidopteran larvae, the head capsule and tubercles, that dot the thorax and abdomen, are composed of the same cuticular proteins that contribute to the hard cuticles of the pupa that cover most of the body surface, the pupal dorsal-fore wing and the abdominal sclerites. The soft cuticles



Metamorphosis, Figure 37 **Three types of development in insects. *Left*, ametabolous development illustrated by *Machlis* (Thysanura). Note that there is little change in external form, and the adults continue to molt. *Center*, hemimetabolous development illustrated by *Rhodnius* (Hemiptera). There are five nymphal (larval) instars, and wing pads are clearly visible in the later ones. Only the adult has functional wings and is capable of reproduction. *Right*, holometabolous development illustrated by the moth *Manduca* (Lepidoptera). Wings in the larva are not visible, as their precursors exist internally as imaginal discs. Both pupae and adults have wings, but they are only functional in the adult. (adapted from H. E. Evans, Insect Biology)**

found across the larval abdomen and in the intersegmental membranes of pupae and adults also share many of the same cuticular proteins. In these cases, the same genes are reused to code for the structural proteins of vastly different morphological structures. The evolution of metamorphosis thus required the development of new morphogenetic signals (architectural plans) affecting the spatial and temporal expression of different genes, so that common structural proteins could be assembled in new ways. Accompanying this was also the appearance of new or modified genes to code for those features that are unique to each metamorphic stage.

It is the complex orchestration of spatial and temporal activities of similar hormones and genes that results in the vast diversity of form and function that is displayed by metamorphosing insects.

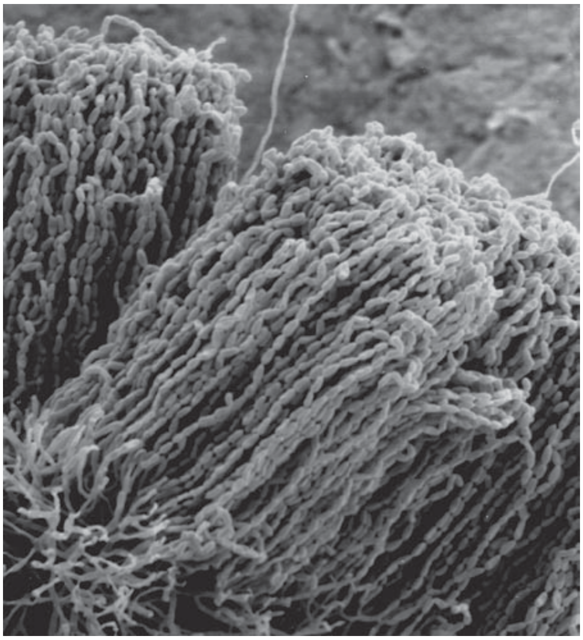
Metarhizium

MICHAEL BIDOCHKA
Trent University, Peterborough, ON, Canada

Metarhizium is a haploid, deuteromycetous, insect-pathogenic fungus and a common inhabitant of soil worldwide. At least two species are formally recognized, *Metarhizium anisopliae* and *Metarhizium flavoviride*. Of the two, *M. anisopliae* is by far more common and occurs over a wide range of insect species. However, based on ITS (internally transcribed spacer region of DNA encodings ribosomal RNA) sequence analysis, vegetative compatibility groups, and population genetics analysis, *Metarhizium* may be represented by a large number of species found worldwide. Thus, the taxonomy and systematics of this genus are not fully resolved. Population genetics analysis showed that in nature *Metarhizium* reproduces clonally but also has the potential for recombination. Recombination may occur through a process called parasexuality, a form of mitotic recombination, where vegetatively compatible hyphae fuse and exchange nuclei to form a heterokaryon. The nuclei fuse to produce a diploid homokaryon, the chromosomes recombine, and thereafter the diploid nuclei haploidize. True sexual recombination also may exist; a *Cordyceps* sp. anamorph has been recorded for at least one of the species and ITS analysis suggests that *Cordyceps* is a related Ascomycete.

Microscopically, the conidia are ellipsoidal in shape (8 × 5 μm^2) and are arranged in columns (Fig. 38). It grows on a variety of commercially available agar and conidiates well on potato dextrose agar. Initially, the colonies are white to buff-yellow and turn yellow-green to olivaceous-buff or



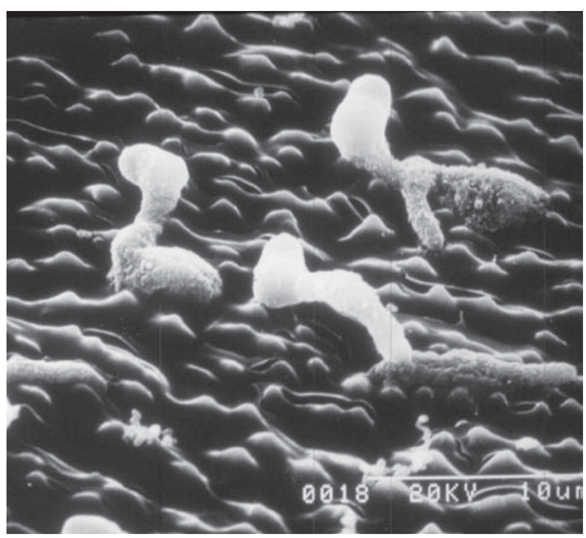
Metarhizium, Figure 38 Scanning electron micrograph of the palisade of conidia produced by *Metarhizium anisopliae*.

dark green when conidia are formed from conidiophores of the mycelia. *Metarhizium* may be selectively isolated from soil on media that contains dodine, chloramphenicol and crystal violet. It also may be isolated from waxworm larvae (*Galleria mellonella*) that have been placed in soil samples in a technique known as the "Galleria bait method".

Metarhizium, the causal agent of the green muscardine disease, is a broad range insect pathogen that frequently infects soil insects. Ecologically, it can best be described as a facultative insect pathogen; it is not an obligate pathogen and grows well on artificial media. Over 200 different insect species are susceptible to infection by *Metarhizium*. One subspecies isolated from Brazil, *M. anisopliae* var. *majus*, shows specificity toward rhinoceros beetle larvae while another from Australia and Mexico, *M. anisopliae* var. *acridum*, shows specificity toward grasshoppers and locusts. However, this level of insect host specificity has not been entirely elucidated with strains from temperate environments. In fact, there is evidence that genotypes of this fungus from temperate areas are associated with different habitats. Generally, *Metarhizium* is isolated more frequently from agricultural or disturbed areas but also can be found in forested habitats. The association of various genotypes of *Metarhizium* with host insect or habitat is still largely unclear.

Of all the insect-pathogenic fungi, *Metarhizium* may be regarded as a model organism for understanding the molecular mechanisms of insect pathogenesis. The infection process includes the following themes: (i) adhesion and germination, (ii) invasion of the host, (iii) dissemination within the host, (iv) role of toxins, (v) avoidance of host immune response, (vi) outgrowth from the host. Like most other insect pathogenic fungi, *Metarhizium* infects the host insect by penetrating the insect cuticle; the fungus need not be ingested. In fact, the potential for infection after ingestion is low since anti-fungal substances may be produced by indigenous microbes in the insect gut. Furthermore, in locusts, food transit time in the insect gut is generally shorter than the time required for germination, and frequent delamination of the peritrophic membrane (approximately every 15 min) restricts fungal attachment to the insect gut.

Infection is initiated when the *Metarhizium* conidium adheres to the insect cuticle. The conidial surfaces are covered by a rodlet, a structural feature composed of "hydrophobin" protein. Since the insect cuticle is hydrophobic, adherence of the conidia to the insect cuticle is achieved through non-specific hydrophobic mechanisms. Once attached to the cuticle, the conidia germinate by utilizing lipids and soluble nutrients found on the insect cuticle (Fig. 39). The germ tube grows for approximately 10–50 μm then differentiates and produces a hold-fast structure on the insect cuticle termed an appressorium, usually within 18 h of infection. From the appressorium, *Metarhizium* hyphae penetrate through the insect cuticle primarily by the action of hydrolytic enzymes. The most important of these enzymes is an extracellular protease termed Pr1. This protease belongs to the subtilisin class of proteases that are homologous to proteinase K from *Tritirachium album* and have a characteristic catalytic amino acid



Metarhizium, Figure 39 Conidia of *Metarhizium anisopliae* germinating on the surface of insect cuticle. Note the appressoria adhered to the cuticle. Under the appressorium, a hyphae penetrates through the cuticle. (Photo courtesy of Dr. R.J. St. Leger, University of Maryland.)

triad of serine, aspartate and histidine. Pr1 is regulated by the presence of carbon and nitrogen. In nutrient rich media, Pr1 is not expressed, but under starvation conditions such as those found on the insect cuticle, Pr1 is expressed in large amounts. Other extracellular enzymes such as trypsin-like proteases, metalloproteases, carboxypeptidases, dipeptidylpeptidases, chitinases and lipases are also implicated in cuticle degradation.

After approximately 48 h, *Metarhizium* transgresses the insect cuticle and enters the insect hemocoel. Since the hemocoel is nutrient rich, Pr1 is not produced. Here, *Metarhizium* differentiates into yeast-like blastospores that proliferate in the liquid insect hemolymph. Many *Metarhizium* isolates produce a toxin called destruxin, a cyclodepsipeptide ionophore that may expedite insect death. *Metarhizium* is confronted with insect immune responses, such as insect blood cells called hemocytes, but can generally outcompete these encounters. *Metarhizium* utilizes the soluble nutrients within the insect and then exits the insect and grows over the cadaver producing conidia. The *Metarhizium* conidia now are able to infect other insects.

There have been many successes using *Metarhizium* to control pest insects. *Metarhizium* is useful especially for control of insects with sucking mouthparts since ingestion is not necessary for infection to take place. Its first documented use was to control wheat cockchafer in Ukraine in 1884, where up to 80% mortality was estimated. *Metarhizium* also has been successfully used to control spittlebugs (Hemiptera: Cercopidae) on sugar cane in Brazil. One of the most interesting applications of *Metarhizium* was to control the larvae of a scarab beetle, *Aphodius tasmanae*, which is a pasture pest in Tasmania. Previously, control of this pest was generally achieved by removing livestock from a pasture and spraying the pasture with chemical insecticides. An economically viable alternative was to apply a bait formulation of *Metarhizium* onto the pasture. At night, the scarab grub would carry the bait to their burrows, where they became infected and died. *Metarhizium flavoviride* has been used to control locusts in Africa where it is formulated with an oil-based emulsion. There are numerous other examples of insect biocontrol using *Metarhizium*.

Mass culture of *M. anisopliae* for biological control has been accomplished using two basic methods: (i) submerged culture, and (ii) surface culture. Submerged culture is much more problematic since *M. anisopliae* produce yeast-like blastospores and/or hyphal fragments when grown in liquid medium. These have little persistence and low infectivity in the field. Submerged culture is most often used in a diphasic system of production. The blastospores and hyphal fragments that are grown in liquid culture are transferred to a surface culture. Surface culture results in the production of aerial conidia. Many inexpensive substrates and culture methods have been used and these generally depend on the availability of substrates in the country of use. In Brazil, *M. anisopliae* has been grown on sterilized rice in polyethylene bags. In the People's Republic of China, conidia are produced on rice, wheat, or ground corn stalks in shallow trays. Unfortunately, *M. anisopliae* is not being extensively used in North America. Problems with public perception, relatively short shelf-life, and longer time for insect kill compared to chemical insecticides have hampered the widespread implementation of *M. anisopliae* as a biocontrol fungus. Nonetheless, many regions, particularly in developing countries, have found that *M. anisopliae* is a viable, locally cultivated and manageable alternative to chemical pesticides for insect control.

Metcalf, Clell Lee

C. L. Metcalf was born at Lakeville, Ohio, USA, on March 25, 1888. He attended Ohio State University, where he received his B.S. and M.S. degrees in 1911 and 1912, respectively. He received a doctorate from Harvard University in 1919. He held several positions in entomology but had the greatest impact at the University of Illinois, where he served as professor and department head from 1921 to 1947. He was known for his teaching, administrative and research prowess. Among his important publications are "Destructive and useful insects" (with W. P. Flint and later with his son, R. L. Metcalf) (1928) and "Fundamentals of insect life" (1932). "Destructive and useful insects" in its various forms remains the most complete and useful treatment of common insect pests of North America, and formerly was the most widely used text and reference manual for economic entomology courses. Metcalf was president of the Entomological Society of America in 1934. Metcalf died on August 21, 1948.

Metcalf, Zeno Payne

Zeno Metcalf was born at Lakeville, Ohio, in 1885. He received a B.A. degree from Ohio State University in 1908 and a D.Sc. from Harvard University in 1924. He was an instructor at Michigan State University from 1907 to 1908, followed by an appointment with the North Carolina Department of Agriculture from 1908 to 1912, before he joined the faculty at North Carolina State University. He served the balance of his career at North Carolina State, leaving for other universities only for brief periods. Metcalf served as head of the Zoology and Entomology Department from 1912 to 1950, as director of instruction for the School of Agriculture from 1923 to 1944, and as associate dean of the Graduate School from 1943 to 1950. Metcalf had an active professional life in addition to his administrative duties. He was a fellow of the Entomological Society of America and the American Association for the Advancement of Science. He also served as president of the Entomological Society of America, the Ecological Society of America, and the American Microscopical Society, served on the editorial board of four journals, and authored nearly 100 papers and nine books. His most significant publishing accomplishment was completion of 15 volumes of "A catalogue of the Homoptera of the World." At the time of his death, several additional volumes were nearly completed. He died at Raleigh, North Carolina, on January 5, 1956.

Methodology

The study of methods. Many writers erroneously use the term methodology when they simply mean methods.

Methods for Measuring Crop Losses by Insects

WENDELL L. MORRILL, B. MERLE SHEPARD
Montana State University, Bozeman, MT, USA
Clemson University, Clemson, SC, USA

Measurement of crop losses that occur within a range of pest insect population densities is fundamental for developing pest management programs. The dynamic and complex relationships between herbivore and host are affected by inherent insect fecundity, the phenology of the pest and crop, and the impact of beneficial organisms such as parasitoids, predators and entomopathogens. Assessments of crop losses are further complicated by soil moisture and nutrient availability that affect plants' ability to compensate for insect injury. The major reason for quantifying crop yield and/or quality losses is to estimate the pest population density at which crop loss value equals the cost of applied control. This estimate must be precise enough to be meaningful yet sufficiently robust to be useful over range of dynamic field situations.

Several methods have been used to estimate the relationship between insect population density and plant yield response. These include observing naturally occurring populations, modification of these populations, creating artificial populations, and simulating insect damage. Each of these methods has advantages and disadvantages. Selected examples are presented along with a brief discussion of the advantages and disadvantages of each.

Observation of Natural Populations

The simplest, and one of the most effective, methods of measuring crop loss is to compare yields from individual plants with different population levels or from infested and uninfested plants. In the example that follows, infested and uninfested stems were compared to assess the damage in wheat by two insect species (Table 4). Larvae of the grass sheathminer, *Cerodontha dorsalis* (Loew) (Diptera: Agromyzidae), feed and pupate within tissues of the leaf sheaths that surrounds stems. Larvae of another pest, the wheat jointworm, *Tetramesa tritici* (Fitch) (Hymenoptera: Eurytomidae), feed and

Methods for Measuring Crop Losses by Insects, Table 4 Impact of two species of phytophagous insects on wheat production

Insect infestation	Mean head weight, grams
Jointworm	0.29a
Jointworm (B) sheathminer	0.28a
None (control)	0.95b
One sheathminer	1.28bc
Two sheathminers	1.51c

(Source: Morrill WL (1995) Insect pests of small grains. APS Press, St. Paul, MN) cause galls to form at the stem joints. The interaction of these pests and yields was investigated by evaluation of mature plants were collected from a field. Plant head weights were determined from plants with and without infestations. Each mean is for 200 plants, and means followed by the same letter are not significantly different (P = 0.05).

Jointworms reduced wheat yields by about 70%. However, yields of plants that were infested by sheathminers were higher than yields of uninfested plants. This suggests that sheathminers may have selected the most vigorous plants for oviposition, or oviposition may have occurred when the primary stems were more vulnerable to attack than the lower-yielding tillers that appeared later.

Preferential selection of host plants by phytophagous insects also plays a role in crop loss. For example, ovipositing wheat stem sawflies, *Cephus cinctus* Norton (Hymenoptera: Cephidae), prefer the largest and most productive wheat stems. The resulting larvae bore and feed within host stems, and material cannot move upward in damaged stems to the developing grain. However, there is very little difference in yields of infested and uninfested plants unless plants within size categories are compared (Table 5). In this example, 400 stems were placed in five categorized according to diameters of the upper stem internodes. Mean weights of grain from infested and uninfested stems and the estimated losses within each category were determined, illustrating that actual loss was over 20%.

The advantage of selecting the largest and most suitable host for progeny production was that female progeny were larger, lived longer, and laid more eggs. Also, individuals that developed in the largest stems were more likely to be females due to selective fertilization at the time of oviposition.

Beneficial insects also affect the extent of damage caused by sawfly larvae. Partially grown larvae are attacked by two species of parasitoids (Hymenoptera: Braconidae). If sawfly larvae are paralyzed at the time of attack, plant damage does not continue.

Methods for Measuring Crop Losses by Insects, Table 5 Percent loss of wheat grain caused by wheat stem sawflies within plant size categories

Stem dia. mm	Percent loss
2.2–2.3	14.4
2.3–2.4	26.1
2.4–2.5	24.0
2.5–2.6	17.5
2.6–2.7	22.4
overall mean loss = 20.8	

(Data from Morrill WL et al. (1994) J Econ Entomol 87:1373–1376)

The advantage of working with naturally occurring pest infestations is that this is very close to real field conditions. A disadvantage is that field trials are dependent upon natural populations that occur over a range of densities.

Modification of Existing Populations

Densities of naturally occurring pest populations in crops can be modified and related to the resulting loss levels by applying different rates or types of insecticides. For this example, we will look at a forage legume, sainfoin, *Onobrychis viciifolia* Scop., that is attacked by *Lygus hesperus* Knight (Hemiptera: Miridae) and several other species of plant bugs. The bugs feed on blossoms and developing seeds, thereby significantly reducing seed production (Table 6).

Three rates of insecticides (carbofuran) were applied when sanfoin reached the blossoming stage. Then, insect populations were estimated twice weekly by using a sweep net. Plant bug population densities were lower in the treated plots, and there was a significant increase in seed production.

Another example of the use of insecticides to eliminate or modify pest populations involves the cereal leaf beetle, *Oulema melanopus* (L.) (Coleoptera: Chrysomelidae). Larvae and adults

Methods for Measuring Crop Losses by Insects, Table 6 Pest insect populations and seed production in sainfoin treated with three rates of insecticide

Carbofuran (kg AI/ha)	Mean number of mirids/10 sweeps		Seed yield (kg/ha)	
	6 days	17 days	24 days	
untreated	48.5a	56.5a	69.3a	238.0a
0.28	11.0b	19.0a	77.0a	290.6b
0.56	4.8b	15.0a	78.0a	277.0b
0.84	0.5b	7.5b	47.8a	339.6c

(Source: Morrill WL et al. (1984) J Econ Entomol 77:966–968)

feed on foliage. The impacts on larval feeding on yields in fields were estimated by applying insecticide in test plots. Wheat leaves were collected, and leaf area consumed was measured by using a flat bed scanner. Data showed that a mean of 0.50 eggs per stem resulted in 0.34 fourth instar larvae. These larvae caused 4.0% yield loss, which equaled the cost of material and application with ground equipment.

The advantage to the use of insecticides is that populations can be easily modified (downward) at all stages of crop development. Disadvantages are that many insecticides produce a "fertilizer" effect, especially the organophosphates and can increase yields over an untreated crop due solely to the added input of nutrients from the insecticide. In addition, most chemical pesticides seriously impact natural enemies, thereby making an otherwise natural field situation unrealistic. The composition of resurgent pest populations may differ from untreated populations. This is important because female and nymphs may feed more than male individuals.

Creating Artificial Populations

Barriers can be used to confine pest insects within selected field regions or plants. For example, six densities of larvae of variegated cutworms, *Peridroma saucia* (Hübner) (Lepidoptera: Noctuidae) were placed on alfalfa enclosed with aluminum barriers, and the subsequent foliage yield and quality was determined. This was then related to the cost of treatment and value of foliage lost.

Cages (Fig. 40) can also be used to confine pest insects at predetermined densities. Malayan black bug, *Scotinophara coarctata* (F.) (Heteroptera: Pentatomidae) feeds on rice in Asia. Adults migrate into fields, and damage from toxins and juice removal includes leaf desiccation, "dead heart," and plant mortality. Caged rice plants were infested with 0, l, 2, 4, or 6 bugs per rice panicle, and were permitted to feed for 1, 2, 4, or 6 days. Plant response recorded included number of filled spikelets, number of unfilled spikelets, and weight of grain per panicle. Grain weight was significantly reduced when two bugs fed for six or more days per panicle. Cages can be used to exclude, and thereby protect, plants from expected pest invasions and attack.

An advantage of using artificial populations is that numbers of insects and feeding durations can be managed. On the other hand, cages have the disadvantage of affecting wind, sunlight, and other environmental factors that impact plant growth and yield. Therefore, the experimental design should include caged and uncaged plants (Fig. 40).

Simulated Damage

Plants can be damaged by leaf/flower or fruit removal to simulate insect feeding (Fig. 40). In one example, manual defoliation and feeding by the migratory grasshopper, *Melanoplus sanguinipes* (F.) (Orthoptera: Arididae), were compared for seedling wheat plants. Treatments were 0, 1/3, and 2/3% foliage removal by grasshopper feeding and by manual clipping with a razor blade. Subsequent plant height, tiller production, and plant weights were compared. Results indicate that grasshopper feeding had more of a negative impact on plant growth than artificial defoliation, suggesting that

Methods for Measuring Crop Losses by Insects, Figure 40 **Techniques in crop loss assessment.** ***Top row*, *left*: applying insecticide to small plots of wheat to remove pest insects *top row right*: assessing insect abundance in a sainfoin plot with a sweep net; *middle row*, *left*: cages used to protect rice from dispersal of ricebugs; *middle row*, *right*: cages to enclose ricebugs with rice plants; *bottom row*, *left*: removal of blossoms and pods from cowpea, simulating insect damage; *bottom row*, *right*: visual estimation of insect abundance and damage in field plot.**

grasshopper feeding may impact wound response of wheat seedlings.

Another example involved a trial with larvae of the bean leaf roller, *Urbanus proteus* (L.) (Lepidoptera: Hesperiidae), which feeds on foliage of beans in southeastern United States. Prior to blooming, plants could lose 66% of their foliage before blooming, or 33% during blooming with no measurable impact on yield. Consumption by last (fifth stage) larvae was 83% of the total consumed during larval development. About two larvae survive from one stage to the next. About 4.4 fifth stage or 70 first stage larvae were needed to reduce yields. Similarly, response of soybean to artificial leaf damage was determined by clipping leaves to represent losses from 17 to 76% defoliation. Foliage losses of 67%, when plants were blooming, did not result in yield losses and 17% leaf loss did not affect yields at any stage of the plants phenology. Greatest losses occurred when 67% of the leaf tissue was removed at pod set or when 17% of the leaf area was removed on a continued basis.

There are major disadvantages to using surrogate injury to mimic insect injury. Most insects feed by gradual removal of plant tissue. Studies that employ the simulated injury often use scissors to excise large sections of tissue. Others defoliating/plant part removal work have used manually removing buds, whole leaves, punching holes in leaves by hole punches, or using forceps to remove various plant parts. Thus, plant compensation for damage by artificial means may be quite different from that caused by insects. In addition, the distribution of manually-induced damage in the field may not be the same as the pest insects. Surrogate injury also excludes insect feeding toxins and vectored pathogens. Another disadvantage is the indirect impact on beneficial insects. Infested plants may utilize the phytophagous insects' saliva to produce volatile chemicals that attract parasitoids.

The advantage of using artificial damage is that it provides an overall gross response to damage. The level of damage can be easily manipulated to allow for a range of damage at any stage of plant development.

Natural Enemies and Crop Loss Assessment

Natural enemies such as insect predators, parasitoids, and entomopathogens often are major factors regulating pest insect populations in the field. Thus, because natural enemies influence in pest densities, resulting estimates of crop losses will change depending upon the communities of natural enemies present. This is particularly true when action thresholds are based on pest insect eggs or early instars; insect life stages that are especially susceptible to the action of natural enemies. Unfortunately, there are few studies of crop losses that include the impact of natural enemies on pests and how this may affect crop loss assessment. Therefore, most field sampling strategies used to make treat/no-treat decisions are based only on insect pest density/crop loss relationships.

A sampling scheme to assess crop loss that included the major predators of planthoppers was developed for rice. This scheme was compared to one based a traditional action threshold that did not include predators as a factor. The result was that there was a higher pest threshold when at least five major predators were found in five samples. The two plans were tested over a range of field situations and insect complexes in Philippine rice fields. The sampling plan that included predators as well as pests led to a significant reduction in the number of insecticide applications without compromising yields.

Another example of how natural enemies can affect crop loss estimates and treatment decisions comes from North Sulawesi, Indonesia. The major pest of cabbage is the diamondback moth, *Plutella xylostella* (Lepidoptera: Plutellidae). Most farmers treat this pest with applications of mixtures of different insecticides at frequent intervals. Field observations revealed populations of diamondback moth with and ensuing outbreak of a disease, *Zoophthora radicans* (Brefeld) Batka, that infects the pest. Collections of diamondback larvae were made and held to determine the incidence of the disease. All of the larvae collected were infected and died of the disease. The field population of the diamondback moth was high enough to cause most farmers to treat with insecticides. However, if farmers understood that the population was dying from the insect disease, all insecticide treatments could have been avoided because little damage resulted.

General

The use of insect-day (ID) can be applied for development of new models. For example, the number of days that the pest insects will feed during the plant's period of susceptibility X number of insects. This can be further modified to "feeding intensity" because the impact of one insect feeding for 10 days (10 ID) can be less than the impact of ten insects feeding for 1 day, also 10 ID.

Pest biology must also be considered. Aphid populations can potentially increase rapidly, but other pests, especially in northern latitudes, have one generation per year. So, pests including army cutworms and grasshoppers cannot increase in number within one growing season. Dispersion of highly mobile pests may require a knowledge of the agricultural landscape.

An understanding of plant phenology is important. Plants may compensate or recover from defoliation that occurs early in the season. For example, the rice whorl maggot, *Hydrellia philippina* Ferino (Diptera: Ephydridae), damages the early seedling stages of rice. Feeding by the maggot inside whorls and on the margins of unopened leaves causes visible damage and rice farmers often apply insecticides that induce outbreaks of other plant feeders such as the brown planthopper, *Nilaparvata lugens* (Stål) (Homoptera: Delphacidae). By scoring damage ranging from 0 to 100% and tagging individual plants, yields were compared at the end of the season. In general, there was no significant difference in yields among plants with different levels of damage. Plants were able to compensate for damage by this early season foliage feeder. This work strongly suggested that insecticide applications to the seedling stage of rice were not needed.

However, the plant cannot compensate for insect feeding directly on the fruit or grain. On the contrary, this feeding damage is often exaggerated as the fruit or grain matures. The type of damage also varies. This includes defoliation, root and stem boring, grain or fruit damage, vectoring of plant diseases, and feeding toxins.

Interaction of pests and plants may be important. Insects may select the most vigorous and therefore the most productive individual plants, thereby maximizing their impact while insuring production of the largest progeny.

In summary, there are a number of methods that can be used to related the population level of the pest insect to plant damage. But all methods have advantages and disadvantages. The most frequently used methods involves natural populations over a range of infestation levels. The use of insecticides to manipulate populations also is common and the use of these two methods will probably suffice in most instances, for determining an acceptable insect pest density/crop loss relationship. All methods, however, must be tested under field conditions in farmers' fields and with current market acceptability. In addition, the use of action levels or thresholds implies that farmers have a viable means of intervention, e.g., they are able to apply an insecticide to reduce the insect population. In developing countries, however, this is not often the case and more long term strategies must be developed (host plant resistance, companion cropping, planting dates, etc.) for sustained suppression of the pest population.

Meyrick, Edward

Edward Meyrick was born at Ramsbury, Wiltshire, United Kingdom, on November 24, 1854. Educated at Marlborough College and Trinity College, Cambridge, he went on to be a schoolmaster for 37 years. The early portion of his career (1877–1886) was spent in Australia and environs, but he served in a similar position in England from 1887 to 1914. Meyrick is well known for his contribution to the Lepidoptera fauna of Australia, New Zealand, the South Pacific Islands, India and Southeast Asia, South Africa, South America, and England. A specialist on the smaller forms of the order, he was a prodigious worker, and described over 20,000 species, many new genera, and several new families. He made major contributions to "Genera insectorum," "Lepidopterorum catalogus," and "A handbook of British Lepidoptera." He also published his own magazine, comprised of over four volumes totaling 2,500 pages, and important books: "Moths and their classification" (1898) and "Moths and their classification, a revised handbook" (1928). Meyrick worked diligently with several zoological, entomological, and natural history societies until he died on March 31, 1938. His immense collection of Lepidoptera was bequeathed to the British Museum.

Mexican Bean Beetle, *Epilachna varivestris* Mulsant (Coleoptera: Coccinellidae)

JOHN L. CAPINERA
University of Florida Gainesville, FL, USA

Mexican bean beetle is native to Mexico and Central America. By the 1800s it was damaging to beans throughout the southwestern United States, wherever beans were cultivated. A major increase in damage followed the accidental transport of Mexican bean beetle to the eastern United States, to northern Alabama about 1918, apparently in shipments of alfalfa hay from Colorado and New Mexico. The beetle, once gaining access to eastern states, spread rapidly to the northeast, and is now found throughout much of the United States and eastern Canada.

Host Plants

Mexican bean beetle develops only on legumes. Other plants are occasionally reported injured. Vegetable crops eaten are cowpea, lima bean, and snap bean, particularly the latter two bean types. Related crops such as faba bean, lentil, and mung bean seem to be immune. Field crops that may be attacked include alfalfa, sweet clover, various dry beans, and soybean. Formerly the field crops other than dry beans were relatively unsuitable and rarely injured. However, starting in the 1970s the eastern, and then midwestern states, began experiencing considerable damage to soybean by Mexican bean beetle. The natural host appears to be tick trefoil, *Desmodium* spp.;

however, in the United States, Mexican bean beetle is almost always found associated with cultivated legumes.

Natural Mortality Factors

Numerous predators, parasitoids, and microbial disease agents of Mexican bean beetle have been identified, but few native natural enemies are considered to be important. Species native to the United States have not adapted to Mexican bean beetle as a host, whereas species imported from Central and South America have failed to establish permanently. A parasitoid from India and Japan, *Pediobius foveolatus* (Crawford) (Hymenoptera: Eulophidae) has been cultured and released in eastern states. Annual release is necessary because the parasitoid is unable to overwinter in the United States. Small gardens, such as those in urban and suburban communities, are most suitable for *Pediobius* release.

Microbial pathogens, especially *Nosema epilachnae* and *N. varivestris* (both Microsporida: Nosematidae), occur in bean beetles. These pathogens are deleterious to Mexican bean beetle; *Nosema epilachnae*, in particular, reduces longevity and fecundity in bean beetles. However, these pathogens also infect the parasitoid *Pediobius foveolatus*. Infection of the parasitoid occurs when the immature stage develops in its host, or when the adult ingests the pathogen.

Although natural enemies may affect bean beetle abundance, weather is also thought to play an important role in population dynamics. Hot, dry weather is thought to be detrimental to survival of all stages, but especially the egg stage. Temperatures above 35–37°C can be lethal.

Life Cycle and Description

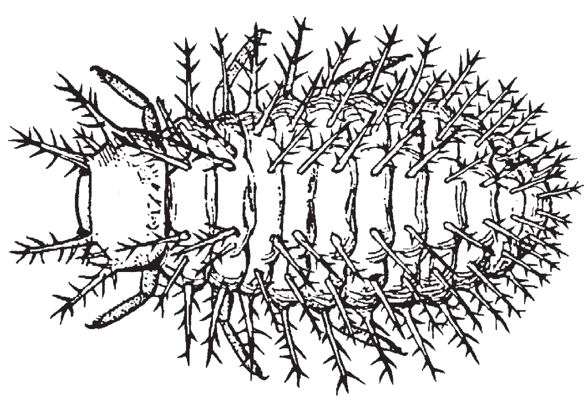
Mexican bean beetle usually exhibits 1–3 generations annually. In the western United States there normally is one complete generation with some individuals reproducing and developing a small second generation. In the southeast, where three generations are more common, a few beetles deposit eggs that form a small fourth generation. Adults are the overwintering stage. A life cycle may be completed in 30–40 days during the summer months, but may require 60 days during cooler weather.

Egg

Eggs are deposited on end in clusters of 40–60 eggs, usually on the underside of leaves. They are elliptical in shape, and measure about 1.3 mm in length and 0.6 mm in width. The eggs generally are yellow in color, but turn orange-yellow prior to hatch. Eggs hatch in 5–14 days, averaging 5.7 days. All females from the first generation deposit eggs, but in South Carolina only 94% of the second and 60% of the third generation beetles reportedly produced eggs as more and more beetles entered reproductive diapause.

Larva

The larvae are yellow in color, and armed with a dense covering of branched spines arrayed in six longitudinal rows (Fig. 41). There are four instars. The mean duration of the instars in a South Carolina study has been reported to be 3.9, 3.6, 3.6,



Mexican Bean Beetle, *Epilachna varivestris* Mulsant (Coleoptera: Coccinellidae), Figure 41 Mexican bean beetle larva, *Epilachna varivestris*.

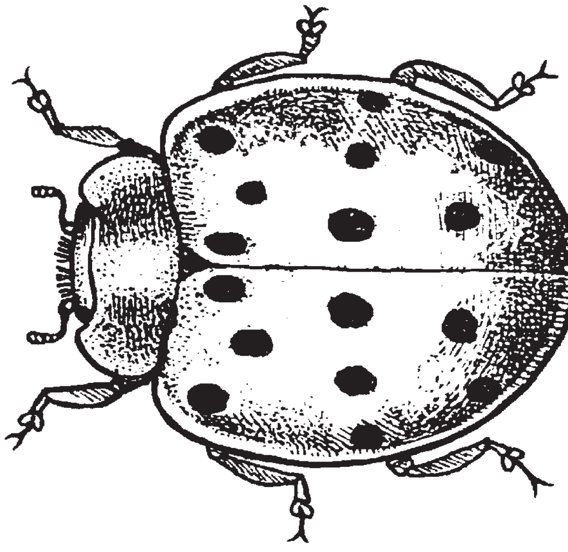
and 3.6 days, respectively. After attaining its full size, about 8 mm in length, the larva attaches its anal end to a substrate, usually the leaf on which it fed, and pupates.

Pupa

During the process of pupation the larval covering, which contains the spines, is pushed back toward the point of attachment to the substrate. Thus, the pupa appears to bear spines, but this is simply remnants of its earlier life, and not firmly attached. Rather, the yellow-orange pupa is quite free from projections. Duration of the pupal stage averages 8.1 days in South Carolina.

Adult

Adults are brightly colored beetles that resemble many beneficial ladybird beetle species. The beetle is hemispherical in shape, and bears 16 black spots. The spots are arranged in 3 rows, with 6 spots in each of the first 2 rows and 4 in the third row; thus, there are 8 on each elytron (Fig. 42). The background color is usually orange or copper, but ranges from yellow when freshly emerged, to reddish brown when old. The beetles normally measure about 6–8 mm in length and 4–6 mm in width, but size varies considerably depending on availability of food. Females commonly produce about 500 eggs, sometimes depositing over 1,200 eggs. Adults overwinter under leaves and other plant debris, and under logs and stones.



Mexican Bean Beetle, *Epilachna varivestris* Mulsant (Coleoptera: Coccinellidae), Figure 42 **Mexican bean beetle adult.**

Damage

Larvae and adults feed principally on leaf tissue, but under high density conditions, and when faced with starvation, they also feed on blossoms, pods, and stems. Bean beetles feed on the lower surface of the foliage, removing small strips of tissue and usually leaving the upper epidermis and veins intact. The upper epidermis soon dies and becomes transparent, leaving characteristic injury consisting of a number of small transparent spots that is reminiscent of a stained-glass window. Entire leaves are quickly reduced to skeletal lace-like remains that have little photosynthetic value and usually dry and die quickly. The larvae are particularly damaging, and a mature larva may consume an entire leaf in a day.

Mexican bean beetle also is capable of plant disease transmission. Larval and adult bean beetles fed on plants infected with cowpea mosaic virus become capable of transmitting the virus to healthy plants for a 2–4 day period

Management

Modern insecticides have relegated Mexican bean beetle to minor status in commercial bean production. They remain a serious problem, however, in home gardens and elsewhere when insecticides are not used. Cultural practices are of limited value. The beetles fly long distances for overwintering, so crop rotation and destruction of overwintering sites is generally not practical. It is a useful practice, however, to destroy bean plants as soon as they have been harvested, as this may disrupt development of many immature insects and inhibit development of additional generations. The principal means of biological suppression of Mexican bean beetle is release of *Pediobius* wasps. However, commercial bean producers rarely consider such an approach, tending to rely instead on chemical insecticides. Some degree of resistance occurs within commercially available cultivars of beans, but this is not completely adequate.

Microbial Control of Insects

LAWRENCE A. LACEY
USDA-ARS, Wapato, WA, USA

A wide variety of pathogenic organisms (virus, bacteria, protozoa, fungi and nematodes) attack insects and result in reductions in insect numbers within natural ecosystems, agroecosystems, and domestic settings. Natural epizootics of insect disease can result in spectacular declines in insect populations of economic and medical importance. However, dependence upon naturally occurring epizootics for insect control can be risky when economic thresholds might be surpassed, or when plant and animal diseases could be transmitted by the insects before they succumb to disease. Microbial control of insects is the concerted use of insect-specific pathogens and nematodes for the biological control of insects. Microbial pesticides have a number of advantages over conventional chemical pesticides. Although the advantages of microbial pesticides are numerous, some of their characteristics are regarded as disadvantages.

Advantages and Disadvantages of Entomopathogens for Insect Control

Advantages

- specificity to the target organism or to a limited number of host species,
- little or no direct impact upon parasitoids and invertebrate predators,
- harmless to vertebrates and plants,
- no toxic residues,
- little or no environmental pollution,
- little or no development of resistance by the target organism (however, resistance has developed in some target insects to *Bt* and *Bacillus sphaericus*)
- no secondary pest outbreak,
- compatibility with other biological control agents,
- possibility of long-term control,
- ease of application, and
- adaptable to genetic modification through biotechnology.

Disadvantages

- specificity only to target organism,
- strict timing of application for maximal effect,

- long period of lethal infection (i.e., little or no "knock-down" effect),
- inactivation by environmental factors (e.g., ultraviolet light, desiccation, temperature extremes, etc.) and therefore, short field persistence,
- expensive to produce, especially for obligate pathogens, and difficult to formulate,
- short shelf life,
- development of resistance by target organisms, especially to *Bt* and *B. sphaericus*, codling moth granulovirus
- expensive to produce except for niche markets, and
- risks or perceived risks associated with genetically-modified organisms.

