[556] When a slow truck heads uphill on a highway, with cars passing as they can, we have a one-dimensional analogue to a kinematic density wave: The pattern of bunched cars persists, even though a given car passes into and then out of the denser part of the pattern. Furthermore, the pattern moves at a slower speed than that of the average car.

— creating a shock wave *along the leading edge of the density wave, which causes a violent compression of the gas.*

As the spiral density waves sweep through the plane of the Galaxy, they recycle the interstellar medium. Old dust and gas left behind from ancient, dead stars are recompressed into new nebulae in which new stars are formed. Because the material left over from the deaths of ancient stars is enriched in heavy elements, new generations of stars are more metal-rich than were their predecessors.

This theory still leaves many open questions. For example: what keeps the density wave going? Why don't they dissipate? The compression of the interstellar gas and dust requires enormous amounts of energy. What mechanism is constantly replenishing this energy? A possible source is the galactic nucleus.

The center of our Galaxy is a mysterious region forever blocked from our view by the intervening interstellar medium. From Shapley's work on the distribution of the globular clusters, as well as Oort's analysis of stellar motions, it was known in the 1920's that the center of our great stellar pinwheel lies in the direction of the constellation Sagitarius. The distribution of infrared radiation *from the nucleus at wavelengths around 2.2 microns looks just like the distribution of visible light from the nucleus of the Andromeda Galaxy. The center of our Galaxy contains a million stars per cubic persec [1 pc equals $206,000$ AU], compared to one star per cubic parsec near the sun.*

Longer-wavelengths infrared observations (around 20 microns) show several intensely bright sources near the center of the Galaxy. The center is also a copious emitter of electromagnetic radiation of other kinds. It emits synchrotron radiation, thermal radiation, 21-cm radiation, molecular radiation, and X-rays. The motion of gas clouds within a few light years of the galactic center were studied in the 1970's. It was shown that a certain spectral line of singly ionized neon, which normally has a wavelength of about 12.80 microns in the infrared, is extremely broad. This line is broadened by motion of gas clouds in which neon is a minor constituent. The broadening has been interpreted as a result of the speed at which ionized gas orbits the galactic nucleus; radiation from gas coming toward us is blueshifted, while radiation from receding gas is redshifted. The final result is to smear out a spectral line over a range of wavelengths corresponding to a range of line-of-sight velocities. The broadening of the line then reveals a velocity spread of about 400 km/sec. On one side of the galactic nucleus, gas is coming toward us at speeds up to 200 km/sec, while on the other side of the galactic nucleus, it is rushing away from us at speeds up to 200 km/sec.

Something must be holding this high-speed gas in orbit about the galactic center. Using Kepler's third law, it is estimated that $10^6\ M_{\odot}$ *of material* *is needed to prevent this gas from flying off into interstellar space. These observations therefore imply that an object with the mass of million suns is concentrated at Sagittarius A West. This object must be extremely compact — much smaller than a few light years over which the infrared neon source extended.*

1925 CE, March 18 The most devastating *tornado* on record, and the greatest tornado disaster in the United States. Known as the *Tri-State tornado* (Indiana, Illinois and Missouri), it remained on the ground for 350 km. The resulting losses included 695 dead, 2027 injured, and damages of about 43 billion in 1970 dollars.

1925 CE, April 1 *The Hebrew University in Jerusalem* opened with a keynote address by **Albert Einstein**. The first academic institution for secular studies in Israel, ever.

1925 CE, Oct. 13 *Scripps Institution of Oceanography* of the University of California came into existence at a site overlooking the Pacific Ocean, just north of La Jolla, California.

1925 CE **Samuel Abraham Goudsmit** (1902–1978, Holland) and **George Eugene Uhlenbeck** (1900–1988, Holland) suggested the electron spin angular momentum. At the same time **Ralph de Laer Kronig** (1904–1995, Holland) had the same idea. He asked W. Pauli for his opinion before publication, and Pauli convinced him that the idea had no merit.

1925–1927 CE *The Atlantic Meteor expedition*: One of the first systematic studies of a single ocean was carried out by the German research ship *Meteor*[557], which made 13 crossings of the Atlantic between 20 °S and 60 °S. The results of this survey were published in a series of atlases. The *Meteor* was the first expedition to use the *echo sounder* (sonar) to measure the depth of the ocean almost continuously along its track. As a result, a more accurate idea of the shape of the ocean floor was obtained than it was possible to form with isolated sounding.

557 Designed to recover gold from the ocean to repay Germany's WWI debts, although it was an unsuccessful enterprise in this respect. The ship was commissioned by the Hydrographic Department of the German Navy.

In 1925, the expedition discovered the *Mid-Atlantic Ridge*. The data obtained — gathered day and night, in all weathers and all seasons — included some 70,000 soundings of the ocean depths over a period of 25 months. There was nothing to equal it for another 30 years: it was not until the International Geophysical Year of 1957–1958 that oceanographers once again undertook to survey an entire ocean.

1925–1932 CE *Rise and decline of the 'talking machines'*. Research in *wireless telephony* conducted during WWI yielded *viable microphones* and *amplifiers* that made *radio broadcast* possible. By 1925, the studio experience and the quality of the recordings improved dramatically. Individual microphones replaced shared recording horns, and artists could now overdub mistakes. Electric amplification made it possible for studio acoustics to emulate the atmosphere and clarity of live performances. A much-expanded frequency range allowed for the improved definition of sharper treble and the weighty force of deep bass.

These innovations sparked another surge in enthusiasm for recorded music that now appeared to complement the popularity of radio. A number of radio-phonograph combination machines were marketed successfully. The grandest symbol of corporate confidence in the alliance was *RCA Victor*, the result of the Radio Company of America's acquisition in early 1929 of the Victor Talking Machine Company.

Later in the same year, however, the predicted death of the phonograph seemed to suddenly become a reality. The industry ground to a halt almost overnight in October when the stock market crashed. People saw little point in spending bread money on records when the radio continued to provide free entertainment. In November, eighty-two year old Edison and his corporate allies discontinued production of records and phonographs. Cylinder records had already begun a sharp and steady decline since the advent of electronic recording. The Edison announcement finally rendered them extinct. Thomas Edison died in 1931.

In 1927, $987,000$ machines were produced and $104,000,000$ records were sold. In 1932 those numbers dropped to $40,000$ and $6,000,000$ respectively. With the exception of a few die-hard collectors, consumers not only quit buying records, they also began to think of the whole phenomenon of "canned music" as part of an outdated culture. Free live radio and the first sound motion pictures (the first feature-length "talkie", *The Jazz Singer*, was released in 1929) seemed to provide more vibrant, immediate and modern cultural outlets. Millions of machines and records found their way into attics and junkpiles. In decades to come, of course, recording would be revived and go through even more dramatic technological, cultural and corporate transformations. However, the Depression, the death of the phonograph's inventor, the drastic decline in consumer interest, and the competition from new forms of audio technology marked the end of the beginning for talking machines.

1925–1934 CE **Ida Eva Tacke Noddack** (1896–1979, Germany). Chemist. Discovered the element *Rhenium* [Re, atomic weight = 186.2; atomic number = 75] with **Walter Karl Noddack** (1893–1960) and **Otto Berg**. It was discovered through X-ray spectra, in a sample of the mineral Columbite.

In 1934 she proposed, counter to Enrico Fermi, that heavy nuclei bombarded by neutrons break down into isotopes of known elements but not neighbors of transuranium element, as Fermi and all other nuclear physicists then believed. In that *she was ahead of her time*; Bohr's liquid-drop model of the nucleus had not yet been formulated, and so there was at hand no accepted way to calculate whether breaking up into several large fragments was energetically allowed.

Noddack's physics was *avant garde*. By 1938 her article was gathering dust on back shelves. But in 1939, her belief in *nuclear fission* was confirmed by Lise Meitner and Otto Hahn.

1925–1944 CE **Erwin Schrödinger**[558] (1887–1961, Austria). Pathbreaking theoretical physicist. Created quantum wave-mechanics[559] and established the fundamental wave equation governing submicroscopic phenomena. The formulation of the '*Schrödinger equation*' (1925) put quantum theory on a firm mathematical basis, and provided the foundation for its further rapid development. It plays a role in modern physics comparable to that played by the equations established by Newton, Lagrange and Hamilton in classical physics.

The Schrödinger equation describes the evolution of the *probability-amplitude function* that governs the dynamics of any physical system (the simplest case being that of a single particle), and specifies how these waves are altered by external influences.

The probabilistic aspect of quantum theory made Schrödinger and other leading physicists profoundly unhappy, and he devoted much of his later life to formulating philosophical *objections* to the generally accepted interpretation of the theory that he has done so much to create!

---

[558] For further reading, see:

- Moore, W., *Schrödinger*, Cambridge University Press, 1990, 513 pp.

[559] Its equivalence to Heisenberg's *matrix-mechanics* was later established by **Dirac**, **Jordan** and **Born**.

The Schrödinger equation had an enormous impact on *chemistry* since the nature of the chemical bond could be formulated in terms of physical concepts.

Schrödinger established the correctness of his equation by applying it to the hydrogen atom, predicting many of its properties with remarkable accuracy. The equation is used extensively in atomic, molecular, nuclear, particle, and condensed-matter physics.

During 1941–1943, while in exile in Dublin, Schrödinger devoted considerable effort to working out a *nonlinear* classical electromagnetic theory previously outlined by Born[560] and Infeld (1934). His conviction that nonlinear theories would be essential for future progress of physics has turned out to be abundantly justified.

From 1943 to 1951, Schrödinger's work was dedicated almost exclusively to a search for a *unified field theory* that would encompass both gravitation and electromagnetism[561]. Like Einstein, he was inspired by a metaphysical belief in the unity of nature which induced in him a feeling of wonder at the simplicity and beauty of the universe as revealed through the window

---

560 The **Maxwell** equations are linear, i.e. the fields and their derivatives occur only in terms of the first degree. A fundamental property of such linear equations is that the fields cannot generate themselves — sources (dynamical or external) must be introduced. In this case, for example, if one introduces a point charge such as an electron, the fields diverge at this point — which is physically unreasonable. Moreover, the mass and charge of the electron are not deducible from the linear theory.

The idea of a nonlinear modification of Maxwell's equations had occurred to Born in 1933. He aimed at developing a theory in which an electron of *finite radius* arises *naturally* out of the field equations. **Born** and **Infeld** (1934) pointed out that the relation of matter to the electromagnetic field can be interpreted from two opposite standpoints: (1) *Unitarian* — only the field exists and particles are singularities of the field, their masses are derivable from the field energy. (2) *Dualistic* — particles are sources of the field, acted upon by the field but not part of it; they have the characteristic intrinsic property of inertia, measured by mass.

The development of *quantum electrodynamics* followed a quite different path, starting with **Dirac**'s relativistic quantum theory of the electron and culminating in the work of **Schwinger**, **Feynman** and **Tomonaga** from 1948 to 1953.

561 Schrödinger and Einstein turned to unified field theories because of their disenchantment with the prevailing state of quantum mechanics. Einstein hoped that field theory would eventually include both the macroscopic systems of cosmology and the microscopic systems of elementary particles and quanta.

of mathematical theory[562]. Schrödinger believed that technology had caused deterioration in the quality of man's relation to the deeper sources of his being.

In 1944, he wrote his popular masterpiece '*What is Life*'. It deals with the impact of quantum ideas on biology, and above all on the molecular processes that underline the laws of heredity. While a good deal of what the book had to say is now dated, it has had a great influence on physicists and biologists because it suggested how the two disciplines join together at their base.

Schrödinger was born in Vienna. He entered the University of Vienna in 1906, served in WWI and moved to Zürich, where he stayed until 1926. In 1927 he was invited to succeed **Max Planck** at the University of Berlin, thus becoming a colleague of **Albert Einstein**. In 1933 he was deeply affected by the political climate in Germany, and realized that he could no longer live in a country in which the persecution of the Jews had become national policy. Consequently he began a seven-year odyssey that took him to Austria, Great Britain, Belgium, the Pontifical Academy of Science in Rome, and finally — in 1940 — the Dublin Institute for Advanced Studies (founded under the influence of Premier Eamon de Valera, who had been a mathematician before turning to politics). Schrödinger remained in Ireland for the next 15 years, doing research both in physics and in the philosophy and history of science. In 1956 Schrödinger retired and returned to Vienna as professor emeritus at the University.

Schrödinger was a man with great charm and a fascinating personality and thus attracted many interesting women in his life. He married Annemarie Bertel in 1920. It was a childless marriage based on friendship alone, providing him a secure haven from importune mistresses. Out of his numerous amorous affairs he had three daughters from three different women: Ruth (b. 1934),

562 Einstein was 36 years old when he published his general theory of relativity; Schrödinger was 38 when he discovered wave mechanics. By 1940, when he began to consider generalized field theory, he was 53. Einstein, then 61, had been working on the problem for twenty-five years without apparent success. In the annals of physics it is unusual to find anyone who had made a major theoretical discovery after the age of 40. Thus it might seem that Einstein and Schrödinger were facing an insurmountable psychological barrier. Revolutionaries in physics must be young people whose minds have not had time to become habituated to well-worn pathways of thought. Thus Schrödinger and Einstein may have had little chance of success in their efforts to discover a unified field theory in the 1940's using methods of the 1920's. Richard Feynman summed up this notion, saying (1962): "*None of these unified field theories has been successful... Most of them are mathematical games, invented by mathematically minded people... and most of them are not understandable*".

Nicole (b. 1945), and Linda (b. 1946). He believed that scientific creativity would be promoted and sustained by erotic excitement, and that love is not an impediment to great efforts but its carrier.

Schrödinger was also an amateur poet, and a book of his poems appeared in 1949. Many of these were love poems which he wrote for his women. Appreciation of one of his poems gave him much more pleasure than any amount of praise for his scientific papers.

By the end of his life, he must have mastered as much general culture — scientific and nonscientific — as it is possible for any single person to absorb in this age of technical specialization. He read widely in several languages, and wrote perceptively about the relation between science and the humanities and about Greek science, in which he was particularly interested.

Of all the physicists of his generation, with the possible exception of Einstein, Schrödinger stands out on account of his extraordinary intellectual versatility and his significant contributions to nearly all branches of science and philosophy.

Worldview XL: Erwin Schrödinger on all that and physics too

* * *

"I don't like it, and I'm sorry I ever had anything to do with it."

(on "Schrödinger's Cat")

* * *

"Only metaphysics can inspire the hard work of theoretical physics."

* * *

"Actions are transitory while works remain."

* * *

"What is Life?, I asked in 1943. In 1944, Sheila May told me. Glory be to God!"

* * *

"In Germany, if a thing was not allowed, it was forbidden. In England, if a thing was not forbidden, it was allowed. In Austria and Ireland, whether it was allowed or forbidden, they all did it if they wanted."

* * *

"One cannot derive philosophical conclusion from physics. In contrast, however, philosophy could influence physics."

* * *

"All great things in the world are worked through love. It produces everything. Love is not an impediment to great effort but its carrier."

* * *

"Thus, the task is, not so much to see what no one has yet seen; but to think what nobody has yet thought, about that which everybody sees."

* * *

"When you feel your own equal in the body of a beautiful woman, just as ready to forget the world for you as you for her – oh my good Lord – who can describe what happiness then. You can live it, now and again – you cannot speak of it."

The Schrödinger Equation[563] *(1925)*

For a free, non-relativistic spinless particle of mass m, the associated de Broglie wave can be written $\psi = e^{-i\frac{1}{\hbar}\chi(\boldsymbol{r},t)}$, with χ satisfying $\frac{\partial\chi}{\partial t} = \frac{1}{2m}(\boldsymbol{\nabla}\chi)^2$. If this particle/wave moves in a potential field with potential $V(\boldsymbol{r},t)$ one may draw parallels with the Hamilton-Jacobi equation of analytic mechanics and identify χ with the action*. This analogy leads to an equation*

$$\frac{\partial\chi}{\partial t} = \frac{1}{2m}(\boldsymbol{\nabla}\chi)^2 + V(\boldsymbol{r},t).$$

But on the other hand, one would like the de Broglie wave to satisfy a wave equation.

Schrödinger then (1925) came up with a wave equation that no one had seen before:

$$\boxed{i\hbar\frac{\partial\psi}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\psi + V(\boldsymbol{r},t)\psi \;=\; H\psi} \tag{1}$$

He arrived at this equation by starting from the classical energy equation for a particle $E = \frac{1}{2m}\boldsymbol{p}^2 + V(\boldsymbol{r},t)$ *and representing the energy and momentum by the respective differential operators*

$$E \to i\hbar\frac{\partial}{\partial t}, \qquad \boldsymbol{p} \to -i\hbar\nabla,$$

acting on the wave function $\psi(\boldsymbol{r},t)$, *where* $V(\boldsymbol{r},t)$ *is a real potential, not depending on* $\boldsymbol{p}$ *or* E*. The Hamiltonian operator now bears the form*

$$H = -\frac{\hbar}{2m}\nabla^2 + V(\boldsymbol{r},t). \tag{2}$$

Note that there is no source term *for* ψ*; rather,* ψ *acts as a source for itself in conjunction with the external field* V*.*

Born (1926) interpreted ψ *as a* probability wave-function*, in the sense that it is large where the particle is 'likely to be' and small elsewhere. In the physical microworld it replaces the deterministic classical trajectory* $\boldsymbol{r}(t)$*. Thus (1) is assumed to provide a quantum-mechanical complete description of the behavior of a particle of mass* m *with potential energy* $V(\boldsymbol{r},t)$*.*

It turned out that in the semiclassical *limit* $\hbar \to 0$, *an approximation (known in optics as the* eikonal approximation*, and in quantum mechanics as the* WKB or WKBJ approximation*) holds, wherein the Schrödinger equation becomes the* Hamilton-Jacobi equation*. To see this we put* $\psi(\boldsymbol{r},t) = Ae^{i\frac{1}{\hbar}W(\boldsymbol{r},t)}$ *into (1) (A constant) and obtain*

$$\frac{\partial W}{\partial t} + \frac{1}{2m}(\nabla W)^2 + V - \frac{i\hbar}{2m}\nabla^2 W = 0 \tag{3}$$

In the limit $\hbar \to 0$*, (3) is the same as the Hamilton-Jacobi PDE for the principal function* W*:*

$$\frac{\partial W}{\partial t} + H(\boldsymbol{r},\boldsymbol{p}) = 0 \qquad \boldsymbol{p} = \nabla W. \tag{4}$$

Since the momentum of the particle is the gradient of W*, the possible trajectories are orthogonal to the surfaces of constant* W *and hence, in the classical* *limit, to the surfaces of constant phase of the wave function ψ. Thus, in this limit, the* rays *associated with ψ (orthogonal trajectories to the surfaces of constant phase) are the possible paths of the classical particle.*

Let us now split the variables in $W(\boldsymbol{r},t)$, putting $W(\boldsymbol{r},t) = S(\boldsymbol{r}) - Et$, namely

$$\psi(\boldsymbol{r},t) = Ae^{i\frac{1}{\hbar}S(\boldsymbol{r})}e^{-i\frac{1}{\hbar}Et} = u(\boldsymbol{r})e^{-i\frac{1}{\hbar}Et}.$$

We shall then have an equation for $S(\boldsymbol{r})$

$$\boxed{\frac{1}{2m}(\nabla S)^2 - [E - V(\boldsymbol{r})] - \frac{i\hbar}{2m}\nabla^2 S = 0} \tag{5}$$

The WKB approximation starts from (5) and expands $S(\boldsymbol{r})$, the logarithm of the wavefunction, in powers of $\hbar$ in the one dimensional case. The leading term, S_0, is real and approximates the phase *of the wave-function (times $\hbar$), while the next term, S_1, both corrects the* phase *(real part) and approximates the* amplitude *(imaginary part).*[564]

Returning to (1) we note that the wave function ψ^* satisfies the complex-conjugate equation

$$-i\hbar\frac{\partial\psi^*}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\psi^* + V(r)\psi^*. \tag{6}$$

For any fixed volume τ, the combined use of (1), (6) and Green's third identity yield,

$$\begin{aligned}\frac{\partial}{\partial t}\int_\tau \psi\psi^*\,d\tau &= \int_\tau\left[\psi^*\frac{\partial\psi}{\partial t} + \frac{\partial\psi^*}{\partial t}\psi\right]d\tau \\ &= \frac{i\hbar}{2m}\int_\tau\left[\psi^*\nabla^2\psi - \nabla^2\psi^*\psi\right]d\tau \\ &= \frac{i\hbar}{2m}\int_\tau \text{div}\,[\psi^*(\nabla\psi) - (\nabla\psi^*)\psi]\,d\tau \\ &= \frac{i\hbar}{2m}\int_S [\psi^*(\nabla\psi) - (\nabla\psi^*)\psi]\cdot\boldsymbol{n}\,dS.\end{aligned} \tag{7}$$

If we let τ engulf the entire space and recede S to infinity under proper behavior conditions of Ψ at infinity, we obtain

[564] The phase-correction part of S_1 vanishes, but this is not so for higher $\hbar^n$ terms.

$$\frac{\partial}{\partial t}\int\limits_{\substack{\text{all}\\ \text{space}}} \psi^*\psi\, d\tau = 0 \qquad\qquad \Rightarrow \qquad\qquad \int\limits_{\substack{\text{all}\\ \text{space}}} \psi^*\psi\, d\tau = constant.$$

By proper normalization the constant can be chosen as unity. The entity $\rho = \psi^*\psi$, *which obeys*

$$\int\limits_{\substack{\text{all}\\ \text{space}}} \rho(\boldsymbol{r}, t)\, d^3\boldsymbol{r} = 1 \tag{8}$$

is given the interpretation of position probability density (Born 1926).