Like insect biological control agents (predators and parasitoids), microbial control agents can be employed in classical, conservation and augmentation biological control. Microbial control agents have been used in most settings where insect pests are found including glasshouse and row crops, orchards, ornamentals, range, turf and lawn, stored products, forests, households, aquatic environments, animal waste, and for control of insects of veterinary and medical importance.

In classical biological control using insect pathogens, the disease causing agents are isolated from diseased insects and introduced into an insect population in which they are not currently present. The objective is to establish the pathogen or nematode within the population resulting in recycling within the insect population and providing long term control. Some of the most successful examples of establishment and long term control include the use of the fungus, *Entomophaga maimaiga* against the gypsy moth, *Lymantria dispar*, the *Oryctes* non-occluded virus against the palm rhinoceros beetle, *Oryctes rhinoceros*, the nematode *Deladenus siricidicola* against the woodwasp, *Sirex noctilio* and the fungus *Zoophthora radicans* for control of alfalfa aphid, *Therioaphis trifolii*. Classical biological control using insect pathogens has been most successful in perennial agroecosystems and forests.

Conservation biological control fosters pathogen abundance by reducing harmful influences and enhancing positive ones. This may entail replacing a broad-spectrum fungicide with one with a narrower spectrum of activity, changing the timing of insecticide use to avoid killing host insects while pathogens are developing and increasing within the population, and other practices that enhance the activity of pathogens that are present within the targeted insect population. An excellent example of this strategy is the encouragement of epizootics of the fungal pathogen, *Neozygites gossypii* in populations of the cotton aphid, *Aphis gossypii*.

Augmentative biological control consists of two types of strategies: inoculative and inundative applications. Inoculative control can be used to counteract seasonally repeating problems typical of annual cropping systems, such as the use fungicides, tillage, etc. Insect pathogens can also be introduced earlier in the season than they would normally occur, giving them time to reproduce and suppress pests earlier in the cropping cycle. The most commonly employed augmentative strategy for microbial control agents is inundative application of microbial pesticides. Inundative approaches differ from classical and inoculative strategies in that the activity of the applied pathogens, not necessarily that of secondary inoculum, provides control of the pest insects. Using this strategy, one to several applications of microbial control agents are made for control of the pest insect. Microbial agents that are currently used in commercial products are listed in the following table.

Entomopathogens Commonly Used for Microbial Control

Bacteria

The most widely used insect pathogen for inundative augmentative control is the bacterium, *Bacillus thuringiensis* (*Bt*). It was the development and commercial production of *Bt* that ushered in the practical use of microbial control on a large scale. The larvicidal activity of *Bt* is due to a proteinaceous toxin inclusion that is formed at the time of sporulation which must be eaten by the targeted insect in order to be active. Collectively, the toxins are referred to as delta endotoxins. For detailed information on their chemistry and mode of action see section on *Bacillus thuringiensis* in this volume. Besides relative specificity and efficacy, the other advantages of *Bt* products are that they can be produced by fermentation on a large scale, may be formulated (as wettable powders, granules, flowable concentrates, etc.) for ease of application and enhancement of activity, are applied using conventional equipment and are stable in storage for months or even years depending on storage conditions.

Several varieties of *Bt* have been discovered over the past century that have activity against Lepidoptera, certain families of Diptera and Coleoptera as well as other insects. *Bt* is used to control a wide

Microbial Control of Insects, Table 7 Representative invertebrate pathogens that are currently used in microbial control products

Microbial control agents	Targeted insects
Bacteria	
Bacillus thuringiensis[a]	
Bt kurstaki, Bt aizawai	Several species of Lepidoptera
Bt tenebrionis	Colorado potato beetle
Bt israelensis	Mosquitoes, black flies, fungus gnats
Bacillus sphaericus	Mosquitoes (especially *Culex* spp.)
Paenibacillus popilliae	Japanese beetle
Serratia entomophila	New Zealand grass grub
Fungi	
Lecanicillium (Verticillium) spp.	Aphids, whiteflies, and thrips
Metarhizium anisopliae	Grasshoppers, termites, cockroaches
Beauveria bassiana	Colorado potato beetle, white flies, other insects
Virus	
Nucleopolyhedroviruses[b]	several species of Lepidoptera
Granuloviruses	several species of Lepidoptera
Nematodes[c]	
Steinernema carpocapsae	Numerous insect pests
S. feltiae	Diptera, Lepidoptera, other insect pests
S. riobrave	weevil larvae, Lepidoptera, Orthoptera
S. scapterisci	mole crickets
S. glaseri	scarab larvae
Heterorhabditis bacteriophora	Numerous insect pests
H. megidis	scarab larvae, other insect pests
Phasmarhabditis hermaphrodita	Slugs

[c]representative species

variety of lepidopteran pests in several row crops, stored foods, orchards and forests. Aerial application for gypsy moth control is one of the larger scale applications of this bacterium against lepidopteran larvae. The beetle active varieties are predominantly used against the Colorado potato beetle, *Leptinotarsa decemlineata*, and certain other Chrysomelidae. The variety *Bt israelensis* is insecticidal for mosquito, black fly, and fungus gnat larvae and certain other nematocerous Diptera. (For further reading on this bacterium for mosquito and black fly control, see Microbial control of medically important insects.) Genes that encode production of *Bt* toxins have been incorporated into varieties of corn, cotton, potatoes and other crop plants. These genetically modified crops provide continuous control of susceptible insects. Various strategies have been proposed or employed to counteract or forestall development of resistance by the targeted pests to the toxins. Public acceptance of *Bt*-transgenic plants is currently a major obstacle to their widespread use as human food.

Other bacteria that are used as microbial control agents against pest insects are *Bacillus sphaericus* (against mosquito larvae), *Paenibacillus popilliae* (against Japanese beetle larvae), and *Serratia entomophila* (against *Costelytra zealandica* [grass grub] in New Zealand). Of these, *B. sphaericus* is second to *Bt* in commercial production and sales. It offers several of the same advantages of *Bt* in terms of ease of production and formulation, application using conventional equipment and good shelf life. It rapidly kills susceptible species within 24 h of ingestion and is more active than *Bti* against certain mosquito species especially in organically enriched habitats. Its two main disadvantages are a narrower host range than *Bti* and the development of very high levels of resistance in certain populations of *Culex quinquefasciatus*, one of the main targeted species.

The success of *P. popilliae* or milky disease as a microbial control agent of Japanese beetle larvae has been variable with substantial long term control reported in certain situations and little or no control reported in others. Spores of *P. popilliae* must be produced in living host larvae or harvested from field collected infected larvae, a distinct disadvantage in terms of large scale production. Properly prepared spore powders can persist for several years. Unlike *Bt* and *B. sphaericus*, infected larvae are not rapidly killed, but slowly develop milky hemolymph and usually die as full grown larvae which serve as source of inoculum for neighboring larvae (Fig. 43).

Viruses

Although there are a huge numbers of viruses that are pathogenic for hundreds of species of

Microbial Control of Insects, Figure 43 **Cabbage looper infected with nucleopolyhedrosis virus, displaying characteristic symptoms including hanging from the prolegs and liquefaction of body contents (photo courtesy of Pat Vail and Darlene Hofmann).**

pest insects, only the baculoviruses have been commercially developed and used on a wide scale. Baculoviruses have been reported with activity against Lepidoptera, Hymenoptera (sawflies), Diptera and a few other arthropods. Most varieties have been isolated from Lepidoptera and are represented by the singly occluded granuloviruses (GV) and multiply occluded nucleopolyhedroviruses (NPV). The GVs and several of the NPVs are specific for one species or closely related group of species. For example, the codling moth GV is highly virulent for codling moth and to a lesser extent related species such as pea moth and the oriental fruit moth, but does not infect most other species in the same family (Tortricidae). The two baculoviruses with the broadest host range are the multiply enveloped NPVs isolated from two noctuids, the alfalfa looper, *Autographa californica* (*Ac*MNPV), and the celery looper, *Syngrapha* (=*Anagrapha*) *falcifera* (*Anfa*MNPV). *Anfa*MNPV has been reported to infect over 31 species of Lepidoptera in ten families. The host range of *Ac*MNPV includes 33 species of Lepidoptera in 12 families. The virulence of both viruses for species in the Noctuidae is especially high. For example, the LC_{50} values for *Anfa* MNPV against *Trichoplusia ni*, *Heliothis virescens*, *Helicoverpa zea* and *Spodoptera exigua* are 0.093, 0.095, 0.147 and 0.327 occlusion bodies/mm^2.

The principal advantages of the baculoviruses are their efficacy, specificity, and production of secondary inoculum (i.e., recycling in host populations). These benefits make them attractive alternatives to broad spectrum insecticides and ideal components of IPM systems due to their lack of untoward effects on beneficial insects including other biological control organisms. The need to produce virus in living cells, either in cell culture or whole insects, increases the cost of virus production. Some of the other drawbacks of using entomopathogenic viruses are their relatively slow action as compared to chemical insecticides, sensitivity to UV light and the need to time applications to coincide with susceptible instars.

Like the bacterial microbial control agents, entomopathogenic viruses must be ingested by the targeted insect in order to be active. This is an important consideration when formulating viruses to facilitate application and protection from UV inactivation; adjuvants that inhibit feeding will reduce efficacy. The use of optical brighteners with baculovirus has markedly improved efficacy against some species of Lepidoptera through their activity on the peritrophic membrane allowing greater contact between virus and the midgut epithelium. Adjuvants that protect the virus from UV inactivation have also improved efficacy, but with an increase in cost.

Some of the baculoviruses have been successfully employed on a large scale for control of agricultural pest insects. For example, the NPV of the velvet bean caterpillar, *Anticarsia gemmatalis*, is currently used to treat approximately one million ha of soybeans in Brazil annually. In many agricultural settings, the cost of entomopathogenic virus will restrict their use to high value niche markets and sensitive areas where chemicals cannot be used.

Fungi

Fungi comprise another large group of microorganisms that have been developed as microbial control agents. A rich diversity of fungi are found causing disease in a wide variety of insects. Because they invade insects via the integument, they are the only effective microbial control agents used for control of sucking insects such as aphids and whiteflies. Viruses, bacteria and protozoa on the other hand must be ingested in order to infect insect hosts. Species of fungi in the order Entomophthorales (subdivision Zygomycotina, class Zygomycetes) are among some of the most virulent and have been responsible for dramatic crashes in insect populations. Their success as natural and classical biological control agents has been mentioned above (e.g., *N. gossypii* and *E. maimaiga*). However, several of the most efficacious Entomophthorales are problematic to manipulate due to difficulty in producing them on artificial media and limited shelf life of infective propagules.

Entomopathogenic species in the Hypocreales (formerly placed in the subdivision Deuteromycotina class Hyphomycetes) are the fungi most commonly used as inundatively applied microbial control agents. These fungi do not have sexual stages, can be produced on artificial media, and are fairly stable in storage (for several months when stored in cool conditions). *Beauveria bassiana*, *Lecanicillium* (*Verticillium*) spp., *Isaria (Paecilomyces) fumosoroseus* and *Metarhizium anisopliae* are commercially produced and have been employed against a wide range of insect species. Most species of fungi require high humidity in order to germinate and infect insect hosts. Environmental manipulation and formulation have been used to improve efficacy and protect spores from deactivation by UV radiation. Although shelf life is somewhat limited relative to bacteria and viruses, refrigeration and formulation have improved the longevity of fungal preparations.

Nematodes

Several families of nematodes parasitize insects. The majority of the research that has been published pertains to the Mermithidae, Steinernematidae, and Heterorhabditidae. The mermithids are obligate parasites of a broad spectrum of insects. One species, *Romanomermis culicivorax* had been commercially produced and used as a biological control agent of mosquito larvae. The necessity of using living hosts for production and a limited shelf life (a few months under refrigeration) has limited the prospects for commercial production of mermithids. On the other hand, they have good potential as classical biological control agents and may persist and recycle in certain habitats in which they have been introduced.

Several species of the Steinernematidae and Heterorhabditidae, collectively referred to as entomopathogenic nematodes, have been grown on artificial media. Infective stages of these families are non-feeding and can be stored for several months, especially under refrigeration. The microbial aspect of steinernematids and heterorhabditids stems from the symbiotic relationship they have with bacteria in the genera *Xenorhabdus* and *Photorhabdus*, respectively. The infective stage of the nematode is the means by which the bacterium gains entry to the insect host. The bacteria facilitate rapid death of the host, digestion of host tissues and the production of antibiotics that provide protection of the host cadaver from invasion by other microbes. The nematodes may actively pursue host insects (cruisers) or wait for hosts to come to them (ambushers). These nematodes have potential for the persistent control of several insect species, especially in soil and cryptic habitats. Their main limitations are prior to invading an insect host. Rapid desiccation severely restricts the window of opportunity for foraging for a host in the absence of sufficient moisture. Some species are limited by temperatures at or below 10°C (*S. carpocapsae*), but there are species that are active at temperatures as low as 5–7°C (*S. kraussei*, *S. feltiae*). Some species have a fairly narrow host range (e.g., *S. scapterisci*) while others attack a wide range of species (e.g., *S. carpocapsae*).

General Considerations

Microbial control agents can be applied using a variety of conventional pesticide application equipment as well as some non-conventional methods. Autodissemination using attractant traps is one of the more innovative approaches. Targeted insects are attracted to traps using pheromones, floral lures and the like and become contaminated with fungi, virus, etc. and disseminate the inoculum to other individuals of their species through direct contact (mating, aggregations) or by dying in larval habitats. The application of microbial control agents using chemagation (application through irrigation systems) in combination with remote sensing also appears to have promise.

Microbial control may provide adequate suppression of insect pests used as a stand alone measure in certain situations or may be integrated into a more complex strategy that includes other biological control agents, environmental modification or manipulation, use of other alternative interventions (such as mating disruption) or the judicious use of conventional pesticides. For example, the use of a chemical pesticide against a specific life stage that is unaffected by the microbial agent, or use of chemical pesticides and a microbial agent in synergistic combination such as the chloronicotinyl insecticide, imidacloprid and the Hypocreales fungus, *Metarhizium anisopliae*.

The comparison of microbial control agents with chemical pesticides is usually made from the perspective of only their efficacy and cost. In addition to efficacy, the advantages of using microbial control agents are numerous including safety for humans and other nontarget organisms, reduction of pesticide residues in food, preservation of other natural enemies and increased biodiversity in managed ecosystems. The selectivity and safety of microbial control agents should facilitate their incorporation into IPM programs where their effects on other natural enemies will be minimal as compared to most presently used chemical pesticides. Increased use of entomopathogens for control of arthropod pests will depend on a variety of factors including improvements in the pathogens related to their efficacy and cost and the perceived benefits of using them relative to conventional chemical pesticides.

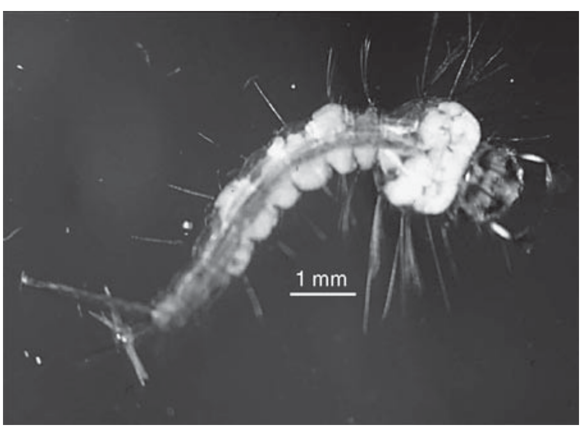
Microbial Control of Medically Important Insects

LAWRENCE A. LACEY[1], JAMES J. BECNEL[2]
[1]USDA-ARS, Wapato, WA, USA
[2]USDA-ARS, Gainesville, FL, USA

Microbial control of insects of medical and veterinary importance is the use of insect-specific pathogens and nematode parasites for the control of insects that are vectors and pests of humans or domestic animals. Medically important insects include those that suck blood such as mosquitoes (Culicidae), black flies (Simuliidae), and other dipterans, lice (Phthiraptera), fleas (Siphonaptera) and those that do not suck blood but are nevertheless a nuisance (house flies, cockroaches, etc.). Infectious agents of some of the most devastating diseases of humans are transmitted by insects. These include organisms that cause malaria, yellow fever, dengue, several encephalitides (such as West Nile virus), plague, onchocerciasis, typhus, sleeping sickness, and Chagas disease. Domestic and wild animals also suffer from insect transmitted diseases, some of which result in death and/or severe economic losses. Pestiferous insects are also causes for decreased quality of life, weight loss in animals and allergic reactions in humans and domestic animals. The majority of research on microbial control of medically important insects has been conducted on the Diptera, most notably larvae of mosquitoes and black flies. This discussion will focus on microbial control of these two groups.

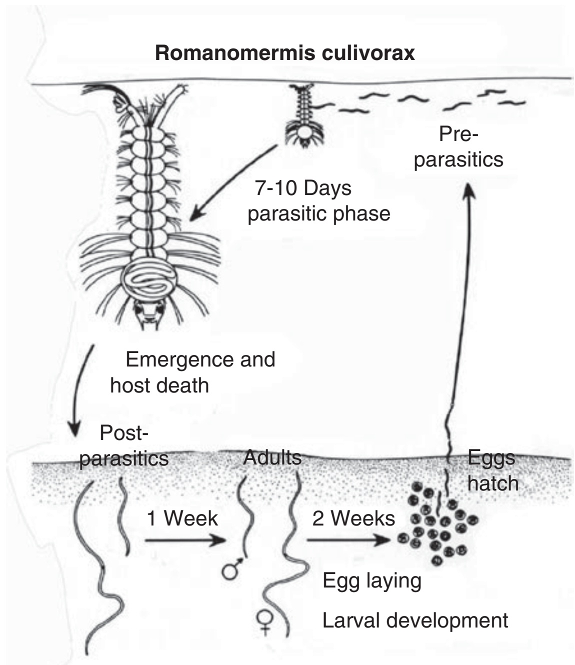
There is a large number of microbial agents (virus, bacteria, fungi, protozoa, rickettsia) and nematodes (Mermithidae and others) reported to infect medically important insects. The most commonly observed in nature are microsporidia [now included in the fungi], other fungi, viruses, and nematodes. Several microsporidia and certain other fungi that infect mosquitoes and black flies include species with complex life cycles, such as *Amblyospora* spp. and *Coelomomyces* spp. that involve intermediate hosts. These requirements and the need to multiply in living hosts decreases their potential as applied microbial control agents. However, their impact as naturally occurring pathogens on populations of medically important insects can be substantial. *Amblyospora* spp. and *Coelomomyces* spp. are particularly common in *Aedes* and *Culex* mosquitoes found worldwide and are a crucial part of a complex of biotic and abiotic factors that impact the dynamics of mosquito populations due to a reduction in the survival, vigor and reproductive success of infected mosquitoes (Fig. 44). Their importance must be viewed not for short-term population reduction but rather for the benefits of long-term abatement as part of an overall management strategy. Some of the other microsporidian pathogens of mosquitoes do not require intermediate hosts. For example, *Edhazardia aedis* is a virulent pathogen of the yellow fever mosquito, *Aedes aegypti* that has good potential as a classical biological control agent. This microsporidian is well adapted to the host mosquito and its container breeding habitats and can persist in *Ae. aegypti* populations through transovarial transmission and spread to additional breeding sites.



Microbial Control of Medically Important Insects, Figure 44 ***Culex salinarius*** **larva infected with** ***Amblyospora salinaria*****.**

Although viruses and mermithid nematodes also require living hosts in order to propagate, certain species have good potential as augmentative and classical biological control agents (see also, Microbial Control of Insects for definitions). The potential of mermithid nematodes has been demonstrated in rice fields and other non-polluted freshwater habitats. An advantage of this group is the potential to become established and recycle in mosquito habitats, but they are less effective in organically enriched and saline habitats. In the case of *Romanomermis culicivorax*, for example, a species that has been studied extensively, the egg stage can be stored in moist sand for use in subsequent microbial control efforts. When flooded with water, stored eggs hatch to produce infective preparasites. These can then be applied to larval habitats with conventional spray equipment. The shelf live of eggs is somewhat curtailed and the cost and logistics of production in living hosts are factors limiting widespread use. A protocol for the application and evaluation of *R. culicivorax* against mosquito larvae in rice fields have been developed. The mermithid nematode *Strelkovimermis spiculatus*, isolated from mosquitoes in Argentina, has a life cycle similar to *R. culicivorax* (Fig. 45). Unlike *R. culicivorax*, *S. spiculatus* has a demonstrated tolerance for high levels of organic pollution and dissolved ions relative to other mermithids and is currently being evaluated for introduction as a biological control agent of mosquitoes, particularly *Culex* spp.

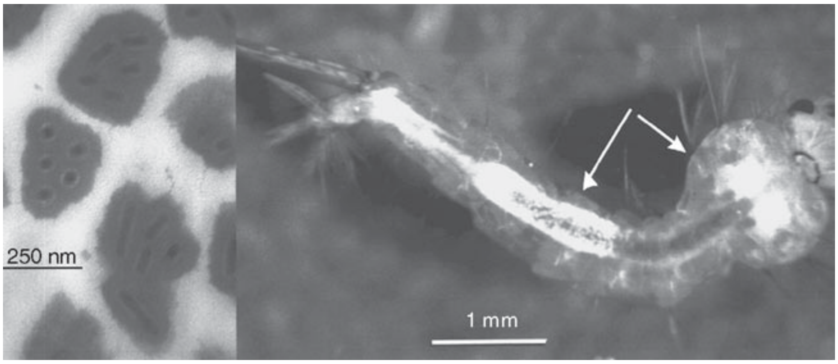
Several insect specific viruses have been reported from mosquitoes and black flies including Deltabaculoviruses, Cypoviruses, Iridoviruses and Densoviruses. Those with the best potential for mosquito control are the Deltabaculoviruses (formerly nucleopolyhedroviruses) within the family Baculoviridae (Becnel, 2007). Deltabaculoviruses (DBVs) have been isolated from thirteen mosquito species within the genera *Aedes*, *Anopheles*, *Culex*, *Ochlerotatus*, *Psorophora*, *Uranotaenia* and *Wyeomia*. Historically, mosquito baculoviruses have been extremely uncommon, difficult to



Microbial Control of Medically Important Insects, Figure 45 **Life cycle of *Romanomermis culicivorax*, an obligate parasite of mosquito larvae (courtesy of Ed Platzer).**

transmit and epizootics in field populations were rarely observed. Recently, a newly discovered DBV, designated CuniDBV, has been discovered that was responsible for repeated and extended epizootics in field populations of *Culex nigripalpus* and *Culex quinquefasciatus* in Florida, USA. CuniDPV infects and destroys the larval midgut (Fig. 46) causing patent infections within 48 h post-inoculation (p.i.) and death 72–96 h p.i. Each of the small globular occlusion bodies measures approximately 400 nm and contains four, sometimes up to eight, singly enveloped virions per occlusion body. While initial attempts to transmit this baculovirus to mosquitoes in the laboratory were unsuccessful, further investigations revealed conclusively that transmission is mediated by divalent cations: magnesium is essential for transmission whereas calcium inhibits virus transmission. This has been an important finding in understanding transmission of baculoviruses in mosquitoes and can explain, in great part, conditions that support epizootics in natural populations of mosquitoes and allow evaluation of CuniNPV as a new microbial control agent.

A multitude of entomopathogenic fungi infect mosquito and black fly larvae and adults. The species *Lagenidium giganteum*, formerly classified with the fungi, has now been placed in the Kingdom Chromista. Compared with mosquitocidal fungi, it has the greatest potential for microbial control. The main advantages of this species



Microbial Control of Medically Important Insects, Figure 46 ***Culex quinquefasciatus* larva infected with nuclepolyhedrosis virus (CuniNPV). White areas of the gastric caeca and posterior midgut (indicated by arrows) are the sites of infection. Inset shows details of viral rods with individual occlusion bodies.**

is that it can be produced on artificial media, has good larvicidal activity against a wide range of mosquito species, and the resting spores have an extremely prolonged shelf life. The infective stage is a short lived zoospore that is formed in vesicles on infected larvae, by mature mycelia in artificial media, or through the germination of resting spores. The zoospores attach to and encyst on the cuticle of mosquito larvae and the subsequent general infection of the larvae results in production of zoospores (secondary inoculum) within 1–7 days of infection depending on environmental conditions and water quality. When grown in artificial media, zoosporogenesis (the production of zoospores) results from nutrient deprivation of mature mycelia (presporangia) from 1–4 week-old cultures. This can be accomplished by diluting mycelial preparations with distilled or deionized water. The application of mature mycelia to larval habitats will result in the production of infective zoospores within hours or days of application depending on conditions. Although resting spores can be stored for extended periods and retain viability, they require 30 or more days of immersion in water before germination begins. The combination of *L. giganteum* mycelia and resting spores could provide a rapid and high level of infection in targeted larvae and a prolonged release of zoospores as new cohorts of larvae begin to hatch. Similarly the combination of larvicidal bacteria and resting spores could provide rapid and continuous control. *Lagenidium giganteum* has become established in several habitats into which it has been introduced providing a certain level of classical biological control in years subsequent to the original introduction. Commercial production of *L. giganteum* has been facilitated by a number of research breakthroughs in the 1980s and 1990s that enabled production of mature mycelia and oospores in artificial media.

By far the most commonly employed pathogens for control of mosquito larvae are *Bacillus thuringiensis* var. *israelensis* (*Bti*) and *Bacillus sphaericus*. *Bti* is also insecticidal for black fly (Simuliidae) larvae. Both bacteria must be ingested in order to be active. The active moieties of each species are proteinaceous toxins that are produced by the bacterium at the time of sporulation. The toxins in *Bti*, found in large parasporal inclusions, are active against a wide range of species in the Culicidae and Simuliidae and certain other families of Nematocera. After ingestion, the toxins are solubilized in the alkaline environment of the midgut and cleaved by enzymes to the active moieties that bind with the epithelial cell membranes. The resultant pore formation in the membranes alters the osmotic balance of the cells, ultimately resulting in rupture of the cells and eventual death of larvae.

In many mosquito abatement programs in North America, Europe and elsewhere, *Bti* is used as the larvicide of choice. In addition to its elevated larvicidal activity, the effects on nontarget organisms, including mosquito predators are minimal to non-existent. Various formulations (liquid, pellets, granules, etc.) and methods of application have enabled a tailored approach to larval control of mosquito larvae in a variety of habitats, including slow release formulations that enable prolonged control in certain smaller habitats. For the most part however, *Bti* has very little residual activity, especially in organically enriched habitats necessitating fairly frequent application when mosquito breeding is continuous.

For control of black fly larvae, *Bti* is a potent larvicide with negligible impact on non-target organisms. As an intervention used in the Onchocerciasis Control Program (OCP), it was responsible for control of *Simulium* vectors of *Onchocerca volvulus*, the causal agent of River Blindness, in an area where the black fly had developed resistance to organophosphate insecticides. It is currently a seasonally implemented control component in the OCP and is used to forestall or avoid the development of insecticide resistance. Because of the nature of black fly habitats (i.e., running water) and the tendency of *Bti* to become rapidly diluted after application, it must be applied at regular intervals in order to control larvae along the course of a river or stream. The distance downstream from the treatment point where control is achieved is referred to as effective carry. As in mosquito habitats, if black fly breeding is continuous, regular applications must be made in order to achieve effective control. The time between applications depends on the developmental cycle of the targeted species.

Bacillus sphaericus functions similarly to *Bti*, but has a narrower host range within the Culicidae and is not active against black fly larvae. Species in the mosquito genera *Psorophora* and *Culex* are highly susceptible to *B. sphaericus* toxins. *Anopheles* and *Mansonia* spp. larvae are also susceptible, but to a lesser extent. *Aedes aegypti* and certain other *Aedes* spp. exhibit little or no susceptibility to this bacterium. One of the main advantages of *B. sphaericus* is greater persistence of larvicidal activity in organically enriched habitats. It has also been reported to recycle within mosquito cadavers and populations under certain conditions. There have been reports in India, Brazil, Thailand and other locations of extremely high levels of resistance to *B. sphaericus* in larvae of *Culex quinquefasciatus*, a common species in organically enriched aquatic habitats.

Microbial Pesticide

Microbial organisms that are applied like chemical pesticides for the suppression of pest abundance. Examples including various bacterial, fungal, viral, and microsporidian pathogens.

► Microbial Control of Insects

Microbiota

The microflora and microfauna of an organism.

Microbivores

Small animal fauna that feed on fungi and other soil flora.

Microcaddisflies

Members of the family Hydrobiosidae (order Trichoptera).

► Caddisflies

Micrococcidae

A family of insects in the superfamily Coccoidae (order Hemiptera).

► Bugs

Microcoryphia

An apterygote order of insects, also called Archeognatha. They commonly are known as bristletails.

► Bristletails

Microdon spp. (Diptera: Syrphidae)

GREGORY S. PAULSON
Shippensburg University, Shippensburg, PA, USA

Ants (Hymenoptera: Formicidae), despite their elaborate social organization, are plagued by a multitude of arthropods that live in their nests, from mites to members of their own family. The majority of these myrmecophilous ("ant loving") arthropods feed upon ant brood, workers, food brought into the colony, or upon other organisms such as fungi which occur in the nest. Some of the most unusual of these myrmecophilous insects are flies of the genus *Microdon* (Diptera: Syrphidae). Unlike most myrmecophiles, behavioral and morphological adaptations to myrmecophily in *Microdon* are found only in the immature stages. Adult *Microdon* are typical syrphid flies that lack the usual adaptations or behavior that would integrate the fly with the habits of the ant. Instead, adult *Microdon* appear to associate with ants only long enough to lay eggs and will be killed and eaten by the ants if they dally too long at that task. In contrast, the slug-like larva are so highly integrated into the nest of their hosts that worker ants will protect them and carry them away from danger as readily as they do their own brood.

There are 31 species of *Microdon* in North America. The adults are about one-half inch long (1.5 cm) and highly variable in appearance between species. The larvae do not have the typical maggot form, and are so atypical in appearance that they were confused with snails and scale insects (Fig. 47), and have been described as such in early literature. Typical of cyclorrhaphous flies (Diptera), *Microdon* exhibits three larval instars, followed by a prepupa and pupa that forms inside the puparium, the hardened integument of the third instar. The larvae, when active, creep through galleries or tunnels of ant nests and are most often found deep within the nest in close proximity to ant brood. For most temperate species of *Microdon*, there appears to be only one generation a year, with the third instar overwintering. Pupation (pupariation) occurs in the early spring about the time ants become active. The integument of the larvae and puparia of most species is

***Microdon* Spp. (Diptera: Syrphidae), Figure 47** **Larvae of *Microdon*. Note the highly sculptured surface. The large protuberance is the posterior spiracle.**

heavily sculpted with a series of fine lateral and connecting ridges, over a strongly convex dorsal surface. In contrast to the larvae, puparia are found most frequently near the drier surface of the nest away from the brood chambers. Presumably this provides the newly emerged adults an opportunity to escape the nest undetected and unscathed. Adults emerge from puparia in the spring and will generally live only 1–2 months.

For many years, the food preference of the larvae was unknown but they were assumed to feed upon either fungi, infrabuccal pellets of ants, or even upon tree sap oozing from gallery wood. It has been determined that many, if not all, species of *Microdon* are actually predators of their hosts, feeding upon ant larvae and pupae. First instars actually will penetrate the cocoon of their host ants to feed upon the enclosed brood. Because of this peculiar relationship, *Microdon* are considered to be "aggressive mimics" of their hosts.

Microdon mimic their hosts physically and chemically. When *Microdon* larvae are disturbed, they will curl longitudinally approximating the shape of an ant cocoon. More importantly, *Microdon* are able to produce chemicals, a variety of large hydrocarbon molecules, that are distributed over their integument. These cuticular hydrocarbons are the same recognition chemicals used by the ants to identify other members of their nest. The type and amount of these molecules produces a colony-specific chemical profile that the *Microdon* are able to almost identically match, chemically integrating them into the host nest. This is truly an example of chemical mimicry. In other words, the *Microdon* larvae are not using cuticular hydrocarbons produced by the ants to camouflage themselves but rather are somehow able to sense the chemical profile of their hosts and produce cuticular hydrocarbons to mimic that profile.

Host range of *Microdon* varies with species. Some species are highly host specific and are found only in nests of one or two species, while others are less specific and can be found in nests of several genera of ants. *Microdon* are found most commonly in nests of *Camponotus* spp. (carpenter ants) and *Formica* spp.

Microencapsulation

A method of formulating insecticides and other chemicals for controlled release. Microscopic spheres containing the chemical are formed from a polymer with various degrees of cross-linking, thickness of the capsule wall, and sphere size, thereby regulating release rates of the chemicals. This usually produces a longer-lasting method of application, reduced volatility, and lower mammalian toxicity. Sometimes bees are at greater risk, however, due to their tendency to confuse the spheres with pollen grains.

► Insecticides
► Insecticide Formulation

Microfauna

Soil invertebrates in the small size class, usually less than 2 mm in width (contrast with macrofauna and megafauna).

Micromalthidae

A family of beetles (order Coleoptera). They commonly are known as telephone-pole beetles.

► Beetles

Micropezidae

A family of flies (order Diptera). They commonly are known as stilt-legged flies.

► Flies

Microphysidae

A family of bugs (order Hemiptera).

► Bugs

Micropterigidae

A family of moths (order Lepidoptera). They commonly are known as mandibulate archaic moths.

► Mandibulate Archaic Moths

► Butterflies and Moths

Micropterous

The condition in which the wings of the insect are small, and usually non-functional (compare with brachypterous and macropterous).

Micropyle

One or more pores or small holes in the egg chorion through which sperm enter.

Microspines

Minute spines located on various locations of the body of some insects; they usually are visible only under high magnification, and impart a rough feel to the body when they are numerous.

Microsporidae

A family of beetles (order Coleoptera). They commonly are known as minute bog beetles.

► Beetles

Microsporidia (Phylum Microsporida)

LEELLEN F. SOLTER
Illinois Natural History Survey, Champaign, IL, USA

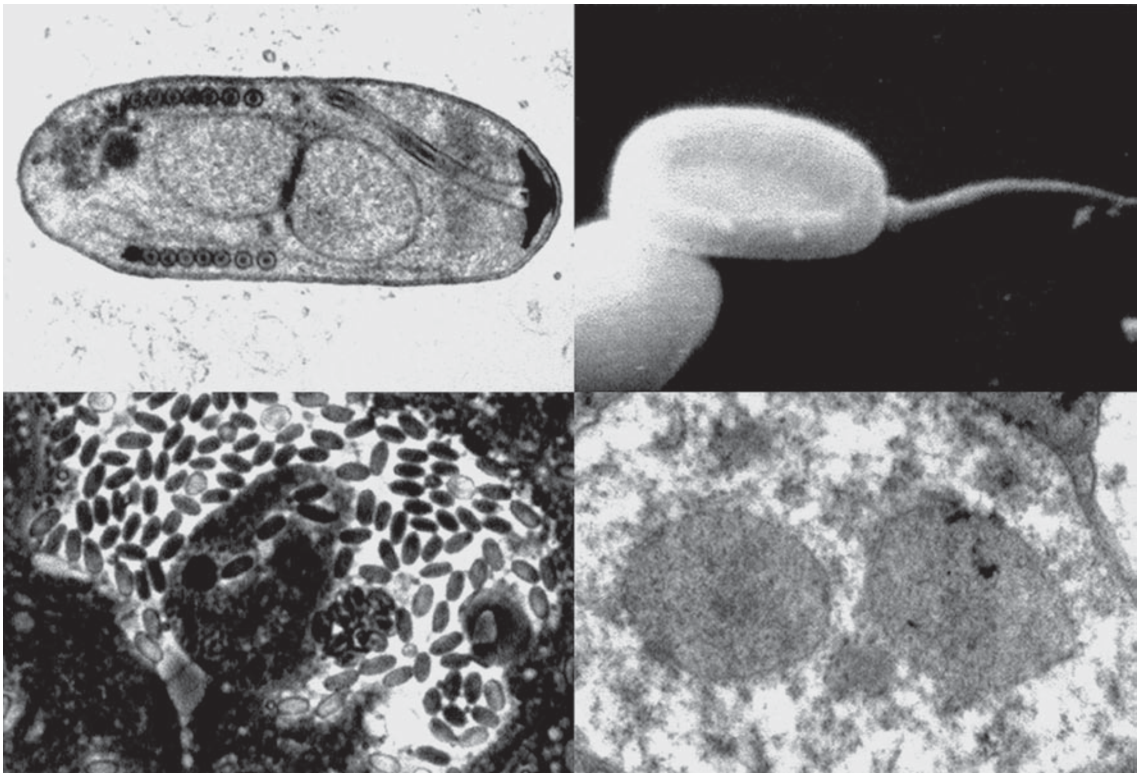
Microsporidia are obligately pathogenic, single-celled, eukaryotic organisms of which nearly 1,000 species have been described, over 700 from insect hosts. Lacking mitochondria, centrioles, peroxisomes and classical Golgi bodies, and possessing a nonmotile amoeba-like vegetative form, microsporidia were considered until recently to be primitive members of the Protozoa. Molecular analyses, however, have determined that the group possesses several gene sequences that suggest a close relationship to the fungi.

The first microsporidium studied was the causal agent of "pebrine disease" of silkworms (*Bombyx mori* L.), a disease that nearly caused the demise of the silk industry in France in the 1860s. Louis Pasteur recognized the infectious nature of the disease and developed a screening technique to rid the industry silkworm colonies of the pathogen. The microsporidium was later described as *Nosema bombycis* Naegli, the type species of the well-known genus *Nosema*.

Microsporidia infect all groups of vertebrate and invertebrate animals, as well as some protozoans, but are particularly common in fish and arthropods. Mammals also host some microsporidian taxa and immune-compromised humans are among the known hosts. Insects, though, comprise the largest group of animals from which microsporidia have been described, probably because of the ease of collecting large numbers of hosts for diagnosis and the impetus to discover biological control agents for insect pests. Some well-studied insect species have been shown to harbor several species of microsporidia. No microsporidia occur as plant pathogens.

Microsporidia from insects are most often and most easily observed in their environmentally resistant infective form, the spore (Fig. 48). Spores are relatively uniform within a species but different species range in size from 1 to 12 μ in length and vary in shape from long oval to round, reniform, spindle-like, or tear-shaped. Species from terrestrial hosts typically possess smooth non-ornamented spores; spores of microsporidia from aquatic hosts such as mosquitoes and black flies may include "wings," mucoid coats, flagella-like appendages, or a patterned surface structure. Spores of all species are discernable as brightly refractive forms under 250–400 x phase contrast light microscopy in crushed host tissues, although aquatic spores, with their typically thinner spore walls may appear more grayish with internal structures somewhat apparent.

Infection by microsporidia occurs either via ingestion of infective environmental spores by a susceptible host, transmission inside or on the surface of eggs oviposited by infected female hosts



Microsporidia (Phylum Microsporidia), Figure 48 **Images of microsporidia. *Top left*, transmission electron micrograph of an environmentally resistant microsporidian spore, approximately 4 μ in length (courtesy J. Maddox and Society of Invertebrate Pathology); *top right*, scanning electron micrograph of germinating spore (courtesy J. Becnel and Society of Invertebrate Pathology); *bottom right*, transmission electron micrograph of vegetative form, approximately 6 μ in diameter (photo by J. Maddox); *bottom left*, light photomicrograph of an insect host midgut epithelial cell cytoplasm filled with spores (photo by L. Solter).**

or, much less frequently, mechanical injection by parasitoids. Very often, a microsporidium is transmitted both orally and via the eggs. The most unique characteristic of microsporidia is the infection mechanism. Along with a single or double nucleus (diplokaryon), cytoplasm and plasma membranes, a polar filament is coiled within the spore. When the spore is activated to germinate by conditions in the gut lumen of the host, the polar filament everts through a disk at its attachment point on the spore and the contents of the spore are emptied into the host gut cell to form a vegetative sporoplasm.

The membrane bound sporoplasm undergoes division in the cytoplasm of the host's gut cells. Some species of microsporidia form a rudimentary autoinfective spore form, which germinates inside the cell and appears to be a mechanism for ensuring that the non-motile pathogen locates the suitable tissues for proliferation and maturation of infective spores. The tissues infected vary for different species of microsporidia; some species pervade all host body tissues and some are limited to one or more specific tissues, such as the midgut or the fat body.

Transmission mechanisms may be determined by the tissues that are targeted. For example, species that infect the gonads, especially of the female hosts, are usually transmitted to the host's offspring. Infective spores from midgut infections may be shed in feces of infected hosts, and silk gland infections may be transmitted by exposure of individual hosts to the silk of infected conspecific individuals. Fat body utilizing species are probably released into the environment when dead larvae decompose. Some microsporidia require an intermediate host for transmission and produce several spore types. For example, the *Amblyospora* spp. in mosquitoes require copepod hosts in the life cycle to produce spores infective in turn to the mosquito hosts.

The effects on hosts of a microsporidian infection vary widely depending on the microsporidian species, initial dosage, mechanism of transmission, host condition, and other factors. Some species are quite virulent, nearly always killing larval hosts prior to or during pupation, but most appear to be chronic pathogens that are more likely to suppress the host populations by lowering fitness of individuals due to decreased adult life span, fecundity and movement, and higher larval mortality in infected offspring. Most microsporidian species seem to have some deleterious effects on the host, but some may be nearly benign.

The epizootiology of microsporidia in host populations also varies greatly but many, if not most, species appear to be strongly host density dependent and can occur in high prevalences, up to 100% of the host population, in high-density host populations. Some species may be maintained in host populations for long periods of time at very low prevalences in stable host populations. There are (Table 8) numerous examples of insect species, both agricultural pests and naturally occurring, that are strongly regulated by the presence of microsporidian pathogens. Two such examples are the European corn borer, *Ostrinia nubilalis*, which is regulated by *Nosema pyrausta* in parts of midwestern North America, and Canadian populations of the spruce budworm, *Choristoneura fumiferana*, which are often strongly suppressed by *Nosema fumiferanae*.

In general, efforts to use microsporidia as microbial insecticides have been unsuccessful. Long-term studies of *Nosema locustae*, the only microsporidium ever registered (U.S. EPA) for use as an insecticide, have shown that it probably functions more effectively as a long-term biological control agent rather than as a "biological insecticide." In general, microsporidia being evaluated for use as biological control agents against insect pests should probably be considered as similar in dynamics and host effects to parasitoids.

One of the most common problems associated with microsporidia are infections in colony insects and arthropods used for research, or in beneficials that are mass produced for biological control projects. As in natural insect populations, symptoms are often subtle and may involve straggling or slow larval development, lowered fecundity, and early larval

Microsporidia (Phylum Microsporidia), Table 8 **Common insect microsporidioses**

Microsporidium	Host	Host common name
Amblyospora spp.	*Aedes* spp. and *Culex* spp.	mosquitoes

Microsporidiosis

Infection with microsporidia.

Microthoraciidae

A family of sucking lice (order Phthiraptera).

► Chewing and Sucking Lice

Microtrichia

Minute hair-like processes on the wings of certain insects, though sometimes this term is used to describe processes elsewhere.

Middorsal

A term referring to the middle of the upper region or "back" (as opposed to the subdorsal or slightly to the side, or lateral).

Midges

Members of the family Chironomidae (order Diptera).

► Flies

Midges as Human Food

MEIR BROZA
University of Haifa, Haifa, Israel

Cakes made from non-biting midges (Diptera: Chaoboridae) are a traditional food in African communities living along the shores of lakes in the African Rift Valley. Chaoborid swarms above the lakes may stretch over 10–32 miles and contain many millions of insects. They were first described from Lake Nyasa by the famous explorer David Livingstone, and also occur on the Ugandan side of Lake Victoria. The swarming gnats are called "E sami" by local people. It has been reported that the people compressed the flies into cakes that were used in some unknown manner as food. Also noted was the malodor of masses of dead flies that accumulated after the swarms, and the fact that the arrival of huge clouds of these gnats produced outbreaks of nasal catarrh among the white inhabitants.

Gnat cakes are called "kungu cakes" (Fig. 49) in the literature. In the Lake Victoria area, kungu is a term used as a prefix for insect specimens, or product made from insects. A major component of such cakes is a species of fly belonging to the family Chaoboridae, *Chaoborus edulis* Edwards. As the specific name implies, F. W. Edwards knew that this species was edible when he described it. Minor constituents of the cake include chironomid species in the genus *Tanytarsus* and *Cladotanytarsus*. Phylogenetically and anatomically, the Chaoboridae are a Nematoceran family somewhat closer to Culicidae than to Chironomidae. They still bear mouthparts, but not functional ones, and they do not feed as adults, similar to chironomid adults. The male flies have plumose antennae, as do chironomid males.

Midges as Human Food, Figure 49 **Midges as human food: *above*, insect "cakes" prepared from lakeflies; *center*, basket for sweeping flies, Lake Victoria, Kenya; *bottom*, swarm of midges above Lake Victoria (bottom photo by Hanna Nadel).**

The chaoborid larvae are known as phantom midges. They rest close to the bottom of the water body during the daytime, but are active predators during the night. A common North

American species in the same family, *Mochlonyx cinctipes*, swarms in clearings of woods at sunset. The African species, *C. edulis*, undergoes a periodic emergence according to the lunar cycle. Synchronous emergence of adult males and females creates huge swarms and mating takes place above the lake surface. The flying females drop their eggs, packed together in gelatinous masses, into the water and the swarm then moves towards the lakeshore.

These clouds of insects on the Kenyan shore of Lake Victoria can be observed during the long rains. They can be seen at a considerable distance from the shore above the middle of the lake during the early afternoon, and they reach land around sunset or soon thereafter. The edge of the lake at this time becomes an impenetrable column of insects that filled the ears, nostrils and eyes. It is reported that four local fishermen once lost their way inside such a cloud in the middle of the lake and died in a subsequent accident. Adjacent plants may be completely covered with flies, wings touching wings. In many cases, the swarms develop during the early afternoon together with a build-up of dark clouds and, according to local claims, their appearance often precedes a strong thunderstorm.

Flies may be collected by local women; it is possible to fill large plastic bags, many gallons in volume, with flies. "Kungu" (insect) cakes are prepared from the flies. They are similar in size to a commercial hamburger, but are completely black. Although preparation and eating these midge cakes is not a common habit today, it still can be seen along the shore of the Rift Valley Lakes. Traditionally, flies are collected by rotating a basket with a long handle in a manner very similar to that (Fig. 49) of a modern insect sweep net. The simple preservation procedure used is as follows: the accumulated flies are removed from the basket and flattened in the hands as when making chapatti bread; the cakes are then laid on banana leaves on the straw roof of the local houses to dry. This takes 3–4 days when sunny. Cakes are stored in a dry place inside the house before cooking in vegetable or chicken soup, or boiling in water only, and serving with a dip prepared from milk and salt. They are also served fresh as a black cake (not too tasty to an inexperienced western palate, in contrast to termites which are delicious).

Analysis of kungu cake indicates that its water content is 20% and the dry weight includes 58.9% protein and 20.3% fats. The other 20.8% is mainly chitin. This protein is highly digestible (about 73%) for human diet, and nutritious. It may serve as high quality food additive.

Midgut

The middle portion of the gut, distinguished as being unprotected by cuticle but lined with a peritrophic membrane. In most insects the midgut is the principal site of digestion and absorption, and the source of digestive (Fig. 50) enzymes. Anatomically, the midgut commences after the proventriculus and terminates at the ileum and juncture of the Malpighian tubules.

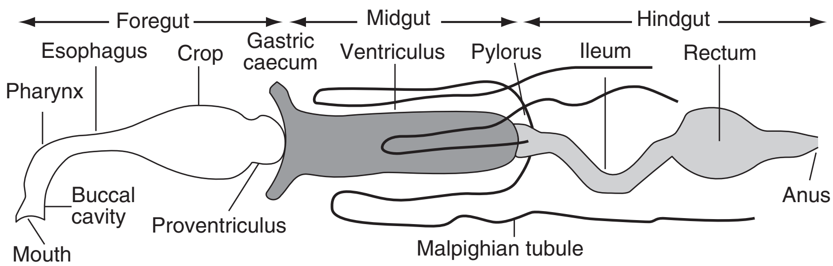
► Alimentary Canal and Digestion



Midgut, Figure 50 **Generalized insect alimentary system (adapted from Chapman, The insects: structure and function).**

Midgut and Insect Pathogens

PING WANG
Cornell University, Geneva, NY, USA

The alimentary canal in insects is the primary location interfacing with their host organisms and other biotic and abiotic factors from the environment. The insect alimentary canal can be divided into three distinct regions, the foregut, midgut and hindgut, based on their embryonic origins, structure and physiological functions. The foregut and hindgut are derived from embryonic ectoderm and are covered by cuticle. The midgut is derived from embryonic mesoderm and does not have the protective cuticle covering. The midgut is the region of the alimentary canal that actively interacts with the gut content from the environment and performs the primary functions of food digestion and subsequent nutrient uptake. In direct contact with the gut contents without protection by cuticle covering, the midgut constantly faces physical, chemical and biological challenges from the environment. It is a primary target and portal of entry for various pathogenic organisms.

Bacterial pathogens primarily target the midgut to gain entry into the hemocoel. Pathogenic bacteria (e.g., *Bacillus thuringiensis* and *B. sphaericus*) commonly produce enzymes or toxins to target and eventually disrupt the midgut epithelium, which enables the bacteria to penetrate through the midgut barrier into the hemocoel for productive infection. The midgut is the primary infection site of the major insect viral pathogens including baculoviruses, cypoviruses and entomopoxviruses. Infection of some viral pathogens in the midgut is limited and the infection in the midgut epithelium is a mode of entry of the viruses into the hemocoel to establish systemic infection (e.g., baculovirus infection and entomopoxvirus infection in lepidopterans). For some viruses, the infection in insects is restricted to the midgut cells (e.g., cypovirus infections in insects). The midgut is not the common portal of entry for fungal pathogens, but fungal infection through the gut may occur in some cases. Protozoan pathogens mostly infect insects through the digestive tract. In addition to microbial pathogens, insect pathogenic nematodes may also enter and penetrate through the midgut as a mode of entry into the hemocoel.

The midgut encounters a variety of microorganisms ingested with dietary materials. In the midgut, insects are equipped with various mechanisms of defense against the pathogens. The midgut peritrophic membrane (PM), alkaline pH in the midgut lumen, digestive enzymes, antimicrobial proteins and other factors contribute to the defense against pathogens. Meanwhile, pathogens have adapted mechanisms to infect insect hosts. The outcomes of midgut-pathogen interactions, which are often multifaceted, critically determine the pathogenesis of the pathogen. The bacterial pathogen *B. thuringiensis* (Bt) produces proteinaceous toxins to target the midgut epithelial cells to break the midgut barrier. The major Bt toxins are known as Cry proteins (crystal proteins) or Cry toxins, which are produced as protoxins in a form of stable crystals in the bacterium. Once ingested by an insect into the midgut, the toxin crystals dissolve in the alkaline pH in the midgut and the dissolved toxin is proteolytically activated by midgut digestive proteinases. The activated Cry toxin then penetrates through the peritrophic membrane and specifically binds to its receptor on the midgut epithelial cells. With involvement of other midgut components, the binding of a Cry toxin to the midgut receptor leads to midgut cell lysis, which enables entry of the bacteria into the hemocoel for infection. The insect pathogenic baculoviruses, cypoviruses and entomopoxviruses are embedded in proteinaceous crystalline inclusions, the viral occlusion bodies, which facilitate survival of the viruses in the environment. In the insect midgut, under the condition of alkaline pH and presence of rich proteinases the occlusion bodies are dissolved and infectious virus particles (virions) are released into the midgut lumen to initiate infection of the midgut cells.

The midgut peritrophic membrane plays an important role in defense against pathogens in general. However, some pathogens have evolved mechanisms to overcome the peritrophic membrane barrier. A unique group of proteases, namely baculovirus enhancins, are produced by some baculoviruses and co-embedded in the viral occlusion bodies. In the midgut, an enhancin is released with the virus particles and specifically degrades the major peritrophic membrane protein, the insect intestinal mucin. The degradation of the intestinal mucin in the peritrophic membrane results in disintegration of the peritrophic membrane structure, leading to permeability of the peritrophic membrane to the virus particles. Similarly, in the infection of malaria parasites in mosquito midgut, the malaria parasite disrupts the peritrophic membrane by secretion of a chitinase to digest the chitin in the peritrophic membrane, enabling the parasite to pass through the peritrophic membrane barrier and reach the midgut cells.

The midgut is in constant contact with various ingested microorganisms, and interactions of the midgut with the microorganisms are complex. The interactions between the midgut and microorganisms critically determine the insect-microbe association to be pathogenic, non-pathogenic or symbiotic.

Migration

A special form of dispersal in which insects move in a specific direction, and movement is at least partly under the control of the insects, rather than passive (e.g., being blown by wind). Migrants that are arriving are called immigrants, and those that are departing are called emigrants.

Migratory Grasshopper, *Melanoplus sanguinipes* (Fabricius) (Orthoptera: Acrididae)

JOHN L. CAPINERA

University of Florida, Gainesville, FL, USA

This native grasshopper is extremely adaptable, and found throughout most of North America. It is found in every state in the continental United States, and in every province in Canada. It is absent from only the northernmost, coldest regions of

Canada, and from southern Florida and Texas. Its distribution does not extend south into Mexico.

Life History

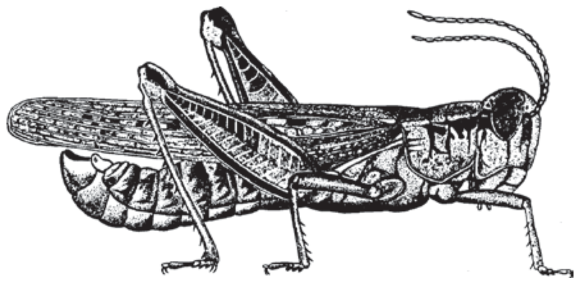
In most areas of its range, migratory grasshopper produces a single generation, and overwinters in the egg stage. However, in southern portions of its range two generations may occur annually. Eggs hatch relatively early, usually beginning in early June but about a week after twostriped grasshopper, *Melanoplus bivittatus* (Say) begins to hatch. Hatching is protracted and may require up to six weeks in an area, resulting in asynchronous development of the population. Early hatching individuals mature early in the summer and have adequate time for reproduction whereas late-hatching individuals are handicapped by the onset of cold weather.

Eggs are yellowish in color, elongate-elliptical and slightly curved in shape. One side is convex and the opposite side concave, causing the eggs to resemble a banana in shape. Eggs measure about 4.5 mm in length and 1.2 mm in width. The eggs are arranged in two columns within a frothy egg pod. Egg pods contain 18–20 eggs per pod, and are buried to a depth of about 35 mm. The pods are curved, about 25 mm in length, and 3–4 mm in diameter. The upper portion contains only froth, allowing ready escape of the nymphs when they hatch. Females can produce 7–10 pods if fed high-quality diets; up to 20 per female is recorded, usually at 2–3 day intervals. Thus, fecundity of about 200 eggs per female is possible. Natural habitats vary greatly in suitability, however, and reproductive potential is sometimes affected. In one study conducted in Montana, for example, females were able to produce only 3–4 egg pods annually. Egg pods are inserted into the soil among the roots of plants. Migratory grasshopper is more likely to deposit pods within crop fields, particularly among wheat stubble, than other common crop-feeding *Melanoplus* spp. Under normal weather conditions about 80% of embryonic development occurs in the autumn before the onset of diapause, with the remainder of development in the spring after a period of cold weather terminates egg diapause.

Nymphs can develop over a range of about 22–27°C, but early instars suffer high mortality at both extremes in temperature. Nymphal development requires about 42, 27, and 23 days when cultured at a constant temperature of 27, 32, and 37°C. Diet also affects development rate. When reared at 30°C, favorable plants such as tansymustard allow complete nymphal development in about 29 days, whereas nymphs developing on less suitable plants such as western wheatgrass require about 42 days. Most field observations suggest that nymphal development requires 35–45 days. Normally there are five instars, though if cultured at low temperatures, six instars is most common.

The nymphs are tan or gray, occasionally greenish, throughout nymphal development. They bear a curved black stripe that extends from behind each eye across the pronotum. The lower edge of the stripe is bordered in white. The outer face of the hind femur is marked with an interrupted black stripe. Body length in instars 1–5 is 4–6, 6–8, 8–11, 11–16, and 16–23 mm, respectively. The number of antennal segments is 12–13, 15–17, 18–20, 21–22, and 22–24 in the corresponding instars.

The adult is a medium-sized species, measuring 20–26 mm in length in males and 20–29 mm in females. They are grayish brown in color, and often tinged with reddish brown. A broad black stripe extends back from the (Fig. 51) eye and about two-thirds of the length of the pronotum. The forewings are grayish brown or brown, usually with a row of brown spots centrally. The hind wings are colorless. The hind femora are not distinctly marked. The hind tibiae are greenish blue or red in color. The cerci of males are broad and flat, turning dorsally at the tip. The subgenital plate is elongate, and bears a notch and groove apically. Females have a preoviposition period of 2–4 weeks. Adults normally



Migratory Grasshopper, *Melanoplus sanguinipes* (Fabricius) (Orthoptera: Acrididae), Figure 51 **Adult male of migratory grasshopper, *Melanoplus sanguinipes* (Fabricius).**

live 60–90 days, though with good food and weather, and living under low density conditions, longevity may be extended considerably. They can mate repeatedly.

Nymphs and adults are affected by daily change in temperature. Activity levels at the soil surface, including feeding, are at their maximum when the air temperature is 18–25°C. This often results in a peak in feeding in late morning, followed by cessation of feeding at mid-day due to excessively hot temperatures, and then perhaps a secondary peak in feeding in the afternoon as temperatures cool. Mass flights by adults take place only if air temperatures are high, often about 29°C, but high densities and light wind also are requisites. When it is hot, grasshoppers tend to climb upward to escape the soil, which is usually considerably warmer than the air temperature. However, they also tend to roost on tall vegetation at night, as this allows them to be warmed by sunlight early in the morning, thus extending their period of activity.

This species accepts a wide range of food plants, and occurs in a wide range of habitats. Relative to the other common crop-feeding *Melanoplus* spp., migratory grasshopper is more tolerant of arid, shortgrass environments. It tends to prefer annual broadleaf plants, but will eat grasses. Dry plant material is an important element of the diet in addition to succulent leaf tissue. Many authors have noted that the population abundance of migratory grasshopper is correlated with the abundance of annual broadleaf plants. Among the preferred plants are dandelion, *Taraxacum officinale*; stinkweed, *Thlaspi arvense*; Johnsongrass, *Sorghum halepense*; Kentucky bluegrass, *Poa pratensis*; shepherdspurse, *Capsella bursa-pastoris*; pepperweed, *Lepidium* spp.; tansymustard, *Descurainia sophia*; western wheatgrass, *Agropyron smithii*; winter mustard, *Sisymbrium irio*; young Russian thistle, *Salsola kali*; and young rabbitbrush, *Chrysothamnus* spp. Among the preferred weeds eaten in North Dakota alfalfa fields are awnless bromegrass, *Bromus inermis*; kochia, *Kochia scoparia*; field sowthistle, *Sonchus arvensis*; field bindweed, *Convolvulus arvensis*; and Russian thistle, *Salsola kali*. On prairie, however, the preferred host plants are Kentucky bluegrass, *Poa pratensis*; leadplant, *Amorpha canescens*; white sage, *Artemisia ludoviciana*; and western ragweed, *Ambrosia psilostachya*.

Migratory grasshopper does not normally infest vegetable crops to a great extent, preferring weedy areas along fences, irrigation ditches, roadsides, and in pastures. However, as favored food plants become over-mature, desiccated, or depleted, grasshoppers will move into vegetable crops. This is especially likely during periods when grasshoppers are extremely abundant. Field crops are more often injured, particularly alfalfa, barley, corn, oat, and wheat. However, as in the case with vegetables, when grasshoppers are numerous they will damage buckwheat, clover, flax, millet, rye, young sorghum, soybean, sugarbeet, timothy, and tobacco. Even fruits such as apple, cherry, currant, grape, peach, plum and strawberry, as well as numerous flowers and shrubs, are attacked during periods of abundance.

Not surprisingly, there is a strong positive relationship between plant preference and grasshopper survival. Among the plants most suitable for nymphal survival were wheat, sunflower, alfalfa, corn and barley, accounting for the reputation of this species as a severe pest in central and western North America. (Alfalfa is an unusual host, however, because although it is quite suitable for large nymphs, it is but a poor source of food for the youngest of the species.) Several broadleaf weeds including dandelion; downy chess, *Bromus tectorum*; tumblemustard, *Sisymbrium altissimum*; slimleaf scurfpea, *Psoralea tenuiflora*; and prickly lettuce, *Lactuca scariola* are quite satisfactory for survival, though not as suitable as the crop plants. Among the least suitable plants are common prairie grasses such as prairie sandgrass, *Triplasis purpurea*; blue grama, *Bouteloua gracilis*; six-weeks fescue, *Festuca octoflora*; needle-and-thread, *Stipa comata*; desert saltgrass, *Distichlis stricta*; green needlegrass, *Stipa viridula*; and Indian ricegrass, *Oryzopsis hymenoides*. Diet also affects fecundity, with favored food such as dandelion resulting in production of a mean value of 3.5 egg pods per female during a 3-week period, whereas grasshoppers fed a mixture of prairie grasses produce only 0.3 pods per female.

Many insects parasitize or eat *Melanoplus* grasshoppers. The most important parasitoids are nymph- and adult-attacking flies (Diptera) in the families Anthomyiidae, Nemestrinidae, Sarcophagidae, and Tachinidae, though egg parasitoids (Hymenoptera: Scelionidae) also cause mortality in grasshopper populations. In Oregon, over 70% of migratory grasshoppers were parasitized by the nemestrinid *Neorhynchocephalus sackenii* (Williston), resulting in reduced longevity and reproduction. Other *Melanoplus* spp. also are affected by this fly, though grasshopper populations on rangeland, not cropland, are usually affected. In a study of migratory grasshopper parasitism conducted in Ontario, the incidence of parasitism reached about 7% by the end of September, with *Blaesoxipha hunteri* (Hough) and *B. atlantis* (Aldrich) (both Diptera: Sarcophagidae) the most effective parasitoids. In Montana, parasitism of migratory grasshopper parasitism was estimated to 15–41%, with anthomyids and sarcophagids accounting for 50 and 35% of the parasitism, respectively.

Among the most important predators are sphecid wasps (Hymenoptera: Sphecidae). Adult sphecids capture and paralyze nymphal and adult grasshoppers, bury them within cells in the soil, and deposit an egg on the surface of the grasshopper. Upon hatching, the larva devours the paralyzed grasshopper. Predatory beetles (Coleoptera) attack the egg, nymphal and adult stages of grasshoppers, and include ground beetles (Carabidae), tiger beetles (Cicindelidae), soldier beetles (Cantharidae), and blister beetles (Meloidae). Blister beetles are most important, though because the grasshopper egg pod is the stage destroyed, their effect is often not appreciated. Several studies conducted during the period 1938–1940 produced an average of 8.8% of egg pods destroyed by blister beetles. Flies also are important predators, particularly robber flies (Asilidae) and bee flies (Bombyliidae). Robber fly larvae and *Gryllus* spp. field crickets (Orthoptera: Gryllidae) occasionally attack egg pods, and robber fly adults routinely attack nymphs and adults of grasshoppers, though other insects also are taken. Robber flies undoubtedly are important predators under rangeland conditions, but predation rates of grasshoppers in cropping systems has not been determined. Also, the propensity of robber flies to capture other predators, such as sarcophagids, significantly reduces their value. Bee fly larvae are predatory on grasshopper eggs and on other insects. In western studies, an average of 6.2% of egg pods were destroyed by bee fly larvae.

Birds are known to be important predators of grasshoppers. They are among the most important sources of food for many avian species due to their large size and abundance. The great abundance of grasshoppers in the spring coincides with the period when most birds are nesting. Birds forage freely on grasshoppers in open areas such as grasslands, with some species consuming 65–150 grasshoppers per day. Although avian predators significantly reduce the abundance of grasshoppers in grasslands, it is less certain that they forage freely in crops.

Microbial pathogens can be quite important mortality agents, especially when weather conditions are suboptimal for grasshoppers, or when grasshoppers are very abundant. The principal microbial pathogens of grasshoppers are fungi, viruses, protozoans, and nematodes and nematomorphs.

The fungus *Entomophthora grylli* causes "summit disease," a behavior wherein grasshoppers ascend vegetation, cling to the uppermost point, and perish. In some areas, particularly near bodies of water, large numbers of dead grasshoppers can be found attached to plants. *Melanoplus* spp. are susceptible to one pathotype of the fungus, and significant grasshopper population decreases have been linked to the incidence of summit disease. Infection normally occurs when nymphs contact spores that are sheltered in the soil. Spores produced in grasshoppers dying from this disease remain in cadavers or soil for protracted periods of time. Attempts to manipulate this pathogen have met with mixed results. This is the only common naturally occurring fungus of grasshoppers.

Several viruses called entomopoxviruses affect grasshoppers. One such virus, *Melanoplus sanguinipes* entomopoxvirus, affects the crop-feeding *Melanoplus* spp. and American grasshopper, *Schistocerca americana* (Drury). The virus disease spreads naturally by cadaver feeding. Infected grasshoppers are pale colored and lethargic, have prolonged developmental periods, and often perish. These diseases are quite rare in the field.

Several types of protozoa are associated with grasshoppers, including amoebae, eugregarines, and neogregarines, but the most important are microsporidia. Species of *Nosema* are most common, and *Nosema locustae* has been developed as a microbial insecticide. *Nosema* spp. affect feeding, development, reproduction and survival, and are transmitted by ingestion. However, they infrequently appear at high levels in natural populations.

Nematodes are important mortality factors of grasshoppers in South America, New Zealand and Australia, but in North America only *Mermis nigrescens*, *Agamermis decaudata*, and *Hexamermis* spp. affect grasshoppers. *Mermis nigrescens* is most important, and is unique in that nematodes crawl from the soil onto vegetation to deposit desiccation-resistant eggs. The eggs hatch when consumed by grasshoppers, and the resulting larvae kill the grasshoppers, return to the soil, and continue the life cycle. These nematodes apparently do not thrive in arid areas, as the adults only emerge during wet periods, and are more common in irrigated croplands than dry rangeland. Sometimes they parasitize up to 70% of grasshoppers in an area. Nematomorphs, commonly called horsehair worms, resemble nematodes but tend to be much longer. They are rare, possibly because part of their life cycle must occur in water, but they attract considerable attention because of their large size.

Migratory grasshopper is greatly influenced by weather. Through most of its range longevity and reproduction are limited by shortage of warm weather. Thus, abnormally warm and dry periods of about 3 years stimulate increase in grasshopper abundance. Warm weather during spring and autumn is particularly important. Cool and cloudy weather in the spring inhibits feeding by young nymphs, and results in high mortality. Also, adults have the potential to be long-lived and highly fecund, but their reproductive effort is normally terminated prematurely by the onset of cold weather. When summers are hot or prolonged, development proceeds faster or longer, resulting in greater egg production. In southern areas grasshoppers are less limited by shortage of warm weather, but more affected by shortages of food. Therefore, occurrence of precipitation early in the season to provide luxurious foliage, especially broadleaf weed vegetation, is an important prerequisite for population increase.

Damage

Migratory grasshopper is a defoliator, often completely removing leafy vegetation and leaving only stem tissue. Sometimes other tissue is eaten; heads of wheat may be clipped, for example. Migratory grasshopper thrives on rangeland that has a high density of broadleaf weeds, so it sometimes moves from grazing land to nearby irrigated crops. In this behavior it differs from some other species, particularly differential grasshopper, *Melanoplus differentialis* (Thomas), and twostriped grasshopper, *M. bivittatus* (Say), which favor the taller undisturbed vegetation usually associated with fences and irrigation ditches, and usually do not develop high numbers on grazing land. Migratory grasshopper is often quite dispersive, and of course this behavior is the basis for the common name. When the grasshoppers are developing at high densities, the weather is abnormally warm, and a light wind is present, swarms of grasshoppers may disperse tens or even hundreds of kilometers and descend without warning to cause immense damage. With the availability of modern insecticides and aircraft for application, such potential disasters can be dealt with quickly and efficiently. When such insecticide and effective application technologies are not available, or where environmentally sensitive land or crops are concerned, grasshopper swarms can be disastrous. This species is the most important grasshopper pest in western North America.

Management

Grasshopper populations are usually assessed by visual observation. A sweepnet is a useful tool to aid in collection, and its use a prerequisite to identification of the species complex. It is important to determine if grasshoppers collected from noncrop areas are crop-feeding species because there are many nonpest grasshoppers that restrict their feeding to grasses or weeds. It is advisable to monitor nearby uncultivated land, particularly weedy areas, in addition to crop plants, due to the tendency of the pest species to invade crops later in the season.

Liquid formulations of insecticides are commonly applied to foliage to protect against damage. Because grasshoppers rarely develop in crops, but instead invade from weedy areas, it is often the edges of crop fields that are most injured. Therefore, application of insecticide to the borders of crop fields is often adequate to protect an entire field. It is even better to apply insecticides to the developing grasshopper populations in weedy areas before they move to crops. This not only minimizes damage to crop plants, but often results in younger grasshoppers being targeted for elimination. Younger grasshoppers are more susceptible to insecticides, with large nymphs and adults sometimes difficult to kill.

Application of insecticide-treated bait is an effective alternative to foliar treatments for *Melanoplus* spp. because these grasshoppers spend considerable time on the soil where they come into contact with baits. Bait formulations are bulky and more difficult to apply than liquid products, so they are less often used, but have the advantage of limiting exposure of crops to insecticide residue and of minimizing mortality of beneficial insects such as predators and parasitoids due to insecticide exposure. Also, the total amount of insecticide active ingredient necessary to obtain control is usually considerably less when applied by bait because the grasshoppers actively seek out and ingest the toxin. Finally, for relatively expensive products that must be ingested to be effective, such as microbial insecticides, baits are the most effective delivery system.

The attractant used most commonly for grasshopper bait is flaky wheat bran, though other products such as rolled oats are sometimes suggested. No additives, other than insecticide (usually 5% active ingredient), are necessary because the wheat bran alone is quite attractive to *Melanoplus* grasshoppers. Other additives such as sawdust, water, vegetable or mineral oil, molasses, amyl acetate, salt, or sugar have been suggested, but provide little or no additional benefit over dry bran. The bait should be broadcast widely to maximize the likelihood of grasshopper contact, and should be applied while grasshoppers are in the late instars because adults ingest less bait.

Elimination of weeds within, and adjacent to, crops is the most important cultural practice, and can have material benefit in preventing damage to crop borders. However, during periods of weather when grasshoppers become numerous they may move long distances and invade crops.

Tillage is an effective practice for destruction of eggs, particularly in migratory grasshopper which is especially likely to deposit eggs among crop plants. Deep tillage and burial are required, shallow tillage having little effect. All the crop-feeding *Melanoplus* species deposit some eggs in crop fields, especially during periods of abundance, but it is fence row, irrigation ditch, field edge, and roadside areas that tend to be the favorite oviposition sites, so tillage is not entirely satisfactory unless other steps are taken to eliminate grasshopper egg pods from these areas that cannot be tilled. Though providing suppressive effects, deep tillage is not consistent with the soil and water management practices in many areas, so may not be a good option.

Row covers, netting, and similar physical barriers can provide protection against grasshoppers. This approach obviously is limited to small plantings, and can interfere with pollination. Also, grasshoppers are capable of chewing through all except metal screening, so this approach does not guarantee complete protection.

The opportunities for biological control are limited. Historically, poultry were found to consume large numbers of grasshoppers and could provide considerable relief if the grasshopper-infested garden was small or moderate in size and the birds were plentiful. This remains a viable option for some people, and turkeys are usually considered most suitable among poultry. The birds may also inflict some direct damage to plants, however, so introduction of poultry is probably most viable when grasshoppers are plentiful and threatening.

The microsporidian pathogen *Nosema locustae* is well studied as a microbial control agent of *Melanoplus* spp. and is available commercially. It is fairly stable, and easily disseminated to grasshoppers on bait. However, its usefulness is severely limited by the long period of time that is required to induce mortality and reduction in feeding and fecundity. Also, the level of mortality induced by consumption of *Nosema* is quite low, often imperceptible. It is best used over very large areas, not just on individual farms, and should be applied at least one year in advance of the development of potentially damaging populations.

Fungi have also been investigated for grasshopper suppression. A grasshopper strain of *Beauveria bassiana* has been effective in some trials, and *Metarhizium anisopliae* var. *acridum* has worked well for grasshopper and locust suppression in Africa and Australia, so it may prove useful for *Melanoplus* spp. Behavioral thermoregulation by grasshoppers, wherein they bask in the sun and raise their body temperatures, is potentially a limiting factor for use of fungi. Basking grasshoppers easily attain temperatures in excess of 35°C; such high temperatures decrease or even prevent disease development in infected grasshoppers. Inconsistent quality control in production of fungi also limits use of these organisms for grasshopper control.

Miller, David

GEORGE HANGAY
Narrabeen, NSW, Australia

David Miller was born in 1890 in Glasgow and was educated in Edinburgh, Dunedin and Wellington, New Zealand. He had a keen interest in entomology from an early age. From 1916 he was Government Entomologist and in 1926 he joined the Cawthron Institute as Chief Entomologist in Nelson. While holding this position, in 1929 he also became the Director of the Forest Biological Research Station. He held this post until 1932, when he was appointed Assistant Director of the Cawthron Institute. He remained in this position until 1956; however, from 1937 until 1956 he was also the Director of the Entomological Research Station, when he became the Director of the Cawthron Institute. Dr. David Miller was a very active, productive entomologist, who left a great body of work behind. He published many scientific papers, monographs and books. One of his most read works is "Common Ins ects in New Zealand" (1971). He was a leading figure in New Zealand entomology, holding two or more important positions simultaneously in scientific institutions during most of his working life. He passed away in Nelson in 1973 at the age of 83.

Millipedes (Class Diplopoda)

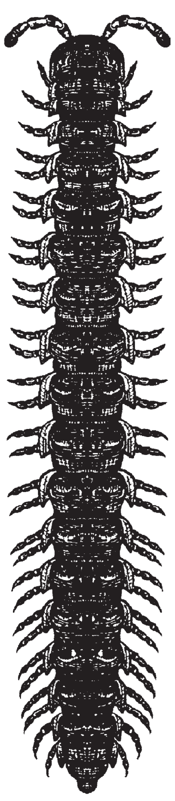
Though the name "millipede" suggests that these animals have 1,000 legs, and although the presence of numerous legs is a characteristic of this group, none have more than 375 pairs, and most have considerably fewer. In differentiating this group from the similar-appearing centipedes and symphylans, the presence of two pairs of legs per body segment is the key character used to identify millipedes.

Classification

The Class Diplopoda is one of six classes in the Subphylum Atelocerata of the Phylum Arthropoda. The other classes in the subphylum are Chilopoda, the centipedes; Pauropoda, the pauropods; Symphyla, the symphylans; Entognatha, the collembolans, proturans, and diplurans; and Insecta, the insects. There are several orders of diplopods, and several arrangements of the taxa have been proposed. These are fairly common arthropods, and as they occasionally are numerous or damaging, they sometimes are confused with insects. More commonly they are confused with centipedes.

Phylum: Arthropoda
- Subphylum: Atelocerata
  - Class: Diplopoda
    - Subclass: Pselophognatha
    - Order: Polyxenida – bristly millipedes
    - Subclass: Chilognatha
    - Order: Glomeridesmida
    - Order: Sphaerotheriida – giant pill millipedes
    - Order: Glomerida – pill millipedes
    - Order: Siphoniulida
    - Order: Platydesmida
    - Order: Siphonophorida
    - Order: Polyzoniida
    - Order: Stemmiulida
    - Order: Callipodida
    - Order: Cordeumatida
    - Order: Julida
    - Order: Spirobolida
    - Order: Spirostreptida
    - Order: Polydesmida – flat-backed millipedes

Millipedes are quite diverse morphologically, though they all consist of a long chain of rather uniform body segments, and lack wings (Fig. 52). Some are rather short, and may be covered with feather or scale-like adornment. Others look greatly like woodlice (pillbugs and sowbugs), and even roll into a ball in the manner of pillbugs. Most, however, are elongate and thin in general body form. There are three basic body regions: the head, which bears a pair of moderately long antennae; the body, consisting of numerous leg-bearing segments, and which normally are rather cylindrical but sometimes bears prominent lateral projections; and the telson, or posterior body segments bearing the anus. The integument is very hard.



Millipedes (Class Diplopoda), Figure 52 Garden millipede, *Oxidus gracilis*.

Life History

Millipedes are poorly known animals, with almost all our information based on studies in northern Europe. The life cycle of millipedes is often long. Many live for a year, but some persist for 2–4 years before attaining maturity. In a *Julus* sp. studied in a temperate environment, oviposition took place in April, with instar 6 to 7 was attained by winter and instars 8 to 9 by the second winter. They overwintered as instars 9–11, then mated and oviposited the following spring, their third year of life, before they perished. Following is a description that is based on the life cycle of a common millipede, *Oxidus gracilis* Koch, a species with a 1-year development time.

Oxidus gracilis is somewhat flattened dorsoventrally, and bears 30 or 31 pairs of legs in males and females, respectively. They generally measure 18.5–22.2 mm in length and 2.0–2.5 mm in width. Initially they are light brown in color but gradually attain a dark brown coloration, and sometimes are bordered with yellow. Adults seem to live for about two months in the spring or summer, and like all millipedes, are intolerant of dry conditions. *Oxidus gracilis* is nocturnal.

The creamy white, yellow or brownish eggs of *Oxidus gracilis* are deposited in the soil, usually in clusters. A glutinous material causes them to adhere to one another. The eggs are nearly spherical in shape, measuring 0.35–0.4 mm in width and about 0.40 mm in length. The female may create a chamber or cell for her eggs. She deposits 50–300 eggs in a cluster, and eggs can be found throughout the summer months. Duration of the egg stage is 9–10 days.