Returning to (3), one defines the probability current density vector

$$\boldsymbol{J} = \frac{\hbar}{2im}\left[\psi^*(\nabla\psi) - (\nabla\psi^*)\psi\right]. \tag{9}$$

It is linked to the probability density $\rho(\boldsymbol{r}, t)$ *via the differential relation*

$$\frac{\partial\rho(\boldsymbol{r}, \boldsymbol{t})}{\partial t} + \operatorname{div}\boldsymbol{J}(\boldsymbol{r}, t) = 0. \tag{10}$$

This has the familiar form associated with the conservation of flows of fluid of density ρ *and current density* $\boldsymbol{J}$, *in which there are no sources or sinks. The vector* $\boldsymbol{J}$ *is thus interpreted as a probability current density. Also, with* $H = -\frac{\hbar^2}{2m}\nabla^2 + V$ *we have*

$$\psi^* H\psi - \psi H\psi^* = i\hbar\frac{\partial\rho}{\partial t}. \tag{11}$$

Ehrenfest *(1927) gave a semiclassical interpretation of the Schrödinger field by linking the motion of a wave packet centroid and the trajectory and dynamics of the corresponding classical particle, whenever the potential* V *changes by negligible amount over the dimensions of the packet (which is the condition for the WKBJ expansion to be useful). This is equivalent to the statement that Newton's second law of motion holds for average quantities.*

To see this we note that if the quantities ρ *and* $\boldsymbol{J}$ *are both multiplied by* m, *the mass of the particle, we obtain mass density* $\rho_m = m\rho$ *and momentum density* $\boldsymbol{P} = m\boldsymbol{J}$, *and the equation of continuity may be interpreted as the law of mass conservation. In the same way, a multiplication by the particle charge* $e^{\cdot}$, *yields the charge density* $\rho_e = e\rho$ *and the electric current density* $\boldsymbol{J}_e = e\boldsymbol{J}$, *and (10) becomes the law of charge conservation. The conservation laws of both mass and charge are identical because one particle, by its probability flow, caused both.*

Mathematically, we get from (9) the expression of the statistical expectation of the total momentum operator in the quantum state Ψ*:*

$$\begin{aligned}\langle \boldsymbol{p}\rangle &= \int_\tau \Psi^* \boldsymbol{p}\Psi \, d^3x = \tfrac{\hbar}{2i}\int_\tau \left[\psi^*\nabla\psi - \psi\nabla\psi^*\right] \, d^3x \\ &= \tfrac{\hbar}{i}\int_\tau \psi^*\nabla\psi \, d^3x = m\int_\tau \boldsymbol{J}\, d^3x\end{aligned} \tag{12}$$

where the second term in the middle equation is reduced by partial integration. It can also be shown (by use of (1), (6) and partial integration) that the semiclassical force acting on the particle is

$$\boldsymbol{F} = -\langle \boldsymbol{\nabla} V\rangle = \frac{d\langle \boldsymbol{p}\rangle}{dt} = \frac{\hbar}{i}\int_\tau \frac{\partial}{\partial t}\left(\Psi^* \boldsymbol{\nabla}\Psi\right)\, d^3x. \tag{13}$$

By a similar derivation it is found that if we define the expected (mean) particle position as

$$\langle \boldsymbol{r}\rangle = \int_\tau \psi^* \boldsymbol{r}\psi \, d^3x, \tag{14}$$

then

$$\frac{d}{dt}\langle \boldsymbol{r}\rangle = \frac{1}{m}\langle \boldsymbol{p}\rangle, \qquad \frac{d^2}{dt^2}\langle \boldsymbol{r}\rangle = \frac{1}{m}\langle -\nabla V\rangle. \tag{15}$$

These relations are analogous to the classical equations of motion

$$\frac{d\boldsymbol{r}}{dt} = \frac{1}{m}\boldsymbol{p}, \qquad \frac{d\boldsymbol{p}}{dt} = -\nabla V. \tag{16}$$

Likewise, the quantum analogs of the laws of the classical angular motion conservation are derived from $\boldsymbol{T}(\text{torque}) = \boldsymbol{r}\times\boldsymbol{F}$ *and* $\boldsymbol{T} = \frac{d\boldsymbol{L}}{dt}$ *($\boldsymbol{L}$ = particle angular momentum) where*

$$\boldsymbol{L} = \frac{\hbar}{i}\int_\tau \Psi^*(\boldsymbol{r}\times\boldsymbol{\nabla})\Psi\, d^3x = \int_\tau m\boldsymbol{r}\times\boldsymbol{J}\, d^3x\ , \tag{17}$$

$$\boldsymbol{T} = -\hbar i\int_\tau \frac{\partial}{\partial t}\left(\Psi^*(\boldsymbol{r}\times\boldsymbol{\nabla})\Psi\right)\, d^3x = \int_\tau \boldsymbol{r}\times(-\nabla\boldsymbol{V})\Psi^*\Psi\, d^3x\ , \tag{18}$$

where the time derivatives in the 2^{nd} *equation can be calculated from (1), (6) (note that in general* $\boldsymbol{L}\neq\langle\boldsymbol{r}\rangle\times\langle\boldsymbol{p}\rangle$, $\boldsymbol{T}\neq\langle\boldsymbol{r}\rangle\times\boldsymbol{F}$*).*

Finally, we define the total energy

$$E = \int_\tau \psi^* H \psi \, d^3x = \int_\tau \psi^* \left\{ -\frac{\hbar^2}{2m}\nabla^2 + V \right\} \psi \, d^3x. \tag{19}$$

Making use of the identity $\psi^* \nabla^2 \psi = \mathrm{div}(\psi^* \nabla \psi) - (\nabla \psi^* \cdot \nabla \psi)$, *assuming that at large distances* Ψ *tends to zero rapidly enough, and using Gauss' divergence theorem,* $\int \mathrm{div}(\psi^* \nabla \psi)\, d^3x$ *vanishes when taken over an infinitely remote sphere, so that* (19) *can be recast in the form*

$$E = \int d^3x \left[\frac{\hbar^2}{2m} (\nabla \psi^*) \cdot (\nabla \psi) + \psi^* V \psi \right] = \int d^3x \, W, \tag{20}$$

where the energy density is

$$W = \frac{\hbar^2}{2m} (\nabla \psi^*) \cdot (\nabla \psi) + \psi^* V \psi. \tag{21}$$

Using the Schrödinger equation, it is easy to demonstrate that the law of energy conservation should be

$$\frac{\partial W}{\partial t} + \mathrm{div}\, \boldsymbol{\Sigma} = 0, \tag{22}$$

where the expected (mean) energy flux vector is

$$\boldsymbol{\Sigma} = \frac{\hbar^2}{2m} \frac{h}{2mi} \left(\boldsymbol{\nabla} \Psi^* \cdot \boldsymbol{\nabla\nabla} \Psi - \nabla\nabla \Psi^* \cdot \nabla \Psi \right) + V \boldsymbol{J} \, . \tag{23}$$

The Ehrenfest analogy [(12)–(17)] provides an example of the correspondence principle, since it shows that the probability-centroid of a wave packet moves like a classical particle subject to the position and velocity uncertainties inherent in the wave function and the uncertainty principle. The correspondence is mainly useful in the macroscopic limit in which the finite size and the internal structure of the packet can be ignored.

When V *is time-independent (as we have so far been assuming), any solution* $\psi(\boldsymbol{x}, t)$ *of Schrödinger's equation can be decomposed as*

$$\psi(\boldsymbol{x}, t) = \sum_j e^{-i(E_i/\hbar)t} \psi_j(\boldsymbol{x}), \tag{24}$$

where j *ranges over all eigenstates,* $\psi_j(\boldsymbol{x})$, *of the Hamiltonian operator* $H = \frac{1}{2m}\boldsymbol{p}^2 + V(\boldsymbol{x})$, *with corresponding eigenvalues (energy levels)* E_j.

Note that $\sum_j$ *usually includes a discrete summation over the bound states, and an integration over the continuum states. The eigenstate condition on* ψ_j *is known as the time-independent (stationary) Schrödinger equation*

$$-\frac{\hbar^2}{2m}\boldsymbol{\nabla}^2\psi_j + U(\boldsymbol{x})\psi_j = E_j\psi_j, \tag{25}$$

and describes e.g. a single, stationary atomic energy state.

A transition between different energy levels (induced e.g. by an external time-varying electromagnetic field) is described by the time-dependent equation, with time-dependent U*. It governs atomic and molecular processes that vary with time, such as absorption and emission of photons and electrons, scattering, and chemical reactions. The Schrödinger equation (SE) in its above form (which is not the most general) is not Lorentz-covariant, and hence requires relativistic corrections.*

For the stationary case, if we multiply both sides of the equation $H\psi = E\psi$ *by* ψ^* *and integrate over the coordinates, we obtain:*

$$E = \frac{\int \psi^* H\psi d\tau}{\int \psi^*\psi d\tau}.$$

This formula enables us to calculate E *when* ψ *is known. If* ψ *is not known exactly, the Rayleigh-Ritz variational principle*[565] *asserts that the above ratio*

---

[565] We seek a complex wave-function ψ for which the functional

$$J[\psi] = \iiint \psi^*(H\psi)dx\,dy\,dz$$

is stationary, subject to the probability-normalization constraint $\iiint \psi\psi^* dx\,dy\,dz = 1$, and with

$$H = -\frac{\hbar^2}{2m}\nabla^2 + V(x,y,z).$$

Assuming that ψ satisfies appropriate spatial boundary conditions we find $\int \psi^*\nabla^2\psi d^3\boldsymbol{r} = -\int(\nabla\psi^*)\cdot(\nabla\psi)d^3\boldsymbol{r}$. Utilizing a Lagrange multiplier λ for the constraint, the condition $\delta J = 0$ now reads $\delta\int F d^3\boldsymbol{r} = 0$, where

$$F = \frac{\hbar^2}{2m}(\nabla\psi^*)\cdot(\nabla\psi) + V\psi^*\psi - \lambda\psi^*\psi.$$

The Euler-Lagrange equations are:

$$\frac{\partial F}{\partial\psi} - \frac{\partial}{\partial x}\frac{\partial F}{\partial\psi_x} - \frac{\partial}{\partial y}\frac{\partial F}{\partial\psi_y} - \frac{\partial}{\partial z}\frac{\partial F}{\partial\psi_z} = 0$$

and a similar (equivalent) equation for ψ^*. These equations reduce to $H\psi = \lambda\psi$.

has a (global) minimal value equal to the ground state energy of the system; choosing a reasonable trial form for ψ *with some free parameter, one can find approximations to* E *by varying w.r.t. these parameters.*

A solution of the time-independent SE *for the electron in a hydrogen atom (Coulomb field) is obtained through the method of separation of variables in spherical coordinates* (r, θ, ϕ). *It yields eigenfunctions of the form* $R_{n\ell}(r)P_\ell^m(\cos\theta)e^{im\phi}$, *where* $\{n, \ell, m\}$ *are known as the orbital quantum numbers.*

Of these, n *is associated with the total energy (permissible values* $= 1, 2, 3, \ldots$*);* ℓ *is the magnitude of the orbital angular momentum in units of* $\hbar$ *(permissible values* $= 0, 1, 2, \ldots, n-1$*), and* m_ℓ *is the projection of the orbital angular momentum along a given axis in the same units (axis chosen to be* z*; permissible values* $= -\ell, -\ell+1, \ldots, 0, \ldots, \ell-1, \ell$*). It was established experimentally that a fourth quantum number is needed to describe the quantized spin (internal) angular momentum of the electron (this is the component of spin angular momentum in units* $\hbar$*; permissible values* $m_s = \pm\frac{1}{2}$*).*

The electron orbital angular momentum states of atoms are designated by the letters s, p, d, f *(and alphabetically ordered thereafter:* g, h, $\ldots$*) which were borrowed from early spectroscopic work and describe those states which give rise to* SHARP, PRINCIPAL, DIFFUSE, *and* FUNDAMENTAL *spectral lines. The letter* s *is used for* $\ell = 0$, p *for* $\ell = 1$, d *for* $\ell = 2$, f *for* $\ell = 3$, *etc.*

To identify λ we multiply it by ψ^* and integrate over x, y, z. The result is $\lambda = E$ where

$$E = \iiint \psi^*(H\psi)d^3\boldsymbol{r}.$$

Further inspection shows the energy E to be a minimum rather than a maximum (except when the spectrum of the operator H is bounded and E is the maximal energy level). Note that the expression for F (above) can be modified to yield the *Lagrangian density* for the time-dependent Schrödinger equation

$$L = -\frac{\hbar^2}{2m}(\nabla\psi^*)\cdot(\nabla\psi) - \frac{\hbar}{2i}\left(\psi^*\frac{\partial\psi}{\partial t} - \frac{\partial\psi^*}{\partial t}\psi\right) - \psi^* V\psi.$$

Indeed, applying the *principle of least action* to $\iiiint Ld^3\boldsymbol{r}dt$ yields:

$$-\frac{\hbar^2}{2m}\nabla^2\psi + V\psi = i\hbar\frac{\partial\psi}{\partial t}.$$

In his dissertation (1942), **R.P. Feynman** derived the Schrödinger equation in this way, thus founding Quantum Mechanics on the Lagrangian method in contradistinction to the traditional Hamiltonian theory of classical mechanics.

Each different combination of n, ℓ *and* m *corresponds to a unique (except for spin) quantum state called an orbital. For cataloging the elements it suffices to designate only the numbers of electrons having various values of these two quantum numbers in the atom's ground (lowest energy) state. Thus,* $(1s)^1$ *represents the ground state of the hydrogen atom with one electron in the level* $n = 1,\ \ell = 0$. *Likewise* $(1s)^2$ *represents helium with 2 electrons in the orbital* $n = 1,\ \ell = 0$ *(one each for spin* $\pm\frac{1}{2}$*).*

The maximum number of electrons in energy level n *is* $2n^2$ $(2, 8, 18, 32, \dots$ *etc.); the* (l, m) *orbitals of given* n *are together called a shell (because mean orbital radius increases with* n*). The configurations and designations of filled shells for the first four energy levels are:* $(1s)^2$ $(n = 1)$; $(2s)^2(2p)^6$ $(n = 2)$; $(3s)^2(3p)^6(3d)^{10}$ $(n = 3)$; $(4s)^2(4p)^6(4d)^{10}(4f)^{14}$ $(n = 4)$.

Due to inter-electron repulsion, inner electron shell partially shield outer electrons from the nuclear charge, and the amount of shielding increases with the ℓ*-value of the outer electrons. Consequently, the single-electron energy levels do vary somewhat within a given* n *shell. Thus* np *is higher in energy than* ns *and filled later;* nd *is only filled after* $(n+1)s$ *(but before* $(n+1)p$*) for* $n = 3, 4$.

In Oxygen, for example, the second shell is not filled and has only 6 electrons. Two of them are in the states $\left\{n = 2,\ \ell = 0,\ m_\ell = 0,\ m_s = \pm\frac{1}{2}\right\}$, *while the other four may, for example, occupy the states* $\left\{n = 2,\ \ell = 1,\ m_\ell = \pm 1,\ m_s = \pm\frac{1}{2}\right\}$. *This shell is not closed, and its deficiency (2) is the valence of oxygen.*

The directionality, rigidity, length, etc. of an inter-atomic bond depends on the spatial symmetry of these orbitals around the nucleus. The quantum numbers ℓ, m *determine the angular dependence of the non-radial factor of the Schrödinger probability amplitude; only the orbital with* $\ell = 0$ *has a spherically symmetric probability distribution*[566]*. The sum of the probability distributions for the three orbitals* $n = 2,\ \ell = 1,\ m_\ell = -1, 0, +1$ *is spherically symmetric; in general, a full shell of electrons (for any given value of* n*) presents a spherically symmetric charge distribution around the nucleus.*

The three orthogonal basis $2p$ *orbitals* $(n = 2,\ \ell = 1)$ *are sometimes chosen to be* p_x, p_y, *and* p_z, *which correspond to certain linear combi-*

---

[566] The fact that $\ell = 0$ does not mean that the electron is at rest but only that its motion is as probable in any one direction as in any other. The spherically symmetric "probability cloud" is the statistical amalgam (a sort of "time exposure" photograph) of all possible classical $\ell = 0$ orbits, which are line segments (degenerate ellipses) with all possible spatial orientations, emanating from the origin (nucleus).

nations of the waves for the m_ℓ *values* $+1,\ -1$ *and* 0[567]. *Their probability amplitude patterns are* $\{\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta\}$, *and contain one angular node each on a plane with null electron density. The 3d orbitals* $(n=3,\ \ \ell=2,\ \ m=\pm 2,\pm 1,0)$ *split into* d_{z^2} $(m=0,\ 3\cos^2\theta-1)$, d_{xz} $(m=\pm 1,\ \sin\theta\cos\theta\cos\phi)$, d_{yz} $(m=\pm 1,\ \sin\theta\cos\theta\sin\phi)$, d_{xy} $(m=\pm 2,\ \sin^2\theta\sin 2\phi)$ *and* $d_{x^2-y^2}$ $(m=\pm 2,\ \sin^2\theta\cos 2\phi)$.