The first instar juvenile millipedes bear only a few segments and three pairs of legs, but body segments, legs, and ocelli are added with each molt. By counting the number of rows of ocelli and adding one, the instar can be estimated for many millipedes. Thus, fourth instar millipedes have three rows of ocelli, fifth instars have four rows, etc. Maturity is often attained after about 10 instars, but some species continue to molt as adults.

In *Oxidus gracilis*, most individuals develop through eight instars before they attain the adult stage. The number of pairs of legs present in the juveniles is about 3, 6, 11, 16, 22, 26, 28, and 30 for instars 1 to 8, respectively. Body length is about 0.5, 1.5, 3.6, 4.1, 4.8, 7.4, 12.4, and 20 mm during the corresponding instars. Development time is 1, 11–18, 13–18, 16–30, 20–38, 28–46, 42–60, during instars 1 to 7, with the final (eighth) instar generally overwintering, though in some cases instar seven overwinters.

Adult millipedes vary considerably in size, often measuring from 10–30 mm in length, but in some species exceeding 100 mm. Their color ranges from whitish to brown and black. The sexes are separate. The external genitalia of adult millipedes are located between the second and third pairs of legs. Some adult millipedes have the ability to molt from a sexually active adult to an intermediate stage that is not functional sexually. Parthenogenesis occurs in some species and some populations, but this is not usual. Millipedes lack a waxy cuticle and are susceptible to desiccation. They have glands, with openings usually located laterally, which secrete chemicals that are toxic and may immobilize predatory arthropods such as spiders and ants.

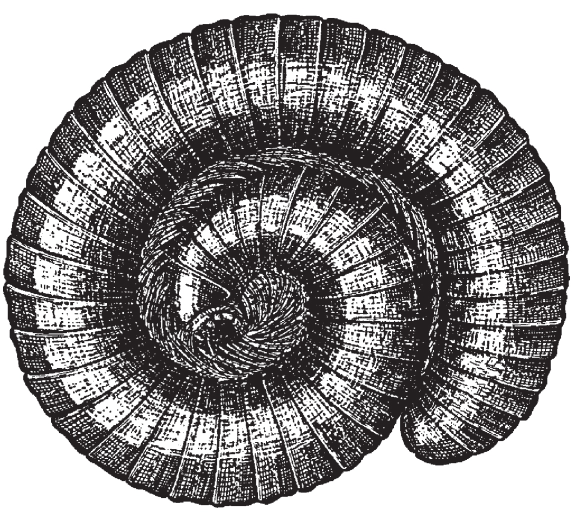
Ecology

Millipedes normally eat dead plant material, usually in the form of leaf litter. However, they occasionally graze on roots and shoots of seedlings, algae, and dead arthropods and molluscs. They are selective in their consumption of leaf litter, preferring some leaves over others. They also tend to wait until leaves have aged, and are partially degraded by bacteria and fungi. Thus, they function principally as decomposers, hastening the break-up of leaf material into smaller pieces, and incorporating the organic matter into the soil. Whether they derive most of their nutritional requirements from the organic substrate or the microorganisms developing on the substrate is uncertain. Millipedes also tend to consume their own feces, and many species fare poorly if deprived of this food source.

Millipedes sometimes are viewed as a severe nuisance as a result of exceptional abundance in an inappropriate location such as in yards, homes, or commercial or food processing facilities. Millipedes can exist in tremendous quantities in the soil and become a problem only when they come to the surface and disperse as a group. This often occurs following abnormally large rainfall events, though hot and dry conditions also are sometimes suspected to be a stimulus for dispersal.

Several species of millipedes are reported to be injurious to plants, or present in high enough numbers to be considered a nuisance. Probably the most important is garden millipede, *Oxidus gracilis* Koch (Diplopoda: Paradoxosomatidae). It apparently was accidentally introduced to most temperate areas of the world from the tropics, probably via transport of specimen plants. In cool areas it is principally a greenhouse pest.

Millipedes produce various foul-smelling fluids (sometimes including hydrogen cyanide) from openings along the sides of their body. Despite the formidable chemical defenses of millipedes (Fig. 53), several natural enemies are known. Small vertebrate predators such as shrews, frogs, and lizards eat millipedes. Invertebrate predators such as scorpions (Arachnida), ground beetles (Coleoptera: Carabidae), and rove beetles (Coleoptera: Staphylinidae) also consume millipedes, though ants are usually deterred. Various disease-causing agents such as fungi, iridoviruses, rickettsia, and protozoa are documented from millipedes, though they seem to be only sporadically effective. Parasitic flies have been reared from millipedes in Europe.



Millipedes (Class Diplopoda), Figure 53 A millipede in a coiled position, a common defensive behavior.

Mimallonidae

A family of moths (order Lepidoptera). They commonly are known as sackbearer moths.

► Sackbearer Moths
► Butterflies and Moths

Mimicry

HEATHER J. MCAUSLANE
University of Florida, Gainesville, FL, USA

Mimicry, broadly defined, is the superficial resemblance of one organism to another organism, usually providing a selective advantage to the mimicker. The term mimicry is used occasionally to describe organisms that mimic inanimate objects in their environment (such as young swallowtail larvae resembling bird droppings and grasshoppers or katydids resembling leaves). However, this phenomenon is also variously labeled as crypsis, camouflage, mimesis or special resemblance, and will not be discussed under the term mimicry.

Many insect species have evolved to mimic other species of insects, and even other groups of organisms, for a variety of reasons. Likewise, some non-insect organisms have evolved to mimic specific insects. The most common type of mimicry is visual, where mimics and their models look very similar to each other. The perceived commonness of this type of mimicry may be elevated somewhat by the visual emphasis of humans, the studiers and cataloguers of nature. However, visual resemblance also can be enhanced by acoustic, olfactory, tactile and behavioral mimicry. The mimicry can be so close that even seasoned entomologists are fooled at first glance.

In the majority of cases, mimicry has evolved in the mimicking species to reduce the likelihood of suffering predation (as is the case in Batesian and Müllerian mimicry). Species that mimic a toxic or unpalatable species experience less predation than those that do not. In many cases, but not all, the toxic or unpalatable species and their mimics have aposematic, or warning, coloration. Aposematic coloration is striking, usually black next to red, yellow or orange, and serves to enhance the learning of distastefulness by predators. Batesian and Müllerian mimicry are effective against predators that are capable of learning and that have good color vision (if the insect is aposematic). Birds, and to a lesser extent, amphibians and lizards, seem to have been the driving force for the evolution of mimicry in insects. The model usually has a true toxin in its body that could kill a predator if the model were consumed in its entirety. However, the model also often contains emetic and bitter chemicals (or the toxin itself may have emetic and bitter properties). Thus, the predator lives another day and associates the regurgitation of the prey item and its bitter taste with a particular morphology or pattern.

In a few cases, insects and other organisms have evolved mimicry so that they become more effective predators (aggressive mimicry) or are better adapted as social inquilines, living in the nests of their host ants (Wasmannian mimicry). In these types of mimicry, the mimics and their models are rarely aposematic.

Batesian Mimicry

This form of mimicry was described in 1862 by Henry W. Bates, an English naturalist studying butterflies in Amazonia, and was later named after him. He noticed remarkable resemblances between palatable pierid butterflies (related to cabbage white butterflies) and unpalatable Ithomiinae butterflies (related to monarch butterflies). The larval host plant of the Ithomiinae butterflies renders them toxic to predators, whereas the diet of the pierid larvae gives them no such protection against predators. He suggested that natural selection had caused the appearance of the palatable pierids to move toward that of the unpalatable Ithomiinae butterflies.

Batesian mimicry, then, is the result of evolutionary convergence in shape, patterning, color, behavior, or smell of an edible mimic toward close resemblance of a less palatable and distantly related model. The predator, after trying to eat a few of the toxic models, learns that an insect with this particular shape, color or smell is toxic and therefore unpalatable. The mimic takes advantage of this predator learning and, in fact, is a parasite on the model species. The model suffers greater predation when it is sympatric with a mimic (sharing the same range) than when it is alone because the encounter of predators with palatable mimics delays the learning process. The predator is also harmed in this system because it learns to avoid a profitable prey item, the mimetic species.

Batesian mimics must evolve very close resemblance to their models so that predators cannot distinguish them. If the mimics become too abundant in the habitat relative to their models, predators may never learn to associate their appearance with distastefulness; thus, both model and mimic suffer increased predation. The models cannot evolve to look too different from their original morphology or they will experience more predation. So, in these situations, it is the mimic that evolves to resemble other toxic model species in the area. The evolution of polymorphisms (many morphs or appearances) is common in Batesian mimics. As one morph becomes too common in a population relative to its model, it is selected against, and other morphs within the population increase in abundance. An extreme example of polymorphism in a Batesian mimic occurs in the African swallowtail species, *Papilio dardanus*. There are thought to be 31 morphs of this species, mimicking several species of danaid butterflies in the genera *Danaus* and *Amauris* throughout their ranges in central and southeastern Africa. The models feed on toxic milkweeds while the mimics are innocuous to predators. Curiously, the males of all *P. dardanus* morphs resemble a typical yellow and black swallowtail and only the females are mimetic.

Batesian mimicry has been studied best among species of butterflies but it is also common in arthropods that mimic bees, wasps or ants – insects that are all equipped with predator-deterring stings. For example, in Honduras, the ant *Camponotus planatus* is mimicked by four species of arthropod: a clubionid spider, a salticid spider, a mirid bug (*Barbariella* sp.), and a praying mantid (*Mantoida maya*). Interestingly, the mimetic mantid nymph resembles the ant model only in the earliest instars when it measures 3–9 mm. When the mantid nymph grows longer than 9 mm, and can no longer pass for an ant, its morphology and color change to mimic a species of vespid wasp common in the area.

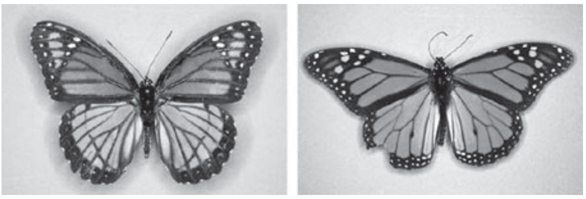
Most examples of Batesian mimicry involve only visual resemblance between models and mimics. However, some insects mimic the sound of their model, in addition to their appearance. For example, a syrphid fly that visually mimics a yellow jacket wasp, also mimics it acoustically, having a wing beat frequency of 147 Hz, which is very similar to the 150 Hz frequency of the wasp. The stridulations of a *Necrophorus* burying beetle that mimics a bumblebee visually have the same frequency as the wing beat of the bumblebee.

Müllerian Mimicry

Henry W. Bates and Fritz Müller, a German naturalist, first noted examples of this type of mimicry in the Neotropics. They wrote independently that many species of unpalatable butterflies resembled each other. In 1879, Müller published a mathematical model that showed that pairs of unpalatable species mutually benefit from resembling each other. Müllerian mimicry, later named for him, is the result of evolutionary convergence in shape, patterning, and color of two, or more, distantly related unpalatable species (Fig. 54). In this type of mimicry, all species benefit from the mimicry because predators need only learn a single appearance and there is less total death among the co-mimetic species than if the predators needed to learn two different patterns. Predators also benefit because they can quickly learn to sight reject unpalatable prey, and avoid wasting time on them.

Müllerian mimicry is common in the tropics of South America. One large mimicry "ring" involves two species of *Heliconius* butterflies and several other more distantly related butterflies and even a day-flying moth. All are toxic due chemicals sequestered from their larval host plants and all resemble each other visually.

The classic example of Müllerian mimicry known from the temperate world is that of the monarch butterfly, *Danaus plexippus*, and the viceroy, *Limnetis archippus*. In this example, adults of the viceroy butterfly are presumed to be palatable mimics of adults of the toxic monarch butterfly whose larvae feed on milkweeds and sequester heart poisons (cardiac glycosides).



Mimicry, Figure 54 The viceroy butterflies (*Limenitis archippus*, left) was long thought to be a palatable Batesian mimic of the toxic monarch butterfly (*Danaus plexippus*, right). Research has indicated that, at least in Florida, the viceroy and the monarch are both unpalatable and are Müllerian co-mimics.

Cardiac glycosides protect monarch butterflies from bird predation. However, this example had to be revised after the 1991 publication of a paper by David Ritland who was a student of Lincoln Brower, one of the pioneers of the study of chemical defense in the monarch butterfly.

Pre-1991, the viceroy butterfly in Florida, whose larvae feed on willow, poplar and other trees, was considered to be a Batesian mimic of the monarch butterfly and the Florida Queen butterfly, *Danaus gilippus berenice*, whose larvae can feed on toxic cardiac glycoside-containing host plants. However, Ritland and Brower found that the viceroy was just as unpalatable to bird predators as was the monarch butterfly. Furthermore, the viceroy was considerably less palatable than the Florida Queen if the larvae of the Queen fed on a host plant that was low in cardiac glycosides. Thus, in this study, the monarch and the viceroy butterflies were actually Müllerian co-mimics and the Florida Queen butterfly was a Batesian mimic of the viceroy and the monarch. Thus, the type of mimicry cannot be ascertained unless the palatability of the species involved is known.

A further issue that complicates our understanding of mimicry complexes is that of automimicry. Researchers have found that the unpalatability of the monarch butterfly varies across a spectrum depending on the larval diet. If a larva feeds on a host plant species with low concentrations of cardiac glycosides, it will develop into an adult that is nontoxic and palatable to bird predators. If a larva feeds on a plant species with high concentration of cardiac glycosides, the butterfly will be toxic and unpalatable. Thus, monarch butterflies with low concentrations of cardiac glycosides are Batesian mimics of monarchs with high concentrations of cardiac glycosides (i.e., automimicry).

Aggressive Mimicry

Aggressive mimicry occurs when one species mimics something that a second species considers desirable. The second species is attracted to the mimic and usually ends up being eaten by the mimic; thus, the mimicry is aggressive in nature. A classic example of behavioral aggressive mimicry occurs in fireflies. It has long been known that male and female fireflies communicate visually by flashing their light organs in a species-specific pattern. Adult female fireflies, usually stationary, flash in response to the flash pattern of flying males. The male locates the female by her flashing and copulation ensues. However, several firefly species in the genus *Photuris* are aggressive mimics of *Photinus* species. The female *Photuris* flashes the female *Photinus*-specific pattern in response to the signaling of the male *Photinus*. The male *Photinus* is lured to the female *Photuris*, expecting a female of his own species, and is then eaten. JE Lloyd has termed these deceptive *Photuris* females "femmes fatales."

An example of aggressive chemical mimicry involves several species of bolas spiders in the genus *Mastophora*. The females in this genus do not spin a web but rather swing a silk thread with a droplet of sticky material at its end (the bolas) at passing insects. The majority of the insects that are caught on the bolas are male moths of a select few species. Chemists determined that the female spiders synthesize the sex attractant pheromone of the females of the moth species that is their predominant prey. Male moths are lured to what they perceive as a virgin female but instead are caught and eaten by the spider.

Wasmannian Mimicry

A final, and very specialized, form of mimicry is Wasmannian mimicry, which occurs in some organisms that live in the nests of ants. E. Wasmann first described this phenomenon in museum specimens of staphylinid beetles. Many species in several genera of staphylinid beetles (e.g., *Wasmannia*, *Myrmeciton*, and *Ecitosius*) live in ant nests and closely resemble ants, having a petiole-like restriction in the abdomen, and an overall slender and dark body. In addition to looking like ants, they produce appeasement substances from glands that calm the ants and allow for their entry into the nests. Wasmann originally thought that the morphology of the staphylinid's body tactilely mimicked the ant's own body and fooled the ant into tolerating its presence. However, because ants rely primarily on chemicals for intraspecific communication, this hypothesis seems less reasonable. It may be that staphylinids that forage outside the nest with their ant hosts may gain protection from potential predators by mimicking the sting-equipped ants.

Miniature Ghost Moths (Lepidoptera: Palaeosetidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Miniature ghost moths, family Palaeosetidae, are a small family related to Hepialidae, comprising eight species worldwide (five in Assam, Thailand and Taiwan, two in Australia, and one in Colombia). The family is in the superfamily Hepialoidea, in the infraorder Exoporia. Adults are small (12–18mm wingspan), with head roughened; haustellum absent (with no mandibles); labial palpi short and 2 to 3-segmented; axillary palpi absent; antennae are relatively short. Maculation can be rather sparkling, with metallic-iridescent markings on the forewings on a brown or blue base color. Adults are crepuscular or active during the day in dark forested areas, typically near wet moss-covered rock faces. Adults often rest head down under leaves in moist, shaded forest areas near water courses. Biologies remain unknown but larvae of a species from Taiwan have been described and are thought to feed on mosses.

Minute Pirate Bugs (Hemiptera: Anthocoridae)

DAVID R. HORTON
USDA, Agricultural Research Service, Yakima, WA, USA

Insects in the family Anthocoridae are referred to as minute pirate bugs or flower bugs. Pirate bugs occur worldwide and occupy a variety of natural and disturbed habitats. All but a few species are predaceous, feeding on small soft-bodied arthropods from a variety of taxonomic groups. Pirate bugs contribute to biological control of pest arthropods in a wide variety of habitats, including orchards, row crops, forests, ornamental plants, greenhouses, and granaries.

Classification and Distribution of the Anthocoridae

The family Anthocoridae includes between 500–600 species in 80–100 genera worldwide. The systematic position of the Anthocoridae and close relatives remains somewhat unsettled, and there is a distinct need for additional taxonomic and phylogenetic work. Diversity of Anthocoridae tends to be highest in the tropics and the Holarctic Region. Thorough faunistic studies for some geographic regions are lacking, and estimates of diversity will require revision as these studies are done. Checklists for the North American fauna, including information on distribution, are available in publications by Kelton, Henry, and Maw et al. Citations for these works are provided at the end of this chapter. Keys to many North American species are available in Blatchley and Kelton.

The discussion of classification and distribution to be presented here is based on treatments by Cassis and Gross, Schuh and Štys, Schuh and Slater, Carayon, and Ford (full citations follow at the end of this article). The Anthocoridae are found in the infraorder Cimicomorpha within the suborder Heteroptera ("true bugs"). Classification of the Anthocoridae has seen extensive study and revision since the family was erected in the 1800s, particularly with reference to placement of related families such as the bed bugs (Cimicidae), bat bugs (Polyctenidae), and web lovers (Plokiophilidae), but also with respect to higher level groupings of taxa within the Anthocoridae. Three modern treatments of the pirate bugs allocate genera among seven or eight tribes (Table 9). Carayon, and Cassis and Gross include three subfamilies (Lasiochilinae, Lyctocorinae, Anthocorinae) within the family Anthocoridae. Schuh and Slater elevate the Lasiochilinae and Lyctocorinae to family rank, following the phylogenetic analysis of Schuh and Štys. Four tribes included within the Lyctocorinae by Carayon (i.e., the Almeidini, Cardiastethini, Scolopini, and Xylocorini) are placed in the Anthocorinae by Cassis and Gross, or in the Anthocoridae by Schuh and Slater. Carayon's Cardiastethini is considered a junior synonym of Dufouriellini Van Duzee in both the Schuh and Slater treatment and in the Cassis and Gross treatment, following the assessment of Štys. Péricart used Carayon's classification in his summary and checklist of the Palaearctic Anthocoridae. I follow the Schuh and Slater scheme throughout this article. Because of the close taxonomic affinity among the Lyctocoridae, Lasiochilidae, and Anthocoridae – and because taxonomic rank for these groups is still open to discussion – the present article will not be limited to the Anthocoridae, but will include as necessary reference also to the Lyctocoridae and Lasiochilidae.

Family Anthocoridae – Tribe Almeidini

This is a poorly known group with few described species, known from the Old World tropics, Japan, Nepal, and Australia.

Anthocorini

The Anthocorini is a highly speciose group found primarily in temperate areas. Members of this group include a number of species important in biological control, particularly in orchards and coniferous forests. The most well known of these insects are in the genus *Anthocoris*, which includes over 50 described species found commonly in temperate regions. Species in the Anthocorini feed on phytophagous arthropods primarily in the canopies of deciduous or coniferous trees, or on the foliage of deciduous shrubs.

Blaptostethini

This is a poorly known group of about seven described species known primarily from the Oriental and Pacific regions.

Dufouriellini

The Dufouriellini is a large group of species whose systematic affinities remain somewhat uncertain. The Dufouriellini are well represented in the Neotropical, Australian, and Palaearctic regions. *Cardiastethus* is the most common genus, comprising about 40 described species having a wide distribution.

Oriini

The Oriini contains the geographically widespread and well-known genus *Orius*, having approximately 70 described species. This group has strong representation in the Oriental, Ethiopian, Palaearctic, and Neotropical regions, but is relatively poorly represented in the Nearctic. The Oriini includes a number of species important in biological control of pests on row crops, in greenhouses, and on ornamental plants.

Modification of a table in Cassis and Gross

Scolopini

The Scolopini include at least 13 genera distributed primarily in the Neotropical Region, but with at least some representation in most areas of the world. Species of *Scoloposcelis* are important predators of bark-feeding Coleoptera.

Xylocorini

The Xylocorini occur virtually worldwide, but have heavy representation in the Palaearctic and Nearctic regions. This tribe includes a single genus, *Xylocoris*, having about 40 described species. Species of *Xylocoris* are sources of biological control in stored products, granaries, and beneath the bark of trees. *Xylocoris flavipes* (Reuter) is a geographically widespread species which has been introduced into a number of regions apparently by human commerce.

Family Lasiochilidae

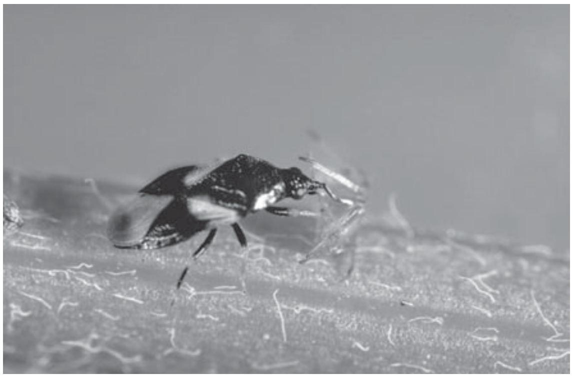
The Lasiochilidae are a poorly studied group with species occurring in most geographic regions, but having the strongest representation in the Neotropical Region and on Pacific islands; the family is virtually absent from the Palaearctic. *Lasiochilus* is composed of approximately 50 described species having a relatively wide distribution. Members of this family are small (3–4 mm), and occur on the ground in litter, under the bark of trees, or on plant surfaces.

Family Lyctocoridae

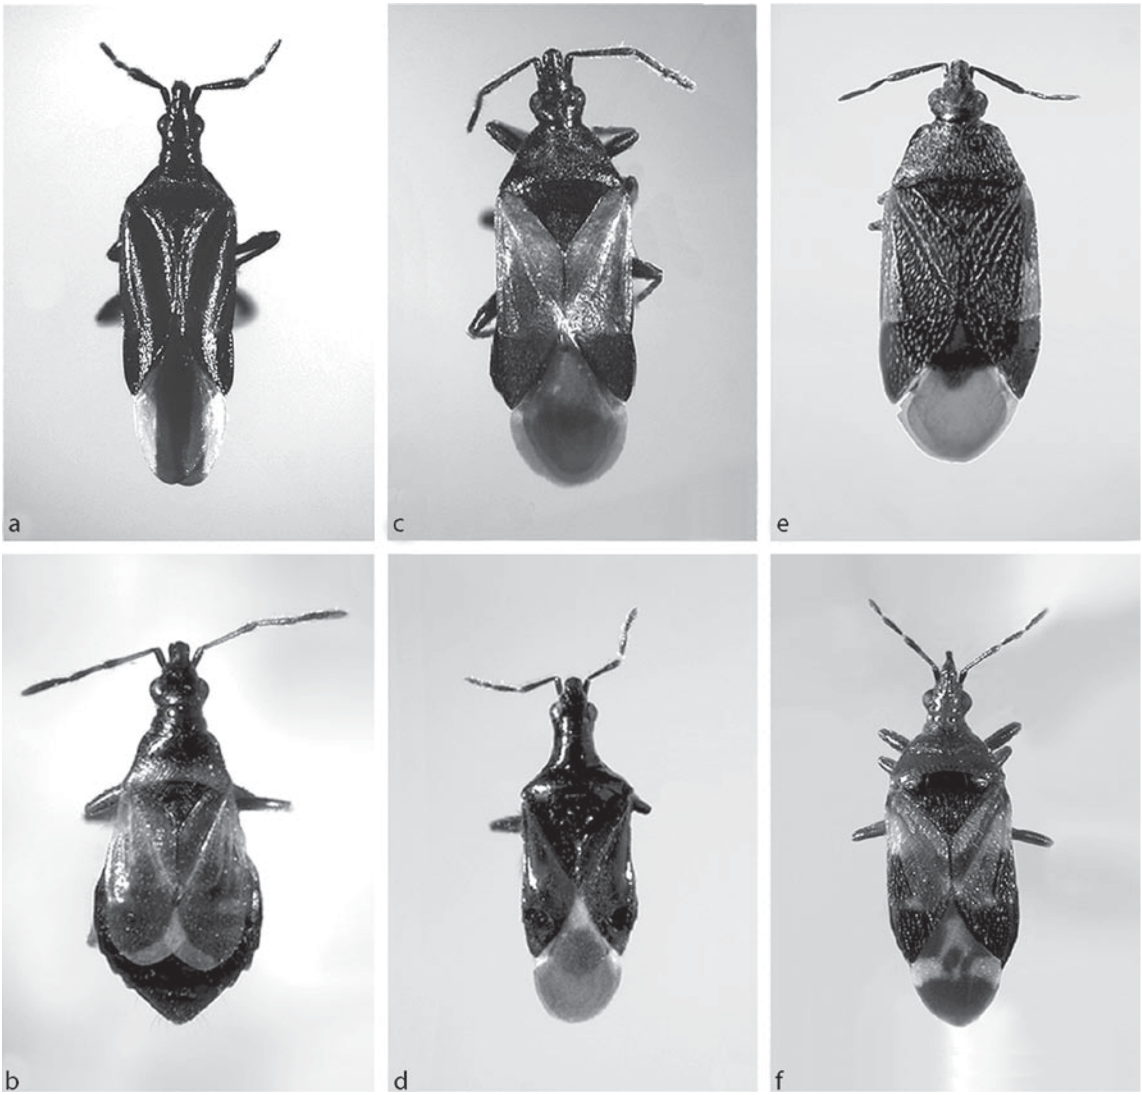
The Lyctocoridae are widely distributed, but with a strong presence in temperate regions. One species, *Lyctocoris campestris* (Fabricius), is essentially cosmopolitan, likely because of unintentional introductions outside of its native range. Members of this family can be found in a number of habitats, including in stored products, in decaying vegetation, beneath bark, and in the nests of birds or mammals.

Morphology

Members of the Anthocoridae are relatively small (1.5–5 mm), having an oval or elongate-oval shape (Figs. 55 and 56). Most are brownish in general coloration. Wing markings or shadings give some species a checkered appearance. The body is generally somewhat flattened, and may be either glabrous or pubescent. The head extends horizontally, with large compound eyes on each side. Paired ocelli are present near the eyes in the adult (ocelli are not present in nymphs). Antennae are four-segmented and inserted anterior of the eyes. Mouthparts are of the piercing-sucking type, in the form of a slender beak or labium. The labium has three visible segments, and may be short or quite long (in some species extending to the end of the abdomen). The labium serves to house the four piercing stylets (paired mandibles and paired maxillae), which collectively form the two channels through which digestive enzymes and the ingested food products are moved. The pronotum is trapezoidal, bearing paired callosities that are



Minute Pirate Bugs (Hemiptera: Anthocoridae), Figure 55 **A common North American pirate bug, *Orius tristicolor* (White) (Oriini) (photograph by Jack Kelly Clark, courtesy of University of California Statewide IPM Program).**



Minute Pirate Bugs (Hemiptera: Anthocoridae), Figure 56 Some Anthocorini and Oriini.
(a) *Macrotrachelia* sp. (possibly *M. nigronitens* (Stål)) (Anthocorini), length approximately 3.3 mm excluding antennae; (b) brachypterous *Anthocoris dimorphicus* Anderson & Kelton (Anthocorini), 2.9 mm; (c) *Elatophilus* sp. (Anthocorini), 3.1 mm; (d) *Macrotracheliella nigra* Parshley (Oriini), 2.4 mm; (e) *Melanocoris nigricornis* Van Duzee (Anthocorini), 3.1 mm; (F) *Anthocoris nemoralis* (Fabricius) (Anthocorini), 3.5 mm.

prominent in some species and inconspicuous in other species. Anthocorids have two pairs of wings: the membranous hind wings, and the thickened forewings (hemelytra) that are characteristic for the true bugs. Most members of the family have fully sized wings, although there are species in some genera (e.g., *Xylocoris*, *Temnostethus*, *Anthocoris*, and *Elatophilus*) that exhibit brachyptery. The forewing has a triangular cuneus, unlike what is found in many other Heteroptera. Genitalia in the male are asymmetrical (discussed below). The ovipositor is well-developed in most species, but is greatly reduced in some taxa (e.g., *Cardiastethus*).

Specimens of Anthocoridae may resemble insects from other families of Heteroptera, including especially members of the Miridae. Morphological characteristics in the Anthocoridae that can be used to separate them from other Heteroptera include: two ocelli; labium with three visible segments; generally an absence of pronounced veins in the hemelytral membrane; presence of a cuneus; and presence of asymmetrical genitalia in males. Insects within the Lasiochilidae, Lyctocoridae, and Anthocoridae may often be very similar in appearance. Placement of specimens in the correct family may require access to faunistic treatments that include keys for identifying genera and species, from which family affiliation can then be derived. Examination of genitalia may be necessary in some cases to confirm or to ascertain family affiliation.

Biology and Life History

Members of the Anthocoridae, Lasiochilidae, and Lyctocoridae are predaceous on small soft-bodied arthropods in a variety of natural or managed habitats. Many species prey upon herbivorous arthropods that attack forbs, shrubs, or trees. Important prey taxa include aphids, psyllids, mites, thrips, scale insects, psocids, and eggs or small larvae of Lepidoptera, Coleoptera, and Diptera. Species of *Orius* are commonly associated with flowers of herbaceous plants, where they feed extensively on thrips and other small arthropods. A number of genera in the Anthocorini (*Melanocoris* Champion, *Tetraphleps*, *Elatophilus*) occur exclusively on coniferous trees, where they feed on aphids and scale insects. Species of *Anthocoris* are common on deciduous trees and shrubs, and prey extensively on psyllids, aphids, and other soft-bodied arthropods. *Scoloposcelis*, *Xylocoris*, and *Lyctocoris* are often found beneath the bark of trees feeding on eggs and larvae of bark beetles. *Xylocoris* and *Lyctocoris* also occur in stored products and granaries, in nests of birds or mammals, in poultry houses, in decaying plant litter, in manure piles, under tree bark, or in ant nests. *Lyctocoris campestris* may occasionally feed on the blood of mammals, including on humans. *Nidicola marginatus* Harris & Drake has been collected from guano beneath roosting bats.

Anthocoridae may often supplement their diets with pollen or plant juices. Species of *Orius* occur commonly in the flowers of herbaceous vegetation, and are known to supplement their diets with pollen. *Orius pallidicornis* (Reuter) appears to have an exclusively plant diet, feeding on pollen from a limited number of species. *Paratriphleps laeviuscula* Champion is a Central and South American species now known to occur in Florida, where it inhabits the flowers of sapodilla (*Manilkara zapota*) and feeds on pollen. Species of *Anthocoris* and *Orius* are known to accumulate systemic insecticides from root-treated plants, due to their habit of ingesting plant juices.

Diet breadth in the Anthocoridae shows a range from highly generalized species to highly specialized species. The generalist species *Anthocoris nemoralis* (Fabricius) has been recorded from over 20 plant genera in Europe and from 13 plant genera in North America, with the latter records occurring only since 1958 following the accidental and intentional introductions of this predator into the Nearctic. *Anthocoris antevolens* White, a widespread North American species, has been recorded from well over 20 plant genera. Species such as *Orius tristicolor* (White) and *Orius insidiosus* (Say) occur on the flowers of a diverse number of plant species, apparently because a primary prey species, the western flower thrips (*Frankliniella occidentalis* (Pergande)), is itself highly generalized. *Lyctocoris campestris* occurs in a variety of habitats, including compost piles, moldy grain, beneath leaf or straw litter, birds nests, mammal burrows, or beneath the bark of trees.

In contrast, many other Anthocoridae show highly restricted diets. Several species of *Anthocoris* reproduce largely or entirely on a few plant species (e.g., *A. gallarumulmi* (De Geer) on elm [*Ulmus*], *A. bakeri* Poppius on manzanita [*Arctostaphylos*], *A. sarothamni* Douglas & Scott on broom [*Cytisus*], *A. dimorphicus* Anderson & Kelton on willow [*Salix*], and *A. visci* Douglas on mistletoe [*Viscum*]). Presumably, the limited host plant range reflects some type of diet specialization (*A. bakeri*, for example, appears to prey extensively on aphids that gall *Arctostaphylos*). Other Anthocoridae are restricted to a few related plant species, and include species of *Melanocoris* (restricted to *Pinus* and *Picea*), *Elatophilus* (restricted to *Pinus*), and *Acompocoris* (*Pinus* and *Picea*). Species of *Elatophilus* often appear to occur in association with scale insects (*Matsucoccus* Cockerell) occurring on *Pinus*; some *Elatophilus* species are attracted to the sex pheromones of *Matsucoccus* scale insects. *Brachysteles parvicornis* (Costa) may feed largely on mites within the Oribatida. Diet breadth in some species may change seasonally. For instance, females of some *Anthocoris* species accumulate on willows (*Salix*) in early spring as the bugs emerge from overwintering sites, and may complete a generation on those hosts before the summer hosts (which can include a number of different plant taxa) are later colonized.

Anthocoridae that occur on plants insert their eggs into plant tissues. Species that attack aphids or scale insects on coniferous trees insert their eggs into the needles, whereas those species that inhabit the foliage of deciduous plants often insert the eggs into leaf tissues. Anthocoridae that occur under bark insert their eggs into the inner surface of the bark, into rotting wood, or into cracks in the bark. Species of *Xylocoris* that inhabit manure piles insert their eggs into cracks in the manure, whereas those species that inhabit straw piles insert their eggs into the decaying straw. In species having a reduced or vestigial ovipositor (e.g., *Cardiastethus*), eggs are deposited on the substrate near prey. Lifetime egg production per female is highly variable even within species, and is probably affected extensively by diet quality. Lifetime estimates of fecundity obtained from laboratory trials are available for *Anthocoris* (70–220 eggs), *Cardiastethus* (35–45 eggs), *Lyctocoris* (95 eggs), *Montandoniola* (50–150 eggs), *Orius* (90–130 eggs), and *Xylocoris* (20–80 eggs).

The pirate bugs have hemimetabolous development, in which the immatures (nymphs) undergo incomplete metamorphosis, and resemble the adults morphologically except in lacking wings, ocelli, and reproductive structures. Nymphs have five instars. Development rates of eggs and nymphs increase with increasing temperature. Anthocoridae in temperate regions overwinter as adults in reproductive diapause. For those species which have been examined, diapause is controlled by photoperiod, with long days prompting reproduction and short days leading to diapause. The critical photoperiod that prompts diapause for a given species may often depend upon latitude. Sex ratios for overwintering adults are often female-biased, and in some Anthocoridae the males appear not to overwinter. Most species of Anthocoridae have two or more generations per year depending upon latitude and elevation. Some species (e.g., *Anthocoris gallarumulmi*) appear to be univoltine throughout their respective geographic ranges.

Reproduction, Mating, and the Paragenital System

The pirate bugs have several reproductive traits and associated structures that differ from most other Heteroptera. Unlike most Heteroptera, the Anthocoridae, Lyctocoridae, and Lasiochilidae (plus some related taxa such as the Cimicidae) have fertilization of the eggs occurring within the vitellarium of the ovaries, rather than in the genital ducts. The anthocorid egg lacks micropyles, and fertilization takes place before the chorion is deposited. Oocyte maturation is inhibited in unmated females. Unfertilized eggs generally degenerate and are resorbed before they reach maturation, and unmated females deposit few or no eggs.

The Anthocoridae and related taxa have evolved a number of unique reproductive structures that are used extensively by taxonomists in developing classification schemes and in defining phylogenetic affinities among higher level taxa (Table 10). In the Anthocoridae and Lyctocoridae, insemination of the female by the male is not done via the usual route through the female genitalia.

Minute Pirate Bugs (Hemiptera: Anthocoridae), Table 10 Comparison of reproductive traits and structures (including the female paragenital system) among Lasiochilidae, Lyctocoridae, and Anthocoridae

	Lasiochilidae	Lyctocoridae	Anthocoridae
1. Insemination	1. intragenital	1. extragenital	1. extragenital
2. Intromittent organ	2. phallus	2. phallus with acus	2. paramere and/or phallus
3. Paragenital system	3. none	3. spermalege	3. spermalege, often in form of copulatory tube(s)
4. Site of copulation	4. female's genital opening (intragenitalic)	4. between segments VII-VIII to right of genital opening	4. variable
5. Sperm storage	5. bursa copulatrix	5. seminal conceptacles	5. seminal conceptacles or spermatic pocket

Rather, insemination occurs outside of the reproductive tract, within the abdominal cavity, and is thus referred to as extragenital insemination. The sperm migrate through the haemocoel or through specialized structures in the female (see below) to the ovaries, and fertilize the developing egg within the vitellarium before deposition of the chorion. It is not clear what evolutionary pressures have led to extragenital insemination in the Anthocoridae or other taxa showing this trait, but it has been suggested that it is a means by which the male circumvents female resistance or bypasses female control of sperm allocation and egg fertilization.

Characteristics of the reproductive system show some similarities and some differences among the Lasiochilidae, Lyctocoridae, and Anthocoridae, and these traits have been used extensively in assessing phylogenetic affinities among these groups. The Lasiochilidae differ from the Anthocoridae and Lyctocoridae in that insemination is of the more typical insect type, occurring within the female's reproductive system (i.e., intragenital insemination), as opposed to the extragenital insemination characteristic of the Anthocoridae and Lyctocoridae. In all three families, the male genitalia are asymmetric. The right paramere is highly reduced or is absent. The intromittent organ in the Lasiochilidae and Lyctocoridae is the phallus. In the Lyctocoridae, the apex of the phallus is sclerotized and in the form of an acus (needle), used to penetrate the abdominal wall of the female for insemination ("traumatic insemination"). For the Anthocoridae, the left paramere or the phallus acts as the intromittent organ. In the Oriini, for example, a portion of the left paramere (the flagellum) is inserted within a specialized female organ (the copulatory tube, as discussed below), and the short membranous phallus slides along the paramere to deposit sperm. The paramere itself may be of quite complex shape in the Oriini, and in fact is used extensively in differentiating species of *Orius* within some difficult species complexes. The Anthocorini exhibit a different strategy. In these species, the paramere is reduced to a relatively simple, sickle-like organ, which is inserted only partially within the copulation site of the female. The male then inflates his long, membranous phallus through the female's copulatory tube to deposit sperm. In the Xylocorini, the left paramere is sharply pointed, and is used to pierce the abdominal wall of the female at the copulation site. Copulation may actually lead to scars that are visible on the surface of the female.

Extragenital insemination in the Anthocoridae and related taxa has led to the evolution in females of structures collectively referred to as the paragenital system (spermalege). These organs are thought to have evolved as a means for the female to reduce costs associated with traumatic insemination, caused by wounding of the cuticle at the copulation site or by the introduction of infections and infectious agents within the haemocoel of the female as the male inseminates her. The spermalege consists of simple to complex structures that act to guide the male's intromittent organ to a specific insemination site (the ectospermalege), and to receive the sperm (the mesospermalege). In some taxa (e.g., the Anthocorini and Oriini), the ectospermalege consists of a specialized copulatory tube, produced as an invagination of the epidermis that opens between sternites VII-VIII on the ventral surface of the female, just lateral of the female's genital opening. The copulatory tube receives the paramere and phallus (as in the Oriini) or phallus (as in the Anthocorini). The distal end of the copulatory tube enters a pouch (spermatic pocket or sperm pouch), which acts to temporarily store the sperm. In the Lyctocoridae, newly deposited sperm collect first in the mesospermalege (a collection of specialized cells at the copulation site), and then migrate through the haemocoel to the sperm storage structures at the base of the ovaries. In the Xylocorini, the mesospermalege may be partially open or completely enclosed. If the mesospermalege is partially open, sperm move from the mesospermalege into the haemocoel, and migrate through the haemocoel to the sperm storage sites at the base of the ovaries. If the mesospermalege is completely enclosed, the structure extends to and connects with the sperm storage structures.

The actual site of copulation in the Anthocoridae and related taxa is highly variable. In the Lasiochilidae, which lacks a paragenital system, insemination takes place within the female's genital tract. In the Lyctocoridae, the male pierces the female on her ventral side between segments VII and VIII, to the right of the female's genitalic opening. Within the Anthocoridae, site of copulation varies among tribes. In the Oriini and Anthocorini, the copulatory tube opens between abdominal segments VII and VIII on the female's ventral side, usually to the left of her genital opening. Female Blaptostethini actually have paired copulatory tubes, located on her ventral side between abdominal segments VII and VIII. In the Xylocorini, the site of copulation in some species is on the dorsal side of the female, towards the anterior end of the abdomen, while in other species copulation takes place on the lateral (right) side of the abdomen.

The spermatheca is reduced to a small vermiform gland having no sperm storage function (Lasiochilidae), or is absent altogether (Lyctocoridae and Anthocoridae). In the Lyctocoridae, sperm travel from the spermalege at the site of insemination through the haemocoel into sperm storage organs (seminal conceptacles) located at the base of the ovaries. In the Anthocoridae, sperm are stored either in the sperm pocket (species having copulatory tubes: Oriini, Anthocorini, Scolopini, Blaptostethini) or in seminal conceptacles (Xylocorini). The seminal conceptacles in the Xylocorini and Lyctocoridae are not homologous, as they derive from different tissues in the two taxa. From the sperm storage organs (sperm pocket or seminal conceptacles), the sperm move to the ovaries through specialized conducting tissues, and fertilize the eggs within the vitellarium.

Economic Importance

The pirate bugs are sources of biological control in annual and perennial crops, in forests, in greenhouse crops, on ornamental plants, and in stored products. Several species of *Anthocoris* are known important sources of biological control in temperate fruit orchards, where they feed extensively on pest psyllids and aphids. Species of *Orius* occur in greenhouses and in a variety of row crops, where they feed on thrips, mites, aphids, and eggs of pest Lepidoptera. These predators may be particularly important natural enemies of flower thrips. *Xylocoris* and *Lyctocoris* attack beetle and moth pests in stored products and granaries. Aphid and scale pests that inhabit the canopies of coniferous trees are attacked by *Elatophilus*, *Tetraphleps*, *Melanocoris*, and *Acompocoris*, whereas bark beetle pests are fed upon beneath bark by species of *Xylocoris*, *Scoloposcelis*, and *Lyctocoris*. Other species are important natural enemies of pests on ornamental plants, including *Montandoniola*, *Macrotrachelia*, and *Macrotracheliella* on ornamental fig (*Ficus*), where they feed on the Cuban laurel thrips (*Gynaikothrips ficorum* (Marchal)). Species reared in insectaries for shipment and release include *Orius insidiosus*, *Orius laevigatus* (Fieber), *Orius majusculus* (Reuter), and *Anthocoris nemoralis*.

The Anthocoridae have been used in a number of classical biological control efforts. Classical biological control is the importation and release of exotic natural enemies for controlling non-indigenous pests. *Anthocoris nemoralis*, a species native to Europe, was released into western North America in the early 1960s to control an introduced psyllid pest of pears (*Cacopsylla pyricola* (Förster)). The predator is now established in British Columbia, Washington, Oregon, and California. Its effectiveness in controlling the psyllid pest of pears, however, is unclear. The North American *Orius insidiosus* has been introduced into Europe and Hawaii for controlling Thysanoptera and Lepido-ptera, and is established in Hawaii. *Montandoniola moraguesi* (Puton) is native to southeast Asia, but has been released in southern California, Texas, Bermuda, and Hawaii to control Cuban laurel thrips. The predator has become established in Bermuda and Hawaii, apparently as a consequence of these introductions. Two species of *Tetraphleps* were introduced into North America from India and Pakistan for control of the balsam woolly aphid (*Adelges piceae* (Ratzeburg)), a non-indigenous pest of various coniferous trees. Apparently neither species became established.

A number of species have become established outside of their native ranges because of accidental introductions or dispersal. Effects of these introductions upon native predators (via competition) and native prey (via predation) are unknown, but are potentially important. There has been speculation, for example, that *Anthocoris nemoralis*, which was introduced intentionally into North America from Europe but which has moved into habitats other than the target pear orchard, may compete with native *Anthocoris* species. Species that associate with stored food products (*Lyctocoris*, *Xylocoris*) have spread dramatically outside of their native ranges, apparently because of human commerce. These and other species of Anthocoridae are regularly intercepted at ports-of-entry on transported flowers, fruits and vegetables, or on other plant materials. As of 1999, it was thought that more than 50% of the anthocorid fauna in Hawaii was non-indigenous, with many of the exotic species arriving because of accidental introductions. *Montandoniola moraguesi*, which has been used extensively in classical biological control efforts against thrips on *Ficus*, is now established in the southeastern United States, apparently because of accidental introduction or natural dispersal. In North America, non-indigenous species that have become established because of apparent accidental introductions or natural dispersal can be found in the genera *Anthocoris*, *Brachysteles*, *Buchananiella*, *Dufouriellus*, *Lyctocoris* (Lyctocoridae), *Montandoniola*, *Orius*, *Temnostethus*, and *Xylocoris*. Effects of these exotic species on North American ecosystems are unknown.

Mite Pests of Crops in Asia

CHYI-CHEN HO
Taiwan Agricultural Research Institute, Wufeng, Taichung, Taiwan

Acarine pests of agricultural crops include mites in the families Tetranychidae, Tenuipalpidae, Tarsonemidae, Eriophyidae, and Acaridae. Members of all these families are reported to damage various crops in Asia. Among the damaging species are *Amphitetranychus viennensis*, *Eotetranychus cendanai*, *Eo. kankitus*, *Eotetranychus pruni*, *Eotetranychus sexmaculatus*, *Eutetranychus africanus*, *Eu. orientalis*, *Oligonychus coffeae*, *O. litchii*, *O. mangiferus*, *Panonychus citri*, *P. ulmi*, *Petrobia latens*, *Tetranychus cinnabarinus*, *T. fijiensis*, *T. hydrangeae*, *T. kanzawai*, *T. macfarlanei*, *T. piercei*, *T. truncatus*, *T. urticae* (Tetranychidae); *Brevipalpus californicus*, *B. obovatus*, *B. phoenicis*, *Dolichotetranychus floridanus*, *Larvacarus transitans*, *Tenuipalpus pacificus*, *Raoiella indica* (Tenuipalpidae); *Phytonemus pallidus*, *Polyphagotarsonemus latus*, *Steneotarsonemus bancrofti*, *S. spinki* (Tarsonemidae); *Acaphylla theae*, *Acaspina litchii*, *Aceria cajani*, *A. doctersi*, *A. eriobotrya*, *A. litchi*, *A. mangiferae*, *A. sheldoni*, *A. tulipae*, *Aculops lycopersici*, *Aculus schlechtendali*, *Eriophyes litchii*, *Phyllocoptruta oleivora* (Eriophyidae); *Rhizoglyphus echinopus*, *R. robini*, *R. setosus* (Acaridae).

Among them, *Amphitetranychus viennensis*, *T. urticae*, *T. cinnabarinus*, *P. citri*, *P. ulmi*, *O. coffeae*, *B. obovatus*, *B. phoenicis*, *B. californicus*, *Polyphagotarsonemus latus*, *Phytonemus pallidus*, *Phyllocoptruta oleivora*, and *A. tulipae* are worldwide-distributed species and are commonly found from East Asia. These species are important pests of a wide range of crops. Many of them are notorious in having developed resistance to various acaricides. In addition, *T. urticae*, *B. phoenicis*, *B. californicus*, and *A. tulipae* are known to be able to transmit virus diseases of plants. Distribution of *Amphitetranychus viennensis* is limited to the temperate zone or, in subtropical areas, to high elevations with cold climates.

Tetranychus kanzawai is another notorious polyphagous mite pest distributed commonly in

East Asia, but is rarely recorded from other area of the world. *Tetranychus truncatus* is recorded from the Far East and Southeast Asia, and is not considered to be a serious crop pest except in China and Thailand. *Eutetranychus orientalis* has been recorded from most Asian countries, mainly infesting citrus. However, it is not considered an important pest in Japan and Taiwan.

The other mites either are recorded as pests from limited countries, or have a narrow host range. *Petrobia latens* infests wheat, barley, sorghum, grasses, and a few other crops and is known from China, India, Japan, Korea, and Taiwan. *Aceria mangiferae* and *O. mangiferus* mainly infest mango and are recorded only from a few Asian countries, though mango is commonly cultivated in southern Asia. *Eotetranychus kankitus*, *Eo. pruni*, and *Eo. sexmaculatus* damage citrus, apple, and citrus and rubber trees in China, respectively. *Aceria cajani* transmits the sterility mosaic virus disease of pigeon pea in India and neighboring countries. *Aceria doctersi* decreases the oil content of cinnamon (*Cinnamomum zeylanicum*) leaves in Indonesia and Sri Lanka by 18–43%. *Aceria sheldoni* and *Aculops lycopersici* are mainly recorded from west Asia. The former species infests citrus. The latter infests tomato and several other crops of Solanaceae, and may cause serious reductions in yield of tomato. *Aculus schlechtendali* is a pest of apple and pear, and is recorded from Japan, India, Pakistan, and Lebanon. *Eutetranychus africanus* is an important pest of durian, a well-known, peculiar fruit produced in several countries of Southeast Asia. *Eotetranychus cendanai*, *T. hydrangeae*, *T. macfarlanei*, and *T. fijiensis* also are important crop pests in Thailand.

Aceria eriobotrya infests the tip of loquat twigs. *Eriophyes litchii* and *Acaspina litchii* cause leaf erenia to litchee. *Larvacarus transitans* is a serious pest of ber in India. *Dolichotetranychus floridanus* is a pest of pineapple. *Raoiella indica* infests betelnut and coconut. *Steneotarsonemus bancrofti* scars the surface of sugarcane. Infestation of *Oligonychus uruma*, *Schizotetranychus nanjingensis*, and *Aponychus corpuzae* can cause the death of entire bamboo forests.

Rhizoglyphus echinopus, *R. robini*, and *R. setosus* are recorded only from a few Asian countries. The former two species are distributed worldwide, and are infamous in being difficult to control. They may be distributed in more Asia countries than their current distribution record, as may *R. setosus*.

Mites (Acari)

LEWIS B. COONS, MARJORIE ROTHSCHILD
The University of Memphis, Memphis, TN, USA

Mites belong to the subclass Acari, the largest and most diverse group in the class Chelicera. Because of their small size and secretive lives, much remains to be known about their biology and classification. Mites are distributed worldwide. Some species are of great economic importance as pests of agricultural crops and vectors of important diseases of man, domestic animals and plants.

Evolution and Diversity of Mites

Mites are an ancient group of chelicerates. The earliest known mite fossils are from the Devonian period of geologic time. The fossil record suggests that during the late Mesozoic to early Cenozoic an adaptive radiation of mites occurred with the development of many nonpredatory species. Flowering plants and insects as well as birds and mammals became more widespread during this same period, providing many novel habitats for mites to exploit.

Mites are distributed throughout the world and inhabit almost every ecosystem. They play an important ecological role as inhabitants of the forest floor and soil where they are secondary decomposers of organic matter. Mites are vectors of diseases that affect humans, livestock and crops, and are stored product pests and crop pests.

Mites can be broadly divided into free living and parasitic species. Free living species are by far the most common and are found in all the orders with the exception of the Ixodida (ticks). Ecto and endoparasitic mites attack both vertebrates and invertebrates. Most of endoparasitic species found on vertebrates reside within the respiratory tract. Mites are the most common arthropod ectoparasites of vertebrates, and humans. Species of the human follicle mite *Demodex* are present on most people throughout the world.

Generalized Life History

All mites pass through the same four life stages, egg, larva, nymph and adult, but much variation occurs within the active stages. The most common active stages include a prelarva, larva, protonymph, deutonymph, tritonymph, and adult. A molt occurs between each stage. During the molt, the old cuticle is cast off and replaced by a new one.

The prelarva is the most primitive postembryonic form and commonly remains within the egg. It is usually a nonfeeding quiescent stage. Larvae of most species are six legged. Larvae lack external genital openings and are not well sclerotized. They have few useful taxonomic characteristics. Most larvae are active feeding forms.

Nymphs are eight legged and their body is more sclerotized and has more taxonomic characteristics than larvae, making them easier to identify. The protonymph is the first nymphal instar after the larvae. Protonymphs are usually found in the same type of environment as are other nymphal instars. The protonymph can be either an active or inactive feeding stage depending on the species. The deutonymph is the next nymphal instar. This stage is like the adult in size and design, but often differs in having a less complex sclerotization and setal pattern. The final nymphal instar is a tritonymph. In its absence the deutonymph molts into an adult. The adult forms can be similar (homomorphic) or dissimilar (heteromophic) in one or both sexes, and various male forms (andropolymorphism) are found in a few groups. Molting is rare during the adult stage but occurs in some species.

Classification: The Orders of Mites

There are over 30,000 named species of mites (Table 11) and possibly up to a million unknown species. A list of the major taxa of the Acari follows.

Most scientists divide the Acari into two major groups, the Anactinotrichida and the Actinotrichida. We consider the Anactinotrichida and Actinotrichida superorders, and the major groups within each as orders. Traditionally, the position of the respiratory opening, the stigmata has been used to name the major groups within the two superorders. However, as discussed under the different orders, this system is ambiguous and has mostly been abandoned for a terminology that ends in "–ida." Many of the orders that use the position of the stigmata are now lesser taxa.

Anactinotrichida

"Anactinotrichida" refers to the lack of a birefringent material in cuticular setae. The Anactinotrichida is divided into four orders, the Oplioacarida, Holothyrida, Ixodida, and Gamasida. Some scientists group the Holothyrida, Ixodida and Gamasida as the Parasitiformes and separate out the Oplioacarida

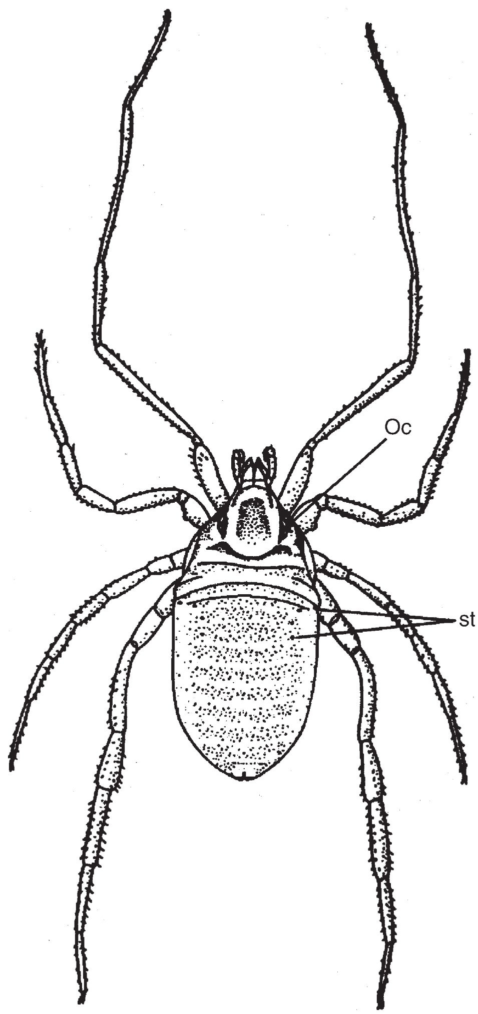
because they appear to be the most primitive mite group. Others group only the Gamasida and the Ixodida as the Parasitiformes (Fig. 57).

Oplioacarida

These are relatively large mites, greater than 1 mm in length, with a leathery cuticle. They resemble the opilones or daddy long-legs. This is the smallest order of mites. One family is recognized,

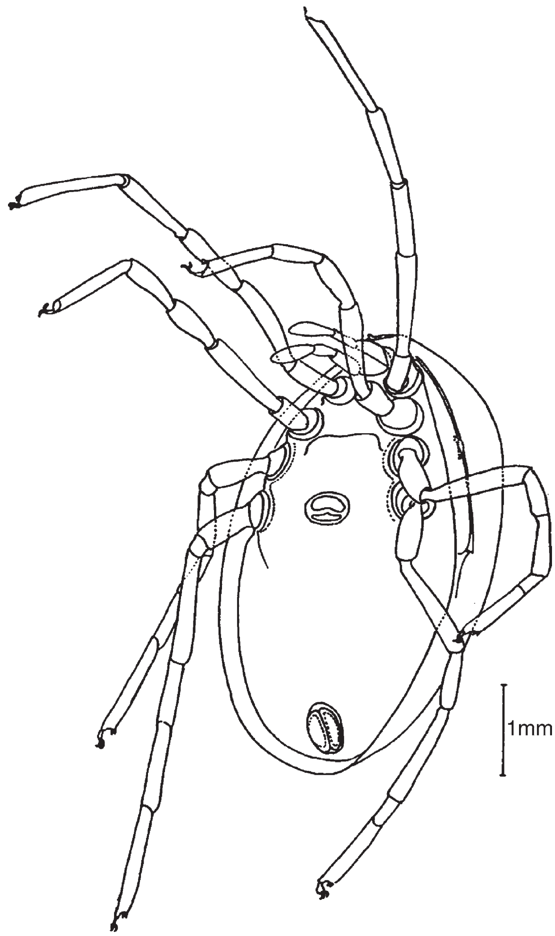


Mites (Acari), Figure 57 Dorsal view of *Opilioacarus segmentatus* (Anactinotrichida, Opilioacarida) *Oc*, ocelli; *st*, stigmata (from Alberti G,Coons LB (1999) The Acari-mites, used with permission of John Wiley and Sons, Inc).

with eight genera and about 20 species. Oplioacarids often have bright pigments distributed in bands across their bodies. The life stages consist of a six-legged quiescent prelarva that molts into a larva. Opiloacarid larvae are unusual in that they have vestiges of the fourth pair of legs. The larva molts into a protonymph, which molts into a deutonymph then a tritonymph which molts into an adult. Adults are unusual in that they may continue to molt. These mites are considered omnivorous, feeding on both small insects and pollen, but they may also be scavengers. Oplioacarids are distributed in Texas in the USA, through South America, the island of Puerto Rico, central Asia through to Africa and southern Europe. They are found especially in semiarid regions where they often are found in the forest litter or dark places such as under rocks, particularly during the day. Oplioacarida are sometimes known as the Notostigmata since they have four pairs of stigmata on the dorsolateral body.

Holothyrida

The Holothyrida have three families, six genera and about 15 species. Holothyrids are found in Australia, New Zealand, islands in the Indian and Pacific Oceans, and the Neotropics. These are large predatory mites that vary in length from about 2–7 mm. The life stages are larva, protonymph, deutonymph, tritonymph and adult. Holothyrids are moderately to heavily sclerotized mites with long legs and an oval body that shows no visible subdivisions. Holothyrids (Fig. 58) are closely related to the Ixodida. They have a sensory area on their first pair of legs that resembles Haller's organ of ixodids. Holothyrids are found under stones or in humus in tropical forests around the world. They may be scavengers that mostly eat solid food such as dead woodlice and amphipods. These mites have been implicated in poisonings of poultry and humans. Holothyrida were previously known as the Tetrastigmata despite the fact that they have only two pair of stigmata.



Mites (Acari), Figure 58 Ventro-lateral view of *Holothyrus coccinella* (Holothyrida) (from Hughes. 1959. Mites or the Acari, used with permission of The Athlone Press).

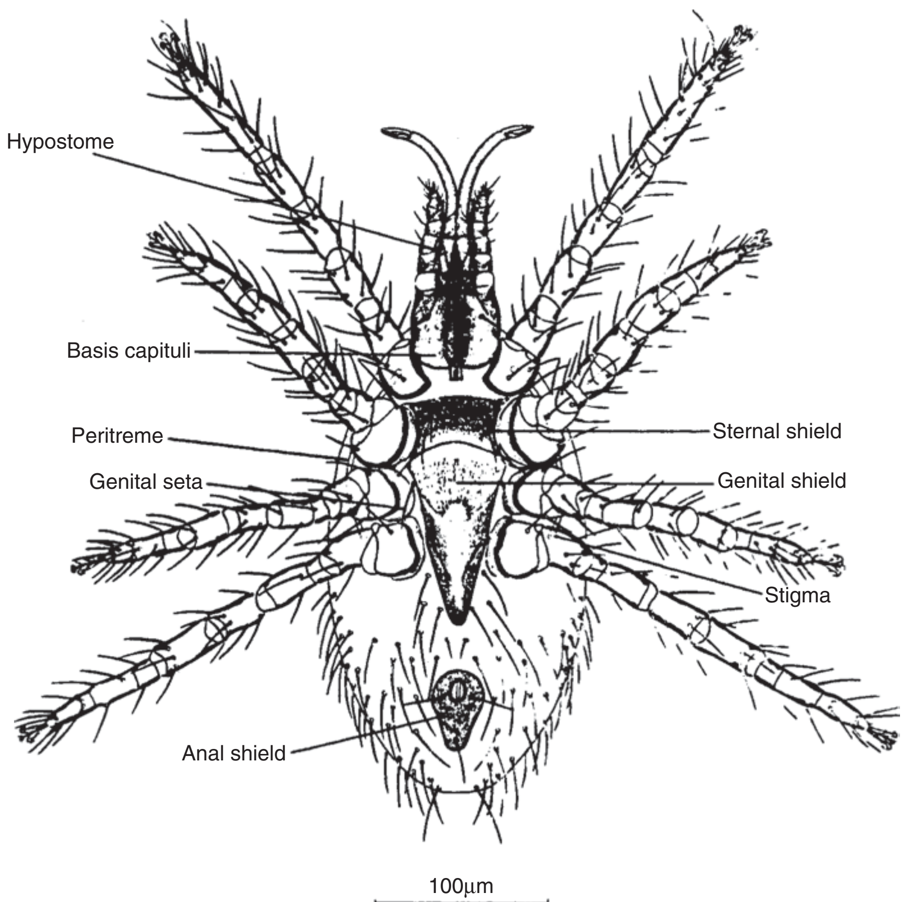
Ixodida

Ixodids or ticks are obligatory blood feeding ectoparasites of vertebrates. Ticks are found worldwide. They are divided into three families, the Argasidae or soft ticks, the Nuttalliellidae with one species, and the Ixodidae or hard ticks. Some 850 species have been described. They transmit serious diseases to humans, livestock and companion animals. Ixodida were previously known as the Metastigmata, however the stigmata are found behind the fourth pair of legs only in the hard ticks while soft ticks have the stigmata between the third and fourth pair of legs. Ticks are covered in a separate entry.

Gamasida

This is the most diverse order and contains the largest number of species in the Anactinotrichida. There are some 77 families divided into 11 subgroups with about 5,000 species. Gamasids are found worldwide in diverse habitats. A typical gamasid life cycle consists of an egg, and four active stages: larva, protonymph, deutonymph and adult. The most common variation on this life cycle is the occurrence of a nonfeeding larval stage and a phoretic stage in the deutonymph. Gamasids range in size from 0.2 to 2.0 mm in length. They are often highly sclerotized with several cuticular shields such as the sternal, genital and anal shields (Fig. 59) that are useful as taxonomic characters as are the positions and number of setae. Setae are hairlike projections of the cuticle and are common on many mites in both superorders. These taxonomic characters are also used throughout the Acari. The Gamasida are still known by some acarologists as the Mesostigmata since they have a pair of stigmata dorsolateral or ventrolateral to the legs.

Most Gamasida are free living predaceous or fungivorous soil-inhabiting mites or are epizoons, attached to the body of arthropods, or commensals with other arthropods. Commensals benefit from a common food supply but do not harm the



Mites (Acari), Figure 59 Ventral view of female tropical poultry mite *Ornithonyssus bursa* (Gamasida, Dermanyssoidea, Macronyssidae) (from Kettle DS (1995) Medical and veterinary entomology, used with permission of CAB International).

other species. Some gamasids are parasites of vertebrates and invertebrates.

The Cercomegistina are made up of four families that are mostly free living mites in litter and humus, but the species of one family are associated with other arthropods. The Antennophorina are divided into six superfamilies with mites that are associated with arthropods, lizards or snakes. The Heterozerconina comprise two families that are commensals or parasites on millipedes, centipedes or snakes. Very little is known about these curious mites. The Sejina contain three families that are associated with other arthropods or found in forest litter or the nests of vertebrates but otherwise their biology is not known. They are distributed worldwide. The little known Microgyniina have a single family found in woody debris in the Holarctic Region.

The Uropodina, with four superfamilies, are found throughout the temperate and tropical zones where they occur mostly in forest litter. Some are seashore dwellers. Species in this group are fungivores, scavengers or predators. Species of Uropodina have phoretic deutonymphs. The Diarthropalloidea, a superfamily of Uropodina, are parasitic on passalid beetles and are distributed in the neotropical and Australian zones. The Epicriina, Zerconina and Arctacarina, each with one family, have similar distributions and habitats. They are found in the northern hemisphere in leaf litter and humus. Their biology is poorly known. The Parasitina contain two families whose species are common in soils and organic debris throughout the world. They are associated with insects or are predators of smaller arthropods and nematodes.

The Dermanyssina, with five superfamilies, have the largest number of species and the most diversity in the Gamasida. This is the only subgroup of Gamasida that contains species of medical and veterinary importance. Parasitic mites of the Dermanyssoidea often have highly modified external morphology and life cycles. The superfamily Rhodacaroidea make up the dominant gamasid predators in tropical soils. The superfamily Veigaioidea contains a single family of predatory mites found in mosses and litter in temperate forests. The superfamily Eviphidoidea are mostly free-living mites found in litter and humus of soils or are associates of other arthropods. This superfamily contains several species of mites that are used as biological control agents. The superfamily Ascoidea are a diverse assemblage of mites. *Phytoseiulus persimilis* (Ascoidea: Phytoseiidae) is used as a biocontrol agent against red spider mites (Tetranychidae) (Fig. 62) in greenhouses. The superfamily Dermanyssoidea includes many economically important parasites as well as predatory species found in nests or in the soil, and contain all gamasid species of medical or veterinary importance. The Dermanyssidae, Macronyssidae, Spinturnicidae, and Histrichonyssidae are parasites that feed on the blood of birds and mammals. The families Halarachnidae and Rhinonyssidae are parasites of the respiratory tracts of birds and mammals. The family Varroidae contains the bee parasite *Varroa destructor* which is further described in the section on "Bee mites."

Actinotrichida

"Actinotrichida" refers to the presence of a birefringent material in cuticular setae. Some workers use the name Acariformes for Actinotrichida. The Actinotrichida contain the largest number of species and has the most morphological and ecological diversity of the two superorders. There are three orders in the Actinotrichida, namely, Actinedida, Oribatida and Acaridida. The last two orders are closely related and are referred to by some workers as Sarcoptiformes.

Actinedida

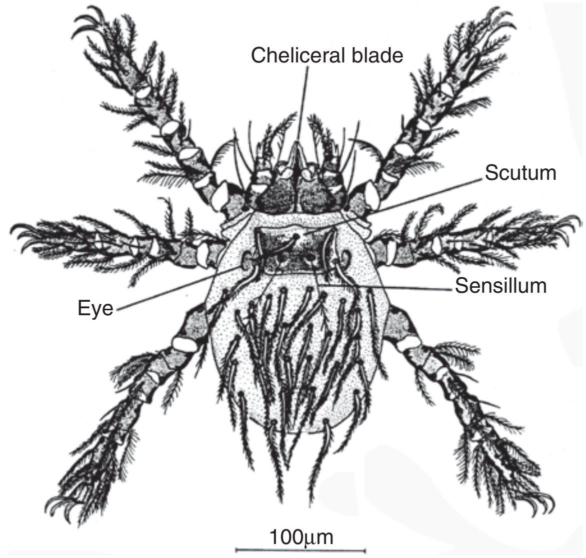
This is the largest order of mites with some 136 families, over 1,100 genera and more than 14,000 species so far described. Unfortunately, the higher classification of this important group is not settled. Actinedids are distributed worldwide in terrestrial, freshwater and marine habitats. They range in size from about 0.1–16 mm. Most Actinedida are soft bodied mites, but heavily sclerotized species occur in some families and there is a wide range of intermediates between the soft-bodied and sclerotized forms. The Actinedida is divided into the Endostigmata and the Prostigmata.

The Endostigmata contain 12 families and is considered to be the most primitive Actinedida. These are small soft bodied free living mites that occur in humus, litter and soil in South Africa. They are believed to be predaceous or microphytophagous.

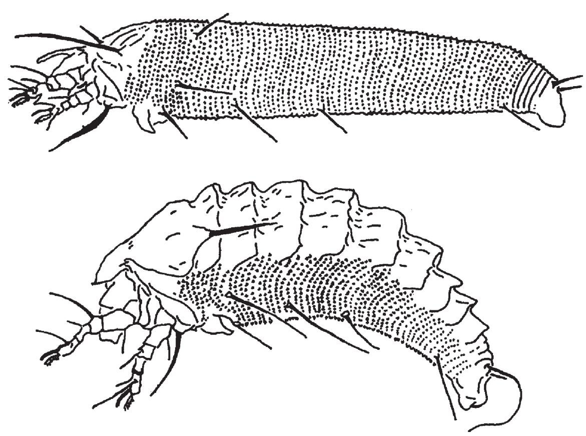
The Prostigmata are divided into three subgroups, the Anystina, Eupodina and Eleutherengona. The Anystina are mostly free-living predators that occur in soil litter, on vegetation and on the seashore. The Parasitengona are a large group of mite species in which most species have a parasitic larva. The Trombidia contain three superfamilies among which are the Trombidioidea with the family Trombiculidae whose larval forms or chiggers are important parasites of terrestrial vertebrates and man (Fig. 60). The other life stages are predators on small invertebrates. The Hydrachnidia contain eight superfamilies. These are freshwater mites, although one family, the Pontarachnidae have secondarily spread into marine habitats.

The Eupodina is the second group and consists mostly of free-living mites. The superfamily Bdelloidea contain the snout mites that prey on other mite species. Some species of snout mites use silk to capture their prey and many spin a cocoon for use during molting. The superfamily Halacaroidea contain marine mites with some freshwater forms. The family Penthaleidae has one species of economic importance, the winter grain mite *Penthaleus major*. The Eriophyoidea (Fig. 61) are plant pests that cause severe damage and can induce gall formation.

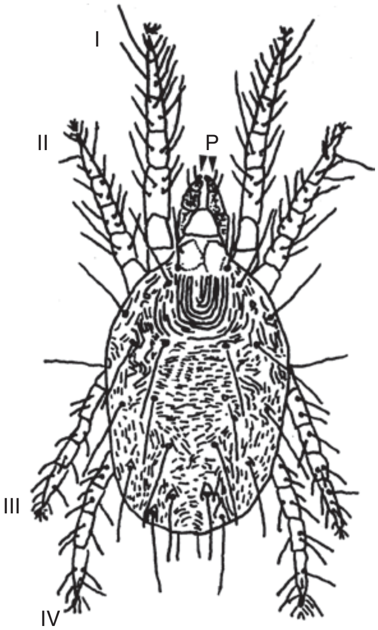
The Eleutherengona are found in various habitats. Spider mites of the superfamily Tetranychoidea are worldwide in distribution. Many species are serious pests of plants. Some produce galls and other types of plant damage (Fig. 62). Some species



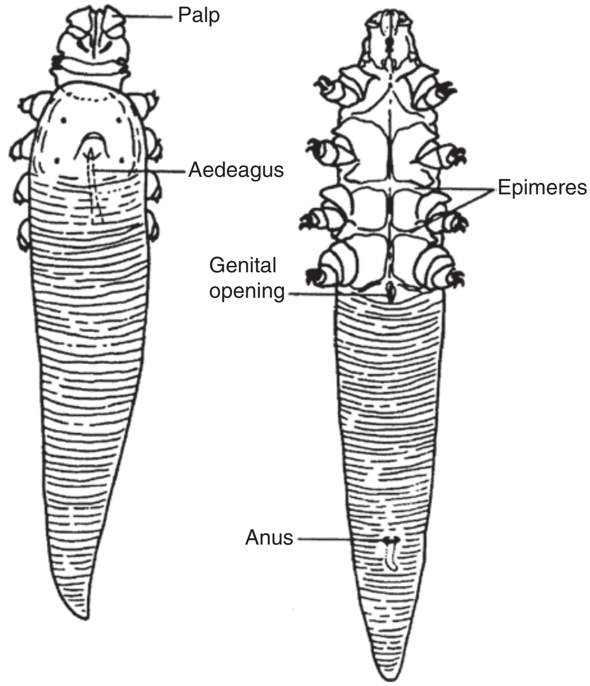
Mites (Acari), Figure 60 **Dorsal view of the larva or chigger of *Leptotrombidium deliense* (Actinedida, Trombidioidea, Trombidiidae), a vector of chigger borne typhus. (from Kettle DS (1995) Medical and veterinary entomology, used with permission of CAB International).**



Mites (Acari), Figure 61 **The two principal body types of Eriophyoidea (Actinedida, Eupodina). *Phytoptus leucothonius* (*top*) with a vermiform body and *Anthocoptes helianthella* (*bottom*) with a fusiform body (redrawn from Lindquist et al. (1996) Eriophyoid mites: their biology, natural enemies, and control, used with permission of Elsevier Science).**



Mites (Acari), Figure 62 **The spider mite *Tetranhychus urticae* (Actinedida, Tetranychoidea). Legs are numbered I, II, III, IV (redrawn from Evans GO, Sheals JG, Macfarlane D (1961) The terrestrial Acari of the British Isles, vol 1. British Museum of Natural History).**

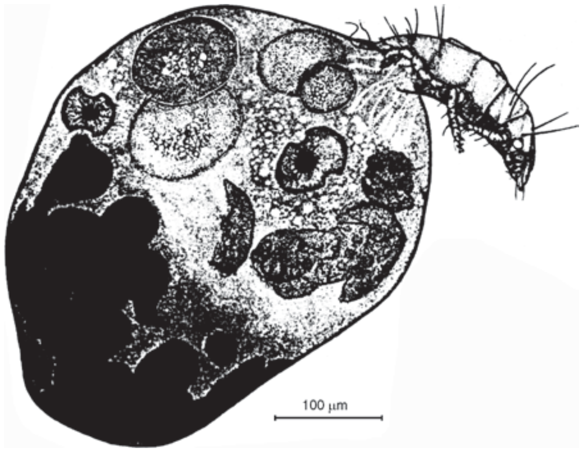


Mites (Acari), Figure 63 **Dorsal view of male (*left*) and female (*right*) *Demodex* (Actinedida, Cheyletoidea, Demodicidae) (from Kettle DS (1995) Medical and veterinary entomology, used with permission of CAB International).**

are the only known mites to transmit plant viruses. An inactive period occurs between each of the final three life stages. During this inactive period, the larva or nymph uses silk to anchor itself to the plant. Spider mites have the capability of rapidly colonizing plants. This ability comes from the large number of generations produced during a given season and not from fecundity. Two heteromorphic females may be produced, the specialized overwintering form, and the typical female form. The superfamily Cheyletoidea are ectoparasites of birds and mammals, and contain the follicle mites. These are further discussed in the section on "skin parasites." Mites of the family Cloacaridae are found in the cloaca of turtles. The superfamily Raphignathoidea contain mostly predaceous mites and species that are pests of plants. The superfamily Pterygosomatoidea contains species that are mostly parasites on other arthropods or on lizards. The superfamily Pomerantizoidea are mostly free living predators in soil litter and humus. The Tarsonemina are small mites from 200 to 600 μm in size. They have unusual life histories and reproductive strategies. Physogastry, a type of reproduction where eggs develop in the female, is found in many parasitic tarsoneminids. In some species, the entire postembryonic development occurs within the female or the eggs transform directly into adults. The physogastric genus (Fig. 64) *Pyemotes* of the family Pyemotidae has a life cycle where all post embryonic development occurs within the body of the female. Some members of the family Pyemotidae are predators of insects of both positive and negative economic importance.

Oribatida

The Oribatida are known as beetle mites (Figs. 65–68) from their outward appearance, or moss mites from their habitats, or box mites from



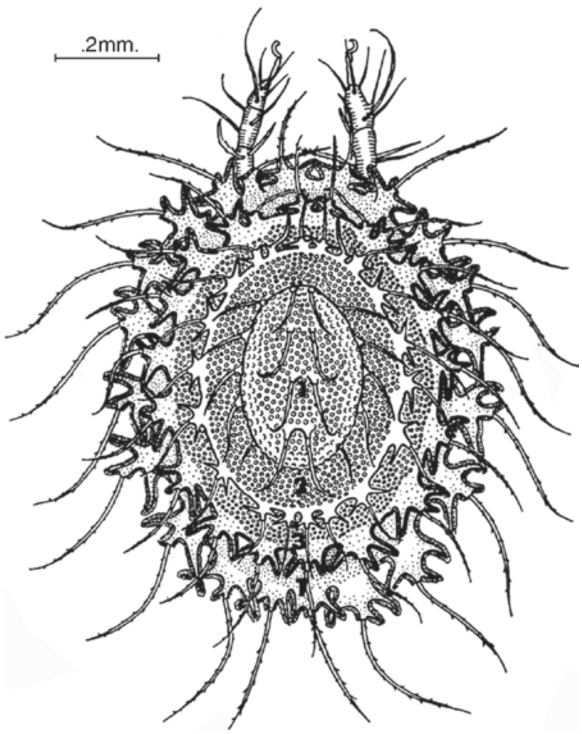
Mites (Acari), Figure 64 Lateral view of a gravid *Pyemotes tritici*. The opisthosoma is the swollen posterior area behind the legs containing eggs and offspring (from Kettle DS (1995) Medical and veterinary entomology, used with permission of CAB International).