If two electrons in the same atom have the same values of $\{n,\ell,m_\ell\}$, *they share the* same *orbital and are said to be* paired. *This is because they must have opposite spins (by the* EXCLUSION PRINCIPLE*), but are identical in every other respect. Since one electron has the spin quantum number* $m_s=\frac{1}{2}$ *and the other has* $m_s=-\frac{1}{2}$, *the* magnetic moments *associated with these spins cancel.*

For an atom or molecule with an unpaired *electron, the electron spin interacts with an external magnetic field, because the spin magnetic moment of the unpaired electron tends to align itself in the direction of the external field*[568]. *A substance is* paramagnetic, *if its bulk magnetization is entirely due to the average alignment by an external magnetic field of its atomic (or molecular) moments. These moments may be due to orbital angular momentum, spin, or both; the atomic nucleus, too, may possess spin.*

The following examples serve to show possible electron configurations of two key atoms:

divalent Oxygen atom: $(1s)^2(2s)^2(2p_z)^2(2p_x)^1(2p_y)^1$

2 paired electrons in $n=1,\ \ell=0,\ m_\ell=0,\ m_s=\pm\frac{1}{2}$

2 paired electrons in $n=2,\ \ell=0,\ m_\ell=0,\ m_s=\pm\frac{1}{2}$

2 paired electrons in $n=2,\ \ell=1,\ m_\ell=0,\ m_s=\pm\frac{1}{2}$

2 unpaired electrons in $n=2,\ \ell=1$ $\begin{cases} m_\ell=+1 & m_s=\frac{1}{2}\text{ or }-\frac{1}{2}\\ m_\ell=-1 & m_s=\frac{1}{2}\text{ or }-\frac{1}{2}\end{cases}$

divalent Carbon atom: $(1s)^2(2s)^2(2p_x)^1(2p_y)^1$

---

567 The linear combinations are chosen such that the corresponding probability distributions for the electron are peaked about the x, y, z axes, respectively. This makes it easier to visualize the orbitals geometrically — especially when it comes to multi-atomic bonds and molecules.

568 This also happens when two or more unpaired electrons, each occupying a distinct atomic (or molecular) orbital, because such electrons tend to have mutually aligned spins (due to a combination of electrostatic and Pauli Exclusion effects) and can thus align *as one magnet* with the external field.

2 paired electrons in $n = 1,\ \ell = 0,\ m_\ell = 0,\ m_s = \pm\frac{1}{2}$

2 paired electrons in $n = 2,\ \ell = 0,\ m_\ell = 0,\ m_s = \pm\frac{1}{2}$

2 unpaired electrons in $n = 2,\ \ell = 1\ \begin{cases} m_\ell = +1 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \\ m_\ell = -1 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \end{cases}$

tetravalent Carbon atom: $(1s)^2(2s)^1(2p_x)^1(2p_y)^1(2p_z)^1$

2 paired electrons in $n = 1,\ \ell = 0,\ m_\ell = 0,\ m_s = \pm\frac{1}{2}$

2 unpaired electrons in $n = 2\ \begin{cases} \ell = 0 & m_\ell = 0 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \\ \ell = 1 & m_\ell = 0 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \\ \ell = 1 & m_\ell = +1 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \\ \ell = 1 & m_\ell = -1 & m_s = \frac{1}{2} \text{ or } -\frac{1}{2} \end{cases}$

In the last case a $2s$ *electron was excited into the (slightly higher-energy) empty* $2p_z$ *orbital, thus conferring on the carbon the ability to bond to more surrounding atoms (hybridization) on its transition from* $\ell = 0$ *to* $\ell = 1$*. The maximum number of electrons in the* n^{th} *energy shell is* $2n^2$.

The solution of the SE for a one-electron atom is of little practical value. All atoms — except hydrogen and certain ions of the light elements — contain several electrons. In these atoms, the Hamiltonian of the whole atom includes the interaction of each electron with the nucleus, and in addition the interaction of the electrons among themselves. Since the motion and quantum state of each electron depends on those of all the others, any modification in the state of one electron must affect the state of all the other electrons.

Therefore we can talk only of the energy of the whole atom (or ion or, indeed molecule) and for the same reason, of a wave function for the complete atom or molecule. But the inter-dependence is more insidious in quantum-mechanics than in a classical system (say, the planets in the solar system), since the motion of a single planet is a valid concept; here there is no single-electron state (although this is often a useful approximate *concept). This impossibility of describing the motion (or even quantum state) of an individual electron means that many-electron atoms, ions and molecules are difficult to quantify exactly, and certain approximations are required. In general, this leads to complex numerical calculations.*

As a first approximation, one may ignore the electron-electron electrostatic interaction term $\sum_{\text{all pairs}} \frac{e^2}{r_{ij}}$*. This is equivalent to assuming that each electron moves independently of the others. Thus we may call this approximation the 'independent-particle model' in which each electron can be described by a hydrogen-like wave function.*

In cases where the known energy levels E_n of a system with Hamiltonian H_0 are slightly perturbed due to an additional term in the Hamiltonian, the first order perturbation in the energy levels is:

$$(\Delta E)_n \approx \int \psi_n^* H' \psi_n d\tau,$$

where H' is the first order perturbation of H_0 and ψ_n are the eigenfunctions of H_0. The new eigenfunctions are given by $\psi_n' \approx \sum_j a_j^{(n)} \psi_j$ where

$$a_k^{(n)} = \frac{1}{E_n - E_k} \int \psi_k^* H' \psi_n d\tau, \qquad k \neq n \quad (a_n = 1).$$

The foregoing technique may be used to solve approximately the problems of the helium atom and the normal Zeeman effect. In the latter case the classical Hamiltonian for an electron of mass m_e carrying a charge $-e$ and moving in a magnetic field whose vector potential is $\boldsymbol{A}$ is

$$H = \frac{1}{2m_e}\{\boldsymbol{p}^2 + 2e\boldsymbol{A}\cdot\boldsymbol{p} + e^2\boldsymbol{A}^2\} + U(r).$$

For a weak field we may neglect the $\boldsymbol{A}^2$ term, whence H becomes the operator $-\frac{\hbar^2}{2m_e}\nabla^2 - \frac{i\hbar e}{m_e}\boldsymbol{A}\cdot\nabla + V(r)$. In the non-relativistic limit of the Dirac equation, H is found to acquire the additional term $\frac{e\hbar}{2m_e}\boldsymbol{\sigma}\cdot\boldsymbol{B}$, with $\boldsymbol{\sigma}$ the Pauli spin matrices and $\boldsymbol{B} = \boldsymbol{\nabla}\times\boldsymbol{A}$ the external field.

First order perturbation of the energy levels of hydrogen is found to be $\Delta E = \left[\frac{e\hbar}{2m_e}B\right](m_e + 2m_s)$, in agreement with experiment. When an atom containing more than one electron is treated quantum-mechanically, a useful first approximation is that the electrons do not interact with one another. In this approximation, the wave function describing each electron is a 'hydrogen-like' wavefunction, characterized by the quantum numbers $\{n, \ell, m_\ell, m_s\}$. The Pauli exclusion principle states that in a multielectron system no two electrons can have identical sets of quantum numbers. In other words, no two electrons may have the same spatial distribution and spin orientation of their wavefunctions[569].

Thus, for example, for the shell with $n = 1$, we must have $\ell = 0$, $m_\ell = 0$ and $m_s = \pm\frac{1}{2}$. Hence, at most 2 electrons may have $n = 1$ in a single atom. For $n = 2$ there are $2(2\ell + 1) = 6$ possible sets for $\ell = 1$

569 Where spin is included in the wavefunction by definition.

$(m_\ell = -1, 0, +1;\ m_s = \pm\frac{1}{2})$ and 2 possible sets for $\ell = 0$, yielding at most 8 electrons in the $n = 2$ shell.

The Pauli principle correctly predicts the numbers of electrons in the closed atomic shells of the periodic table of the elements.

Further elaboration on this important principle is linked to the concept of exchange symmetry of wave functions.

In classical mechanics, the existence of sharply definable trajectories for individual particles makes it possible in principle to distinguish between particles that are identical except for their paths, since each particle can be followed during the course of an experiment. In quantum mechanics, the uncertainty principle limits our ability to follow the motions of the particles without disturbing the system, so that we can never be certain which one of a number of identical particles we have actually found at a given point — because the particles are indeed physically indistinguishable. This places certain restrictions upon the mathematical form that the wave-function for several identical particles may have.

In the modern view of atoms, the electrons in the space surrounding the dense, point-like nucleus may be thought of as existing in motional orbitals, but these are smeared into continuous, overlapping spatial distributions. At most two electrons, in opposite spin states, can occupy a single orbital — according to Pauli's exclusion principle. The orbital occupied by a pair of electrons of opposite spin is filled: no more electrons may enter it until one of the pair vacates the orbital. Moreover, the exclusion principle extends to a wider exchange-symmetry rule.

An example will serve to explain this principle: A helium-like atom or ion has a nucleus of charge Ze surrounded by two electrons, which we label as 1 and 2. In the 'independent-particle

model' it follows from the Schrödinger equation that the wave function of the atom should be the product of the wave functions for each electron, or a linear combination of such products. If we designate the orbital quantum numbers $\{n, \ell, m_\ell\}$ of electron 1 by a and the corresponding quantum numbers of electron 2 by b, we may then write $\psi_{\text{atom}} = \psi_a(1)\psi_b(2)$, where the arguments 1 and 2 of the wavefunctions are shorthand for $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$, respectively. This result in a joint spatial probability distribution $|\psi_a(1)|^2|\psi_b(2)|^2$.

Since the electrons are identical and indistinguishable, ψ_{atom} must be constructed in such a way that the exchange of electrons 1 and 2 will not affect $|\psi_{\text{atom}}|^2$, i.e. the joint spatial distribution will be symmetric between the two electrons. This will be achieved if we construct either of the two linear combinations $\psi_{\text{atom}} = \psi_a(1)\psi_b(2) \pm \psi_a(2)\psi_b(1)$. (All wave functions thus far are *spatial — no reference to spin, yet). The plus sign yields a symmetric wavefunction whereas the negative sign represents the antisymmetric counterpart, namely*

$$\psi_S(1,2) = \psi_a(1)\psi_b(2) + \psi_a(2)\psi_b(1), \quad \psi_A = \psi_a(1)\psi_b(2) - \psi_a(2)\psi_b(1).$$

It can be shown that the energy of the atom associated with ψ_A is larger[570] *(less strongly bound) than that associated with ψ_S.*

Thus, a two-electron atom has two sets of stationary states and energy levels, one described by symmetric orbital wave functions and the other by antisymmetric orbital wave functions. An exception occurs when $a = b$ (the two sets of orbital quantum numbers of the electrons are identical), for which $\psi_A = 0$.

When the electron's spin is taken into account, the vectorial sum of the spins of the two electrons can either be zero ($S = 0$; singlet state-Parahelium*) or $S = 1$ [triplet, orthohelium; with $M_S = +1$, (both spins with positive components), or $M_S = 0$ (vanishing z component, vectorial sum normal to z axis), or $M_s = -1$ (both spins with negative z component)].*

The total spin wave function of the singlet state ($S = 0$) is antisymmetric *in the two electrons*

$$\chi_A = \frac{1}{\sqrt{2}}\left[\chi_+(1)\chi_-(2) - \chi_+(2)\chi_-(1)\right],$$

where χ are spin wavefunctions; $\chi_\pm(1)$ are the 1 electron wavefunctions for the cases of spin up $\left(m_s = +\frac{1}{2}\right)$, for subscript "+", or spin down for "−". On the other hand, the total spin wave functions of the triplet ($S = 1$) are symmetric *in the two electrons: $\chi_S = \chi_+(1)\chi_+(2)$ for $M_S = 1$, $\chi_S = \chi_-(1)\chi_-(2)$ for $M_S = -1$ and*

$$\chi_S = \frac{1}{\sqrt{2}}\left[\chi_+(1)\chi_-(2) + \chi_+(2)\chi_-(1)\right]$$

for $M_S = 0$.

The total *wave function of the atom for each state is the direct product*

$$\psi_{\text{total}} = [\textit{orbital (space) wave functions}] \times [\textit{spin wave function}].$$

570 Because Ψ_A vanishes at more spatial configurations and thus confines the electrons to a smaller average volume, resulting in higher *zero-point kinetic* energy by virtue of the uncertainty principle.

Now, an empirical examination of the energy levels of the helium atom (e.g. by spectroscopic methods) reveals that the state described by symmetric orbital wave functions ψ_S *are always spin singlets* $(S = 0)$, *while the states described by antisymmetric orbital wave functions* ψ_A *are always triplets* $(S = 1)$. *In either case* ψ_{total} *is antisymmetric. We know from spectroscopic experience that this result is not restricted to the helium atom, and can be elevated to the level of a general principle, stating that the total wave function of a system of electrons must be totally antisymmetric.*

This may be considered as an alternative, and more general, statement of the exclusion principle since the antisymmetry of the wave function implies the validity of the exclusion principle.

This can be seen in a simple way by writing the total wave function of an atom with N *electrons in the independent-particle model. Designating by a single letter (a, say) the orbital-spin state* $\{n, \ell, m_\ell, m_s\}$, *the configuration in which one electron is in state* a, *another in state* b *etc. may be expressed by the Slater determinant* representation of the wave-function:

$$\psi_{abc\cdots} = \frac{1}{\sqrt{N!}} \begin{vmatrix} \psi_a(1) & \psi_a(2) & \psi_a(3) & \cdots \\ \psi_b(1) & \psi_b(2) & \psi_b(3) & \cdots \\ \psi_c(1) & \cdots & \cdots & \cdots \\ \vdots & \vdots & \vdots & \vdots \end{vmatrix}.$$

This expression is antisymmetric since the interchange of any two columns (two electrons) changes the sign of the determinant. Moreover, if any two electrons have the same quantum number, the determinant is identically zero; thus the exclusion principle follows from the antisymmetry of the multielectron wave-function when the independent-particle model is used.

For a concrete example we return to the helium atom with $S = M_S = 1$. *Then*

$$\begin{aligned} \psi = \psi_A \chi_S &= \frac{1}{\sqrt{2}} \left[\psi_a(1)\psi_b(2) - \psi_a(2)\psi_b(1)\right] \chi_+(1)\chi_+(2) \\ &= \frac{1}{\sqrt{2}} \begin{vmatrix} \psi_a(1)\chi_+(1) & \psi_a(2)\chi_+(2) \\ \psi_b(1)\chi_+(1) & \psi_b(2)\chi_+(2) \end{vmatrix}. \end{aligned}$$

In this triplet state (spins parallel, antisymmetric spatial wave-function, $S = 1$), *when electrons 1 and 2 are close together, the value of* $|\psi_A|$ *is very small. The result is that the probability density is such that there is little chance of finding them close together. This has nothing to do with a Coulomb repulsion because we assumed ab initio that there is no explicit interaction between the electrons.*

This tendency of the electrons in the triplet state to be relatively far apart, can be interpreted as being due to an exchange *or* Pauli force*, that* repels *the electrons from each other. In the singlet state* ($S = 0$, *spins antiparallel, symmetric spatial wave-function), when electrons have almost the same coordinates, the probability density has the value* $2|\psi_a(1)|^2|\psi_b(2)|^2$, *which is* twice *the value expected without Pauli's principle.*

Thus, in the singlet state, the two electrons of opposite spin act as if they attract *each other, i.e. are under the influence of an* attractive exchange force*; again, this force has nothing to do with the electromagnetic forces between the two like charged, oppositely-magnetized electrons.*

Exchange forces arise not only between two electrons of the same *atom; they are an important factor in inter-atomic and molecular forces. The Pauli force is of a purely quantum origin and has no classical counterpart.*

Exchange symmetry rules can be generalized as follows:

(1) Identical particles having an integral quantum number for their intrinsic spin can be described only by wave functions which are symmetric *with respect to the interchange of the space* and *spin coordinates of any two such identical particles. [Such particles are said to obey the Bose-Einstein statistics; examples are the photon (spin 1), graviton (spin 2),* α*-particle (spin 0),* π*-meson (spin 0) of given charge, etc.]*

(2) Identical particles having a half integral quantum numbers for their intrinsic spin can be described only by wave functions which are antisymmetric *with respect to the interchange of the space* and *spin coordinates of any two such identical particles. [Particles obeying the Fermi-Dirac statistics – such as electrons, protons, neutrons, neutrinos,* μ*-mesons, quarks, etc.]*[571]

The Pauli principle, in both of its alternative formulations, cannot be derived from a more general basic principle. We do not know yet why nature

[571] In case the identical particles are endowed with other intrinsic quantum numbers besides spin – such as *isospin*, *color* (in the sense of quark-gluon forces), *strangeness*, *charm*, etc. – the above rules are generalized to include these further degrees of freedom within the spin coordinates.

seems to prefer antisymmetric state functions for fermions rather than symmetric functions and vice-versa for bosons; although the problem is definitely linked to causality via the *'spin-statistics' theorem*[572].

The above rules have the effect of limiting our choice of wave functions for a system containing several identical particles, to those which exhibit the proper type of exchange symmetry. This introduces fundamental new physical effects which are of importance in many phenomena. Some of them are:

- *As compared with the behavior of hypothetical equal but distinguishable* particles, *Bosons exhibit an additional mutual attraction. Identical fermions of the same spin state, on the other hand, repel one another.*
- *At a given temperature, the energy content and pressure of a system of Bose particles are less than (and those of a system of Fermi particles are greater than) the respective energy content and pressure of a corresponding system of equal but distinguishable* particles.[573]
- *If the individual particles of a system are acted upon by some outside force (but do not interact with each other), the quantum states of the system correspond to the various particles occupying certain of the eigenstates available to a single particle. Bosons tend to occupy the same quantum states, while fermions cannot occupy the same quantum states.*

The above properties are responsible for such diverse phenomena as the saturation of chemical bonding forces, the condensation of liquid helium into a superfluid state, the periodic system of the elements, superconductivity and lasers.

---

572 This theorem states that in a relativistic quantum field theory, any attempt to assign the wrong statistics to particles results in the violation of *causality*. It follows that the Dirac field (spin $\frac{1}{2}$ relativistic field) *must* be quantized using anticommutator relations. This was unknown to Pauli when he formulated his exclusion principle. Furthermore, a strong candidate for a spontaneously broken symmetry of unified field theories of particle physics, is supersymmetry — in which each boson is linked to a corresponding fermion via an intrinsic "rotation".

Supersymmetry extends the concepts of differential geometry to non-commuting coordinates. It is related to such abstract algebra structures as *graded Lie algebras* and *affine Lie algebras*, and plays a key role in superstring theories and (probably) in the ultimate theory of *quantum gravity*.

573 This has important consequences for *lasers*, superconductors, metals, semiconductors, superfluids, Bose-Einstein condensates, neutron stars, white-dwarf stars, and early-universe cosmology.

The quantitative *analysis of the helium two-electron system proceeds schematically as follows: take the nucleus (positive charge 2e) at coordinate 0, and two electrons at* $P_1(\boldsymbol{r}_1)$ *and* $P_2(\boldsymbol{r}_2)$*. The potential function will be*

$$V(\boldsymbol{r}) = -\frac{2e^2}{r_1} - \frac{2e^2}{r_2} + \frac{e^2}{r_{12}}, \qquad r_{12} = |\boldsymbol{r}_1 - \boldsymbol{r}_2|.$$

If we write $\nabla_i^2 = \frac{\partial^2}{\partial x_i^2} + \frac{\partial^2}{\partial y_i^2} + \frac{\partial^2}{\partial z_i^2}$ $(i = 1, 2)$, *the time independent Schrödinger equation is*

$$-\frac{\hbar^2}{2m}(\nabla_1^2\psi + \nabla_2^2\psi) - 2e^2(\frac{1}{r_1} + \frac{1}{r_2})\psi + \frac{e^2}{r_{12}}\psi = E\psi,$$

with $\psi = \psi(\boldsymbol{r}_1, \boldsymbol{r}_2)$.

Since the spin does not occur explicitly in this equation[574]*, one need not carry along the spin nomenclature. In the absence of the term* $\{e^2/r_{12}\}$, *solutions are known in the form*

$$\psi = \psi_{n,\ell,m}(1)\psi_{n',\ell',m'}(2), \quad \Psi_{n,\ell,m;i} = R_{n,\ell}(r_i)Y_{m,\ell}(\theta_i, \phi_i), \quad E_n = -\frac{8}{n^2}R_\infty.$$

For $n = 1$ *we have* $E_0 = -8 \times 13.6\ eV = -108.8\ eV$. *Here* R_∞ *is the Rydberg constant.*

Consider now the case for which both *electrons are in the lowest (ground) state, corresponding to* $n = 1$, $\ell = 0$ *(this is allowed since the two spins are opposite); and* $H = e/r_{12}$ *is considered as a perturbation to the Hamiltonian. The first order correction to the energy,* W'*, is given by the* Coulomb integral

$$W' = \int_{\tau_1}\int_{\tau_2} [\psi_{1,0,0}(1)\psi_{1,0,0}(2)]^2 \frac{e^2}{r_{12}} d\tau_1 d\tau_2,$$

$$\psi_{1,0,0}(r_i) = Y_{0,0}R_{1,0}(r_i) = \frac{1}{\sqrt{\pi}}\left(\frac{2}{a_0}\right)^{3/2} e^{-\frac{2}{a_0}r_i},$$

$$a_0 = \frac{\hbar^2}{me^2} = first\ Bohr\ radius.$$

This integral represents the positive *energy contribution due to the mutual electrostatic repulsion of the two electrons.*

The exact integrals in this approximation yield $W' = \frac{5}{4}\frac{e^2}{a_0} = 34\ eV$. *Using the earlier zeroth-approximation, the energy of the ground state of helium is*

[574] We are ignoring all spin effects, for the moment, *except* that the two electrons have opposite spins, so they may be spatially *distinguishable*.

calculated to be $W = E_0 + W' = -108.8 + 34.0\ eV = -74.8\ eV$. *The experimental value is* $-78.62\ eV$.

*More refined calculations (**E.A. Hylleraas**, 1930), using a variational method, gave a theoretical value in excellent agreement with the observed value.*

If the two electrons do not have the same orbital quantum numbers, and are in a singlet or triplet spin state, the total energy perturbation integral is

$$W'_{\pm} = \frac{1}{2}\int_{\tau_1}\int_{\tau_2} [\psi_a(1)\psi_b(2) \pm \psi_b(1)\psi_a(2)]\,\frac{e^2}{r_{12}}\,[\psi_a^*(1)\psi_b^*(2) \pm \psi_b^*(1)\psi_a^*(2)]\,d\tau_1 d\tau_2$$

or $W'_{\pm} = J_{a,b} \pm K_{a,b}$, *where*

$$J_{a,b} = \int_{\tau_1}\int_{\tau_2} \frac{e^2}{r_{12}}|\psi_a(1)|^2|\psi_b(2)|^2 d\tau_1 d\tau_2;$$

$$K_{a,b} = \int_{\tau_1}\int_{\tau_2} \frac{e^2}{r_{12}}\psi_a(1)\psi_b(2)\psi_a^*(2)\psi_b^*(1) d\tau_1 d\tau_2.$$

The quantity $J_{a,b}$ *is the Coulomb integral, calculated earlier for the ground state. It is the interaction energy of the two electrons, assuming that they are distributed with charge densities* $\rho_1 = -e|\psi_a(1)|^2$, $\rho_2 = -e|\psi_b(2)|^2$, *respectively.*

The quantity $K_{a,b}$, *the exchange integral, giving the interaction energy of charges with effective (sometimes complex!) densities* $\rho'_1 = -e\psi_a(1)\psi_b^*(1)$ *and* $\rho_2 = -e\psi_b(2)\psi_a^*(2)$. *It results from quantum interference between the two exchanged configurations.*

*An important solution of the SE with a periodic potential field, was obtained in 1931 by **Kronig** and **Penney**. It could be directly applied to the electron motion in a periodic structure, such as a crystal lattice.*

Consider a periodic square-well potential in one dimension with height V_0, *width* b *and spacing* a. *If this is caused by regularly spaced atomic nuclei, we would expect to find a similar periodicity in the electron charge distribution, and thus in the wave function modulus. The wave equation will be*

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}(E - V_0)\psi = 0 \qquad (0 \le x \le b)$$

and

$$\frac{d^2\psi}{dx^2} + \frac{2m}{\hbar^2}E\psi = 0 \qquad (b \le x \le a + b).$$

Let us consider a lattice with volume $L = N(a+b)$. *We look for periodic solutions* $\psi = u(x)e^{i\alpha x}$ *with* u *periodic with period* $(a+b)$ (***F. Bloch***[575], *1928). Imposing also the periodic boundary condition* $\psi(x+L) = \psi(x)$, *we find* $\alpha = \frac{2\pi K}{N(a+b)}$ $(K = 0, \pm 1, \pm 2, \ldots, \pm M)$, *with* $M = \frac{N-1}{2}$ *(N odd),* $M = \frac{N}{2}$ *(N even).*

A substitution of the 'Bloch function' into the above pair of Schrödinger equations, yields a pair of ordinary second-order differential equation for $u(x)$, *whose solutions are*

$$u_1 = e^{-i\alpha x}[A\,\mathrm{ch}\,\gamma x + B\,\mathrm{sh}\,\gamma x] \qquad (0 \le x \le b),$$

$$u_2 = e^{-i\alpha x}[C\cos\beta x + D\sin\beta x] \qquad (b \le x \le a+b),$$

subject to the boundary conditions

$$u_1(b) = u_2(b), \quad u_1'(b) = u_2'(b), \quad u_1(0) = u_2(a+b), \quad u_1'(0) = u_2'(a+b).$$

The parameters β, γ *are defined as follows:*

$$\beta = \sqrt{\frac{2mE}{\hbar^2}}, \qquad \gamma = \sqrt{\frac{2m(V_0 - E)}{\hbar^2}}.$$

These conditions impose an algebraic system of 4 equations in A, B, C, D. *For non-trivial solution this requires the determinant to vanish, leading to the characteristic equation*

$$\left(\frac{\gamma^2 - \beta^2}{2\beta\gamma}\right)\mathrm{sh}\,\gamma b \cdot \sin\beta a + \mathrm{ch}\,\gamma b \cdot \cos\beta a = \cos\alpha(a+b).$$

It is instructive to consider the limiting case $V_0 \to \infty$, $b \to 0$ *such that* $\lim \frac{\gamma^2 ab}{2} = P$ *(a finite constant); physically, this means that the lattice atoms (nuclei and their localized valence electrons) interact with a moving (conduction) electron through a periodic delta-function potential.*

The characteristic equation then reduces to

$$P\frac{\sin\beta a}{\beta a} + \cos\beta a = \cos\alpha a.$$

[575] **Bloch Theorem**: The eigenfunctions of the SE for a periodic potential are of the form $\psi_{\boldsymbol{k}}(\boldsymbol{r}) = u_{\boldsymbol{k}}(\boldsymbol{r})e^{i(\boldsymbol{k}\cdot\boldsymbol{r})}$, where $u_{\boldsymbol{k}}(\boldsymbol{r})$ has the periodicity of the crystal lattice, i.e., $\psi_{\boldsymbol{k}}(\boldsymbol{r}+\boldsymbol{\Lambda}) = e^{i(\boldsymbol{k}\cdot\boldsymbol{\Lambda})}e^{i(\boldsymbol{k}\cdot\boldsymbol{r})}u_{\boldsymbol{k}}(\boldsymbol{r}+\boldsymbol{\Lambda}) = e^{i(\boldsymbol{k}\cdot\boldsymbol{\Lambda})}\psi_{\boldsymbol{k}}(\boldsymbol{r})$.

This is an implicit equation for a set of energy levels that depend on the geometrical and physical parameters of the lattice. The possible values of βa (i.e., those solving the equation for some Bloch wavenumber α) fall into separate bands. *Thus the spectrum of β, and therefore of E, consists of a number of* continuous bands *separated by intervals in which there are* no *energy levels. Note that α is continuous, since we take the infinite volume limit $N \to \infty$.*

The number P represents the strength of the binding of the moving (conduction) electrons to the lattice. Thus, $P = 0$ leads to the solutions $\beta a = 2n\pi \pm \alpha a$ (n integer), and since α can vary continuously, this means that all continuous energies are allowed; the conduction electrons are now free.

On the other hand, as $P \to \infty$ we must have $\sin \beta a = 0$, that is, $\beta a = n\pi$ $(n = \pm 1, \pm 2, \ldots)$ and the energy spectrum is now discrete *with values $E_n = \frac{n^2 h^2}{8ma^2}$. These are exactly the levels of a particle confined to move between two impenetrable potential barriers a distance a apart. The electrons are now completely bound.*

For finite P values, only certain bands of energy are allowed to an electron, and these bands are separated by forbidden regions representing energies which the electron cannot have.

The problem of solving the SE with a periodic structure in 3 dimensions is very complicated. Nevertheless, the problem has been solved in many cases of special interest. The general result, however, is qualitatively very similar to that which has been obtained for a one-dimensional crystal.

Consider, for example, bringing together a large number of isolated atoms to form a crystal. The electrons in each isolated atom can occupy a series of discrete energy levels. As the atoms are brought closer and closer together, these discrete energy levels split up into bands of energy, so that the resulting allowed energies for that separation of the atoms which finally correspond to the atomic spacing in the crystal are qualitatively similar to the energy bands which we have seen in the one-dimensional case above.

Modern material science allows scientists to adjust and select the effective lattice spacings almost at will, enabling the creation of so-called engineering bandgaps *— with numerous applications in microelectronics, photonics, telecommunications and computers.*

History of the Theories of Light IV (1900–1925)

D. The Ultimate Synthesis: Wave-Particle Duality[576]

It follows directly from Kirchhoff's law of blackbody radiation (1859) that the spectral EM energy density can be written as $u_\nu(T) = \frac{8\pi}{c}K_\nu(T)$, *where* c *is the velocity of light in vacuum,* T *is the absolute temperature,* ν *the radiation's frequency and* $K_\nu(T)$ *is a universal function independent of the nature of the bodies in equilibrium with the radiation field. The four decades that followed Kirchhoff's discovery of the said law, witnessed many unsuccessful attempts to derive the correct form of* $K_\nu(T)$, *or what amounts to the same thing — the spectrum of blackbody radiation as a function of frequency and temperature.*

The first formula, derived by **W. Wien** *(1893) on the basis of thermodynamics is known as Wien's displacement law. According to this law* $K_\nu(T) = \nu^3 F\left(\frac{\nu}{T}\right)$. *However, thermodynamics did not specify the form of this function. Using a somewhat heuristic argument, Wien proposed (1896) the explicit form* $F = \alpha e^{-\beta\frac{\nu}{T}}$, *leading to the so-called Wien's radiation law. The values of the constants* α *and* β *that appear in this law did not follow from Wien's arguments and had to be determined empirically.*

Subsequently (1900), **Lord Rayleigh** *showed that the application of the equipartition theorem of classical statistical mechanics to electromagnetic vibrations in a cavity leads to a certain radiation law. When later corrected by* **J.H. Jeans** *(1905) for a simple error, it became known as the Rayleigh-Jeans law:* $K_\nu(T) = \left(\frac{\nu}{c}\right)^2 kT$.

We note that both Wien's radiation law and the Rayleigh-Jeans law are of the form required by Wien's displacement law. However, careful measurements carried out around the turn of the century revealed that neither of them completely agrees with the experimentally determined energy distribution in the spectrum of blackbody radiation. It turned out that Wien's radiation law was a good approximation for sufficiently high frequencies and low enough temperatures, whereas the Rayleigh-Jeans law was a good approximation for the opposite regime.

Thus, both thermodynamics and electromagnetic theory failed to predict the energy distribution in the spectrum of blackbody radiation.

---

[576] Adapted from: "Einstein's Researches on the Nature of Light" by **Emil Wolf**, *Optics News* **5**, 24–39, 1979.

Just a few months after the 1900 *publication of Rayleigh's paper,* ***Max Planck*** *discovered the correct law that is in complete agreement with experiment:*

$$K_\nu(T) = \frac{h\nu^3}{c^2}(e^{h\nu/kT} - 1).$$

(He outlined the essential features of his new derivation at a meeting of the German Physical Society in Berlin on Dec. 14, 1900.)

Planck's radiation law reduces to the Wien's radiation law when $\nu/T \gg 1$ *with* $\alpha = \frac{h}{c^2}$*;* $\beta = \frac{h}{k}$*. When* $T/\nu \gg 1$ *it yields precisely the Rayleigh-Jeans law. In deriving the law, Planck found it necessary to introduce the notion of the* quantum of energy $E = h\nu$, *which represents the smallest amount of energy that an oscillator can emit or absorb at a given frequency. The need of introducing such a quantum of energy was in flat contradiction to Maxwell's electromagnetic theory and Lorentz' classical electron theory, which places no restriction on the amount of energy that an oscillator can emit or absorb.*

Even though Planck's introduction of the concept of energy quanta led eventually to one of the greatest scientific revolutions of all times, his heuristic derivation did not, at first, attract much attention. One of the first scientists who clearly recognized that Planck's discovery initiated a new era in physics was a young man who was just appointed (1902) to the rank of "Technical Expert, Third Class" at the Swiss patent office.

In 1905, *this man, as yet unknown to the scientific world, published a paper in the* 17^{th} *volume of the journal* Annalen der Physik *entitled (in translation)* "On the heuristic point of view concerning the creation and conversion of light". *In modern textbooks it is usually referred to as "Einstein's paper on the photoelectric effect". Actually it contains appreciably more. In fact, Einstein's whole discussion of the photoelectric effect covers less than 4 pages; but as in most of his writings, Einstein was able to get to the root of the problem in a few lines, with simple language that was remarkably free of complicated mathematics.*

What Einstein essentially did in this paper was to put forward a great deal of evidence that not only do the processes of emission and absorption of radiation take place in discrete amounts of energy (as appears to have been established by Planck) but that radiation itself behaves under certain circumstances as if it consisted of a collection of particles (photons)[577]*. Thus in this*

[577] Einstein's argument runs as follows: If n particles are thrown into a box of volume V, the probability that *all* n particles will end up in a subregion ΔV is $p(n) = \left(\frac{\Delta V}{V}\right)^n$. On the other hand, invoking Wien's radiation law and some general principles of thermodynamics, Einstein showed that the probability that at a given instant *all* the energy E will be concentrated in this subregion is

paper Einstein reintroduced a corpuscular theory of light — first advanced by Newton in the 17^{th} *century. This was 90 years after the corpuscular theory was completely discredited by* ***Fresnel****'s wave theory and 40 years after* ***Maxwell*** *put the wave theory of light on firm foundations.*

Another example that Einstein gave in this paper in support of his view regarding the corpuscular nature of radiation, was the photoelectric effect*. This is the phenomenon of ejection of electrons from a metal when electromagnetic radiation of short enough wavelength impinges on a metal surface. The effect was discovered by* ***Heinrich Hertz*** *(1887).*

Experiments conducted during 1899–1902 by P.E.A. Lenard (1862–1947, Germany) disclosed that the electron energy did not depend on the intensity of the light illuminating the metal surface, but did depend on the frequency of the light. The number *of ejected electrons was found to increase with the light intensity. Einstein's photoelectric equation[578]explained at once Lenard's experiments.*

Einstein's analysis showed the need for more drastic changes than those brought about by Planck's assumption of quantized energy of the emitting and absorbing oscillators. It indicated that not only do emission and absorption of energy take place in discrete energy quanta, but that the radiation field itself *behaves, in certain situations, as if it consisted of such corpuscles of energy.*

In spite of the clarity and simplicity of Einstein's arguments, his views about the particle structure of radiation were strongly opposed at that time — and for a long time afterwards — by many eminent physicists, including Planck. Undeterred by opposition, Einstein continued to explore the consequences of his corpuscular theory, and to probe more deeply into the nature of radiation.

In 1909, Einstein published a paper with the title: "On the present status of the problem of radiation", in which he showed that Planck's radiation law itself implies that the radiation field exhibits not only wave features but also corpuscular features. This result was the first clear indication of the so-called

---

p (all $E \in \Delta V) = \left(\frac{\Delta V}{V}\right)^{E/h\nu}$. Comparison of the two results shows that this probability is the same as if the radiation field consisted of n particles, where $n = \frac{E}{h\nu}$, i.e., of n particles each carrying energy $h\nu$.

578 $(E_{\text{kin}})_{\text{max}} = h\nu - W$, where W is the work required to remove the electron from the metal. In 1905, when Einstein put forward his equation, quantitative studies of the photoelectric effect were in their infancy. It took nearly a decade of difficult experimentation before Einstein's equation could be tested. It was largely confirmed by the work of **R.A. Millikan**, who at first completely disbelieved Einstein theory.

wave-particle duality, that many years later became an accepted feature of modern quantum physics.

Bohr's quantum theory of the hydrogen atom (1913) did not give any indication of the laws governing the *amplitudes* of the atomic spectral lines. Moreover, Bohr's frequency condition $\Delta E = h\nu$ was simply *assumed*. Einstein's epochal paper "On the quantum theory of radiation" (1917) provided the first real insight into the laws that govern the transitions from one allowed state of the atom to another. Einstein showed therein that Planck's law follows directly from the interaction between radiation and matter. The probabilities that Einstein assumed for each of the elementary processes taking part in the interaction are examples of what is known today as *transition probabilities* between states.

In the above paper, Einstein also considered the question of *momentum transfer* between gas molecules and the radiation field. He showed that, when a molecule absorbs or emits a quantum of energy $h\nu$ under the influence of external radiation from a *definite direction*, momentum of magnitude $\frac{h\nu}{c}$ is transferred to the molecule; and that the change in the momentum of the molecule is in the direction of the incident radiation if the energy is absorbed, or in the opposite direction if the energy is emitted. More surprisingly, Einstein showed that if an energy quantum is emitted in the absence of any external influence (spontaneous emission), the momentum transfer is also a *directed process*.

In Einstein's words (1917):

"There is no radiation in spherical waves. In a spontaneous emission process the molecule suffers a recoil of magnitude $\frac{h\nu}{c}$ in a direction that in the present state of the theory is determined only by 'chance'... These properties of elementary processes... make it seem practically unavoidable that one must construct an essentially quantum mechanical theory of radiation".

Einstein's conclusion that a quantum of energy $h\nu$ carries a momentum whose magnitude is $\frac{h\nu}{c}$ and has a definite direction, was verified by **H.A. Compton** (1923) in his experiments on scattering of X-rays.

Successful as Einstein's notion of radiation field quanta was in elucidating various phenomena involving the interaction of light and matter, many puzzles surrounded it. All the derivations of Planck's radiation law, including Einstein's 1917 derivation, appealed at some point to classical electromagnetic theory, which is in direct contradiction with the quantum features of the radiation field. Being well aware of these difficulties (quantum mechanics was only formulated about 8 years later), Einstein took a few important steps in this direction that have a bearing on the question of the nature of light, particularly with regard to its statistical properties.