Mites (Acari), Figure 65 *Phthiracarus* sp. (Oribatida, Phthiracaroidea), a box mite. When attacked, the mouthparts (gnathosoma) and retracted legs are covered by an operculum-like aspis (arrows), and the lateral body parts are covered by cuticular plates or pteromorphs (arrowheads) (redrawn from Alberti G, Coons LB (1999) The Acari-mites, used with permission of John Wiley and Sons, Inc.).

their ability to (Fig. 65) cover their retracted legs with their body. There are some 150 families, over 1,000 genera, and more than 7,000 described species of Oribatida. The order is divided into the

Mites (Acari), Figure 66 The oribatid *Eupelops torulosus* has a well developed cerotegument or secretion layer (CR) that covers the body surface (S), and movable cuticular plates or pteromorphs that cover lateral body parts (arrowheads) (redrawn from Alberti G, Coons LB (1999) The Acari-mites, used with permission of John Wiley and Sons, Inc.)

Mites (Acari), Figure 67 The oribatid *Heterochthonius gibbus* (Heterochthonioidea, Heterochthoniidae), a beetle-like mite. Note the eyes (arrowheads). The long dorsal setae are able to erect (from Alberti G, Coons LB (1999) The Acari-mites, used with permission of John Wiley and Sons, Inc).



Mites (Acari), Figure 68 **A tritonymph (T) of the oribatid *Cepheus dentatus* (Cepheoidea, Cepheidae) with three scalps on its dorsum, one from each of its previous instars, larva (1), protonymph (2), deuteronymph (3) (relabeled from Hughes TE Mites of the Acari, used with permission of The Athlone Press).**

Macropylina, also known as lower oribatids or Archoribatida, and the Brachyplyina, also known as the higher oribatids or Euoribatida. The Macropylina are divided into five subgroups, and the Brachyplyina are divided into two subgroups. The Oribatida were previously known as the Cryptostigmata but many of these mites completely lack a stigmata or a tracheal system.

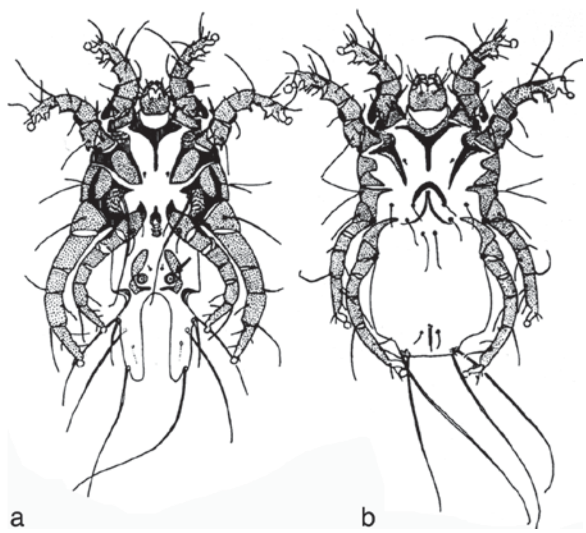
Oribatids are worldwide in distribution. Most range in size 0.3–0.7 mm in size with the smallest 0.15 mm and the largest 1.5 mm in size. Sexual dimorphism is scant or nonexistent. Most oribatids are soil dwellers, but they are also found in moss, humus, lichens, and occasionally on vegetation. A few species are phoretic, usually on beetles. Phoresy is discussed in the section on "Dispersion of mites." Oribatids are slow moving, particulate feeders with mouthparts modified to cut or tear particles up so they can be swallowed. They are saprophagous on decaying higher plant material or microphytophagous on soil microorganisms. The fecal pellet contributes to the soil structure. The oribatids act on the soil system principally by regulating the rate of organic matter decomposition and are considered to be important decomposers. This order is most diverse in the tropics where these mites are the dominant Acari in soils. Some oribatids are intermediate hosts to the sheep tapeworm *Moniezia expansa*. Many species are parthenogenetic, otherwise sperm transfer occurs by stalked spermatophores deposited by a penis. The female picks it up with the genital vestibule. An ovipositor is common. Oribatid mites have a lower fecundity than most other mites.

Acaridida

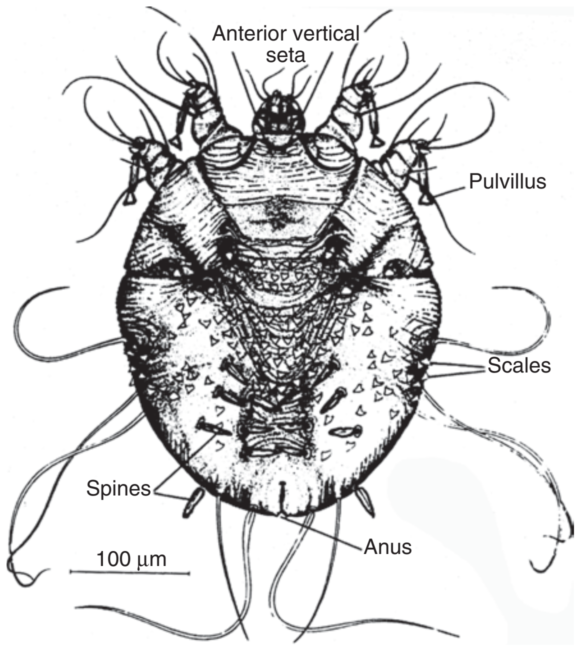
The Acaridida contain some 70 families divided into 800 genera and about 5,000 species. The Acaridida are thought to have evolved within the Oribatida. Acaridids are worldwide in distribution. Sperm transfer occurs by the use of a penis or aedeagus. Sexual dimorphism is common. Most species have a hypopus in the deutonymphal stage. The hypopus is highly modified for survival in marginal conditions and for dispersal by phoresy, or by wind. Acarids include free living species and those that are associated with other animals such as mammals, birds and insects. Parasitic species include skin, hair follicle, or feather parasites of birds and mammals. Others are respiratory parasites of birds and mammals. Most are nonpredatory. Free living species are found in a variety of habitats including decaying organic matter and nests of other animals. The free living forms have evolved some interesting and unusual feeding habits that vary from filter feeding of microorganisms to eating solid food to direct absorption of food material. Many Acaridida have a short generation time which rapidly produces large populations. This allows the exploitation of patchy or ephemeral food resources. Acaridida are weakly sclerotized mites, although sclerotization of the dorsal area occurs to some extent in several species. Acaridida were known as the Astigmata.

The Acaridia are divided into two subgroups, the Acarida and the Psoroptidia. The Acarida contain seven superfamilies. The Schizoglyphoidea are only known from the phoretic deutonymphs collected from a tenebrionid beetle in New Guinea. The Histiostomatidea contain the Anoetidae, the slime mites. Slime mites are filter feeders with a unique gnathosomal structure that strains microorganisms and other food substances. Species of slime mites are found worldwide in liquid or semiliquid habitats where organic matter is undergoing putrefaction. Some slime mites are found in marine environments such as intertidal algal habitats, others occur in the unusual aquatic habitat of pitcher plants. The Guanolichidae are unusual acarids in that they are completely sclerotized in the adult forms. These mites are found in bat guano where they are most likely filter feeders. Canestrinioidea are mostly commensals or parasites found on adult Coleoptera. Most are found under the elytra of beetles where they are thought to feed on exudates, but some occur near the mouthparts of the host from which they obtain food. They are widely distributed except in the Nearctic. The Hemisarcoptoidea occur in a variety of habitats. Most species are associated with wood related habitats. Other habitats of hemisarcoptids include the nests of solitary bees, intertidal zones, and some species live in aquatic or semiaquatic habitats in sap exudates of water-filled tree holes. Mites of the superfamily Glycyphagoidea are mostly associated with mammals, birds, and insects, but some species are pests of stored food products. Most species of the Acaroidea are found in the nests of vertebrates and insects, but some species are found in carrion and dung. The super family Hypoderatoidea are believed to be closest to taxa of the Psoroptidia. Species of Hypoderatoidea are found in the nests of birds and rodents. Often the deutonymphs are subcutaneous or less commonly internal parasites.

The Psoroptidia contain three superfamilies. Mites of the superfamilies Pterolichoidea and Analgoidea are associated with birds. All the Pterolichoidea and part of the Analgoidea constitute the feather mites. Feather mites (Fig. 69) are a large group that are commensals or parasites of birds. They are found on wing, tail feathers or flight feathers. A few are free living in birds nests. In some feather mites with male polymorphism, homeomorphic males have female-like mouthparts and heteromorphic males have strongly aberrant enlarged chelicerae and elongated palpi. Other species of Analgoidea are parasites of the respiratory tract of birds. The superfamily Sarcoptoidea (=Psoroptoidea) contains many economically important mites. Some species cause mange and (Fig. 70) scabies, which are further described in the section on "skin parasites."



Mites (Acari), Figure 69 **Male (a) and female (b) of the feather mite *Euschizalges laglaizeae* (Acaridida, Analgoidea) showing sexual dimorphism. Note the adanal suckers of the male (arrow) (from Kettle DS (1995) Medical and veterinary entomology, 2nd edn, used with permission of CAB International).**



Mites (Acari), Figure 70 Dorsal view of a female scab mite *Sarcoptes scabei* (Acaridida, Sarcoptoidea). Legs III and IV are not visible from the dorsum (from Kettle DS (1995) Medical and veterinary entomology, 2nd edn, used with permission of CAB International).

Dispersion of Mites

Although mites lack the wings of insects, they have other means of dispersal. Crawling short distances is one method. Wind borne dispersal is a common and effective method. In the Tetranychoidea (Actenida: Prostigmata) two methods of becoming airborne occur. Some species use silk threads produced from glands in a form of ballooning. Other species use a dispersal posture to launch themselves into the air.

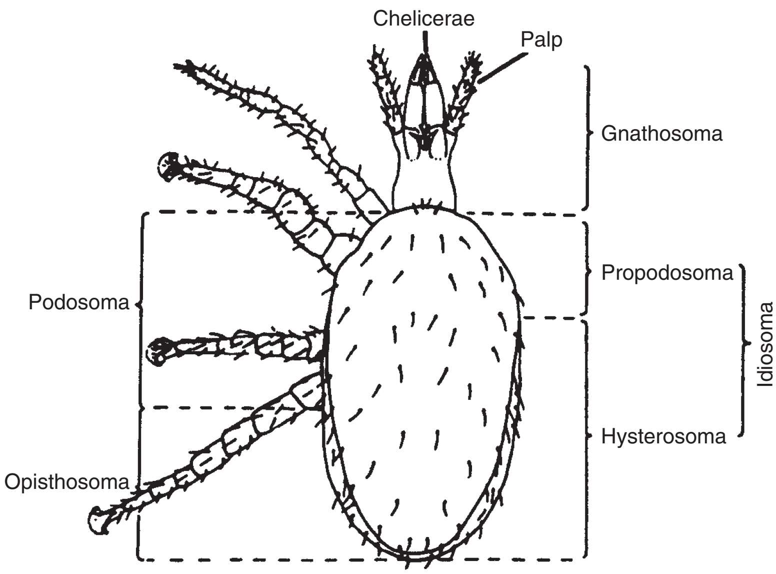
Phoresy, the process where a mite actively seeks out and becomes attached to the outer surface of another animal is an important method of dispersion. Phoretic mites do not feed and ontogenetic development ceases. Phoresy is the most common method of dispersal from one temporary sources of food to another. Phoresy occurs in the Gamasida, the Actinedida, the Oribatida and the Acaridida. Phoretic forms vary from those that resemble the non-phoretic instar to highly specialized forms such as hypopi. *Phoretic hypopi* use claspers or suckers to attach to other animals. Not all attach to animals, some are inert and rely on wind dispersion. The association between phoretics and their hosts ranges from the specific use of a single host species, to the use of a variety of host species. Most phoretic mites are species that can rapidly colonize and exploit temporary habitats. These mites are r-strategists with high rates of reproduction and rapid ontogenetic development. Some associations are not strictly phoretic, i.e., the mites derive nourishment from their hosts. In these mites, the larva is the dispersal form and the other life stages are free-living and usually predatory.

The host is used by ticks and many other parasitic mites for dispersal. This is most effective when the parasitic mite is not host specific, or when the host has a large home range, as is the case of some birds.

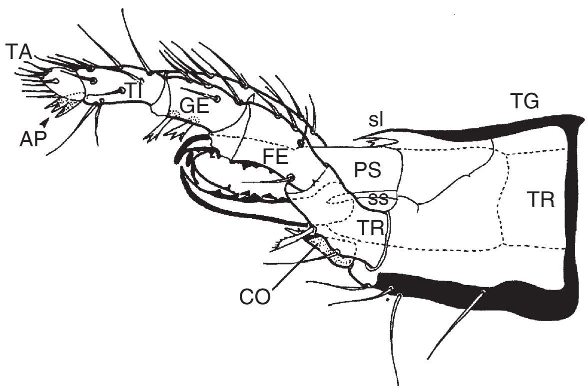
External Anatomy

The body of mites, like all arthropods, can be divided into regions that are based on segments and their appendages. However, mites have little external evidence of segmentation, which makes naming body regions (Fig. 71) difficult. Acarologists have relied on developmental evidence of segmentation during embriogenesis. The most obvious body divisions is the anterior gnathosoma, and the rest of the body, the posterior idiosoma. Another division is the prosoma which constitutes that part of the body that bears the appendages and includes the gnathosoma and the podosoma. Divisions of the idiosoma are discussed below.

The gnathosoma bears the mouthparts. It is not comparable to the head of insects, except that both contain the mouthparts. The gnathosoma (Fig. 72) lacks eyes, antenna, mandibles and does not contain ganglia of the nervous system. The head of insects contains all of these.



Mites (Acari), Figure 71 **Divisions of the body of a mite (from Kettle DS (1995) Medical and veterinary entomology, 2nd edn, used with permission of CAB International).**



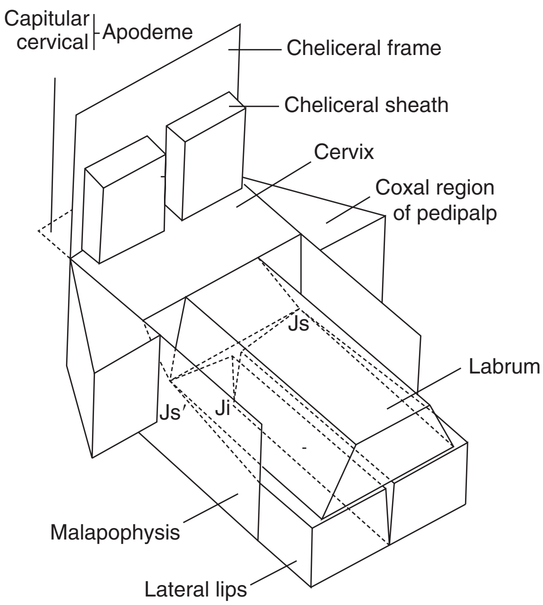
Mites (Acari), Figure 72 **Lateral view of the gnathosoma of a gamasid mite. *AP*, apotele (tined claw); *CO*, corniculus; *FE*, femur; *GE*, genu; *TA*, tarsus; *TI*, tibia; *TG*, tegulum; *TR*, trochanter (of chelicera and palp); *PS*, principal segment of chelicera; *sl*, supracheliceral limbus (gnathotectal process); *ss*, salivary stylus (from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc).**

The gnathosoma is specialized for sensory perception and food gathering. The adaptations of the gnathosoma to the many types of food used by mites is comparable to the great diversity of mouthparts in insects and has helped make the extensive colonization of diverse habitats by mites possible.

Gnathosoma

The gnathosoma is separated from the idiosoma by a circumcapitular furrow or suture. In many taxa the gnathosoma fits into an anterior cavity formed by the idiosoma, the camerostome.

Because it is composed of several complicated structures in a small space, the gnathosoma is best understood by a diagram of its main components, simplified and drawn in such a way as to emphasize their relationship to one another. The gnathosoma is made up of two components, the cheliceral frame (Fig. 73) and the infracapitulum (=subcapitulum or hypostome). In ticks, the hypostome becomes the toothed device that is used to anchor the parasite to its host. The cheliceral frame, which is part of the integument, serves to anchor the cheliceral sheath. The infracapitulum is located ventral to the chelicerae and bears the palps or pedipalps, labrum and lateral lips. Each palp inserts into the cheliceral frame via the cheliceral sheath which is the coxal region of the chelicerae. The mouth or oral cavity is a space designed to move food into the pharynx and esophagus. The muscular pharynx acts to "suck up" the food. Three structures commonly



Mites (Acari), Figure 73 A diagram that shows the relationships of the main components of a typical gnathosoma. For clarity, only the base of the pedipalps and chelicerae are shown. *Ji*, inferior commissure; *Js*, Js, superior commissures (from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc).

delineate the mouth: dorsally the labrum, and laterally a pair of lateral lips. A fourth structure, the labium, occurs ventral to the lateral lips, but it is most often reduced or highly modified. The paired malaphophysis lie lateral to the labrum and lateral lips. In some gamasids the malaphophysis have been modified into a corniculus. They may be further modified in other mites. The infracapitulum encloses the mouth and the pharynx.

Chelicerae are movable and function to rip, squeeze, cut, or pierce the wide variety of food utilized by present day mites. Chelicerae often consist of a basal article or trochanter, a principle segment or body which ends with a fixed digit that is heavily sclerotized or hardened, and a movable digit located ventrad of the fixed digit and hinged to the principle segment. The heavy muscles of the chelicerae attach to the trochanter. In this configuration, the chelicerae take the form of a pincer. The chelicerae of the varroa mite *Varroa destructor* have a vestigial fixed digit and a movable digit with two strong teeth that are used to tear the cuticle of the bee to allow the mite to feed on its hemolymph. Chelicerae tend to be elongated in obligate blood feeders of the Dermanyssina and form a channel through which blood can pass into the preoral channel. Chelicerae may be modified for functions other than food gathering. In some gamasida, male chelicerae are modified as gonopods that transfer packages of sperm, the spermatophore, to females.

The palps which were originally sensory appendages used to probe surroundings for the presence of food, remain so in many species. However, in several groups the palps have undergone many modifications: they may be leg-like, as in many gamasids, grasping as in the Cheyletidae and Hydrachnidia, involved in spinning silk in some species of spider mites, reduced to one or two segments in some species of Tarsonemina and Tetranychoidea. Palps may have as many as five segments which are named from proximal to distal: trochanter, femur, genu, tibia, and trochanter.

The gnathosoma has undergone changes for adaptation to the different habitats and type of food used by different mites. One of the most unusual involves the filter feeding slime mites of the Histiostomatoidae (Acaridida, Histiostomatoidea) who inhabit wet, rotting organic material. These mites have modified palps and chelicerae adapted for filter-feeding. The palps have a freely movable flattened distal segment, used to sweep the fluid food suspension towards the anterior part of the infracapitulum. From here particles are raked back into the preoral cavity by means of the specialized non-chelate chelicerae. Other unusual adaptations include the gnathosoma (=capitulum) of ticks and the gnathosoma of *Psoroptes equi*. The former is discussed in the entry on “Ticks,” the latter in the section on “skin parasites.”

Idiosoma

The body proper or idiosoma varies considerably in shape and is closely adapted to the type of habitat occupied by the mite. Common body shapes include a dorso-ventrally flattened body found in unfed hard ticks, a vermiform or fusiform shape, a sac-like body found in gravid Pyemotes, and a box shape. Other shapes such as a laterally flattened body can occur. Sexual dimorphism occurs in some mites.

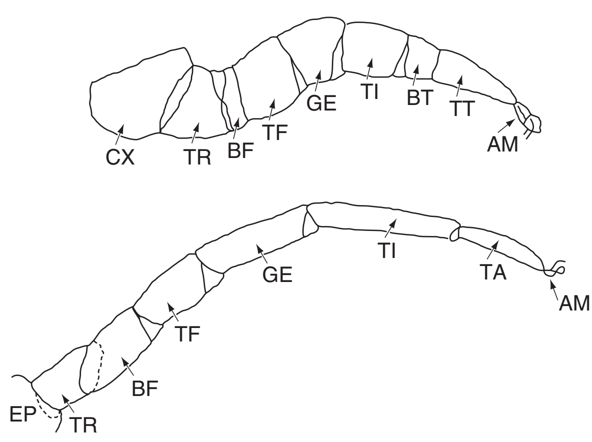
The idiosoma is further divided into the podosoma which contains the four pair of legs, and the opisthosoma which is the rest of the body posterior to the legs. Other divisions of the idiosoma include the propodosoma which contains the first pair of legs, and the hysterosoma which contains the last pair of legs and the rest of the body.

Specialized structures are found on the surface of the idiosoma. The tritosternum is a medioventral structure that extends from the groove separating the gnathosoma from the idiosoma in all orders of Actinotrichida except the Ixodida. In some gamasids it functions to direct prey fluids to the mouth region. A pair of podocephalic channels or canals, which may be open or closed, occur in all Actinotrichida. They usually run from the bases of the first pair of legs to the gnathosoma and carry the products of the coxal glands and other glands. In Opilioararida, these channels run from an area between the first pair of legs to the gnathosoma. No other order of Anactinotrichida has these. Ventral and dorsal sclerotized (hardened) cuticular shields and plates occur on the idiosoma of mites. The shape and location of these are important taxonomic features. A genital opening and an anus are found on the ventral idiosoma. Some mites have a penis (aedeagus). The position of these three structures varies with the species of mite.

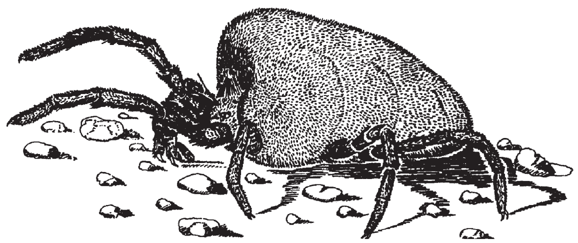
The cuticle of many blood sucking ectoparasitic mites, such as *Echinolaelaps echidninus* and *Dermanyssus gallinae* (Gamasida, Dermanyssoidea, Dermanyssidae) expands during feeding to accommodate large quantities of blood. The most dramatic of these occur in female ixodid ticks that greatly increase their body size during feeding (see the entry on "Ticks"). Some species of oribatids can retract their gnathosoma and legs like a box into an operculum-like device of the cuticle like a box. Others have cuticular plates termed pteromorphs that extend over the lateral body parts and protect them. Some Euroribata carry the dorsal cuticle from a previous molt around as a scalp which may help conceal the mite from predators. Other oribatids stick debris on to their body surface which may have the same function.

Legs

Legs are numbered I through IV from anterior to posterior. Each leg is divided into segments or podomeres which are from proximal to distal: coxa, trochanter, femur, genu, tibia, and tarsus. The distal end of the tarsus forms (Figs. 74 and 75) the terminal part of the leg, the ambulacarum, which bears the claws and a pulvillus



Mites (Acari), Figure 74 Legs of a gamasid (*top*) and an actinedid (*bottom*) mite showing the podomers. *AM*, ambulacrum; *BF*, basifemur (femur I); *BT*, basitarsus; *CX*, coxa; *EP*, epimeron (coxisternum); *GE*, genu: *TA*, tarsus; *TF*, telofemur (femur II); *TI*, tibia; *TR*, trochanter; *TT*, telotarsus (redrawn from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc.).



Mites (Acari), Figure 75 **A velvet mite, *Trombidium meyeri* (Actinedida, Trombidoidea, Trombidiidae) that uses its first pair of legs as feelers (from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc).**

between the claws which functions as a type of cushion. Secondary divisions, especially with the trochanter and femur can occur. A free movable coxa exists in the Anactinotrichida but not in the Actinotrichida. Many acarologists doubt the presence of a true coxa in the Actinotrichida and therefore use the term epimeron for this leg component. Epimeres are often fused with other components of the ventral idiosoma and are sometimes referred to as a coxisternum. Joints between the body and the legs, between the podomeres, and between the tarsus and the apotele allow movement of the legs. Muscles and tendons run between joints. Muscles, hydrostatic pressure from hemolymph, and bending stresses are used to produce movement of leg segments.

Legs of mites are modified for different types of locomotion, and for special uses such as habitat adaptation, nutritional and sensory functions, and sexual behavior. In general, slow moving mites have stout heavily sclerotized legs, while faster moving mites tend to have long, slender legs. Many Acari have the first legs modified as elaborate sense organs or feelers that are used to touch the soil with their distal parts or are waved in the air in a similar fashion as insect antenna. Often these legs are not used for locomotion. In some soil mites the second pair of legs is much stronger and bears modified setae adapted for digging. Often endoparasitic mites have reduced legs. In some Gamasida, males have specialized leg spurs that grasp the female during sperm transfer. In some Acaridida legs are modified for holding females during copulation. Mites capable of jumping occur in all orders of Actinotrichida. Jumping is associated with modification of the fourth pair of legs.

Many water mites (Hydrachnidia) are fast and elegant swimmers. Their legs have movable, flattened seta that passively erect during the power stroke to increase the thrust and collapse during the recovery movement of the leg to reduce water resistance.

Integument

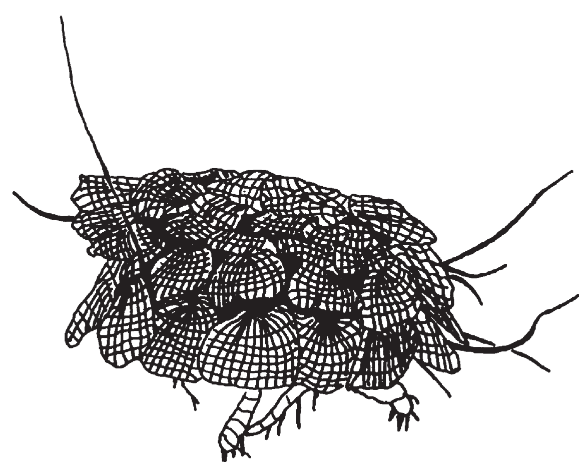
The integument is made up of a non-cellular cuticle and an underlying layer of cells, the epidermis. The epidermis secretes the cuticle (Fig. 76). Interposed between the epidermal cells are trichogen cells that extend into seta and dermal gland cells whose product is released into canals that lead to the surface. The cuticle is shed during molts which allow the mite to grow in size and develop adult characteristics. The cuticle is thrown into projections termed setae. Shapes of setae commonly include but are not limited to simple hair like projections, bipectinate, spine-like, fan-like. Setae may be scarce, or they may completely cover the body of the mite. Some setae have the ability to erect. Setae have different functions. Some are sensory and are further discussed in the section on "Nervous and sensory organs." The number, position and shape of setae are important taxonomic characteristics. Cuticular scales occur in some mites.

The cuticle has many functions. It acts as a barrier to pathogens such as bacteria and pathogenic protozoa and the eggs of insect parasites. It provides protection from mechanical injuries of predators.

The cuticle helps to prevent desiccation through loss of water. Hydrophobic substances in the cuticle prevent excess wetting. The cuticle is involved in gaseous exchange with the atmosphere when the tracheal system is lacking or not well-developed as in all larval mites and in acaridid mites. Cuticular spines and ridges help retain a film of air around the body during flooding. In aquatic species these cuticular modifications are further developed for use in plastron respiration. Regularly spaced surface microstructures or granulations occur on some mites in polar regions. A layer of air trapped by the granulations may facilitate survival by providing a mechanism of cuticular respiration in waterlogged polar soils. This layer of air may also prevent freezing by insulating the mite from direct contact with the ice. The cuticle is a site for muscle attachment. Glands and receptor organs open onto the surface of the cuticle.

A cuticular lining occurs in the fore and hind gut of the digestive system, the tracheae, ducts of many glands, and part of the reproductive system.

The general structure of the acarine cuticle is similar to the cuticle of other arthropods. The cuticle is either sclerotized or unsclerotized. Sclerotization is a process that imparts greater strength by hardening the cuticle. Heavily sclerotized armor plates protect against the attacks of predators (Fig. 77). Unsclerotized (Fig. 76) cuticle is more flexible. The cuticle has two layers, a thicker internal procuticle and a thinner external epicuticle. Chitin is found in the procuticle. In some cases, the procuticle is divided into an inner epicuticle and an outer exocuticle. The epicuticle contains several sublayers depending on the mite species. These are named from the most external: the cement, wax, cuticulin, and dense homogeneous layers. External to the cuticle, two additional layers may be present that are collectively termed the secretion layer or cerotegument. The secretion layer may take the form of distinct granules or other structures which contribute to the appearance of the surface (Fig. 77). Pore canals pass through the procuticle to join structures known as epicuticular canals, wax filaments or wax canals that extend through the epicuticle to the surface. Pore canals have an unknown function, they may allow the exchange of material such as gas, water and lipids between external and internal compartments.

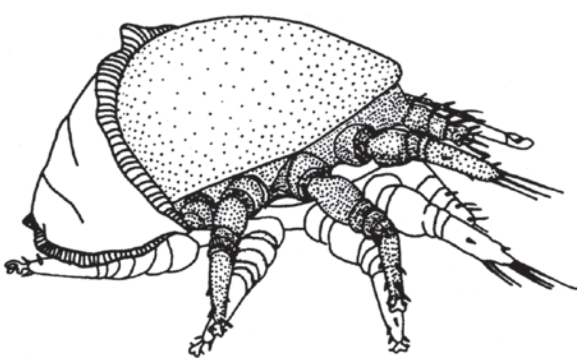


Mites (Acari), Figure 77 Tritonymph of *Conoppia palmicincta* (Oribatida, Cepheoidea, Cepheidae) with fan-shaped setae that completely cover the body (redrawn from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc).

The cuticle varies considerably in thickness depending on the species of mite and the region of the body. It is a dynamic structure; many of its parts can be modified, or rebuilt or replaced during molting, sclerotization, wound repair or after abrasion of the secretory layers. The impermeable nature of the cuticle is important in preventing desiccation. Mineralization of the procuticle in some Oribatida may further harden the cuticle.

Molting includes apolysis, the separation of the old cuticle from the epidermis and ecdysis, the casting off of the remnants of the old cuticle. In between apolysis and ecdysis, the old separated cuticle, except for (Fig. 78) the epicuticle and secretion layers, is digested and a new cuticle is deposited. Following ecdysis, the new cuticle may be sclerotized or mineralized. The pharate form is the next instar still within the old exuviae. Molting is similar in most mite species. In general, the old cuticle splits along different lines depending on the species of mite, and the new instar leaves the exuvia. Little is known about the hormones involved in the molting of mites.

In some mites there is little or no period of inactivity accompanying apolysis. In others, the instar becomes inactive just before and during apolysis. In general there are no molts after the adult phase except in Prostigmata.



Mites (Acari), Figure 78 Molting in *Uroobovella marginata* (Gamasida, Uropodoidea, Urodinychidae). The old cuticle has split around the anterodorsal border, and the new instar leaves the exuvia (from Alberti G, Coons LB (1999) The Acari-Mites, used with permission of John Wiley and Sons, Inc).

Physiology of Mites

Glands

Mites have endocrine and exocrine glands. Endocrine glands or endocrine organs produce hormones and empty internally while exocrine glands produce a variety of substances and empty onto the surfaces of the mite.

Unlike insects where endocrine organs have been identified and well studied at the cell and molecular level, acarine endocrine organs are classified only by their structure, and thus they are spoken of as putative endocrine glands. These are located mostly around the central nervous system and consist of a retrocerebral organ complex, the lateral organs and paraganglionic plates.

Exocrine glands are described based on their morphological location. Dermal glands are common throughout the Acari. They are small glands located within or just below the epidermis. A duct leads to the cuticular surface. These glands have a variety of functions that include secretion of an allomone, a sex attractant pheromone in ticks and some other mites, and the secretion of a glue in some males of the family Arrenuridae (Hydrachnidia: Arrenuroidea) that is used to attach the female during mating. Arrenuroids are freshwater mites. Other glands are the prosomal glands, lateral glands and anal glands. Two important types of prosomal glands are salivary glands and silk glands. Salivary glands produce digestive enzymes used by the mite to liquefy or predigest their prey and other food prior to swallowing it. In ticks, salivary glands are specialized for osmoregulation. Silk produced by silk glands is used for a variety of functions.

Muscles

All muscles in mites are striated. There are two types of striated muscles, somatic and visceral. Somatic muscles are connected to the integument via specialized attachment complexes. Somatic muscles are divided into three groups: those muscles that move the legs, those that move the gnathosoma and those that move the body proper. Visceral muscles are found around hollow organs such as the digestive system, Malpighian tubules, and parts of the reproductive organs. They are used to move their contents. In many mites a specialized structure, the endosternite, lies within the podosoma. It is analogous to a "floating tendon" and serves as a central suspensory attachment for certain somatic muscles.

Fat Body

The fat body is a diffuse organ that consists of strings of cells, the trophocytes, that are often closely associated with trachea, internal organs and nephrocytes. While a fat body occurs in both superorders, not all mites have a fat body and some develop a fat body only during certain parts of their life cycle. In mated fed female ticks, the fat body under the influence of the hormone ecdysone, undergoes a complete ultrastructural reorganization and produces the female protein vitellogenin, which is secreted into the hemolymph and taken up by developing eggs to become the yolk protein vitellin. Yolk is used as food for the developing embryo.

Circulatory System

Mites have several types of hemocytes that circulate in the hemolymph. Some mites have a pulsating organ or heart, other mites do not. The heart has a specialized striated muscle with an ultrastructure similar to the striated muscle of insect hearts. Hemolymph enters the heart through openings, the ostia, and then is pumped out the anterior end. With or without a heart, circulation is aided by body movements and muscular contraction.

The hemolymph of ticks undergoes coagulation when exposed to air. Mites can recognize self from nonself and can initiate encapsulation of large foreign objects, such as parasite eggs, by hemocytes. Encapsulation is a defense designed to isolate foreign objects. Mites have immune reactions similar to those of insects.

Nephrocytes or pericardocytes are round single cells that are associated with various organs, especially reproductive organs. They function to sequester certain toxic compounds from the hemolymph.

Respiratory System

Mites have three different respiratory mechanisms: gas diffusion through the integument, gas transportation through a tracheal system, and gas exchange through specialized porose areas on the integument. All prelarvae and most larvae respire through their integument. In adults, respiration through the integument is limited to soft bodied forms such as the Acaridida. Respiratory mechanisms in mites must also be adapted to avoid desiccation as well as exchange gasses in these small animals with large surface areas.

A tracheal system is made up of internal tubes that become smaller as they lead to the various organs. Spiral coils inside trachea termed taenadia impart rigidity that keeps them open. Trachea lead to the outside through openings, the stigmata, that are sometimes associated with a peritreme, a canal or gutter-like extension from the spiracles. In some species the peritreme is partially closed. A peritreme usually extends anteriorly or less commonly posteriorly from the stigma. It is thought that peritremes evolved to help keep the spiracles free from blockage. Peritremes are found only in the Holothyrida, Gamasida and Prostigmata. The peritreme and stigma are sometimes surrounded by a prominent sclerotized shield like area of the cuticle, the peritrematal shield. The position of the stigmata, the presence and shape of the peritreme and associated shield are used as taxonomic characteristics.

In mites that live in water, plastron respiration occurs as trapped air in specialized areas of the body. Often a plastron is associated with modifications in a peritreme. Trapped air is also believed to act as a flotation bubble. Porose areas of the integument that are involved in gas exchange occur in some species of Oribatida. They are believed to have originated independently from the respiratory systems of related mites.

Digestive System

Mites utilize a wide variety of food that ranges from solids such as pollen, fungi and tissues of prey to liquids such as vertebrate blood and plant fluids. The range of food habits in free living mites include predaceous (feeding on animals), phytophagous (plant feeding), mycetophagous (feeding on fungi), saprophagous (feeding on dead organic matter), microphagous (feeding on small food pieces), and coprophagous (dung feeding) forms.

The digestive system has three major divisions: a foregut lined with cuticle that extends from the mouth, a midgut that lacks a cuticle, and a hindgut that also has a cuticular lining. The foregut consists of the muscular pharynx and esophagus that passes through the synganglion to enter the midgut. The foregut acts mostly as a conduit of food into the midgut where digestion and absorption of food takes place. Mites partially digest their food before it is taken up into the digestive system using secretions from prosomal glands, especially salivary glands. The meal is taken up in cells that line the midgut, sorted into the lysosomal system of the cell and digested within the lysosomes in a process termed heterophagy. The digested material is then released into the hemolymph. A peritrophic membrane occurs in some mites. The digestive system, especially the midgut, is modified depending on the type of food eaten. Substantial modifications occur in the blood feeding ticks which take in a large meal of blood and in the plant feeding mites which must deal with plant fluids. Microorganisms, which are probably symbiotic, occur in the digestive systems of mites.

Several generalized anatomical types of digestive systems occur in mites. A parasitiform type occurs in the Oplioacarida, Holothyrida, Ixodida, and Gamasida. It is characterized by an esophagus, a small ventriculus with relatively large paired caeca, a short postventricular midgut leading to a short hindgut that in turn leads to an anus. One pair of Malpighian tubules is present except in the Holythrida which have two pair. A trombidiform type of digestive system occurs in most of the Actinedida. It consists of an esophagus that leads to a midgut that is divided into a small ventriculus with large paired caeca. The midgut ends blindly, no postventricular midgut or anus exists. The midgut is closely associated with a dorsomedian excretory organ that opens to the outside via a uropore. A sarcoptiform type of digestive system occurs in the Oribatida and Acaridida. It consists of an esophagus that leads to a midgut that is divided into a ventriculus with small caeca and a postventricular midgut consisting of a colon and postcolon that in turn lead to a hindgut and anus. Malpighian tubules, described in the section on the "Excretory system," are present in some taxa but reduced or absent in others.

Excretory System and Osmoregulation

Excretory organs are involved in the elimination of the end products of nitrogenous metabolism, which in the Acari is guanine and rarely uric acid. Excretory organs include Malpighian tubules and the dorsomedian excretory organ. Osmoregulatory organs regulate water and or ions, and include coxal glands or nephridia, the salivary glands of ixodid ticks, genital papillae, ClaparÈde organs, axillary organs and pregenital capsules.

Malpighian tubules originate in the posterior region of the digestive system and end blindly within the anterior hemocoel. They are present in the Holothyrida, Ixodida, Gamasida and some Acaridida, but are absent in the Actinedida and Oribatida. The ultrastructure of cells in the Malpighian tubules are similar to those of Insecta.

Wastes from the Malpighian tubules pass into the digestive system and are eliminated with the feces.

The dorsomedian excretory organ is found in actinedids and consists of the postventricular midgut and the hindgut which together are modified as an excretory organ. The organ functions in nitrogenous metabolism and osmoregulation. It is most developed in mites that are predators on plants such as the tetranychids. Some mites such as the human follicle mite store metabolic wastes in cells rather than eliminate them.

Coxal glands are derived from the nephridia of annelid arthropod ancestors and are found in both superorders. Coxal glands consist of a thin walled sacculus that faces the hemolymph and a convoluted tubule that leads to an opening to the outside. The sacclus filters the hemolymph, and the convoluted tubule is thought to reabsorb substances including ions from its lumen. Salivary glands are the principal osmoregulatory organs of ixodid ticks during feeding. In addition, they play an important role in preventing dehydration by secreting a compound that takes up water from the air onto the mouthparts. The compound is swallowed or reabsorbed through a specialized cuticular region of the tick.