S. Bose *(1924) published a manuscript in which he essentially treated the light quanta as particles of a gas, with the difference that those particles that belong to the same elementary cell of phase space, of volume h^3, are intrinsically indistinguishable. This assumed property of the quanta led to a statistical procedure that differs from that of classical statistic mechanics, and indeed provided a complete derivation of Planck's radiation law —, without any appeal to classical electromagnetic theory.*

Einstein (1925) applied Bose's method not to a gas of light quanta, but to a real gas, consisting of monoatomic molecules, thus establishing the quantum theory of an ideal gas[579]*.*

Bose's and Einstein's papers are the foundation of the Bose-Einstein statistics. It applies to photons and to many other elementary particles and antiparticles which were as yet unknown in 1925.

Between the appearance of Einstein's first and second papers on the quantum theory of an ideal gas (a period spanning less than five months), ***Louis de Broglie*** *put forward his theory of matter waves. In his second paper, Einstein outlined the connection that he believed to exist between de Broglie's hypothesis of matter waves and his own investigations on the quantum theory of the ideal gas. These remarks have stimulated* ***Ervin Schrödinger*** *only a few months later to develop one form of modern quantum mechanics — namely wave mechanics.*

Thus, the structure that Einstein built with his 1905 "photoelectric paper", his 1909 *paper containing the first clear evidence for the wave-particle duality, his* 1917 *paper on the elementary processes of interaction between molecules and radiation, and his* 1924 *and* 1925 *papers on the quantum theory of an ideal gas — not only elucidate the nature of light and radiation in general, but also proved to be of fundamental importance to the gestation and final formulation of wave mechanics.*

[579] Einstein showed that the variance of the energy fluctuations of an ideal gas is expressible as the sum of two terms; the first term can be attributed to classical particles and can be understood on the basis of the *Maxwell-Boltzmann* statistics of noninteracting molecules. The second term, which is analogous to the contribution from wave interference in the radiation problem, cannot be understood from the classical particle theory.

1925–1956 CE **Marietta Blau**[580] (1894–1970, Austria and USA). Experimental nuclear physicist. Pioneer in the field of nuclear emulsions (i.e. tracking nuclear particles in photographic emulsions). First to use nuclear emulsions to detect neutrons by observing recoil protons in the emulsions (1925). First to *identify* (1925) proton tracks resulting from either the elastic scattering of α-particles by protons in the hydrogen in the emulsion or the reaction of α's with the nuclei of the emulsion. Also determined for the first time the spectrum of neutrons resulting from specific nuclear reaction processes.

Her life and career were tragically disrupted by the Nazi Germans and Austrians in 1938. She maintained, however, a life line to the world physics through her simple portable technique she subsequently created. **Einstein** and **Born** praised her work highly, and Erwin **Schrödinger** nominated her for the Nobel Physics Prize, to no avail — others received the prize she so rightly deserved.

Blau was born in Vienna and received her Ph.D. (1919) from the University of that city. Between 1923 and 1938 Blau's investigations were centered at the Institut für Radiumforschung in Vienna and at the Second Physical Institute. But she was never paid and never promoted because, as she was told by a professor: "...you are a woman and a Jew, and the two together are simply too much".

On Friday, 11 March 1938, the Germans entered Vienna. Blau fled first to Oslo, but could not find a permanent employment there. Desperate to rescue her mother from Vienna she began exploring the possibility of getting to Mexico. With the recommendation of **Einstein**, Blau was appointed professor at the Technical University in Mexico City. She took a German ship to America; en route the Gestapo confiscated all her scientific papers, including work on particle tracks in nuclear emulsions.

In May 1944 Blau moved to New York City and then moved (1950) to the Brookhaven National Laboratory. Although this place initially seemed congenial, even that resting spot did not last: personal friction with some staff members, coupled with dire financial difficulties and health problems, led her back to Vienna (1960).

Marietta Blau had moved some ten times, lost all her scientific papers and notebooks and still had no clear path to a permanent position. Several physicists tried to gather funds for her. Erwin Schrödinger put her up for the Schrödinger Prize (which she won) and Otto Frish tried to convince the big film companies to grant her a sinecure in recognition of the industry of nuclear emulsions that she helped create. All they were willing to contribute

---

[580] Peter L. Galison: "Marietta Blau: *Between Nazis and Nuclei*" Physics Today, November 1997, pp 42–48

were £100 per annum which she declined despite her poverty (1964). She died five years later poor and virtually unknown.

1925–1958 CE **Raymond Dart** (1893–1988, South Africa). Anatomist and paleoanthropologist. Discovered and pioneered the pre-human evolutionary stage formed by the *australopithecines*. This species, found in Southern Africa and recognized as *Australopithecus africanus*, spans a period from 3 to 2.5 million years ago.

At the start of the 20th century the search for the supposed "missing link" between apes and human focused on the Far East and Europe, where finds such as "*Pithecanthropus erectus*" ("Java man") had been made. This is now identified as *Homo erectus*, some way along the human line.

In 1925, the anatomist Raymond Dart dared to identify a new kind of ape-man on the basis of the isolated skull of a young primate found during mining work at *Taung*, near Kimberley, South Africa, the previous year. He knew he was challenging a powerful, if poorly founded assumption that human first evolved in Europe, and that their big brains developed before other human features.

According to Dart, the shape of the skull and probable shape of the brain, together with the design of the teeth and jaws and the upright angle of the skull where it would have topped the (vanished) spinal column, all announced a recruit that was more human than any known ape. Dart labored for decades before he and another researcher **Robert Broom** (1866–1951, South Africa) eventually began to establish a new genus with the help of more skulls, jaws, teeth, and post-craniel bones from additional cave sites.

Dart was born in Brisbane, Queensland, Australia. He graduated from the universities of Brisbane and Sydney, and after holding a number of posts and fellowships in the UK and the USA, was appointed to the chair of anatomy at Witwatersrand University, Johannesburg (1923).

It is now well established that the australopithecines represent an early stage in the evolutionary differentiation of man and that these fossils demonstrate that one of the first features to be evolved was terrestrial bipedalism. Only later came the substantial brain expansion and jaw reduction which characterize modern man.

The significance of bipedalism was that it completely emancipated the arms and hands from support of and locomotive function. Whether the South African australopithecines actually made tools is uncertain.

After an initial burst of praise, the scientific establishment in Britain rejected the Taung baby[581] as an ape. Virtually the only supporter of Dart was Robert Broom. Dart did travel to London (1930) to try and win support for his Taung baby, but his find was overshadowed by the recently discovered *Peking Man* skull.

Dart gave up fossil hunting for many years, concentrating instead on his work at the Witwatersrand anatomy department. In the late 1930s and early 1940s Broom found many more australopithecines fossils in South Africa, and in the late 1940's Dart's position was vindicated when many scientists finally accepted that australopithecines were hominids. Once Piltdown Man was out of the picture, the center of gravity of physical anthropology moved to Africa, where it belonged.

1925–1965 CE **Jan Hendrik Oort** (1900–1992, Holland). Astronomer. Elucidated the kinematics and dynamics of the Milky Way system through his pioneering work on the *differential galactic rotation* (1925–1927) and the 21 cm radiation associated with the hydrogen flow along the *spiral arms* of the galaxy (1951). Established (1950) the now accepted hypothesis about the *source* (if not the ultimate origin) *of comets*; He concluded that the observed distribution of cometary orbits could be explained by supposing a cloud of 1.9×10^{11} comets surrounds the sun as far as 50,000 to 150,000 AU and affected from time to time by the perturbing effects of passing stars. This reservoir of cometary nuclei is called the *Oort cloud*[582].

---

581 At the time, *Piltdown Man* was widely accepted as a human ancestor, and *Taung*, with its apelike skull and human-like teeth, seemed difficult to reconcile with Piltdown's human skull and apelike jaw.

Piltdown Man: name given to fossil remains found (1908) at Piltdown, England, thought to be human and 200,000 to 1 million years old. In 1950, fluorine tests and X-ray analysis proved that Piltdown Man was a forgery. The fraud endured for more than 40 years in part because of the desire of European scientists to find evidence for the European origin of man.

582 Astronomers discover *long-period comets* (orbital periods of 100,000 years to 1 million years) at a rate of about one per month. These comets travel along extremely elongated orbits and consequently spend most of their time at distances of ca 4000 to 20,000 AU from the sun — comprising the *inner* Oort cloud; the tenuous, weakly bound *outer* cloud extends out to ca 50,000 AU from the sun, i.e about $\frac{1}{5}$ of the way to the nearest star. Thus it is reasonable to suppose that there is an enormous population of comets on the outskirts of the solar system. Only with such a large reserve of cometary nuclei can we understand why we see so many long-period comets even though each one takes up to 1 million years to travel once around its orbit.

Oort determined that stellar perturbations of cometary orbits over the lifetime

Oort was born in Franeker, Friesland. He completed his training at Leyden Observatory, where he remained for the rest of his career, becoming director in 1945.

In 1932 he estimated the mass density of the galactic disc in the solar neighborhood, known as the *Oort limit*[583]. By measuring the expansion rate of the dissipating material from the Crab Nebula he confirmed that it was the remnant of the exploding star seen as the 1054 *CE* supernova.

1925–1966 CE **Andrei Nikolaevich Tikhonov** (1906–1993, Russia). Mathematician. Obtained fundamental results in a wide range of modern mathematical fields: topology and functional analysis (1925–1935), ordinary and partial differential equations and their application to problems in mathematical physics (1948–1960), and computational mathematics (1960–1966).

Tikhonov was born in Gzhatska, Smolensk region, Russia. He graduated from Moscow University (1927) and became a professor there (1936).

His initial works (1925–1930) are related to the pioneering results of **Uryson** on the condition for the metrization of a topological space. He

---

of the solar system would completely rearrange the orbital orientations into a random distribution, even if their initial orbits began with a preference for the ecliptic plane. Thus the wide variation of orbital inclinations for observed comets with nearly parabolic orbits was explained in a natural way. Oort then asked how many comets would be required in the cloud to explain the observed flux of one dynamically new comet passing each year inside a sun-centered sphere with a radius of 1.5 AU. Assuming only the effects of stellar perturbations, he determined some 1.9×10^{11} comets with a total mass of about 10^{27} grams, of order of the mass of the earth! Much of the work on the source of comets since 1950 has supported Oort's basic ideas concerning the provenance of long-period comets.

583 It is possible to estimate the *mass density* of the galactic disc in the solar neighborhood, using *Jeans' equations* in cylindrical coordinates R, z (which in turn are derived from the collisionless Boltzmann transport equation of statistical mechanics), in conjunction with the *Poisson equation*. Oort's analysis yielded the relation

$$\frac{\partial}{\partial z}\left[\frac{1}{\nu}\frac{\partial}{\partial R}(\nu\overline{V_z^2})\right] = -4\pi G\rho,$$

where $\nu = \nu_0 e^{-2.4R/R_0}$ is the *spatial density* of stars, R_0 the sun's distance from the galaxy's rotational axis, and $\overline{V_z^2}$ is the mean-square vertical velocity. He thus concluded (1932) that

$$\rho_0 = \rho(R_0, z = 0) \simeq 0.15\ M_\odot pc^{-3},$$

which is known as the *Oort limit*.

then defined the product-space of topological spaces and went on to prove that the product-space of any set of compact topological spaces is compact. Tikhonov's '*embedding theorem*' concerns the mapping of a topological space into an infinite-dimensional space[584]. He later (1935) found conditions for a topological space to be metrizable. His work led from topology to functional analysis with his fixed-point theorem for continuous maps (1935). These results are of importance in both topology and functional analysis and were applied by him to solve problems of mathematical physics. In the 1960's he shifted his attention to numerical methods for the solution of nonlinear ill-posed problems.

1925–1969 CE **Salomon Bochner** (1899–1982, Germany and USA). Mathematician. Made important contributions to *harmonic analysis*, *probability theory*, *algebraic geometry* and *topology of harmonic vector fields*. His research profoundly influenced development of a wide area of analysis in the second half of the 20^{th} century such as:

- Classification of compact manifolds.
- Higher-dimensional geometry in String Theory.
- Infinite-dimensional representation of non-compact semi-simple Lee groups.
- Complex analysis in several variables.

He also presaged the Zorn Lemma (1933) already in 1928.

Bochner was born into an orthodox Jewish family in Podgorze (near Krakow), Poland. In 1915, the family moved to Germany, seeking greater security. After graduating from a Berlin Gymnasium, Bochner entered the University of Berlin (1918) and received his doctorate there in mathematics (1921). He then worked with Harald Bohr in Copenhagen, G.H. Hardy in Oxford, and J.E. Littlewood in Cambridge. In 1933 he came to the United States and spent the next 35 years at Princeton University. During 1968–1975 he was the chairman of the Mathematical Department of Rice University, Houston, Texas.

---

[584] Infinite dimensional spaces are relevant to mathematical physics, with applications to differential equations and to functional equations via *fixed-point theorems* extending those long known for finite–dimensional spaces. In 1930 **Schauder** proved a fixed-point theorem for continuous mapping of a closed convex subset of a Banach space onto a countably-compact subset of itself. In 1935 Tikhonov proved a similar theorem. In 1922, **Birkhoff** and **Kellos** extended Brouwer's fixed point theorem to functional spaces.

During 1966–1969, Bochner contributed to the *history of Science* through his books: *The Role of Mathematics in the Rise of Science* (1966) and *Eclosion and Synthesis: Perspective in the History of Knowledge (1969).* Therein, he attempted to differentiate periods in science according to their peculiar thought-patterns.

1926 CE **Vladimir Ivanovich Vernadsky** (1863–1945, Russia). Geochemist and mineralogist. Founder of modern *biogeochemistry*. In his book *La Biosphere* he developed the ideas of **Eduard Suess** (1875) and **Jean Baptiste Lamarck** to those we accept today.

Moscow University (1898–1911); State Radium Institute, Leningrad (1926–1938); Founder and director of biogeochemical laboratory of Leningrad Academy of Sciences.

Vernadsky was a Russian liberal who grew up in the 19^{th} century. Accepting the Russian Revolution, he did much of his work after 1917, although his numerous philosophical references were far from Marxist.

1926 CE **Carl Eckart** (1902–1971, U.S.A.). Physicist. Establishes independently that **Schrödinger**'s wave mechanics is mathematically equivalent to the matrix mechanics of **W. Heisenberg**, **M. Born** and **P. Jordan**.

1926–1928 CE **Kalman Tihanyi** (1897–1947, Hungary). Electrical engineer and inventor. Electronic television pioneer. Patented his fully electronic television system in 1926.

The idea to utilize the cathode ray tube as image converter on the side of transmission surfaced in 1908, and was described in detail by **A.A. Campbell Swinton** in a paper he published in 1911. In the 1920's, variations on the Campbell Swinton design were proposed by Zworykin. All were electrical analogues of mechanical scanners, in that electron emission would occur only during the momentary contact by the scanning ray of each elemental area of the photocell. In 1925 a demonstration by Zworykin with his system produced discouraging results.

The decisive solution — television operating on the basis of continuous electron emission with accumulation and storage of released secondary electrons during the entire scansion cycle — was first described by Kalman Tihanyi in 1926, with further refined versions patented by him in 1928.

Tihanyi was born in Uzbeg and studied electrical engineering and physics in Budapest.

1926 CE **Robert Hutchings Goddard** (1882–1945, U.S.A.). Among the pioneers of modern rocketry and space flight. Experimented during 1909–1945 with solid and liquid propellant rockets which led to the development of intercontinental missiles, earth-orbiting satellites and the exploration of space. He was first to develop rockets equipped with propellant pumps, gyro-controls, and other instrumentation. Goddard foresaw many of the space flight ideas that later became reality.

In his treatise "*A Method of Reaching Extreme Altitudes*" (1919) he proposed trying to reach the moon by rocket. In 1926 he successfully launched a liquid fuel rocket. Ridiculed[585] as a "moon man", Goddard lived to see his work win recognition for putting man on the threshold of space.

1926–1927 CE *The WKBJ method*[586] for the approximate treatment of

585 On January 30, 1920, an anonymous editorial-page writer from the *New York Times* mocked **Robert Goddard** for suggesting that a rocket could someday reach the moon: "*That Professor Goddard, with his 'chair' in Clark College, and the countenancing of the Smithsonian Institution, does not know the relation of action to reaction and of the need to have something better than a vacuum against which to react — to say that would be an absurd. Of course, he only seems to lack the knowledge ladled out in high schools*".

The *Times* went on to cite "the same mistake" in Jules Verne's description of firing a rocket to adjust the course of a manned moonship: "*The Frenchman, having got his travelers to the moon in a desperate fix of riding a satellite of a satellite, saved them from circling it forever by means of an explosion, rocket fashion, where it could not have had in the slightest degree the effect of releasing them from their dreadful slavery*".

Such ignorant criticisms of Goddard's work scared off many supporters for ten years, until Charles Lindbergh courageously laid his own prestige on the line to boost Goddard's.

Almost 50 years later, after two manned lunar expeditions had already used a pure Vernesian rocket maneuver to escape from lunar orbit and return to earth, the Apollo 11 moon-landing expedition was launched. In a special section of the newspaper, the *Times* printed a small box titled: "*A Correction*". In it, the newspaper's original Goddard criticism was quoted and retracted: "*Further investigation and experimentation have confirmed Isaac Newton in the* 17^{th} *century and it is now definitely established that a rocket can function in a vacuum as well as in the atmosphere. The Times regrets the error*".

586 The method treats the asymptotic solutions of the equation

$$\frac{d^2W}{dz^2} + \nu^2 Q(z,\nu)W = 0,$$

where the parameter ν is taken to be large and positive and where $Q(z,\nu)$ tends to a limit as $\nu \to \infty$ for fixed z. A change of variables from (z,W) to (u,X) through the relations $z = z(u)$, $W = X\left(\frac{dz}{du}\right)^{1/2}$ trans-the Schrödinger wave equation is discovered independently by **Léon Brillouin** (1889–1969, France), **Hendrik Anthony Kramers** (1894–1952, Holland) and **Gregor Wentzel** (1898–1978, Germany and U.S.A.). This general mathematical technique had been used earlier by **Liouville** (1837), **Rayleigh** (1912) and **Harold Jeffreys** (1891–1989, England) in 1923.

1926–1929 CE **John Logie Baird** (1888–1946, Scotland). Engineer and inventor. Pioneer of television. A self-taught inventor, who matched inventive wits against the accumulated wisdom and vast resources of great laboratory physicists and engineers. Invented the *noctovision* (1926), a television system that uses infrared rays to take pictures in the dark. In the same year he gave the first public demonstration of television broadcasting in England, using a high-speed *electro-mechanical* scanning system.

---

forms the original equation into $\frac{d^2X}{du^2} + \left[\nu^2 Q z'^2\right] X = \left[\frac{3}{4}\left(\frac{z''}{z'}\right)^2 - \frac{1}{2}\frac{z'''}{z'}\right] X$, $\left(' = \frac{d}{du}\right)$. One then chooses $z(u)$ such that $\nu^2 Q \left(\frac{dz}{du}\right)^2 = -u$, thereby yielding $u = (\pm i)^{2/3}\nu^{2/3}\Phi(z)$ where $\Phi(z) = \left[\frac{3}{2}\int_{z_0}^{z}\sqrt{Q}dz\right]^{2/3}$. The differential equation thus assumes the form $\frac{d^2X}{du^2} - uX = \nu^{-4/3} r_1(u) X$ with $r_1(u) = -\frac{1}{2}\nu^{4/3}\{z,u\}$ and $\{z,u\} = \frac{z'''}{z'} - \frac{3}{2}\left(\frac{z''}{z'}\right)^2$ is the *Schwarzian derivative* of z with respect to u. Since $\frac{dz}{du} \propto \nu^{-2/3}$, $\frac{d^2z}{du^2} \propto \nu^{-4/3}$, $\frac{d^3z}{du^3} \propto \nu^{-2}$, it follows that $r_1(u)$ tends to a ν-independent limit. Neglecting the r.h.s. of the last differential equation, the solutions of this equation tend to those of the *Airy equation* $\frac{d^2X}{du^2} - uX = 0$. Its general solution is known to be (in the original variables)

$$W \approx \nu^{-1/3}\left[\frac{\Phi}{Q}\right]^{1/4}\left[c_1 Ai\left\{e^{-2\pi i/3}\nu^{2/3}\Phi\right\} + c_2 Ai\left\{-e^{-2\pi i/3}\nu^{2/3}\Phi\right\}\right]$$

where c_1 and c_2 are constants and $Ai(z) = \frac{1}{\pi}\int_0^\infty \cos\left(zs + \frac{1}{3}s^3\right)ds$. Away from *turning points* [roots of $Q = 0$], and in regions where $Q > 0$, the above solution simplifies to the WKBJ modified plane wave

$$W \approx \nu^{-1/2}Q^{-1/4}\left[c_1 e^{i\nu\int_{z_0}^{z}\sqrt{Q}dz} + c_2 e^{-i\nu\int_{z_0}^{z}\sqrt{Q}dz}\right].$$

In optics, this is related to the ray approximation for a high-frequency wave, propagating in an inhomogeneous medium; whereas in quantum mechanics, it describes the semiclassical motion of a particle when $\hbar$ is small relative to the classical scales set by the energy, potential, mass etc.

Baird's electro-mechanical system consisted of a light sensitive camera behind a rotating disc. It delivered a crude picture consisting of 30 lines at 12 frames per second to a television receiver that displayed an uneven and tiny orange and black image. By 1932 Baird had developed the first commercially viable television system and had sold 10,000 sets. He was unable to obtain a patent protection to his device, because it contained the already patented Nipkow disc. He transmitted a television image between London and Glasgow by telephone lines in 1927, and between London and New York by radio in 1928. He also experimented with color and three-dimensional television.

The British Broadcasting Corporation adopted Baird's system for their first television programme in 1929, but in 1937 it was abandoned in favor of an *electronic* scanning system.

Baird was born in Helensburgh, Scotland and studied at Glasgow University. He came to Trinidad (1919), escaping from the harsh Scottish climate that was plaguing him with colds and fevers and bronchial infections. During his nine months in Santa Cruz he made his basic breakthrough in television.

Back in Britain, he made his first public demonstration in 1925. He developed a system for televising onto large cinema screens, and covered the 1931 and 1932 Derby live. Although by the mid 1930's mechanical television was being overshadowed by the all-electronic technology developed in the United States, what really interested governments all over the world was not the entertainment or commercial value of television, but its military applications.

Thus, Baird was secretly working on new uses for television which had profound impact on WWII[587].

Baird probably had a lot to do with the chain of radar stations built along Britain's vulnerable coasts in preparation for war as early as 1935, with radar-controlled anti-aircraft guns that appeared around London in 1940. He also contributed to the system which guided high-flying bombers to their targets while flying above cloud and with high-speed wartime signaling techniques which used television for *facsimile transmission of maps* and written material without interception.

In 1943, when the battle for the Atlantic was at its height, Baird was seen in Port of Spain, Trinidad, for several weeks. Trinidad was an assembly point for trans-Atlantic oil convoys, and the battle against the German submarines which preyed on them was being won, largely through improved methods of detection and radar-surveillance. He was now being deployed in defense of

587 Some even claim the 1936 Crystal Palace fire, where Baird's research and production was based, was the work of Nazi Germany, intended to destroy Baird's work.

Trinidad's lumbering convoys and the Western World's struggle against Nazi Germany.

1926–1929 CE **Oscar Klein** (1894–1977, Sweden and USA). Theoretical physicist. His work had broad impact on 20th century physics and his name is associated with several major accomplishments: *Klein-Gordon Equation* (1926), *Kaluza-Klein Theory* (1926), *Jordan-Klein matrices* (1927), *Klein-Nishina scattering* (1929). Contributed also to statistical mechanics, thermodynamics, superconductivity and cosmology.

Klein was born in Mörby, Sweden, the youngest son of Sweden's chief Rabbi, Gottlieb Klein, who arrived there from Germany. He was educated at the Universities of Stockholm (Ph.D., 1921) and Copenhagen. Collaborated from an early age with **Arrhenius**, **Bohr** and **Kramers**. Held professorial positions at the Universities of Ann Arbor, Michigan (1923–1925), Copenhagen (1927) and Stockholm (1930–1962).

Let us summarize briefly the achievements of Klein:

- In his work with **Y. Nishina** on the Compton scattering of photons by free electrons in the framework of quantum mechanics, he derived the differential and total cross-sections. Through this work he was able to convince physicists of the soundness of Dirac's relativistic wave equation.

- His work with **Pascual Jordan** (1902–1980, Germany) on the *second quantization* problem in quantum mechanics demonstrated the close connection between quantum fields and quantum statistics. It was shown that second quantization guarantees that photons obey Bose-Einstein statistics, and that one can quantize the *wave function* of the non-relativistic Schrödinger equation.

- With **Walter Gordon** (1893–1939) introduced a Lorentz-covariant relativistic wave-equation for the electron, known as the *Klein-Gordon equation*

  $$\frac{\partial^2 u}{\partial t^2} = c^2\nabla^2 u - \frac{m_e^2 c^4}{\hbar^2} u$$

  with m_e the electron rest–mass. This marks the beginning of *relativistic quantum mechanics*. Oddly enough, Schrödinger himself privately developed the equation slightly earlier (1926) – even including minimal coupling to EM fields – but he never published his results. The equation turned out to be *fundamental* only for *spinless* bosonic particles.

- In 1938, suggested that a spin-1 particle mediates beta-decay and plays a role in weak interactions in a similar manner to a photon in electromagnetic theory. This idea was resurrected by J. Schwinger only in 1957, and a decade later it was incorporated into the unified ("electroweak") theory of weak–nuclear and electromagnetic forces.

- Introduced major modifications to the 5-dimensional Kaluza unification scheme of Maxwell's electromagnetic theory with Einstein's GTR. Kaluza's theory suffered from two defects: first, classical behavior of the fields was assumed without considering the effects of quantum mechanics. Second, the theory did not describe the nature of the 5th dimension.

  To rectify this, Klein assumed that the extra fifth dimension was curled up into a circle that was of the order of *Planck's length*, 10^{-33} cm. This extra dimension, albeit curled up, was still *Euclidean* in nature. Klein also assumed it to be periodic with a period $\tau = \frac{\hbar c}{e}\sqrt{2\kappa}$, with e the electron's charge (in absolute value) and κ Einstein's gravitational constant in 4-dimensional spacetime, $\frac{8\pi G}{c^4}$. The extra dimension was not observable but was a physical quantity conjugate to the electron's charge. By this Klein attempted to explain the atomicity of electricity as a quantum law.

The combined theory is known as the *Kaluza-Klein* Theory[588]. Over the 80 year period since its inception, physicists have had difficulty correlating the Kaluza-Klein Theory or the now-popular higher dimensional extensions of it, to physical reality. However, the last decades of the 20th century witnessed a revival of the theory and its amalgamation into various unification programs. In particular, those involving *superstrings* and supergravity could e.g. have 6 or 7 (rather than 1) curled-up dimensions. But it now seems doubtful that any given scheme for curling up the "small" spatial dimensions can be shown to be unique, stable, or dynamically feasible.

A Centennial Nobel Symposium was held in September 19–21, 1994 in honor of Oscar Klein.

---

[588] A 5-dimensional unification scheme was apparently discovered independently by two other physicists at about the same time. The first was **Heinrich Mandel** (Germany) and the second was **Vladimir Alexandrovich Fock** (1898–1974, Russia). Fock, a theoretical physicist, was born in St. Petersburg, graduated from its University in 1922, and became a professor there (1932).

Applied Group Theory[589]

In the 19^{th} *century the theory of groups arose primarily as the theory of transformation groups. However, in the course of time it became more and more clear that the most significant of the results obtained depend only on the fact that transformations can be multiplied and that this operation has a number of characteristic properties. On the other hand, objects were found having nothing to do with transformations, but to which the main theorems of the theory of transformation groups could be applied. As a result, the concept of a group was applied not only to systems of transformations, but also to systems of arbitrary elements.*

For the physicist, group theory is an extraordinarily useful tool for formalizing semi-intuitive concepts and for exploiting symmetries. Group theory became a useful tool for the development of crystallography, solid state physics, atomic, nuclear and particle physics and even cosmology.

The extension of group theory to continuous groups (groups with an infinite number of elements, where a general element depends on one or more parameters which vary continuously), has led to applications to special relativity, quantum theory and the particles, fields and high energy physics.

As knowledge of our physical world expanded explosively in the first third of the 20^{th} *century, new mathematical structures were revealed which were already anticipated by mathematicians of the* 19^{th} *century. Chief among them was* ***M.S. Lie****.*

The importance of Lie groups (and their associated algebras) in modern physics *(especially quantum field theory, STR and GTR) stems from the demand for* covariant[590] *physical laws* under space and time translations, ro-

590 Covariant equations have the same *form* in different coordinate systems so that there is *no preferred fiducial reference system* w.r.t. the given group of transformations.

tations in real 3-dimensional space, Lorentz transformations and rotations in various abstract spaces.

The demand for covariance under translation is based on the homogeneity *of space and time. Covariance under rotation is an assertion of the* isotropy *of space. The requirement of Lorentz covariance is based on the acceptance of special relativity. Together, the above three transformations form the* inhomogeneous Lorentz group, *also known as the* Poincaré group.

From the point of view of pure mathematics, *a number of results were obtained for Lie algebras at the turn of the* 20^{th} *century that are similar to the fundamental results on associative algebras, although the proofs and statements are here more complicated. This was mainly due to the efforts of* ***Killing*** *and* **Cartan**, *who classified all simple Lie algebras over the field of real and complex numbers.*

In the early 1930*'s the theory of representations of Lie algebras by matrices was constructed, principally by* **Cartan** *and* **Weyl**, *and proved to be a remarkable tool for the solution of many problems.*

A Lie group that plays an important role in relativity theory, electrodynamics and relativistic quantum mechanics is the Lorentz group, *the "one-dimensional boosts" subgroups of which depend on a single real parameter. It is represented by the one-dimensional* (x, t) *Lorentz transformation (LT)*

$$\begin{bmatrix} x' \\ t' \end{bmatrix} = \gamma \begin{bmatrix} 1 & -v \\ \frac{-v}{c^2} & 1 \end{bmatrix} \begin{bmatrix} x \\ t \end{bmatrix}, \qquad \gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2}.$$

Indeed, the set of all matrices

$$A(v) = \begin{bmatrix} 1 & -v \\ -\frac{v}{c^2} & 1 \end{bmatrix}$$

form a continuous group with $A(v_1)A(v_2) = A(v_3)$ *where* $v_3 = \frac{v_1+v_2}{1+\frac{v_1 v_2}{c^2}}$. *The inverse transformation is obtained by replacing* v *by* $-v$.

Upon the substitution $\gamma = \cosh\theta, \quad \gamma\frac{v}{c} = \sinh\theta, \quad x_4 = ict,$ *the LT can be recast in the form of an orthogonal transformation*

$$\begin{bmatrix} x_1' \\ x_4' \end{bmatrix} = \begin{bmatrix} \cosh\theta & i\sinh\theta \\ -i\sinh\theta & \cosh\theta \end{bmatrix} \begin{bmatrix} x_1 \\ x_4 \end{bmatrix}.$$

A LT for which the determinant of the transformation is equal to $+1$ *is said to be* proper *(choice* $\gamma > 0$*). This condition is equivalent to requiring that*

$t' \to \infty$ as $t \to \infty$ for fixed x_1, which corresponds to the invariance of the direction in which time is measured. Such a LT is said to be orthochronous[591].

Since

$$\begin{bmatrix} \cosh\theta & i\sinh\theta \\ -i\sinh\theta & \cosh\theta \end{bmatrix} \equiv I\cosh\theta - \sigma_2\sinh\theta = e^{-\theta\sigma_2},$$

where $I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$, $\sigma_2 = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}$, *we can say that σ_2 generates representation of this Lorentz transformation.*

Returning to the case of three space dimensions, when the relative velocity $\boldsymbol{v}$ is not parallel to any coordinate axis, it can be shown that the generator is the 4×4 matrix

$$\sigma = \begin{bmatrix} 0 & 0 & 0 & -i\lambda \\ 0 & 0 & 0 & -i\mu \\ 0 & 0 & 0 & -i\nu \\ i\lambda & i\mu & i\nu & 0 \end{bmatrix},$$

where (λ, μ, ν) are the direction cosines of $\boldsymbol{v}$.

The transformation itself is given by the 4×4 matrix

$$L(\boldsymbol{v}) = e^{-\theta\sigma} = I - \sigma\sinh\theta + \sigma^2(\cosh\theta - 1).$$

In this general case, however, the product of two Lorentz transformation matrices $L(\boldsymbol{v}_1)$ and $L(\boldsymbol{v}_2)$ yields a third Lorentz transformation $L(\boldsymbol{v}_3)$ only if the two velocities $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ are parallel. If $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ are not parallel we find that $L(\boldsymbol{v}_3) = RL(\boldsymbol{v}_2)L(\boldsymbol{v}_1)$, where R is a 3×3 space rotation matrix (Wigner's rotation).

The matrix L has the property that $LGL^T = G$, where

$$G = \begin{bmatrix} 1 & & & 0 \\ & 1 & & \\ & & 1 & \\ 0 & & & -1 \end{bmatrix}$$

is the metric matrix of Minkowski space (in its imaginary – 4^{th} component representation).

591 The basic relation $x^2 - c^2t^2 = x'^2 - c^2t'^2$ can accommodate both $\gamma > 0$ and $\gamma < 0$.

Together with the spatial-rotations Lie group SO(3), the set of orthochronous boosts $L(\boldsymbol{v})$ forms a 6 parameter Lie group of linear transformation in $3+1$ dimensions, $SO(3,1)$ the Lorentz group.

Another important Lie group applicable to relativistic spinors is $Sp(2n)$, the symplectic group of all matrices A of dimension $2n \times 2n$ which satisfy the equation $AGA^T = G$, where G is a given skew-symmetric matrix and is usually taken as

$$G = \begin{bmatrix} 0 & 1 & & & & & \\ -1 & 0 & & & & & \\ & & 0 & 1 & & & \\ & & -1 & 0 & & & \\ & & & & \ddots & & \\ & & & & & 0 & 1 \\ & & & & & -1 & 0 \end{bmatrix}.$$

1926–1932 CE **Werner Karl Heisenberg** (1901–1976, Germany). Distinguished theoretical physicist. One of the major figures in the transition from classical to quantum physics. Together with **M. Born** and **P. Jordan** developed *Quantum Matrix Mechanics* based on non-commutative matrix algebras[592], the germ of which had existed in the quaternions of **Hamilton**, 83 years before.

In 1927 he published his *Uncertainty principle*, for which he is best known; he showed that quantum mechanics embodies a very general principle through which the least possible errors in measurement of position are necessarily correlated with the least possible errors in measurement of momentum. A similar

---

592 When Heisenberg discovered *matrix mechanics* (1925), neither Heisenberg nor Born knew what to make of the appearance of matrices in the concept of the atom. David Hilbert told them to go look for a differential equation with the same eigenvalues. They did not follow Hilbert's advice and thereby may have missed discovering the Schrödinger wave equation.

'*uncertainty*' relation exists between energy and time, angle and angular momentum, different components of spin or orbital angular momentum, phase and intensity of a light wave, electric and magnetic fields, as well as other pairs of so-called 'canonically conjugate observables'.

Heisenberg studied theoretical physics at Münich under **A. Sommerfeld**, receiving his doctorate degree in 1923. In the same year he became assistant to **Max Born** at Göttingen. He then worked under **Niels Bohr** at Copenhagen (1924–1927). During 1927–1941 he was professor of theoretical physics at Leipzig. From 1942 on he was associated with the Max Planck Institute for physics at Göttingen. He was awarded the Nobel prize for physics in 1932.

Werner Heisenberg was among the few renowned scientists who stayed in Nazi Germany. In his youth, he was associated with organizations whose philosophy was close to that of the Nationalist socialist party (e.g. *The White Knights*). The organizations were elitist, opposed to the Weimar Republic, willing to submit unquestioningly to a leader, fanatically devoted to a romanticized German culture, and strongly convinced of German superiority. He decided early on that he would not leave Germany. When Jewish professors were dismissed from the universities, he made vigorous efforts to replace them by Dutch professors (non-Jewish, of course); they all turned him down.

Clearly, to Heisenberg at that juncture, maintaining a strong physics establishment took precedence over human rights, justice or dignity. From the beginning, Heisenberg was sympathetic to the Nazi's national aims. He later participated in the German war effort and made propaganda trips to occupied countries, thus becoming a willing, active participant in Germany's politics and war aims. Even after the war Heisenberg never gave up his strong belief in the superiority of German culture and science. There was perennial conceit, continued arrogance and more than a touch of condescension in his attitude toward U.S. science, as well as a strong tendency to trivialize U.S. scientific accomplishments during the war.

He was accused by physicists of collaboration with the Nazis, and after the war was virtually ostracized by the international scientific community.

The Uncertainty Principle and the Copenhagen formulation of Quantum Mechanics (1925–1930)

__Schrödinger__ (1925–1926) transformed __de Broglie's__ (1924) rather vague ideas about electron waves into a precise and coherent mathematical formalism that applied to electrons or other particles. At the heart of Schrödinger's approach was a dynamical equation that dictated the way any given particle or system of particles would evolve with time. Schrödinger's equation is mathematically of a kind similar to those that had been used since the 19th century to study waves of sound, light and radio. Physicists in the 1920's were immediately able to set about calculating the energies and other properties of all sorts of atoms and molecules. Despite this success, nobody at first knew what physical quantity was oscillating in an electron wave, especially since the wave amplitude is complex. __Born__ (1926) suggested that the wave function at any point tells us (through its squared modulus) the probability density that the electron is near that point.

Neither Schrödinger nor de Broglie were comfortable with this interpretation of electron waves. However, __Heisenberg__ (1927) adopted the Born interpretation to arrive at his uncertainty principle, claiming that electrons have neither a definite position nor a definite momentum.

Physicists continued to wrangle over the interpretation of quantum mechanics for years after they had become used to solving the Schrödinger equation; they still do. While __Einstein__ rejected quantum mechanics altogether, most physicists were simply trying to understand it.