Genital papillae are commonly found in Actinotrichida where they are considered to be a characteristic feature of this taxon. Genital papillae have different shapes but generally consist of an eversible sac-like structure located anterior to the genital opening. This sac-like structure has an ultrastructure typical of transporting cells. The papillae are protected by two progenital lips. The number of papillae varies or they may be completely lacking. In some species of water mites, multiple papillae may be found on the external surface. Prelarvae and larvae, which lack a progential chamber, have Claparède organs located between the bases of legs I and II which function as osmoregulatory organs. Axillary organs are found on some acaridid mites that inhabit semiaquatic or aquatic environments. These organs are found between the bases of the first and second pairs of legs and have an elevated band of sclerotized porous cuticle. Cells associated with these organs have an ultrastructure typical of transport cells. Axillary organs are probably homologous to ClaparÈde organs. Pregenital capsules occur only in the Opilioacarida where they are found anterior to the genital openings in both sexes. Their function is unknown. Each capsule has an external cover and an evertable sac.

Nervous and Sensory System

The ventral chain of ganglia, which is common in arthropods, is condensed in mites into a mass of nervous tissue termed the synganglion. This is the central nervous system from which sensory and motor nerves originate and extend to parts of the body and organs. A peripheral nervous system is present in some species.

The sensory system includes setiform sensilla sensory hairs and sensory setae which are often grouped as setiform sensilla, nonsetal sensilla, and photoreceptors. Different setiform sensilla function as chemoreceptors, temperature and humidity receptors, and mechanoreceptors. Some setiform sensilla have multiple functions, for example, as both a chemoreceptor and a mechanoreceptor. The ultrastructure of mite sensory receptors is similar to those of insects. A great number of setae are found on most mites, only some of which are known to have a sensory function. The position and pattern of setae is an important taxonomic characteristic.

Sensory setae, like those of insects are classified by their external shape as follows. A peg or cone shaped seta is a sensillum basiconicum, a bristle or spine shaped seta is a sensillum chaeticum, and a seta that has its external portion freely moving in the form of a hair articulated with a base is a sensillum trichodeum.

Nonsetal sensilla function as mechanoreceptors that can sense a variety of stimuli such as gravity, substrate vibrations, sounds and strains within the exoskeleton caused by movements of the mite. Nonsetal sensilla are classified as slit sense organs, cupules, and lyriform fissures. The latter are unlike those of spiders.

Photoreceptors in mites are divided into three types: eyes, secondary light receptors and photosensitive areas. The eyes of mites are simple ocelli that lack facets found in the compound eyes of insects. Typically they have a lens, which is the only cuticular part, and an underlying photoreceptor apparatus. Eyes are located in various places on the prosoma depending on the species of mite. Not all mites have eyes.

Reproductive System

A major reason for the success of mites is their diversity of reproductive strategies. Few common themes occur, but all mites are dioecious, i.e., with separate sexes, and all have internal fertilization. Three modes of reproduction exist in the Acari: diplodiploidy, haplodiploidy and thelytoky.

Mites with diplodiploidy are biparental, parthenogenesis is absent. Sexual reproduction is used to produce offspring. Somatic cells of both sexes are diploid. Diplodiploidy is thought to be the ancestral form of reproduction in mites, and it is the most common mode of reproduction of the Acari. It is found in the Ixodida, the Gamasida, the Actinedida, the Acaridida and the Oribatida. Diplodiploidy is the dominant form of reproduction in the Ixodida and Oribatida.

Parthenogenesis occurs in haplodiploidy and thelytoky. Haplodiploidy produces diploid females and haploid males. Two kinds of haplodiploidy, arrhenotoky or parahaploidy, occur. Arrhenotoky produces diploid females from fertilized eggs while haploid males are produced parthenogenetically. This results in biparental females and uniparental males. Often arrhenotoky produces a female-biased sex ratio. Arrhenotoky is not common in mites, but is found in some Acaridida. Fertilization occurs in parahaploidy, but the paternal set of chromosomes is lost in the diploid male embryo and thus only the maternal set of chromosomes are passed on. Parahaploidy occurs in the Phytoseiidae (Gamasida, Ascoidea). Either sex can develop from unfertilized eggs in deuterotoky. Deuterotoky is not considered to be an independent type of reproduction, but is part of a cyclical type of parthenogenesis. Thelytoky produces females by parthenogenesis. Males are either rare or most commonly absent. It is most common in the Oribatida.

Mites have both indirect and direct sperm transfer. In indirect sperm transfer, the male uses a package of sperm, a spermatophore, that it places on the substrate, and the female transfers the spermatophore to its reproductive opening. In direct sperm transfer, sperm is directly transferred to the genital opening of the female in a spermatophore, or transferred with a penis during copulation. Direct sperm transfer using a spermatophore can occur via the primary genital opening of the female in a process termed tocospermy or via the insemination pore, a secondarily developed genital opening in a process termed porospermy. Insemination pores lead to a complex specialized organ, the sperm access system in the Dermanyssina (Gamasida). Copulation occurs in some mites of the Actinedida and Acaridida.

Economic Importance

Skin Parasites

Skin parasites of vertebrates are found in all Orders of mites except Opiloacarida and Holothyrida. We shall consider only those known to cause pathology in humans and domestic animals. The canary lung mite, *Sternostoma tracheacolum* (Gamasida: Dermanyssoidea: Rhinonyssidae), occurs in the respiratory tract of canaries and can cause illness and even death. This mite is thought to be larviparous. Treatment includes pesticides administered in diets or as aerosols. *Pneumonyssoides caninum* (Gamasida: Dermanyssoidea: Halarachnidae) is usually a benign inhabitant of the sinuses and nasal passages of dogs, but they can cause pathological conditions such as sinusitis. *Pneumonyssus simicoloa* (Gamasida: Dermanyssoidea: Halarachnidae) is found in the lungs of monkeys and baboons. It is tolerated in the natural state, but in captivity can cause a disease with a mortality up to 70%. The tropical rat mite, *Ornithonyssus* (=*Liponyssus*) *bacoti* (Gamasida: Dermanyssoidea: Macronyssidae) is found in tropical and temperate regions worldwide. It is normally a parasite of rats but can bite humans producing a sharp pain and severe itching. Sensitive people can develop a dermitis from the bite.

Several species of skin parasites attack poultry. The tropical fowl mite, *Ornithonyssus bursa* (Gamasida, Dermanyssoidea, Macronyssidae), occurs in tropical and subtropical areas worldwide. It is a common parasite of the English sparrow, *Passer domesticus* and an ectoparasite of poultry. Heavily infested poultry can become listless. Workers associated with poultry are frequently bitten resulting in a slight irritation. The northern fowl mite, *Ornithonyssus sylviarum* (Gamasida, Dermanyssoidea, Macronyssidae), occurs in the north temperate regions, and in New Zealand and Australia. Heavy infestations in poultry can reduce egg production. This mite bites poultry workers and can cause extensive itching. The chicken mite (red chicken mite or roost mite), *Dermanyssus gallinae* (Gamasida, Dermanyssoidea, Dermanyssidae), is worldwide in distribution. It parasitizes domestic poultry, pigeons, starlings and sparrows. The mite attacks at night; during the day it hides in crevices, under floors and in debris where its eggs are laid. Damage to poultry includes less egg production, and weight loss which makes poultry less marketable.

The house mouse mite *Liponyssoides* (=*Allodermanyssus*), *sanguineus* (Gamasida, Dermanyssoidea, Dermanyssidae) transmits the pathogen of rickettsialpox to humans. Both nymphs and adults feed on the blood of a variety of rodents. The mite is a nest dweller and is usually found on its host only when feeding. Rickettsialpox is caused by *Rickettsia akari*, a member of the spotted fever group of rickettsiae. Rickettsialpox is found in many urban areas of the United States, Russia, and Korea. The disease is mild with no recorded fatalities, and has a benign clinical course. Rickettsialpox is characterized by a vesicular rash, a local eschar or tache noire, and a local cutaneous lesion. The eschar, an ulcer covered with a black crust, is a local reaction that occurs at the bite site. The antibiotics tetracycline and chloramphenicol are used as treatments. Prevention includes controlling rodent and mite populations.

Chiggers are larvae of trombiculids (Actinedida: Prostigmata: Trombidioidea: Trombiculidae) that parasitize every major group of terrestrial vertebrates. In humans, chiggers transmit the serious disease chigger-borne typhus. The adults are fungivorous mites that feed within fungal cells using stylettiform chelicerae. The small chelicerae of chiggers are used for penetration of the hosts epidermis and serve as anchors during the attachment of the parasite. A saliva produced by the mite dissolves the integumental layers producing a feeding channel, the stylostome, through which the parasitic larvae takes up predigested material.

Several species of larval trombiculids transmit chigger-borne typhus also known as scrub typhus or tsutsugamushi disease. The causative agent of this disease is *Orientia tsutugamushi*, a member of the typhus group of rickettsiae. Chigger-borne typhus is a zoonosis, humans are only accidental hosts of the pathogen. The disease has four essential components: *Orientia tsutugamushi*, chiggers, rats, and secondary or scrub forms of vegetation. Chigger-borne typhus occurs in Australia, India, Korea, and Japan. *Orientia tsutugamushi* exists as three major antigenic types which has prevented the development of an effective chigger-borne typhus vaccine. Infection with one strain produces long term immunity only to that strain. Other strains can cause another cases of chigger-borne typhus in the same individual. All strains produce a similar disease which manifests itself as chills, fever, and headache after an incubation period of one to three weeks. An eschar followed by a skin rash occurs in less than half of the cases.

Fatal outcomes of chigger-borne typhus ranges from 0 to 50%. The same antibiotics used for rickettsialpox are used to treat chigger-borne typhus.

All species of the genus *Demodex* (Actinedida, Cheyletoidea, Demodicidae) are parasites on mammals and cause demodectic mange or demodecosis which can be serious or of little pathology depending on the host species which include but are not limited to humans, dogs, cats, cattle, hogs, deer, hamsters and various rodents. Transmission is by bodily contact. Two species parasitize humans. These mites are minute, 0.1–0.4 mm long, with an elongated abdomen and eight stubby legs. The follicle mite, *Demodex folliculorum*, lives head down in hair follicles. It is the most widespread parasite of man with a prevalence that approaches 100%. All life stages including eggs may be present in a single follicle. These mites are most common in facial areas, especially oily regions around the eyelids and nose. *Demodex brevis* is found in sebaceous glands. Neither mite causes much pathology. *Demodex canis* causes a more serious pathology in dogs. The demodecosis is either localized or generalized. The latter is a severe form and must be treated or a fatal septicemia can develop. About 10% of cases are of the generalized form.

Many species of the family Pyemotidae (Actinedida: Tarsonemina: Pyemotoidea) are stored product pests and secondarily cause problems with workers. *Pyemotes tritici* which kills its prey with a toxin can cause skin lesions and other problems in humans. The hay itch mite, *Pyemotes ventricosus*, attacks people who come in contact with infected grain or hay.

Mange and scabies are terms often used interchangeably to describe diseases caused by species of mites from the families Psoroptidae and Scarcoptidae of the superfamily Sarcoptoidea (Acaridida). Usually scabies or the scab describes a collective disease, while mange is used to distinguish which mites cause the disease.

Three genera of Psoroptidae, *Psoroptes*, *Choriptes*, and *Otodectes*, are important skin parasites of mammals. These are non-burrowing mites. Psoroptic mange, caused by species of the genus *Psoroptes*, is severe and can sometimes be fatal in cattle and sheep. The family Psoroptidae is worldwide in distribution and is found on many mammalian species. Psoroptic mange is caused by a single cosmopolitan ectoparasitic species, *Psoroptes equi* (Acaridida: Sarcoptoidea: Psoroptidae). This mite has many varieties that are named for their hosts, thus *P. equi* var. *ovis* on sheep, *P. equi* var. *bovis* on cattle, etc. *P. equi* is a very small mite about 0.5 mm in length that spends its entire life on its host. Mites are spread rapidly by the close contact of animals. *Psoroptes equi* is most often found at or near the base of hairs. Mites pierce the host's skin to feed on lymph and tissue fluids which results in an inflammatory response that causes a debilitating dermatitis and mangy or puritic scab formation. The mouthparts of *Psoroptes equi* are adapted to feed on liquefied and semi-liquefied material from abrasions caused by the shearing actions of their mouthparts. The mouthparts form a suctorial cup that serves to direct food into the preoral cavity. Infected animals often have lesions that ooze, and they suffer a great deal of irritation. This irritation often causes the infected animal to scratch against objects to relieve itching which results in further damage to fur and skin. A complete life cycle of *Psoroptes equi* from egg to egg can occur in as little time as 11 days in some hosts, or up to three weeks in others. In sheep and cattle, psoroptic mange is most common in autumn and winter. In the summer the disease enters a latent phase due mostly to shearing or shedding of hair, host nutrition and grooming. Psoroptic mange annually causes millions of dollars in losses in North America.

Chorioptic mange, caused by species of the genus *Chorioptes*, is a less serious disease than psoroptic mange. Chorioptic mange is caused by two species of mites, *Chorioptes bovis* that infests horses, sheep goats, cattle and llamas, and *Chorioptes texanus* that infests goats and cattle. These mites feed on debris on the skin surface and do not burrow. Their mouthparts are modified to scrape the surface of the hosts skin. The mites infest new hosts by contact with uninfected animals.

Parasitic otitis is caused by *Otodectes cynotis* (Acaridida: Sarcoptoidea: Psoroptidae). These mites infest the ears of a wide variety of carnivores. Convulsions can occur in heavily infested dogs and cats.

Sarcoptic mange occurs in a variety of mammalian hosts including man. It is caused by the scab mite *Sarcoptes scabiei* (Acaridida: Sarcoptoidea: Sarcoptidae), which has varieties on different hosts. Scab mites are very small; females are about 0.3–0.5 mm long and 0.2–0.4 mm wide. Males are about 3/4 the size of females. Most scab mites complete their life cycles in 10–14 days. The varieties that infest humans, dogs and hogs are the most studied. Males and females burrow about 1 mm into the skin of the host. Gravid females lay eggs in the burrows. The hexapod larva commonly enters hair follicles where they feed and molt into an octopod protonymph. This stage is followed by a tritonymph and the adult.

The scaly leg mite, *Knemidokoptes* (=*Cnemidocoptes*, = *Knemidocoptes*) *mutans* (Acaridida: Analgoidea: Knemidokoptidae), causes scaly leg disease in domestic poultry. This mite burrows into the skin where it lives and deposits its eggs in channels. The disease presents as a swollen condition in the shank of the bird with deformity and encrustation of shank scales. Mites are easily transmitted from bird to bird by contact. The depluming mite, *Knemidokoptes gallinae* (Acaridida: Analgoidea: Knemidokoptidae), feeds at the base of feathers causing intense itching in the bird which then may pluck its feathers for relief. Mange of parakeets is caused by *Knemidokoptes pilae* (Acaridida: Analgoidea: Knemidokoptidae). *Knemidokoptes jamaicensis* infests canaries. *Epidermoptes bilobatus* (Acaridida: Analgoidea: Epidermoptidae) can cause a scaly skin disease in poultry that can result in weight loss, and is fatal in some birds with heavy infestations.

Two species of mites are internal parasites of poultry. *Cytodites nudus* (Acaridida: Analgoidea: Chytoditidae) is found in the linings of the respiratory tracts of poultry, mostly chickens. *Laminosoptes cysticola* (Acaridida: Analgoidea: Chytoditidae) is found in the tissue of chickens and turkeys where populations can reach in the millions. The condition presents itself as nodules that become calcified on the death of the mite thus reducing the value of the meat. This mite occurs in North and South America, Australia, and Europe.

The Listrophoridae or fur mites are parasites that have evolved specialized structures to attach to the skin and hair of their hosts. The gnathosoma of the fur mite, *Listrophorus leuckarti* (Acaridida: Sarcoptoidea: Listrophoridae), is hidden under a projection that together with the mouthparts and modified legs grasp the hosts hair shaft and provide support to the attached mite. The mite grazes on the hair surface using unmodified chelicerae. The clasping apparatus is closed or opened indirectly by movements of the gnathosoma.

Stored Product Pests

Some species of mites are serious pests of stored products. Many of the stored product pests can also cause a type of dermatitis known as occupational acarine dermatitis. *Lardoglyphus zacheri* (Acaridida: Acaroidea: Acaridae) is a pest of stored meat and *Lardoglyphus konoi* (Acaridida: Acaroidea: Acaridae) is a pest of dried fish. The acarid bulb mites, *Rhizoglyphus echinopus* and *R. callae* (Acaridida: Acaroidea: Acaridae), are pests on ornamental and vegetable bulbs, tubers and the roots of some cultivated crops. *Carpoglyphus lactis* (Acaridida: Acaroidea: Carpoglyphidae) occurs in fruit, dried milk products, flour and other stored food, and honey from hives where this mite lives. *Chortoglyphus arcuatus* (Acaridida: Acaroidea: Chortoglyphidae) is found in stables in hay dust or fodder. The mold mite, *Tyrophagus putrescentiae* (Acaridida: Acaroidea: Acaridae), is found in processed cereals and causes grocer's itch or copra itch which can affect anyone handling infected products. The scaly grain mite, *Suidasia nesbitti* (Acaridida: Acaroidea: Acaridae), causes wheat pollard itch. The dried fruit mite, *Carpoglyphus lactis* (Acaridida: Acaroidea: Carpglyphidae), causes dried fruit dermatitis. The grain mite, *Acarus siro* (=*Tyrophagus farinae*) (Acaridida:

Acaroidea: Acaridae), causes baker's itch. The house mite, *Glycyphagus domesticus* (Acaridida: Glycyphagoidea: Glycyphagidae), and *Lepidoglyphus destructor* (Acaridida: Glycyphagoidea: Glycyphagidae), are common on the walls, furniture and clothing in dwellings where dampness helps the growth of fungi. The former species causes a contact dermatitis described as a form of grocer's itch which occurs mostly in food handlers. *Glycyphagus destructor* (Acaridida: Glycyphagoidea: Glycyphagidae) causes hay itch.

House Dust Mites

Some ten species of mites of the family Pyroglyphidae are common in human dwellings throughout the world where they exist in the dust found on floors, furniture and bedding. The most common house dust mites are the American house dust mite, *Dermatophagoides farinae* (Acaridida: Analgoidea: Pyroglyphidae) the European house dust mite, *D. pteronyssinus* and *Euroglyphus maynei* (Acaridida: Analgoidea: Pyroglyphidae). The European house dust mite and *Euroglyphus maynei* prefer climates with a higher humidity while the American house dust mite occurs in more temperate zones. These mites can produce human allergies especially in susceptible individuals. House dust mites feed on shed human and animal skin. The allergens they produce are in their feces and in their skins shed during molts. Allergic reactions range from asthma and atopic dermatitis to itchy noses and eyes. House dust mites survive best at relative humidities greater than 70% and temperatures from 75 to 80°F. They do not survive well at low relative humidities and higher temperatures. Under the best conditions, their life cycle takes approximately one month from egg to adult.

Pests of Agricultural Crops

The most serious mite pests of agricultural crops are found in two Actinedida superfamilies, the Tetranychoidea and the Eriophyoidea. A comprehensive list of pest species of tetranychids and eriophyoids can be found in the books given in the literature cited section of this article. Here, we will consider only the most economically important species.

There are five families in the Tetranychoidea with over 450 phytophagous species. The most important pests are found in the Tetranychidae or spider mites and the Tenuipalpidae or false spider mites. Many of these are important pests of agricultural crops worldwide. Spider mites can infest every major food crop and many ornamental plants. Their chelicera are modified into whip-like structures which they insert either through or between palisade cells of the plant into the parenchyma which lies below. Here they feed and may inject a toxic saliva. Destructive symptoms include reduction of plant growth, loss of plant vigor, stippling of the tissue at the feeding site and drop off of the leaf and fruits.

The clover mite, *Bryobia praetiosa* (Actinedida: Tetranychoidea: Tetranychidae), infests grasses throughout the world. These mites can overwinter in any stage. In the spring they can occur in large numbers in buildings where they molt and oviposit. The clover mite may be a complex of races that differ somewhat in their life histories and the plants they infest. The brown mite, *B. rubrioculus*, is a pest of pome and stone fruits. However, the brown mite may be a race of the clover mite. The brown wheat mite, *Petrobia latens* (Actinedida: Tetranychoidea: Tetranychidae), the legume mite *Petrobia apicalis*, and *Tetranycopis horridus* (Actinedida: Tetranychoidea: Tetranychidae), a pest of filberts, are serious crop pests. The two-spotted spider mite, *Tetranychus (Tetranychus) urticae*, (Actinedida: Tetranychoidea: Tetranychidae), and *T.* (*Armenychus*) *mcdanieli*, infest deciduous fruit trees. The European red mite, *Panonychus ulmi* (Actinedida: Tetranychoidea: Tetranychidae), attacks deciduous fruit trees in Europe, North America and Japan. In North America, South Africa and Japan, the citrus red mite, *Panonychus citri*, is a serious pest on citrus fruit trees.

The false spider mites (Actinedida: Tetranychoidea: Tenuipalpidae) are most common in subtropical and tropical climates but some species occur in the temperate region. Three genera contain economically important species: *Brevipalpus*, *Tenuipalpus*, and *Cenopalpus*. These mites usually feed on the underside of a leaf. Some species attack grass and occur in leaf sheaths. Some species occur in galls. Three species of *Brevipalpus*, *B. lewisi*, *B. obovatus*, and *B. phoenicis* attack citrus trees in commercial orchards. *Brevipalpus* species also attack ornamentals, grapes, berry crops, orchids and olives. Species of *Tenuipalpus* attack grasses, tea, orchids and other crops. *Cenopalpus lanceolatisetae* and *C. pulcher* attack deciduous fruit trees in North Africa, Asia and Europe.

Members of the superfamily Eriophyoidea (Actinedida: Eupodina), are distributed worldwide. In their northern areas of distribution, some species produce deutogynes that function as overwintering females. Eriophyoids are found mostly on perennial plants. They injure but seldom kill plants. Eriophyoids feed in a similar manner as tetranychids, but eriophyoids are more host specific and produce very different host reactions. These host reactions have resulted in several common names for this group as gall mites, blister mites, bud mites and rust mites. *Catarhinus tricholaenae* (Rhyncaphytopidae) causes leaf rust on corn in Brazil. The peach silver mite, *Aculus comatus* (Eriophyidae), causes leaf spotting or curling. Galls are reactions of the plant to feeding by mites. Several eriophyoid mite species cause galls of different shapes, but all are due to abnormal growth of papillary material of the plant. Galls may be open or closed but all provide an area where mites can feed without pressure from predators and where feeding mites are protected from desiccation. *Eriophyes brachytarsus* (Eriophyidae) attacks California black walnut where it causes either leaf puckering or purse galls. Blisters are formed within the parenchymal leaf tissues by feeding mites. The *Eriophyes pyri* species complex produces blisters on pears, apples, and other pomaceous plants. The citrus bud mite, *Eriophyes sheldoni*, causes deformation in fruit and leaves. Some species of eriophyids can spin silk which may act as a defense against predators. Eriophyid mites also cause plant stunting, shortening of internodes and adventitious twig development or witches broom. Some species of Eriophyidae transmit plant viruses. *Eriophyes tulipae* transmits wheat streak and wheat spot mosaic virus. *Cecidophyopsis ribis* transmits currant reversion, a viral disease of black currants. *Eriophyes ficus* transmits fig mosaic virus. *Eriophyes insidiosus* transmits peach mosaic virus. *Aculus fockeui* transmits latent plum virus.

Bee Mites

Over 100 species of mites are associated with honey bees. Three species are important pests: the varroa mite, *Varroa destructor* (formerly *jacobsoni*) (Gamasida: Dermanyssoidea: Varroidae); and the tropilaelaps mite, *Tropilaelaps clareae* (Gamasida: Dermanyssoidea: Laelapidae); the honey bee tracheal mite, *Acarapis woodi* (Actinedida: Tarsonemoidea: Tarsonemidae).

The varroa mite is considered the major pest of bees. It is found throughout the world with the exception of Australia, New Zealand and Hawaii. It causes varroasis (varroatosis or varrosis). The mite rips open the integument of the bee and feeds on hemolymph. It prefers young bees to older workers. Female mites are phoretic on adult bees. *Varroa destructor* is now considered to be a complex of at least five species. Control has been hard to achieve because chemicals must kill only the mites, and biological methods are often very labor intensive. Both the honey bee tracheal mite and the varroa mite have also been implicated in the spread of bee viruses.

The tropilaelaps mite is found in Asia from Iran south to New Guinea. It has a similar but shorter life cycle to that of the varroa mite. Female mites are phoretic on bees. It is believed that the mites feed only on the soft tissues of brood bees. Tropilaelaps mites can out-compete varroa mites because they have a shorter life cycle, and emerging mites spread by attaching to adult bees. However, both species can coexist because they occupy different niches in the same hive.

The honey bee tracheal mite lives within the tracheae of their hosts and have a foreshorten life cycle with only three stages. In the tracheae, they feed on bee hemolymph. Except for a brief period when searching for a new host, these mites spend their entire life within the tracheae. Females prefer to lay their eggs in the tracheae of younger bees, preferably drones. Infestations cause a cascade of problems from loss of brood area, and smaller bee populations, to lower honey yields. The honey bee tracheal mite is found worldwide except in Denmark, Sweden and Norway, New Zealand and Australia and Hawaii.

Several other species of mites are parasites of wild bees. *Locustacarus buchneri* (Actinedida: Tarsonemoidea: Podapolipidae) is a tracheal parasite of bumble bees of the genus *Bombus*. The female mite overwinters in the trachea of queen bees. In the spring she feeds on hemolymph and lays a moderate clutch of eggs that hatch into non feeding fertile males and motile six legged fertile larviform females. Mating occurs just after hatching and the gravid females go directly to worker bees where they attach inside the tracheal system and molt to an adult female. The adult female is sac like and much larger than males. She has only one pair of legs. In this unusual life cycle, eggs hatch directly into adult or adult like forms.

Miticide

A pesticide used to control mites. It also is called an acaricide.

► Acaricides and Miticides
► Insecticides

Mitochondrion, (pl., Mitochondria)

An organelle that occurs in the cytoplasm of all eukaryotes, capable of self-replicating. Each mitochondrion is surrounded by a double membrane. The inner membrane is highly invaginated, with projections called cristae that are tubular or lamellar. Mitochrondria are the sites of oxidative phosphorylation which result in the formation of ATP. Mitochondria contain distinctive ribosomes, transfer RNAs, and aminoacyl-tRNA synthetases. Mitochondria depend upon genes within the nucleus of the cells they inhabit for many essential mRNAs. Proteins translated from mRNAs in the cytoplasm are imported into the mitochondrion. Mitochondria are thought to be endosymbionts derived from aerobic bacteria that associated with primitive eukaryotes and have their own circular DNA molecules. The genetic code of mitochondria differs slightly from the universal genetic code. Mitochondria are transferred primarily through the egg, and thus maternally inherited.

Mitosis

The sequence of events that occur during the division of a single cell into two daughter cells.

Mixed Infection

Concurrent infection by two or more pathogenic microorganisms.

M'Lachlan, Robert

Robert M'Lachlan was born near Ongar in Essex, England, on April 10, 1837. He was educated at Ilford and was independently wealthy, allowing him to pursue his interests in botany and entomology. He became a leading British authority on Neuroptera and became the first editor of the British journal "Entomologist's Monthly Magazine." He was a member of many scientific societies, and published monographs on caddisflies and psocids, in addition to Neuroptera. He died in London on May 23, 1904.

► Butterflies and Moths

Mode of Action

The means by which a toxin affects an organism physiologically or metabolically. This term is usually used in concert with discussion of insecticides. Most insecticides are neurotoxins, disrupting normal nervous transmission by affecting either axonic or synaptic transmission. Others are metabolic inhibitors, affecting central cellular metabolic functions such as membrane permeability. Still others are more selective, affecting insect growth or molting.

► Insecticides

Molannidae

A family of caddisflies (order Trichoptera).

► Caddisflies

Molar

The grinding surface of the insect mandibles, often ridged or roughened.

Mole Crickets (Orthoptera: Gryllotalpidae) and Their Biological Control

J. Howard Frank, Norman C. Leppla
University of Florida, Gainesville, FL, USA

Mole crickets are strange creatures, highly adapted for a subterranean existence, including the development of their forelegs for digging. They are currently classified into two tribes, Gryllotalpini and Scapteriscini, although some taxonomists consider these to be subfamilies, Gryllotalpinae and Scapteriscinae. Adult of most species are long-winged and capable of flight, but in some species the adults are brachypterous and flightless. Within some species there are populations having long-winged adults and populations with brachypterous adults. The trochanter of each foreleg bears a long blade. The medial (inner) side of the tibia of each foreleg bears a tympanum (hearing organ). The tibia of each foreleg also bears a line of (in Gryllotalpini) four, or (in Scapteriscini) three or two large, fixed (immobile) dactyls (claws). There also are mobile tarsal dactyls. Each forewing of males bears a harp-shaped cell and a stridulatory file of minute pegs; these structures are used to produce a loud, species-specific song, of about 70 decibels when adequately projected. Adequate projection entails construction of a calling chamber at the mouth of a tunnel in the soil, formed in the shape of a loudspeaker and needing adequate moisture to make it fully functional. Song is projected by males to attract flying females, from sunset onward on humid nights in the flight season. The flight season is that time of year when most flight occurs, and in some species there may be a major flight season in spring and a minor one in autumn. Flying adults are mainly females. Females of at least some Gryllotalpini care for their eggs and the resultant small nymphs, showing a presocial behavior. The number of nymphal instars is variable even within species, ranging perhaps from seven to ten. At all events, the nymphs develop slowly. The number of generations per year may vary even within a species, so the populations of a given species may have as few as one generation every two years at high latitudes, but one annual generation at lower latitudes, or may have one generation per year at higher latitudes, but two at lower latitudes. For the most part, the diet of adults and nymphs is plant material, but in some species the diet has adapted to a major proportion of animal material such as earthworms and some small insects. Adults and nymphs spend most of their lives in the ground, but venture to the surface on warm, humid nights. They form galleries (temporary horizontal tunnels only just below the soil surface) as well as deeper, more permanent tunnels.

More than 90 species of mole crickets have been described, but only a few have been reported as pests. In eastern and southern Asia, some islands of Indonesia and the Philippines, some Pacific islands, and southern Africa, these are species of *Gryllotalpa*. In South America, the West Indies, the southern USA, and eastern Australia, they are species of *Scapteriscus*. Almost all control attempts have been by physical methods or by use of chemical pesticides. There have been few attempts at biological control albeit that some level of population regulation by native natural enemies undoubtedly occurs everywhere.

Five mole cricket species have been the targets of classical biological control programs. In Hawaii an invasive species of *Gryllotalpa* was detected in the late 19th century. Its precise origin and means of arrival seem unreported. However, it is not *G. africana* Palisot de Beauvois as was initially assumed, and it may be *G. orientalis* Burmeister, a species native to southeastern Asia. It was reported to damage sugarcane. There are no native mole crickets in Hawaii. In Puerto Rico, *Scapteriscus didactylus* (Latreille) is of South American origin. Hundreds of years ago it began a gradual range extension northward through the chain of islands of the Lesser Antilles, eventually reaching Puerto Rico and Hispaniola. This range extension most likely was by flight, from island to island. At all events, there is evidence that it had reached Puerto Rico at least as early as the eighteenth century. By the late nineteenth century, it was reported to cause severe damage to sugarcane and many other crops in Puerto Rico. Early reports of its presence in Cuba, Jamaica, and the southeastern USA were incorrect, the result of mistaken identity. Much later, it was detected in New South Wales, Australia, undoubtedly having arrived at least by 1982 as a contaminant of some air cargo or sea cargo. There are no native (pre-Columbian) mole crickets in Puerto Rico. In Florida, three South American *Scapteriscus* spp. arrived at dates between 1899 and 1925, very likely in solid (sand) ballast of ships trading with ports in southern South America. They are *S. abbreviatus* Scudder, *S. borellii* Giglio-Tos, and *S. vicinus* Scudder. They were first noticed as pests of vegetable crops. Later, as they spread and, as turf- and pasture-grasses of foreign origin (bermudagrass and bahiagrass) were imported and grown widely, the three mole crickets caused more and more damage to these grasses. There are no native species of the tribe Scapteriscini in Florida.

Thus, appropriately, classical biological control attempts were made only in new territories that the mole cricket species had invaded. All were attempts to find and import specialist natural enemies, especially from the homelands of the pest species.

Larra (Hymenoptera: Sphecidae) Imported into Hawaii

In 1924, small numbers of two South American *Larra* spp. (Hymenoptera: Sphecidae) were imported. Observation showed that the mole crickets were not suitable hosts for them, which was not surprising because their natural hosts are *Scapteriscus* mole crickets, not *Gryllotalpa*. A few were released and failed to become established. In 1925, *Larra polita* (Smith) ssp. *luzonensis* Rohwer specimens captured in the Philippines were imported into Hawaii, released and became established. It is now believed that the mole cricket attacked by *L. polita* in the Philippines is *G. orientalis*, which is thought to be the natural host of that wasp. The precise effect of the establishment of *L. polita* was not measured. The only evidence of success is lack of subsequent reports of damage caused by mole crickets in Hawaii.

Larra (Hymenoptera: Sphecidae) Imported into Puerto Rico

Puerto Rican entomologists in the 1930s explored northern South America for potential biocontrol agents of their pest mole cricket, *S. didactylus*. In Belém, on the Amazon in Brazil, they encountered *Larra bicolor* (F.) and, after several attempts, finally got it established in their island. They noted heavy use of a nectar-source plant, *Spermacoce verticillata* L. (Rubiaceae), by its adults in Brazil and Puerto Rico. Damage by pest mole crickets seems to have declined dramatically in Puerto Rico since that time, but nobody has measured the effect of *L. bicolor* as a contributor to that decline. It may not have been the only contributor, especially because *Bufo marinus* L. (Amphibia: Bufonidae), a generalist predator of large insects had already been imported by the same Puerto Rican entomologists, and became established. To the extent that *S. didactylus* and two other *Scapteriscus* spp. (*S. abbreviatus* and *S. imitatus* Nickle and Castner) are still at least occasional pests in Puerto Rico (they seem to be constant pests on golf courses), continued effort in their biological control might have been expected. But control attempts after ~1950 reverted to the use of chemical pesticides, and renewed effort in biological control did not occur until the twenty first century.

Larra (Hymenoptera: Sphecidae) Imported into Florida

University of Florida entomologists in the 1940s noted what seemed to have been achieved by importation of *L. bicolor* into Puerto Rico and made feeble attempts to do the same. They were unsuccessful, in part because a war was then in progress and travel was difficult, in part because of the discovery of the chemical chlordane, which seemed at least to their administrators to provide a long-term and inexpensive means of controlling mole crickets, so that there was no need for biological control. Those entomologists were aware of the importance of *Spermacoce verticillata*, and it may have been they who introduced this plant into Florida. The presence of the plant in Florida was not detected by botanists until the 1960s, so the timeline matches. After chlordane was banned by the US EPA in the 1970s, University of Florida entomologists were mandated by the Florida legislature to begin a program that would solve the problem caused by *Scapteriscus* mole crickets. One of their early actions was importation of *L. bicolor* wasps from Puerto Rico, released at sites prepared with plantings of *Spermacoce verticillata*. They were successful at their first attempt in 1981 with a release at Ft. Lauderdale, but unsuccessful with subsequent releases at sites farther north. Regrettably, the *L. bicolor* population near Ft. Lauderdale failed to spread. Worse, its measured effect on the local pest mole cricket population was trivial. Perhaps the reason was because the founding stock was originally from the equator, and was too tropical to spread widely in Florida.

In 1988–1989, University of Florida entomologists imported stock of this same wasp species from a higher altitude, in Bolivia, and released it in northern Florida (Gainesville). The Bolivian stock became established and began to spread and, as of August 2006, has been reported from 28 Florida counties (reports from a few additional counties need confirmation by specimens or photographs). A satellite release at Tifton, Georgia, in 2001, established it there; it has subsequently been reported from Georgia locations 150 miles northeast and >100 miles southwest of Tifton. It has also been encountered in coastal Mississippi; assuming that it spread there from Florida or Georgia, it should be present in coastal Alabama and may possibly spread to coastal Louisiana and Texas. There is no published evaluation of its effect on pest mole crickets anywhere in the USA. A preliminary estimate for two sites in Alachua County is of almost 70% mortality of *Scapteriscus vicinus* in the autumn months of 2000–2001, but verification needs mathematical modeling because there are several wasp generations per one annual mole cricket generation. At all events, *L. bicolor* is a major mortality agent of pest mole crickets in northern Florida, and its population should spread everywhere in Florida where there are pest mole crickets.

Adult female wasps are active during the warmest hours of each day. They search the ground surface for evidence of mole cricket activity, entering mole cricket burrows and chasing the denizens to the surface. There, they grapple with the mole cricket in attempt to sting and paralyze. A sting to the head paralyzes a mole cricket for a few minutes only, during which time the female wasp lays an egg on the underside of the thorax. From the egg hatches a larva (grub) that feeds as an ectoparasitoid (on the outside of the mole cricket). When the grub has killed the mole cricket, it spins a cocoon and pupates in the ground. The duration of the pupal stage is highly variable, lasting many months during the winter in northern Florida, and allowing survival of the population during freezing temperatures. There are more annual generations in tropical areas and fewer generations in more temperate areas, with the pupal stage in diapause acting as the means of surviving winter in places where freezing temperatures occur. The northern limit of occupation by *L. bicolor* in the southeastern USA has not yet been determined, but likely is little more than 31°N.

Ormia depleta (Diptera: Tachinidae) Imported into Florida

Ormia depleta (Wiedemann) larvae parasitize at least some species of *Scaptericus* mole crickets. This fly's distribution includes not only Amazonian Brazil (as was discovered by Puerto Rican entomologists) but also southern Brazil at least as far as 30°S, and at least part of Paraguay. Stock of the fly obtained at 27°S at Piracicaba in the Brazilian state of São Paulo was imported into Florida in several shipments in the late 1980s. Painstakingly reared individually by the thousands on mole cricket hosts, progeny were first released in 1988 near Gainesville (Alachua County) and Bradenton (Manatee County). More releases followed over the next four years in all parts of Florida. By 1994, it was recognized that the stock had occupied all peninsular counties (38 of them) to 29°45' N, but that occupation of the northernmost of these counties was temporary, with a permanent population occurring only south of 28°45' N, and with increase of that area but little to the north each autumn. The established stock of the fly did not overwinter routinely north of about 28°45' N. Southernmost Brazil (Rio Grande do Sul) was then explored for this same fly, and stock was imported from the southernmost locality where it was detected (at 30°S), near Osorio, northeast of Porto Alegre, in 1999. Progeny were reared, and were supplied to collaborators in Georgia, Louisiana, and North Carolina for release, but these collaborators reported no evidence of establishment in their areas. Study of the diapause capabilities of this southern stock was entrusted to two University of Florida PhD students who were to characterize development of the fly at assorted conditions of photoperiod, temperature and humidity, and determine whether diapause can or cannot occur, the idea being to determine whether the fly can survive cold winters in diapause. Neither student succeeded before the fly culture died out, likely due to inbreeding. For the present, we have to conclude that there is no evidence that the fly can diapause in winter, so perhaps there is no hope that it can establish permanent populations in northern Florida and states to the north.