Much of this debate went on at the University Institute for Theoretical Physics in Copenhagen, under the guidance of __Niels Bohr__. By 1930 the discussion at Bohr's Institute led to an orthodox 'Copenhagen' formulation of quantum mechanics. The essence of this interpretation is a sharp separation between the system itself and the apparatus used to measure its configuration:

During the time intervals between measurements the wave function of the quantum system evolves in a continuous and deterministic way, dictated by its Schrödinger equation. While this is going on, the system cannot be said to be in any definite configuration of classical phase space. If we measure the configuration of the system (e.g. by measuring all the particles' position or all their momenta, or one's position and another's momentum, or a combination of momentum and position for each particle), the system jumps into a state that is definitely in one configuration or another of the measured variables, *with joint probability density given by the square modulus of the one– or many– particle wave function*[593] *just before the measurement.*

While human beings had no special status in Newtonian physics, in the Copenhagen interpretation of quantum mechanics humans (or at least, macroscopic measuring devices) play an essential role in giving meaning to the wave function by the act of measurement. Where the Newtonian physicist spoke of precise prediction, the quantum mechanician now offers mainly calculation of probabilities.[594]

Although it seems weird at first, quantum mechanics provides a precise *framework for calculating energies, spectra, bulk properties of matter, transition rates and probabilities.*

An idealized plane electromagnetic wave of total energy E transmits a linear momentum $p = \frac{E}{c}$. Since for a single photon (of frequency ν and wavelength λ) $E = h\nu$, the momentum of a single photon is $p = \frac{h\nu}{c} = \frac{h}{\lambda}$, i.e. $\lambda = \frac{h}{p}$. This particle aspect of radiation – first understood by Einstein – is borne out by many experiments, such as the photoelectric and Compton effects.

The complementary wave *aspects of material particles, predicted by de Broglie and Schrödinger, were confirmed via the experiments of* **Davisson** *and* **Germer** *(1927), who showed that a beam of electrons reflected from the surface of a nickel crystal form diffraction patterns, exactly analogous to the Bragg diffraction of X-ray electromagnetic radiation from the same crystal. This is successfully explained by assigning a* de Broglie wavelength $\lambda = \frac{h}{mv}$ *to an electron of mass m and velocity v.*

Thus, for both light waves/photons and electron particles/waves, the dualism of wave and particle is governed by the simple relation $p = \frac{h}{\lambda}$. It has a fundamental consequence regarding the unambiguous and complete description of a subatomic system's behavior in space and *time:*

Consider, for example, the free electron in one dimension: the corresponding time-dependent Schrödinger equation is

$$\frac{\partial^2\psi}{\partial x^2} = \frac{4\pi m}{hi}\frac{\partial\psi}{\partial t}$$

[593] Or some linear transform of it. In case it is the particle momenta that are being measured, it is the $3n$ dimensional Fourier transform, with n the number of particles.

[594] Although many predictions — such as atomic spectra, laser or maser frequencies and some low-temperature many-body observables — are *more* precise in quantum mechanics than is possible in classical physics.

and its general solution is

$$\psi(x,t) = \int_{-\infty}^{\infty} g(p) \exp\left[\frac{2\pi i}{h}(px - Et)\right] dp$$

where

$$E = E(p) = \frac{p^2}{2m}$$

is the classical Newtonian relation of momentum to kinetic energy.

We assume that $g(p)$ is only appreciably different from zero in the neighborhood of a given momentum p_0 and has the form of a Gaussian wave-packet,

$$g(p) = A \exp\left[-\frac{(p-p_0)^2}{4s^2}\right].$$

Clearly the packet group velocity is $\left(\frac{\partial E}{\partial p}\right)_0 = v_0 = \frac{p_0}{m}$. *Then, the stationary-phase approximation to the integral yields ($\hbar = \frac{h}{2\pi}$ is the reduced Planck's constant):*

$$\psi(x,t) = 2sA\left[1 + \frac{2its^2}{m\hbar}\right]^{-1/2} \exp\left\{\frac{i}{\hbar}(p_0x - E_0t)\right\} \cdot \exp\left\{-\frac{s^2}{\hbar^2}\frac{(x-v_0t)^2}{1+\frac{2its^2}{m\hbar}}\right\}.$$

This means that the coordinate probability distribution of the electron is

$$|\psi(x,t)|^2 = 4s^2|A|^2\left[1 + \frac{4t^2s^4}{m^2\hbar^2}\right]^{-1/2} \exp\left\{-\frac{2s^2}{\hbar^2}\frac{(x-v_0t)^2}{1+\frac{4t^2s^4}{m^2\hbar^2}}\right\}$$

while its momentum probability distribution is

$$|g(p)|^2 = |A|^2 \exp\left\{-\frac{(p-p_0)^2}{2s^2}\right\}.$$

Both distributions are represented by Gaussian functions: the root mean square deviations from the most probable values (x_0 and p_0 respectively) are given by the respective widths $\Delta p = s$, $\quad \Delta x = \frac{\hbar}{2s}\left[1 + \frac{4t^2s^4}{m^2\hbar^2}\right]^{1/2}$ *at time t.*

At $t = 0$, *these indeterminacies are reciprocal, such that*

$$\Delta x \cdot \Delta p = \frac{1}{2}\hbar.$$

As t increases, Δp stays unchanged, but Δx increases towards the asymptote $\Delta x \approx \frac{st}{m} = \frac{(\Delta p)t}{m}$, which is merely the classical *position uncertainty due to the initial spread in velocities.*

It can be shown that Gaussian wave packets are actually optimal*, as far as simultaneous measurements of x and p is concerned; thus in general, $(\Delta x)(\Delta p) \geq \frac{1}{2}\hbar$, which is the celebrated* Heisenberg uncertainty relation *(Mathematically, it follows from the* Cauchy–Schwartz inequality*).*

The simultaneous measurement of the position and momentum of an electron necessarily involve minimal uncertainties which are related in accordance with this inequality.

If one attempts to localize a particle of mass m to within a Δx of order or less than its Compton wavelength, $\Delta x \lesssim \hbar/(mc)$, one enters the realm of field quantization*, or in other words,* quantum field theory *— the union of special relativity and quantum mechanics. In that regime ($\Delta x \lesssim 10^{-11}$ cm for electrons), the very number of particles becomes uncertain, for the zero-point energy associated with the act of measurement — i.e. the kinetic energy due to the "fuzziness" in momentum created by measuring x to an accuracy of Δx — culls out of the vacuum* virtual *particles rendering them* real *(actual).*[595]

Field quantization introduces its own set of uncertainty relations; these are simple functional extensions of Heisenberg's original, 'first-quantized' version. Thus, in Quantum Electrodynamics*, the electric and magnetic fields measured in the same small volume element, obey such an uncertainty relation; so do the* intensity *and* phase *of a light wave (the latter fact has found applications in the technology of* quantum optics*).*

Quantum Electrodynamics itself was originated, along with second quantization (known today, more accurately, as "field quantization") by ***Heisenberg*** *and* ***W. Pauli****.*

Descending to even smaller values of Δx (implying more accurate position measurements), it is known today — from considerations involving quantum gravity *— that problems with the very concept of a smooth spacetime continuum, dictate a lower bound to Δx, of order $\ell_P = \sqrt{\frac{\hbar G}{c^3}}$. (Here $\hbar$ is the reduced Planck constant, c the speed of light in vacuo, and G the constant of universal gravitation.) ℓ_P is known as the* Planck length *and it is an extremely small length scale — approximately 10^{-33} cm; twenty orders of magnitude smaller than typical nuclear sizes.*

Qualitatively, the implied inequality is of fundamental importance since it states that measuring distances smaller than the Planck length is meaningless*,*

[595] This is possible since for $\Delta x \lesssim \frac{\hbar}{mc}$, the zero-point energy is of order $\gtrsim mc^2$.

at least within the classical (or even Minkowskian or General-Relativistic) description of spacetime. This circumstance is somewhat reminiscent of the situation in 'p-adic' number systems — in which the Archimedean axiom (according to which any given segment on a straight line can be refined by dividing it into smaller segments) is abandoned.

This has suggested to some physicists that spatial geometry on a small enough scale is not only non-euclidean *(as follows from GTR) and* quantized *(as shown from what little we know of quantum gravity), but is furthermore based on* non-Archimedean arithmetic. *However, these latter speculations have thus far not proven fruitful.*

It is inaccurate to regard the uncertainty relations as a restriction which nature places on our knowledge of the microworld[596]. *The meaning of the relation* $(\Delta x)(\Delta p) \geq \frac{1}{2}\hbar$ *(and the other similar relations in first–quantization and for quantized fields) is rather that instantaneous, simultaneous and sharply defined numerical pairs of values of position and momentum (or angle and angular momentum, electric and magnetic field, etc.) are simply not objective properties of micro-systems — and that this is just the way things are. Micro-objects are neither particles nor classical waves and it is impossible to fully describe them in terms of "common sense" classical notions. The wave-particle duality of micro-objects should be interpreted as their potential ability to behave differently under different conditions, or even in two classically-contradictory ways at the same time. The following consequences of the uncertainty principle will illustrate this:*

---

[596] Prior to 1925, physics recognized only one type of fundamental uncertainty: statistical mechanics (thermal) uncertainty. It stems from the physical fact that there are of order 10^{23} particles in one mole of matter, subject to statistical laws summarized by the *second law of t hermodynamics* and its non-equilibrium extensions. While Maxwell posited that super-fast, microscopic and sentient "Demon" might micro–manage molecules and violate the Second Law, **Szilard** and **Brillouin** showed that the Demon's requisite information processing must generate heat – thereby restoring the "thermal uncertainty". While we do not yet possess a theory of quantum gravity, its severe challenges have led to various bold approaches to the problem of spacetime description at or below the Planck (ℓ_p) length scale. One approach posits that *twistors* (spinor variables underlying local light cones) replace *spacetime* as the fundamental variables of quantum gravity.

The *Heisenberg uncertainty relations* express the fact that while we inhabit a deterministic infinite-dimensional Hilbert-space, our macroscopic sense perception force a description of nature in terms of a 4-dimensional space-time, and the former fact severely constrains one's ability to so describe a *microscopic* system.

- *Why does an atom not collapse? This question remained unanswered in Bohr's model; why does an electron, when revolving about the nucleus in the lowest Bohr orbit, not radiate EM wave-energy (which would lead to its eventual fall into the nucleus)?*

An electron in its ground state (lowest–energy quantum orbital) is moving in a localized region of about 10^{-8} *cm in size. If it falls into the nucleus, it will be localized in a much smaller region, of about* 10^{-13} *cm in size. But then, on the strength of the uncertainty principle, the random components added to its velocity by this very precise "measurement" of its position by the nucleus electric field, increases by a factor of order 100,000. The electrostatic attractive force of the atomic nucleus would not be able to hold such a fast-moving electron within the nucleus. The uncertainty principle thus does not allow the electron to fall. Had the velocity uncertainty been a mere statistical matter (i.e., were the electron's velocity is well defined, albeit unknown to us), then occasionally,* some *atom in its ground state would radiate. Yet in quantum mechanics this* never *happens (another example of an instance in which quantum reality actually renders physics* less *uncertain!).*

- *Do electron orbits exist? From classical physics, an electron in an atom has a speed of the order of* 10^8 *cm/sec. Since the dimensions of the atom are* $\sim 10^{-8}$ *cm, the uncertainty relation yields a* velocity uncertainty *of* $\Delta v \sim \frac{\hbar}{m(\Delta x)} \simeq \frac{10^{-27}}{9\times10^{-28}\times10^{-8}} \simeq 10^8$ *cm/sec, that is to say, the error in determining the velocity is comparable with the velocity itself!*

Thus, the notion of electron orbits turns out to be invalid (except for very high quantum numbers n*), and we see again that, to describe micro-objects, new concepts must be introduced. (Atomic physicists and physical chemists speak instead of smeared-out* orbitals.*) Of these, the concept of probability is, perhaps, the most important in quantum mechanics; we may not speak of orbits, it is only meaningful to speak of the* probability density *of finding the electron at a given velocity or given distance from the nucleus. Yet, as we noted above, the stochasticity of quantum mechanics is different in character from classical (or thermal) stochasticity.*

In some sense, the use of probabilities to describe quantum mechanics is due to our own predilection, as macroscopic, almost classical atomic aggregates, for a phase-space description of subatomic motion! The fact that the probabilistic interpretation of quantum mechanics is not required as an independent postulate of quantum mechanics, was first exposed clearly by **Hugh Everett III** *(1930–1982), in his so-called 'Many-World' interpretation of quantum mechanics.*

Systems containing large numbers of particles, whether classical or quantum, require for their description an entirely new approach, that of statistical physics. *In classical physics one solves Newton's equations and, provided the* *initial conditions are specified, the future motion of all particles is fully determined – as so vividly expressed in Laplace's famous dictum. The laws of classical physics are therefore deterministic, and elements of randomness (statistical description) are only relevant when we study systems of large number of particles (e.g. gases) — to compensate for our imperfect knowledge of initial conditions.*

In quantum mechanics of a single or a few microparticles, the situation is quite different. The statistical, or probabilistic, approach is applied even to the motion of one single particle; *whether or not we shall find the electron at a given region near the nucleus — this is a matter of chance. However, unlike statistical mechanics, few-particle quantum mechanics is fully deterministic — as long as we describe its evolution in terms of wavefunctions rather than classical phase space! In* quantum mechanics *of a many-body system, the two kinds of uncertainty are both operative. To illustrate this, we consider the following example:*

Conversion of a disordered state into an ordered state, such as putting a mixed deck of cards back into a properly ordered sequence, may be accomplished by any intelligent person (or computer). Similarly, the task of converting the probable Maxwellian velocity distribution into an improbable distribution might be accomplished if there existed a supremely deft intelligent agent, traditionally known as "Maxwell's demon", keeping watch at a small sliding panel between two halves of a box (each half enclosing molecule samples at nearly equal temperatures), which he opens briefly whenever a fast molecule approaches from the left or a slow molecule from the right. By this procedure the demon should be able to separate slow and fast molecules in a time very much shorter than the time needed for this separation to occur by a statistical fluctuation without any panel.

Clearly, the demon cannot operate successfully unless he can distinguish fast molecules from slow ones. Now, knowledge whether a molecule is fast or slow requires about one bit of information. This has led some authors to consider "information" as a source of "negative entropy", which Maxwell's demon transfers to the gas whenever he uses one bit of information during one operation of the panel. In this fashion the total entropy of the system need not decrease during the demon's operations, provided the demon and his store of negative entropy are counted as part of the system.

This proposal becomes quantitatively feasible if one assigns to one bit of information a negative entropy of amount $S_0 = -k \log 2$ *(k = Boltzmann's constant), with the understanding that entropy is additive — thus making two bits of information equivalent to a negative entropy of amount*

$2S_0 = -k \log 2 - k \log 2 = -k \log 2^2$, *and generally* n *bits of information represent a store of negative entropy of amount* $nS_0 = -k \log 2^n$. *This interconvertibility of information and entropy is further justified on the grounds that the demon's velocity measurement, and subsequent action (opening, or closing the panel), involve* data processing, *which in turn converts some useful energy source into heat.*

The above discussion implies that Maxwell's demon will always be capable of acquiring the information necessary for performance of his task. However, quantum mechanics places a further fundamental limitation on any such demon. If the temperature of a gas consisting of N *molecules of mass* m *in a volume* V *is held below a critical value*

$$T_0 = \frac{\hbar^2}{mk} \left(\frac{N}{V} \right)^{2/3} \quad (\hbar = 1.05 \times 10^{-27} \; erg \; sec)$$

the demon is incapable of distinguishing fast and slow molecules with sufficient accuracy, on account of the uncertainty relation $\Delta p \Delta x = m \Delta v \Delta x \gtrsim \hbar$ — *which states that localization of a molecule to within a length* Δx *engenders an* inevitable *uncertainty in the knowledge of its velocity by the amount* $\Delta v \gtrsim \hbar / m \Delta x$.

To see this we note that at temperature T, *the difference in speed between the slowest and the fastest molecules is of order* $(kT/m)^{1/2}$, *and the uncertainty in the demon's knowledge of the velocity, must clearly be less than that for his project to succeed:* $(kT/m)^{1/2} \gtrsim \Delta v$. *However, if the average speed of the molecules is* v *and the area of the panel* d^2, *about* $vd^2 N/V$ *molecules will hit the panel per second, giving the demon not more time than* $\Delta t \approx V/(vd^2 N)$ *between successive openings and closings of the panel.*

This amounts to a localization of the passing molecule of amount $\Delta x \approx v \Delta t \approx V/(d^2 N)$, *thus engendering an uncertainty in the knowledge of its velocity* $\Delta v \gtrsim \frac{\hbar d^2 N}{mV}$.

The dimension d *of the opening will also require a (transverse) localization of the particle during passage; in order that the corresponding quantum uncertainty in the particle's velocity is not larger than the overall* Δv, *one must give this opening at least the size* $d \gtrsim \frac{\hbar}{m \Delta v}$; *so that one has the combined inequality* $\Delta v \gtrsim \frac{\hbar^3 N}{m^3 V (\Delta v)^2}$, *which when solved for* δv *yields* $\Delta v \gtrsim \frac{\hbar}{m} \left(\frac{N}{V} \right)^{1/3}$. *By substitution into* $(kT/m)^{1/2} \gtrsim \Delta v$, *one thus finds that successful operation of the demon requires a temperature*

$$T \gtrsim \frac{\hbar^2}{mk} \left(\frac{N}{V} \right)^{2/3} \equiv T_0.$$

The value of T_0 for the case of helium molecules $(m = 6.5 \times 10^{-24}$ g), compressed to a density near that of liquid water (about 1 g/cm^3) is $T_0 \approx 3.5\,^\circ K$.

Heisenberg based his new mechanics on the postulate that the atomic theory rests solely on such geometrical or physical entities as are measurable; e.g. the locus of the electron's entire orbit must be excluded, but frequencies and amplitudes of spectral lines that are emitted by the atom are legitimate observables, as are (for instance) any position or momentum Cartesian components (but not both along non-perpendicular directions) of the electron at a given time.

He thus developed a mathematical scheme, based on matrices, that was suitable for the description of the new sub-atomic reality[597]*. This new mathematical framework enabled him to explain various observation that defied Bohr's semiclassical approach.*

Schrödinger's and Heisenberg's work on quantum theory had a profound impact on the development of physics and many other branches of fundamental and applied science – in particular molecular, atomic, nuclear and particle physics; material science; chemistry; biology; optics; electrical engineering, astrophysics, and cosmology.

In 1932 Heisenberg introduced the concept of isospin[598] *and expounded its mathematical theory. [*isospin = *isotopic spin* or *isobaric spin. The former is a*

---

[597] As an illustration of how matrices entered his scheme, consider a hydrogen atom emitting a photon in a transition between the Bohr orbits m, n. Classically, the strength of the radiation is proportional to $\left[\ddot{\boldsymbol{X}}(t)\right]^2$, where $\boldsymbol{X}(t)$ is the trajectory of the emitting electron (*Larmor's law*). Heisenberg treated $\boldsymbol{X}(t)$ as an operator (an infinite-rank matrix) and suggested that the strength of the spectral line is related to the square of the *modulus* of the *complex* amplitude $[\boldsymbol{x}(t)]_{mn}$, and that the time dependence of this complex matrix element is proportional to $e^{i\omega_{mn}t}$, where $\omega_{mn} = \frac{1}{\hbar}(E_m - E_n)$. This explains nicely, among other things, the hitherto-unexplainable (empirical) '*Ritz Combination Law*' of atomic spectra.