Adult flies are nocturnal and gravid females are phonotactic (use the song of mole crickets to detect hosts). They larviposit, and larvae penetrate the host mole cricket, killing it within ~8 days. Larvae then pupate in the ground for 11–12 days before the new adult generation emerges. Evaluations of mole crickets trapped in pitfall traps in May 1993 and May 1994 in Orange County revealed parasitism of 24–25%. Because parasitized mole crickets die after ~8 days, and because *O. depleta* has several generations each year in contrast to just one for the mole crickets, the mortality inflicted by the fly is likely to be considerable. At all events, the level of control exerted by this fly is now free in central and southern Florida. If funds were made available, it should be possible to further evaluate current effects and to design methods to enhance effects. An effort to import the fly into Puerto Rico in the 1930s was unsuccessful, and the effort has not been repeated.

Steinernema scapterisci (Rhabditida: Steinernematidae) Imported into Florida

Detected by its emergence from dying pitfall-trapped *Scapteriscus* mole crickets in Uruguay in 1995, this nematode was brought to Florida and later described as a new species. Dauer larvae of *S. scapterisci* Nguyen and Smart harbor specialist bacteria of the species *Xenorhabdus innexi* Lengyel et al. When the larvae, lurking in the soil, detect a passing *Scapteriscus* mole cricket, they attempt to enter it through its mouth or spiracles. If they are successful, they break into its body cavity and release the bacteria. The bacteria reproduce inside the insect's body cavity, killing it through septicemia. The nematodes feed within the dying mole cricket, mature, undergo two generations, and release bacterium-carrying dauer larvae back into the soil. This process (from attack to release of offspring into the soil) can be accomplished within ~10 days at warm temperatures, but may perhaps be extended for weeks at cool winter temperatures when pest mole crickets retreat deeply into the soil and activity by mole crickets and nematodes alike is greatly slowed. A further complication is that *Scapteriscus* nymphs are scarcely susceptible to attack by *S. scapterisci*, perhaps because their body apertures (mouth and spiracles) are too small to be penetrated by the dauer larvae. Releases of this nematode, reared within laboratory cultures of mole crickets, were first made in Florida on a very small scale in 1985. They established permanent populations and began to spread.

Development of mass-production methods by industry allowed sales of *Steinernema scapterisci* (several trade names have been used) as a biopesticide. It also allowed experimental applications on a bigger scale than before. These experiences showed that applications are best timed when adult mole crickets (not nymphs) are abundant and active, so in February–April and September–November in central and southern Florida (February is perhaps too early in northern Florida). Applications are effective against *Scapteriscus borellii* and *S. vicinus*. They do not kill as high a percentage of pest mole crickets measured in the short term (days) as do the most effective chemicals. However, applications generally initiate permanent populations that suppress pest mole cricket populations for years in pastures, playing fields, and golf courses. Cost of application in pastures has been greatly reduced by treating one swath (strip) in eight across a pasture, because easily within the space of a year the nematode population spreads throughout the pasture. Such spread is due to transport of nematodes within newly-infected mole crickets. The same transport eventually allows the nematode to occupy distant sites with mole cricket populations.

Steinernema scapterisci (Rhabditida: Steinernematidae) Imported into Puerto Rico

In 2001, under USDA-APHIS permit, *Steinernema scapterisci* was applied at two localities in Puerto Rico, and in subsequent years in three more localities, all in the west of that island. In the laboratory, it was demonstrated to be effective in attacking and killing adult *Scapteriscus didactylus*, but survival of its dauer larvae in some Puerto Rican soils seemed to be poor. Such soils included highly organic sandy soils in which antagonists may have been present. They also included a sandy loam. Such high mortality had not been observed in the sandy soils where survival has been so good in Florida. Nevertheless, the nematode should now be established in Puerto Rico and should gradually spread.

Conclusion for Florida

Classical biological control of *Scapteriscus* mole crickets in north-central Florida has been highly successful due to establishment of three biological control agents from South America, and success is spreading throughout Florida as populations of *Larra bicolor* and *Steinernema scapterisci* spread (*Ormia depleta* may already have spread to its fullest possible extent). The ultimate level of success should be enough to obviate all need for chemical treatment of lawns, playing fields, and pastures to control pest mole crickets. This leaves four situations where classical biological control may need enhancement. The first, in pastures where *Steinernema scapterisci* is not yet present; owners/operators need to be aware of the availability of this nematode, and that it may be applied in swaths (strips) across a mole-cricket-infested pasture, at the level of one treated swath per seven untreated swaths, to achieve distribution throughout the pasture within a few months, a big reduction in cost over complete pasture treatment; they also should be aware of the possibility of planting *Spermacoce verticillata* to enhance *Larra bicolor* presence. The second is organic farms, where owners/operators need to be aware of their ability to buy and apply *Steinernema scapterisci* if it has not already been applied, and to plant *Spermacoce verticillata* or another nectar-source plant to encourage populations of *Larra bicolor* (alternatives to *S. verticillata* are under investigation). The third is regular commercial vegetable farms where owners/operators need to be aware that use of *Steinernema scapterisci* is compatible with use of many if not all chemical insecticides, so they should not be reluctant to buy and apply the nematode because this provides partial control of pest mole crickets indefinitely, at a huge potential cost saving. The fourth is golf courses, most of which have experienced a decline in damage caused by mole crickets. Although this decline is due to the spread of classical biological control agents, the golf course personnel in general have no experience in detection of the presence of any of the three biological control agents, so their assumption has been that they now have wonderful new chemical insecticides that solve their previous problems with mole crickets. A little thought should reveal to them that it is strange that the wonderful new "chemicals" have suppressed mole crickets only, while damage by other insect pests has "increased" dramatically. What of course has happened is that classical biological control has decreased pest mole cricket populations dramatically, and that golf course personnel are left to deal with the previously minor (at least in Florida) problem caused by larvae of Scarabaeidae. Further, mole cricket populations have declined also in pastures, where chemicals are not applied. There is an enormous educational task to be performed – and a new biological control challenge – how to suppress populations of pest scarab larvae, many of which are native.

Conclusion for Other Southeastern States of the USA

Larra bicolor should continue to spread, deliberately helped or not, to the coastal areas of Alabama, Missisippi, Lousiana, and Texas. It is unlikely to spread much to the north of about 31°N. *Ormia depleta* is highly unlikely to spread to northern Florida, and not beyond Florida's borders. *Steinernema scapterisci* may (at least at present) be purchased and applied against pest mole crickets anywhere in the continental USA. Its purchase and application is a good investment if applied in early spring, even if it cannot overwinter. But perhaps it can overwinter, in at least parts of Alabama, Louisiana, Mississippi, North Carolina, South Carolina, and Texas and suppress pest mole crickets for several seasons. It is up to entomologists/nematologists in those states to investigate. At all events, it does overwinter in southern Georgia. If sales of *Steinernema scapterisci* are not sufficient, its producing company is likely to discontinue production. Thus, *now* is the time for trial applications in states north of Florida.

Conclusion for Puerto Rico

Larra bicolor seems to have provided partial suppression of pest mole cricket populations for many decades. *Steinernema scapterisci* should now be established in northwestern Puerto Rico. If so, it should continue to spread. Landowners/managers should familiarize themselves with biological control solutions and urge distributors to import *Steinernema scapterisci* for sale; there should be no bureaucratic impediment to such importation because that nematode already is established. It may be possible to introduce *Ormia depleta*.

Conclusion for Eastern Australia, Islands of the Lesser Antilles, and the Dominican Republic

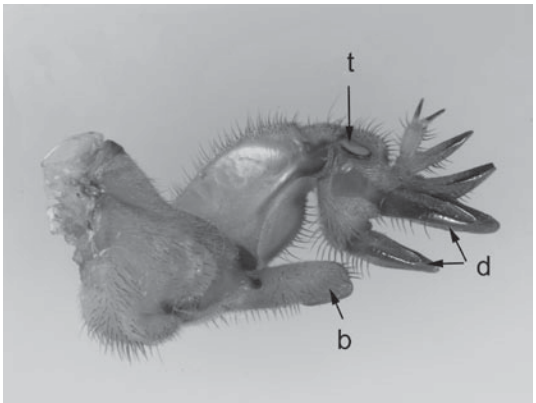
Now is the time to consider whether importation of biological control agents (*Ormia depleta*, *Larra bicolor*, *Steinernema scapterisci*) would be an advantage over current repeated chemical applications against *Scapteriscus didactylus* control. It is not a good idea to delay because the easiest source of these biological agents is Florida, where biological control expertise is winding down with retirements.

Conclusion for South America

Where *Scapteriscus* mole crickets are a problem, for example on golf courses using fresh soils that *Steinernema scapterisci* has not yet reached, application of the nematode is the most immediately viable biological control option. This would now demand the purchase of these nematodes from the only current producer, in North America.

Conclusion for Hawaii

There is no current problem with pest mole crickets. It would be satisfying to identify definitively the one pest species present, which may or



Mole Crickets (Orthoptera: Gryllotalpidae) and Their Biological Control, Figure 79 **Medial (inner) side of left foreleg of *Scapteriscus borellii* Giglio-Tos showing trochantal blade (b), tympanum (t), two fixed dactyls of tibia (d), and movable tarsal dactyls. Photo: Lyle Buss.**

may not be *Gryllotalpa orientalis*, and is not *Gryllotalpa africana* as was assumed for decades.

Conclusion for Africa and Southern Asia Including the Philippines and Indonesia

Taxonomic revision of Asian mole crickets is essential. Decades of "basic" studies of potential biological control agents may be necessary before suitable species for use in any given geographical area are adequately researched. The various biological control agents researched in Florida and Puerto Rico for use against *Scapteriscus* mole crickets are not suitable for use against *Gryllotalpa* mole crickets (Fig. 79).

Molecular Biology

A term broadly used to describe biology devoted to the molecular nature of the gene and its biochemical reactions such as transcription and translation.

Molecular Diagnosis

MARIA NAVAJAS[1], GEORGE RODERICK[2]
[1]INRA, UMR CBGP (INRA/IRD/Cirad/ Montpellier SupAgro), Montferrier-sur-Lez, France
[2]University of California, Berkeley, CA, USA

Molecular diagnosis refers to the taxonomic determination of organisms based on molecular criteria. Correct taxonomic determination is critical for entomological applications in many fields, including agriculture, environmental science, biosecurity, and human health. Because a major challenge in taxonomy is the discrimination among closely related forms, diagnosis mainly concerns the identification of organisms at the species level. One example is the case of cryptic species complexes, which are groups of closely related species that are difficult or impossible to distinguish by morphological traits alone. These complexes are known from a wide variety of arthropods and have been well studied in medically and economically important insects. For example, despite a near identity in morphological appearance, several sibling species of mosquitoes are separable with a variety of molecular-based methods. Conversely, molecular systems can be used to establish synonymy between presumed cryptic species. Often, identifying closely related species using traditional taxonomic methods is difficult for non-specialists and requires expert knowledge of the group; molecular identification keys based on targeted DNA sequences can provide a valuable identification system for such groups, as for example for species of thrips in the genus *Scirtothirps*. Molecular diagnosis is a great motivation for recent initiatives in DNA barcoding in which a standard section of DNA, typically part of mitochondrial cytochrome-oxidase I, is used to identify species.

The Species Concept

There has been considerable debate in the literature concerning the most appropriate definition of species. Classically, species are described on the basis of morphological characters, and the common basis for species identification is the presence of one or more fixed or non-overlapping differences. If these differences are both shared and derived, the groups are considered phylogenetic species. However, morphological data alone may be inadequate for defining species boundaries. For example, two species may be sympatric in range (overlapping) or parapatric (abutting), but be so similar in morphology that their specific status goes undetected. Conversely, morphological variation may be so great in one species, that identification of single biological unit is difficult.

Another commonly held view of species is the evolutionary species concept, in which a species represents a single lineage of ancestral-descendant populations that maintains its identity from other lineages and that has its own evolutionary tendencies. This view is similar to the biological species concept, in which species are viewed as a set of interbreeding organisms. While the biological concept of species is a meaningful one for many applications in which a species determination is necessary, biological experiments to assess biological species are not possible for some species.

Tools of molecular biology provide a powerful means to determine whether organisms belong to a single evolutionary lineage or interbreeding unit. Analysis of gene genealogies using coalescent theory can be used to identify single lineages. Individual organisms differ in the DNA sequences that make up their genomes and differentiation between species is based on mutations in the genes that accumulate through time. Because any given allele in an organism derives from an allele in an ancestor, DNA data have the potential to define the genealogies of genes and infer phylogenetic relationships of taxa. Molecular genetic data can also help to understand the nature of biological species, as well as the extent and causes of intra-specific variability, including ecotypes, host races, or phenotypically adapted forms.

Molecular Methods for Diagnosis

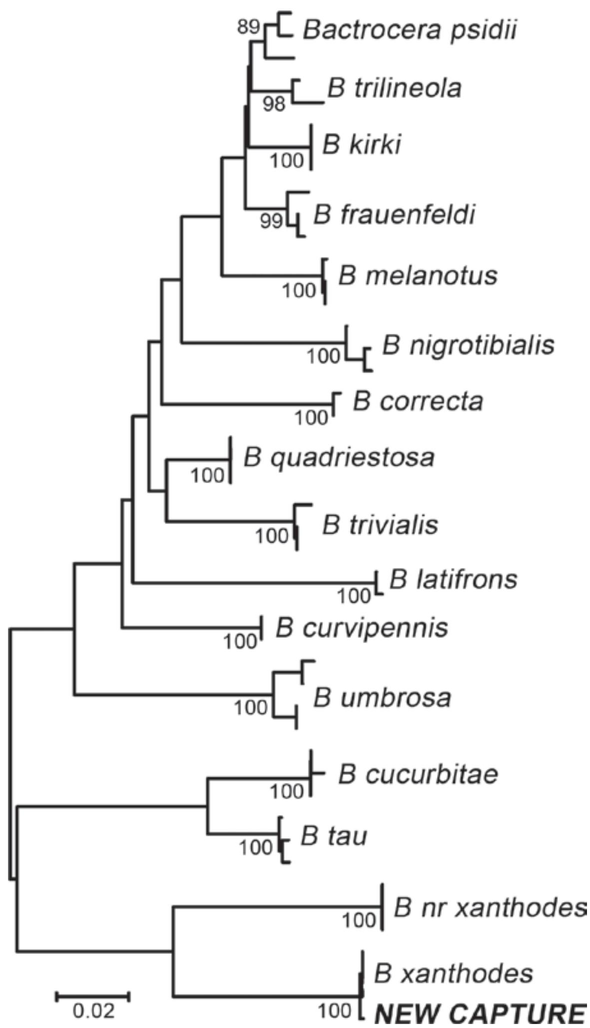
The analysis of DNA is an increasingly important tool in studies of insects, particularly for systematics and population biology. DNA has several significant features that make it especially useful: (i) the genotype rather than the phenotype is assayed; (ii) one or more loci appropriate to a problem can be selected on the basis of evolutionary rate or mode of inheritance, (iii) the methods are applicable to all developmental life stages and both sexes, and (iv) DNA can be prepared from small amounts of tissue and is relatively stable, even in tissues that are not stored cryogenically (deep frozen). One reason for the success of molecular diagnosis is the use of the polymerase chain reaction (PCR) in which specific stretches of DNA are amplified, allowing the development of fast and sensitive molecular techniques. As a result, only a small portion of the insect is needed for molecular diagnosis.

Two major classes of DNA-based approaches are used in taxonomy. The first involves comparison of nucleotide sequences for a particular locus or loci, usually amplified by PCR. The DNA sequence variation can be examined directly following automated DNA sequencing. This is the approach used in DNA barcoding. Sequence variation can also be assessed indirectly by comparing electrophoretically homologous DNA fragments to look for variation in number, size or conformation. In a method termed restriction fragment length polymorphism (RFLP), a PCR product is first generated and then digested to completion with a restriction enzyme to yield a species-specific pattern of bands that can be visualized on a gel. Another powerful technique, allele specific amplification (ASA), is based on the fact that *Thermus aquaticus* (*Taq*) DNA polymerase will only extend primers that are matched to their template DNA and will not extend primers that do not match the template DNA. PCR primers can therefore be designed so that they only match one allele and, providing that the allele is specific to a species, a PCR product will only be generated with the primer matching the genomic DNA of the corresponding species. Other approaches for assessing similarity of sequences are based on the fact that the presence of point mutations of the nucleotide sequence that differ among species will affect the tertiary conformation of the DNA molecule.

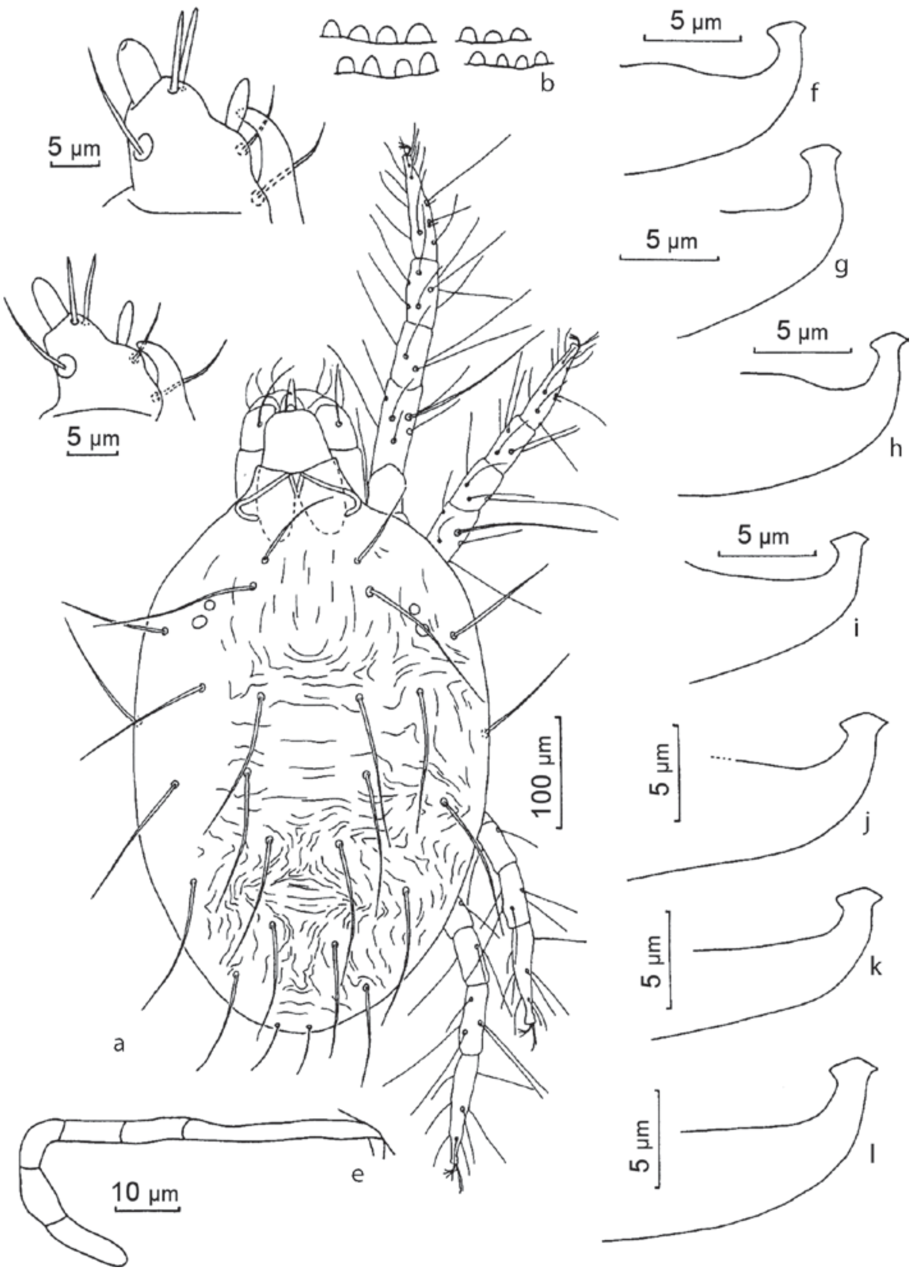
The second class of approaches used in DNA taxonomy is so-called DNA fingerprinting or fragment analysis. Each of these methods simultaneously screens many different DNA regions or fragments, which are thought to be distributed randomly throughout the genome. Although fingerprinting and fragment approaches offer less resolution than nucleotide sequencing in some respects, they are powerful and cost-effective alternatives where large numbers of individuals or large segments of a genome are being screened. In general, these techniques have the great advantage that they can be applied to systems where there is no prior molecular information about particular loci. Multi-locus markers are often detected by annealing primers of arbitrary short sequences during PCR amplification and looking for species-diagnostic bands among the array of randomly amplified fragments, as in the method of randomly amplified polymorphic DNA (RAPDs). More complex and more reliable methods use a combination of restriction enzymes and PCR, as is the case of amplified fragment length polymorphisms (AFLPs). The most widely used markers for population genetics of insects are now microsatellites, which are non-coding sections of repeated small motifs of a few base pairs. Microsatellites are repeatable and can be sufficiently variable for use in many types of population studies including studies of the origins of individuals, population structure, and hybridization. Typically, microsatellite loci must be developed anew for each new species, or set of closely related species.

There is a trade-off between the detailed information that can be obtained by sequencing the DNA at one or a few loci and the more abundant, though less detailed, information that can be obtained through studies of restriction sites, fingerprinting, or microsatellite analysis. For most population genetic analyses the power of a statistical test increases with the number if loci examined. Towards this end, single nucleotide polymorphisms (SNPs) provide the smallest possible (and potentially the greatest number) of genetic loci, but to date studies involving SNPs have only been possible for organisms where there is some prior genomic information that can help to guide the discovery of loci, such as through whole genome sequencing. Initially whole genomes were available only for a select group of model organisms, including species of *Drosophila*, mosquitoes, and the honey bee. However, in the last few years many new projects have made available the genome sequence of more insects and other arthropods (e.g., ticks and spider mites) and the list of these species is continuously increasing. Currently, advances in sequencing technology and bioinformatics are revolutionizing the production of genomic sequence data; accordingly, in the not too distant future whole genomes will be available for a wide spectrum of species.

Selecting the sequence or markers to be analyzed is the first decision to be made in designing any molecular systematic or population genetic study, whether it concerns DNA sequences or fragment variation. In broad terms, choices are made according to evolutionary rate and mode of inheritance. The ribosomal DNA (rDNA) and the mitochondrial DNA (mtDNA) have been the most commonly used genomic regions for systematic studies of animals. The processes governing the evolution and inheritance of mtDNA and rDNA are now well understood and have an impact in their relative performances for systematic inference. For example, the two very closely related but reproductively isolated spider mite species, *Tetranychus urticae* and *T. turkestani* are polyphyletic for mtDNA but monophyletic for rDNA. The influence of life history, mainly haplodiploidy of these species and their female-biased sex-ratio, might explain this apparent contradiction. Another fundamental to establish synonymy between presumed species choice is whether information concerning the phylogeny of the alleles is necessary; some techniques (e.g., RAPDs, AFLPs, microsatellites, SNPs) provide information only on the latter. Recent developments in population genetic theory use information on allele relationships as well as their distribution to combine inferences about population structure and history. However, for species diagnosis, information on allele frequency distributions may suffice.



Molecular Diagnosis, Figure 80 **Identification of a tephritid fruit fly species using DNA barcoding. In this example, fly eggs from an unknown species were found in fruits that were intercepted at the border in New Zealand. Because the eggs of tephritid fruit flies are not possible to identify to species morphologically, similarity in mitochondrial DNA COI was used to match the intercepted eggs (noted as "new capture") with DNA from known voucher specimens. In this example, the unknown species was identified as *Bactrocera xanthodes*. (Data used with permission of Karen Armstrong, Lincoln University, New Zealand; for additional examples, see Clarke et al., 2005.)**



Molecular Diagnosis, Figure 81 The morphological characters classically used to separate *Tetranychus* species are presented for *T. pueraricola*: a = female dorsum; b = lobes on dorsa hysterosomal striae of female (schematic); c = distal palpus segment of female; d = distal palpus segment of male; e = female peritreme; and f–i = aedeagi. Comparison of *T. peuraricola* aedeagi (f–i) with *T. urticae* aedeagi (j–l) illustrates the difficulty in separating the two species by morphological criteria alone. (Data used with permission of Tetsuo Gotoh, Ibaraki University, Japan.)

DNA Barcoding

DNA barcoding is the use of a short DNA sequence from a standardized and agreed-upon position in the genome for molecular diagnosis and identification at the species level. For most animals, including insects, the cytochrome C

Molecular Diagnosis, Figure 82 **Molecular diagnosis of two closely related species of agricultural mite pests, *Tetranychus urticae* and *Tetranychus pueraricola*, which are impossible to separate by morphological criteria. Shown is a PCR-RFLP test in which the second internal transcribed spacer (ITS2) of the ribosomal DNA has been PCR amplified and digested by the restriction enzyme *Rsa*I for the two species. In the figure, *Rsa*I digestion of the PCR-amplified ITS2 derived from the DNA of a single mite clearly shows that *T. urticae* sequence produces 3 fragments (implying 2 recognition sites of the enzyme; lane 2), while the restriction profile of *T. pueraricola* yields only 2 fragments (implying a single recognition site; lane 3). In lane 1 the "100 base pair (bp) ladder" size marker is shown.**

oxidase subunit 1 mitochondrial region (COI) has become the standard barcode region. Because of conserved genetic regions flanking this gene and because it is so abundant within individuals, the COI gene sequence is easily obtained from insects. Within species, COI sequence variability is typically very low, making it useful as a species diagnostic marker. Species are identified based on the similarity of COI sequences to known voucher specimens. However, the widespread use of DNA barcoding has been controversial, particular in its application to systematics. Accordingly, it is now well recognized that additional loci and other sorts of biological data will be necessary for applications in evolutionary and population biology that involve systematics or studies of complex population histories including hybridization (Figs. 80–82).

Molecular Genetics

Genetic studies that focus on the molecular nature of genes and gene expression.

Molecular Phylogeny

An analysis of the relationships of groups of organisms as reflected by the evolutionary history detected in molecules (proteins, DNA).

Molicutes

A class of wall-less microorganisms, surrounded by a membrane, and related to bacteria. They are small, gram-negative, and highly variable in appearance.

Molt

To shed or cast off the outer body covering, a necessary prerequisite to grow and attain the adult stage. The period of molting is a vulnerable stage for insects, as they are susceptible to desiccation and easy prey for predators.

Molting Fluid

An enzyme-rich fluid secreted into the apolysial space by the epidermal cells. The molting fluid consists of proteinases and chitinases that digest the endocuticle during molting. The molting fluid is reabsorbed through the epidermal cells shortly before ecdysis in many insects, though in some insects the new instar apparently swallows the old fluid.

Molting Hormone

A homone regulating molting in insects. Also called ecdysone.

Mompha Moths (Lepidoptera: Momphidae)

JOHN B. HEPPNER
Florida State Collection of Arthropods,
Gainesville, FL, USA

Mompha moths, family Momphidae, total 127 species worldwide, with about half from the Palearctic. The family is part of the superfamily Gelechioidea in the section Tineina, subsection Tineina, of the division Ditrysia. Adults small (8–18 mm wingspan), with head smooth-scaled; haustellum scaled; labial palpi recurved; maxillary palpi small, 3-segmented. Wings elongated and hindwings mostly lanceolate with long fringes (Fig. 83). Maculation often white with golden iridescent markings, or darker with

Mompha Moths (Lepidoptera: Momphidae), **Figure 83** **Example of mompha moths (Momphidae), *Mompha eloisella* (Clemens) from Florida, USA.**

various marks. Adults mostly diurnal or crepuscular. Larvae mostly leafminers, but some are borers in flowers and stems, or gall makers. Hosts are only known in Onagraceae.

Monarch Butterfly, *Danaus plexippus* L. (Lepidoptera: Danaidae)

THOMAS C. EMMEL, ANDREI SOURAKOV
University of Florida, Gainesville, FL, USA

The monarch is one of the world's best-known butterflies. Its distribution is among the widest for any butterfly species. Not only it is found throughout the Americas, including the islands of the West Indies, but it reaches as far as Australia and New Guinea, and occasional individuals migrate to Western Europe.

The monarch butterfly is native to tropical America where populations breed throughout the year. These sedentary populations are different from the migratory North American ones and bear separate names. For example subspecies, *megalippe* Hübner is found in Mexico and Central America and southeastern United States. The southern South American subspecies is called *menippe* Hübner. Several subspecies have also been described from the islands in the Caribbean. None of these geographic races are "pure," with occasional individuals of the migratory subspecies phenotype, *D. plexippus plexippus*, found in all of them. It has even been suggested, yet not proven, that sedentary subspecies might indeed prove to be separate sibling species. Due to the versatility of its weedy host plants – the milkweeds – and its ability to cover large distances, this highly adaptable butterfly occupies a variety of ecological zones, but is found mostly in open sunny areas. In Costa Rica, for example, monarchs fly from sea level up to 2,500 meters in elevation and are particularly common above 1,500 meters.

Though the monarch male has been observed to exhibit a basic kind of courtship behavior, wiggling in its flight while approaching a female, the essence of the mating "ritual" in this species can be described as "rape." Copulation involves the male grasping the female with its legs in flight and bringing the female down from the air to the ground in order to clasp her abdomen with the external genitalia. The white eggs are laid singly on the flowers or the underside of the leaves of one of the many milkweed species, and larval feeding commences immediately upon hatching; there is no diapause stage, except that adults on the overwintering sites go into reproductive diapause. Toxicity of the milkweeds varies and so does toxicity of resulting butterflies, as has been demonstrated through bird-feeding experiments. The striped larvae with two pairs of tentacles (the elongate tubercles, the function of which remains unknown) develop into green, gold-studded pupa within two weeks. The larvae from the Caribbean island of Hispaniola show much wider black stripes than these of the North American population. Differences in length of tentacles and abundance of gold coloration in pupae have also been recorded between the migratory population and one in Jamaica. Overall, though it was one of the earliest butterflies to acquire its scientific name (Linnaeus, 1758), the taxonomy of *Danaus plexippus* remains a widely debated issue.

Monarch Migration

At some time in the relatively recent past, probably during the Pleistocene advances and retreats of great glacial masses across the northern areas of temperate North America, a subset of the North American monarch population began its marvelous annual movements. Its movements represent a true migration, involving a periodic movement from a given area and a return to that area, and likely evolved to exploit dozens of seasonally available milkweed species north of the tropics. Migration apparently is triggered by changes in temperature in an ultimate sense and perhaps changes in photoperiod in a proximate sense. Typically, the monarch populations across the North American continent begin moving in a generally southerly direction starting each fall around September 1. West of the Rocky Mountains, these populations move primarily to about 129 sites along the Pacific coast of California and Baja California. There, they hang in trees such as coastal groves of pine, cypress, redwood, and the introduced Australian eucalyptus trees in clusters or colonies of several hundred to several tens of thousands of individuals from late fall to early spring. Some overwintering colonies have recently been discovered in Saline Valley, north of Death of Valley in the eastern desert areas of California, while other population movements through southern Nevada and Arizona suggest that there are still as yet undiscovered overwintering sites in northern Mexico for these western monarchs.

East of the Rocky Mountains, Canadian and U.S. monarchs move south to the Gulf Coast where the vast majority turn southwest and enter Mexico across the Texas border, flying south by the hundreds of billions. They ascend the Sierra Madre de Oriente into the Central Plateau and eventually end up in the high coniferous forests of the Transverse Neovolcanic Belt of central Mexico, principally within the states of Mexico and Michoacan. The existence of an over-water pathway used by eastern Monarchs has been documented recently. They fly across the Gulf of Mexico between the southwest coast of Louisiana to the northeast coast of Tamaulipas, Mexico, an over-water flight of 400 miles. In addition, some monarchs are known to fly to various points on the northern Florida coast (from which they may still cross the Gulf of Mexico) or to south Florida, from which they may fly to overwinter in Cuba. Most of the eastern monarchs, flying in a south-southwesterly direction, take advantage of southward moving cold fronts. The stored fat allows for only 11 h of wing-flapping flight, or 44 h of cruising flight, but thanks to the frequent tail winds, monarchs use soaring flight that allows for a theoretical transit distance to exceed 1,000 km on their available energy sources without refueling. In actual fact, monarchs feed heavily during migration, and arrive at the overwintering sites with more stored fat than when they started. Migratory monarchs have been observed flying at altitudes as high as 11,000 feet above the land and individuals normally fly 11–12 h, covering 200–400 miles a day. Much of our understanding of the movement rates and migratory pathways followed by the monarchs have been revealed by tagging programs, initiated in 1952 by F.A. Urquhart at the Royal Ontario Museum in Toronto, Canada, and subsequently taken up by hundreds of other workers. The maximum distance traveled by a single tagged monarch is 2,595 miles (from New Brunswick, Canada, to the Cerro Pelon colony in Michoacan).

Once the monarchs arrive at their overwintering sites, they remain largely quiescent for a period of 4.5 months, until late the following March. They may leave the colony area briefly to drink water or nectar but return the same day (often in the same hour or two) to their trees. The overwintering butterflies remain reproductively inactive with the diapause being terminated in late March by the combined influence of temperature and photoperiod onto the monarchs' neuroendocrine system. In the last ten days of March, the Monarchs become increasingly active, mate at the colony site and then take off again for the north. These same individuals who flew south in the fall return in a generally northward direction to recolonize the North American continent for the summer. The adults from the Mexican colonies are known to reach the southern boundary of the United States by early April, lay their eggs, and then die. The eggs are laid on newly leafed out milkweed plants and growth is rapid. The first generation of adults for the new year emerges in late April, flies north through the middle tier of states and lays eggs throughout the area. The second generation of adults emerges by late May or early June and again flies northward. A third and fourth annual generation may emerge by the end of August. At this point, third, fourth and even fifth generation adults of the original northward moving migrants prepare to move south, over a path that they have never followed themselves.

Physiologically, monarchs have to build up fat protein reserves for the migration. However, they arrive on the overwintering sites with even more lipid reserves than they started with; this increase (up to 73% of their dry body weight) is due to heavy feeding on desert flowers as they fly south through the Central Plateau. Adequate lipid energy reserves are essential for passing the winter successfully. Spring monarchs are severely depleted of fat reserves (fat accounts for only 37% of dry weight in March) and they need to feed heavily during their spring northward movement to successfully reach the United States again and reproduce.

The monarch movements represent the world's greatest modern animal migration, involving the movements of at least one billion individual monarchs annually and perhaps as many as three billion in some years. The orientation ability of the monarchs to move nearly 3,000 miles and arrive precisely at a point to which they have never been before (at the end of the fall migration) is only beginning to be understood. A remarkably accurate sun compass mechanism keeps the monarchs on their general bearing. Considerable evidence also exists for orientation by magnetic fields. The Mexican Transvolcanic Range where the largest overwintering colonies exist contains magnetic anomalies a hundred times stronger than other surrounding terrain, due to heavy metallic ore deposits. The presence of magnetic materials in the monarchs' head and thorax has been demonstrated, significantly exceeding magnetite contained in its non-migratory relatives. Scent may be involved in locating the exact trees that their ancestors used the year before. The odor must come from billions of scales and perhaps scent molecules which still remain on the evergreen firs into the fall months, following the spring departure of their predecessors. Almost equally remarkable is the ability of the monarch colony to adjust its exact position on the mountain slope in elevation above sea level, height in tree, and even position on tree trunks and fir boughs daily to compensate for changes in weather, nightly temperature minima, fluctuating insulation values in cloud cover, etc.

Migration of the monarchs is truly one of the natural wonders of the world, a phenomenon equal to none and one that richly deserves preserving for posterity. It impressed the early civilizations: images of monarchs were carved in the ancient stonework at the San Juan Teotihuacan archeological site north of Mexico City more than 1,300 years ago. It continues to impress us now, with monarchs remaining the most popular insect in modern North American cultures.

Conservation Concerns

The greatest threat to the monarch is not the direct destruction of the butterfly species but the destruction of its overwintering habitat sites. Along the California coast, where the species once ranged from Mendocino County southward 650 miles to Baja California, a great many sites have been destroyed or severely altered by development. In Mexico, a number of the high mountain sites (10,000 to over 11,000 foot elevation) are being threatened by logging, firewood gathering, forest thinning by fires, and clearing for agriculture. Forest thinning opens the colony sites to severe winter storm effects, colder temperatures, and restriction of available area to shift the colony site if environmental conditions change. The Mexican government on both federal and state levels has responded with declarations of preserves, parks, and protection for the butterfly. Most of the protection, however, depends on the *ejidos* or associations of local communities that only recently have begun to recognize the economic benefits of ecotourism. monarch colonies today attract hundreds of thousands of visitors annually from throughout Mexico and abroad. Though tourism creates economic incentives for conserving the forest around the colonies, development of permanent trails with concrete steps up the mountains and hundreds of shops and small restaurants also take their toll on the environment.

Another, recently emerged concern is tied to genetically engineered crops in the U.S. It appears that the pollen from Lepidoptera pest-resistant corn plants that contain genes of the bacterium *Bacillus thuringiensis* (known as Bt corn), once fallen on the milkweeds adjacent to corn fields and ingested by the monarch caterpillars, causes the death of the latter. Studies are underway to estimate the effect this phenomenon might have on monarch populations. However, it is known that field margins and hedgerows have been the monarchs' breeding grounds in the highly developed environment of the North American Great Plains, and losing this breeding environment might indeed prove to be detrimental for the migratory population.

Monarchs Among Other Butterflies

The Jamaican monarch, *Danaus cleophile* (Godart), is a smaller species found in the highlands of Jamaica and Hispaniola. Remarkably, to date nothing is known about the life history of this colorful, though much less glamorous, butterfly. *Danaus*

Monarch Butterfly, *Danaus Plexippus* L. (Lepidoptera: Danaidae), Figure 84 Aggregations of overwintering monarchs in northern Mexico (photo T. Emmel).

Monarch Butterfly, *Danaus Plexippus* L. (Lepidoptera: Danaidae), Figure 87 **Viceroy, *Limenitis archippus*, a Müllerian mimic of monarch, Florida (photo A. Sourakov).**

cleophile is an extremely local and relatively rare island isolate that flies in the montane areas of the islands, ovipositing almost exclusively on *Asclepias nivea*. As far as is known, it is non-migratory. Within the subfamily Danainae, all monarchs belong to the tribe Danaini, subtribe Danaina, genus *Danaus Kluk*. None of the other 11 species in the genus is migratory. However, *Anetia panthrata* (Martyn), a primitive danaeine from Hispaniola, recently has been found to aggregate by the hundreds on pine trees in the highest mountains of Hispaniola.

Almost all danaines, monarchs included, form aggregations of dozens of adult individuals that feed on alkaloid-rich plants such as Boraginiaceae and Fabaceae (Fig. 84). The alkaloids play a role in pheromone production. It also has been suggested that they might contribute to the butterflies being toxic to the predators, though most of this toxicity has been attributed to larvae incorporating the substances called cardenolides from the milkweed host plants (Figs. 85 and 86).