[598] Since the strong nuclear forces are charge-independent in the sense that the proton-proton and neutron-neutron strong forces are the same (and qualitatively similar to the neutron-proton strong forces), and since these two constituents of the nucleus may be transformed into each other and are close in mass, it is physically meaningful to consider them to be 2 different "*states*" of one heavy nuclear particle — the *nucleon*. In contradistinction to our common concept of different states of one system, these 2 nucleonic states *differ w.r.t. their charge*. It is convenient for the theory of the nucleus to distinguish the 2 states *formally* by the components $[T_z = \frac{1}{2}$ (proton) and $T_z = -\frac{1}{2}$ (neutron)] of a new quantum number called *isospin*. The (weak–nuclear–force mediated)

misnomer since the proton and neutron are not really isotopes, as they differ in charge.] The isospin symmetry, although approximate, predicts various successful relations between nuclear energy levels and probabilities of different nuclear reactions and transitions.

In the standard model *of particle physics, the proton, neutron, pions and other* hadrons *are understood to be made of* quarks; *isospin invariance (symmetry) is understood to be an approximate* accidental *symmetry, but other "internal" (i.e. non-spacetime rotations in internal space)* are *fundamental symmetries in this theory. These are the* non-abelian gauge transformations *under which a quark's "color" or a lepton's* charge *are changed; and under which (for example) an up-quark (charge $+\frac{2}{3}e$) can be converted to a quantum – coherent mixture of down- and strange quark states (both of charge $-\frac{1}{3}e$), with color unchanged.*

β-decay, where a neutron is transformed into a proton, then corresponds to the quantum transition $\Delta T_z = 1$ (isospin flip). Since nucleons are fermions, the nuclear wave function must be totally antisymmetric w.r.t. the combined spatial, spin and isospin degrees of freedom.

The *mathematical* transformation of a proton into a neutron, or vice versa, is then a special case of rotation in abstract isospin space. The strong nuclear interactions are covariant under such iso-rotations, and the corresponding "angular momentum" $\boldsymbol{T}$ (of which T_z is but one component) is thus conserved by these interactions. This limited charge-independence does *not* mean that the *nn* and *pp* forces are exactly the same. The (small) electromagnetic and weak corrections to these forces violate isospin conservation, and are responsible for the observed charge-dependence of nuclear masses, lifetimes and scattering cross sections (electromagnetic effects are by far the dominant isospin-violating nuclear effect).

Causality and Determinism in Quantum Theory[599] — *or, Where is the particle when no one is looking? (1925–1965)*

Science, the systematic effort of man to explore natural phenomena, started with the Greek school of ***Thales*** *and Anaximander in the 6th century BCE. It reached its pinnacle during the period 400–200 BCE, the period of Democritos, Socrates, Plato,* ***Aristotle*** *and* ***Chrysippos****, referred to as the classical period of Greek philosophy. It was followed by the Hellenistic period, which lasted up to the 2nd century CE. Then an era of decline set in, although the investigative efforts continued to some extent until the 6th century CE.*

Except in a very few fields such as astronomy and geometry, Greek philosophy is based on speculations, hypotheses and theories. However, the extraordinary intuition and perspicacity of Greek philosophers produced concepts that are in some respects amazingly close to the ideas of modern science, particularly physics.

Thus, the concept of the atom was first proposed by ***Democritos*** *and* ***Leucippos****.* ***Anaximander*** *was first to envision the possibility of the transformation of one primary substance into another one.* ***Heraclitos****' foremost fundamental principle — that everything is in constant flux (the famous* $\pi\alpha\nu\tau\alpha\ \rho\epsilon\iota$*) — is the forerunner of the notion that* energy *transformations are at the base of all changes in the world. He assumed fire to be the basic element, but if one replaces 'fire' with 'energy', the doctrine of Heraclitos is in some ways quite close to the story told by modern physics.*

Plato*, contrary to Democritos, held that the smallest units of matter are geometrical forms (platonic regular solids) transformable into each other. In the last analysis, the elementary particles are for Plato not substance but* mathematical forms*. In modern physics, too, elementary particles are considered as forms — moving configurations of energy, irreducible representations*

[599] For further reading, see:

of symmetry groups, states in Hilbert space, et cetera. In Greek philosophy, however, these forms were considered to be static, whereas modern physics stresses their dynamic nature.

Since the beginning of modern science in the 16th and 17th centuries, there has been a continuous parallel development of new philosophical ideas and systems stimulated by concepts emerging from the new scientific knowledge[600]*.*

Among the outstanding philosophers of the early period were ***Francis Bacon*** *(1561–1626) in England and* ***Rene Descartes*** *(1596–1659) in France. Bacon, primarily a philosopher, understood the importance of mathematics, and stressed empiricism and the skeptical observation of Nature. He wrote the first classical works in which serious attempts were made to build bridges between the new information resulting from scientific observations and knowledge on the one hand; and philosophical thinking — hitherto still strongly influenced by Aristotelian philosophy — on the other.*

Since the days of Descartes and Newton scientists have regarded the physical universe as a system in which all events proceed in an unbroken chain of cause and effect, according to a universal principle of causality. In a universe in which the principle of strict determinism is meaningful and holds, the laws of nature are at least partially deterministic[601]*; experimental verification of determinism is furnished by the predictability of events. The principle of strict determinism asserts that, if all pertinent details concerning the present state of an isolated system are known, it is possible by means of suitable laws of nature (governing causal agencies) to predict that system's state at any later (or, indeed, earlier) time. The conclusion is drawn that everything that ever did or will happen in such a system, is completely determined (at least in principle) by its present state.*

---

600 These movements became particularly strong in the 20th century; quantum mechanics and the theory of relativity had a profound impact on philosophical thinking. Indeed, **Einstein**, **Bohr**, **Born**, **Heisenberg** and **Pauli** analyzed in their writings and lectures the philosophical implications of the newly gained knowledge and experience.

601 *Determinism*: the ability to determine the state of a system at a given time on the basis of information about the state at an earlier time.

Newtonian Causality: causes precede effects (and are best described via mechanical contact forces or influence).

Classical Causality: If a system is perturbed at time t_0, as reckoned in a locally–inertial frame, the perturbation at infinitesimal distance R away (as measured in that frame) cannot arrive before time $(t_0 + \frac{R}{c})$, where c is the velocity of light in vacuo.

Within the confines of classical physics, Newtonian (or, later, relativistic local) causality and determinism were thus largely synonymous. One could, perhaps, imagine a universe in which successful quantitative prediction schemes — such as Babylonian astronomy — exist without any underlying mechanism ('laws of nature'). In such a putative universe, causation *would reduce to its narrow empiricist definition as rendered by* ***David Hume****: A* causes *B whenever it is found to always precede it, all other circumstances being allowed to vary.*

One could also imagine a causal universe in which some casual agencies are inherently difficult to measure or predict, thus rendering determinism less than perfect (as, indeed, happens in thermal physics).

However, the universe in which Newton and his successors thought they found themselves, was one in which relatively simple mechanisms could, and did, account for far-flung chains of causation. The concepts of 'causality' and 'determinism' were thus conflated in classical physics — a situation which was to change with the rise of quantum mechanics, as we shall see.

Determinism was automatically built into Newtonian mechanics in the 17th century. Thus, treating the solar system as an isolated system, the planetary positions and velocities at one moment suffice to determine uniquely, via Newton's laws, their positions and velocities at all subsequent times. Moreover, since these laws contain no directionality of time, the present state suffices to uniquely fix all past *states as well: one may predict eclipses into the far* future*, and also retrodict their occurrences in the past.*

In a causal, deterministic world, the past and future are contained in the present in the sense that the data needed to construct the past and future states of the world are implicit in its present state. The entire cosmos is then, in effect, a gigantic machine or clockwork, slavishly following a pathway of change already laid down from the beginning of time; God is thereafter reduced to a mere archivist turning the pages of a cosmic history book already written. In the words of the astronomer-poet Omar Khayyam in his Rubaiyat *(ca 1100 CE):*

'With Earth's first clay they did the last man knead,
And there of the last harvest sow'd the seed:
And the first morning of creation wrote
What the last Dawn of reckoning shall read.'

Immanuel Kant *(1724–1804) concluded (1781), like other philosophers before him, that only part of our knowledge is based upon experience. What we would now call the 'raw data' of experience is acquired by our senses, but it is our mind (reason, thought, intelligence) that brings law, order and* *regularity into the phenomena observed. We understand these phenomena because we approach them with certain notions and concepts which Kant characterized as a priori. Among such necessary notions are space, time and the law of causality.*

Without these three a priori notions we would be unable to perceive a well-ordered universe. These a priori concepts are, of course, based on Newtonian mechanics, which strongly influenced not only Kant's philosophical thinking but that of 19th century thinkers as well. Their limited applicability only became apparent in the 20th century, through the results of modern physics. Moreover, the geometry that formed an essential basis of Newton's physics was that of Euclid.

*Not till the 19th century were new kinds of geometry developed, particularly through the pioneering work of **Gauss** (1777–1855); this greatly influenced later thinking in physics and astronomy. Kant obviously could not have foreseen the startling developments of modern physics — neither the theories of relativity (which forced changes in the 'a priori' concepts of space and time) nor quantum mechanics, which profoundly transformed the law of causality for microscopic systems and divorced it from any direct connection with the determination of results of future measurements.*

Indeed, prediction is quite impossible for the trajectory of a photon or electron in Young's or similar apparata; its motion after passing the two slits is not determined by its condition immediately before it reached the plane of the slits. Two photons, identical in every observable way, could pass from source to plane in the same way and yet reach quite different destinations thereafter. And yet, despite this quantum indeterminacy, any single photon passing through the apparatus obeys the principle of causality! The seeming contradiction is resolved as follows. The only attribute of the photon that evolves causally is its wave function (a 'ray' in an abstract, infinite dimensional vector space known as Hilbert space).

This (complex) wave function is created, along with the photon it describes, at the light source; thereafter it evolves smoothly in time, according to a Schrödinger equation, subject to the boundary conditions imposed by the two slits. However, this mathematical wave is quite different in nature from classical waves (such as acoustic or elastic waves in bulk matter, many-photon electromagnetic waves in vacuo, etc.). The difference is that the amplitude of the quantum wave does not represent any observable physical attribute of the photon.

Its only relation to such observables is indirect and stochastic in nature — when the photon is observed (e.g. by allowing it to impinge upon a photographic screen at some distance downstream of the slits plane), the distribution of its measured attribute (whether position, momentum etc.) can be *predicted from the pre-measurement quantum wave amplitude. Thus causality is relegated to operate in an abstract mathematical space; and should we nonetheless insist (as we must!) on describing a quantum system in terms of observable entities (such as positions, velocities, electric fields, polarizations, etc.) — the price that must be paid is* determinism: *future (or past) states of the system* cannot *be fully predicted, irrespective of how much we know about its present state.*

These remarkable observations hold quite generally for optical, electrical, mechanical or any other phenomena: it is impossible to predict the behavior of individual photons, electrons etc., no matter how carefully conditions are controlled. Yet the quantum wave pattern does *predict, to any desired precision, the statistical distribution of large numbers of the quanta per given arrangements of the measurement apparata. This is true whether the particles are passed through the apparatus one by one or in a volley (for the case of light, if the volley is sufficiently dense, quantum theory predicts that the light is approximately describable as a classical electromagnetic wave — the (real) amplitudes of which are directly observable as electric or magnetic field components.)*

Starting in the 19th century — long before the photon aspect of light was recognized — statistical methods were used to describe the observable properties of gases *in terms of the (Newtonian) mechanical behavior of their component* molecules. *Yet in spite of the superficial similarity, there is a fundamental difference between the two situations. In the case of gases, statistical methods are employed because the large number of molecules involved makes it impractical to ever carry out a detailed analysis. But for the* photons, *electrons etc., in our above discussion – and for molecules too, since they obey quantum mechanics as well – statistical considerations enter in a more fundamental manner. It is entirely possible to preserve all wave-optical effects in an optical experiment while making the light intensity so low that there is only one* photon *present at a time in the entire apparatus. Nonetheless, it is impossible (as we saw above) to determine the behavior of this single photon — for the laws to which its quantum evolution is ascribed, yield no more than statistical prediction concerning the position, energy or polarization of the photon at the downstream screen*[602].

[602] It is worth noting, though, that for phases of bulk matter cold and/or dense enough — such as many liquids and solids, as well as the recently achieved *Bose-Einstein Condensate* phase of monoatomic gases at ultra-low temperatures — the quantum 'fuzziness' of individual atoms competes with (or even take precedence over) the Newtonian (thermal) uncertainties. And conversely, photon gases in which individual photons interact frequently with matter or with each other — as happens inside the sun or an incandescent light bulb —

Modern physics has taught us that this peculiar quantum description holds for matter *particles as well as for light. Thus electrons, neutrons, whole atoms and other particles can be diffracted (one by one or en masse) as waves through crystal lattices; again it is found that causal evolution applies to an abstract 'quantum amplitude' wave, and that the information encoded in this wave concerning future or past experiments is indirect, incomplete and statistical in nature.*

As another example, consider a radioactive radium nucleus, which can (and eventually must) emit an α*-particle. The precise emission time of the* α*-particle cannot be predicted; only the average time of emission is determinable. In observing the emission one does not — indeed cannot — identify any preceding event that determined the emission to occur at the precise instant it did.*

Nevertheless, the causal mechanism for the α*-decay* is *known — but it operates at the rarefied heights of abstract Hilbert space; this precise knowledge, when converted to actual observation of the actual decay, becomes diluted into a mere statistical distribution.*

Thus, practically speaking, the forces in the radium nucleus responsible for the α*-decay cannot be determined accurately, but only as a probability distribution of possible outcomes (decay time and* α*-particle momentum).*

According to ***Max Born****'s statistical interpretation of the complex de Broglie-Schrödinger wave, the squared modulus of the wave gives the probability density for finding the particle at that position. All that quantum theory could do, he realized, was predict the wave-shape, and hence the probability distribution of various attributes of a quantum particle or system. In most cases it could not predict with certainty the outcome of any single measurement of those properties, as did the old classical physics. Thus, the description of the motion of a quantum particle is inherently* statistical*, and the waves are not material, as de Broglie and Schrödinger wrongly supposed. Furthermore, not all observable attributes are even simultaneously measurable; there is no sense in which an electron's position and velocity vectors, for example, both have definite values at the same instant of time —* even in principle.

How are we supposed to think about the atomic world of the quanta? Atoms, photons, and electrons really exist as particles, but their attributes — such as their locations in space, momentum, energy, discrete angular momentum state and sometimes even their numbers and types — exist only on a contingency basis (unless we are willing to view these observables as operators *rather than knowable* numbers*).*

---

often behave similarly to Newtonian ideal gases, with the photons playing the role of atoms (a mole of photons is called an *einstein*).

An important feature of quantum probability distributions — one which distinguishes them from the probability distributions of card hands, dice or roulettes — is that quantum probabilities propagate through space as waves rather than diffusively; This is the Schrödinger wave. The predictive power of quantum theory resides in the fact that it determines precisely the shape of the wave and how it moves — how the potential probabilities of all possible measurements change in space and time. Here we see for the first time a new meaning of causality in quantum theory — it is probability of possible outcomes of potential measurements that is causally determined into the future, not individual events[603].

The randomness at the foundation of the material world does not mean that knowledge is impossible or that physics has failed. To the contrary, the discovery of the indeterminate universe is a triumph of modern physics and reveals a wholly novel aspect of nature; one without which matter would not have the stability allowing an emergent classic approximation to arise. The new quantum theory makes many predictions — all in agreement with experiment. But most of these predictions are for distributions of events, not individual events — like predicting how many times a specific hand of cards gets dealt on the average.

In the wake of Born's statistical interpretation, physicists struggled to deepen the understanding of the new quantum theory. What knowledge of nature was possible in the framework of the new theory? For example, the mathematics of quantum theory permitted both particle-like and wave-like representations for the electron. But clearly these two representations were opposed, and this duality thus comes into conflict with any common sense ideas.

Is the electron a wave or a particle? ***Bohr***, ***Heisenberg***, *and* ***Pauli*** *in Copenhagen, and many others debated these questions for over a year. Frustration set in, but Bohr's persistent optimism kept up a spirit of inquiry.*

[603] However, as stressed by **Everett** and others, wavefunctions are more than probability amplitudes. For one thing, a quantum measurement is properly viewed as a continuous (though limited in time) interaction with a macroscopic (many–body system) measuring apparatus. This measurement is itself describable (in principle) by a deterministic Schrödinger equation of the combined system (observed system plus apparatus). Thus, the notorious subjective "collapse" of the wave function upon measurement is merely a useful simplification — whereas with cards, the probabilities really are subjective (dependent on one's state of knowledge). Furthermore, a wavefunction contains more information than its modulus — its *phase* too can, in some cases, be partially measured (e.g. in **Bohm-Aharonov** type experiments.)

Finally in 1927, Bohr and Heisenberg each in his own style had come to new ideas which were conceptually equivalent: Heisenberg had discovered the uncertainty principle*, and Bohr had discovered the* principle of complementarity*. Together these two principles constituted what became known as the* Copenhagen interpretation *of quantum mechanics. This interpretation revealed the internal consistency of the quantum theory, a consistency which was purchased at the price of modifying age-old notions of determinism and objectivity in the natural world.*

Heisenberg's uncertainty relation (first of many such) states that the product of the simultaneous uncertainties (root-mean-square random deviation) in a position component (Δq) and in the corresponding momentum component (Δp) (were one or *the other to be exactly measured at any given, common instant of time) must be greater than a fixed quantity — essentially, Planck's constant. If this constant were equal to zero in the real world rather than a tiny finite number, then we could simultaneously measure both the position and momentum of a particle. But because Planck's constant is not zero, this is impossible[604]. Heisenberg's relation does* not *apply to a single measurement on a single particle: it is a statement about a statistical average over many measurements of position and moment.*

Let us consider Zeno's arrow paradox *in the light of quantum mechanics: Suppose that the arrow were of the dimensions of a single atomic particle. According to classical Newtonian physics the '*arrow-particle*' has determinate and measurable volume, velocity and position at all times. Zeno supposed that because the particle always occupies a determinate position, the possibility of motion is thereby excluded. Contemporary physics tells us that the precise simultaneous determination of the particle's position and velocity is impossi-*

---

[604] To get a feel for what the Heisenberg relation implies for various objects, we can compare the product of the size of an object times its typical momentum to Planck's constant, h — a measure of how important quantum effects are. For a flying tennis ball, the uncertainties due to quantum theory are only of order one part in 10^{34}. Hence a tennis ball, to a high degree of accuracy, obeys the deterministic rules of classical physics. Even for a bacterium the effects are only about one part in a billion (10^{-9}), and it really does not experience the quantum world either as a whole body. For atoms in a crystal we are getting down to the quantum world: the uncertainties can be of order one part in a hundred (10^{-2}) although it can be larger (e.g for Helium atoms in the solid state). Finally, for electrons moving in an atom, molecule or metal the quantum uncertainties completely dominate, and we have entered the true quantum world governed by quantum mechanics.

ble[605]*. Zeno's insight seems to have been that motion and precise localization at an instant have an element of contradiction between them. (Indeed, this element appears in our common sense visualization of a moving body, since when we think of it as being at a definite position we cannot simultaneously form an image of what is its rate of motion!) In this sense, then, Zeno is closer to modern physics than to Newtonian physics.*

However, Zeno's paradox is fallacious also in the realm of quantum mechanics, because there is nothing in quantum physics to prevent our measuring the precise positions of a particle at two different times*, and then calculating what the intervening motion was on average.*

But there is one more twist in this comparison of quantum mechanics with Eleatic philosophy. Theoretically an over-zealous observer, applying a sequence of too-frequent measurements to the arrow's wavefunction, may completely alter its Schrödinger equation, and actually prevent the arrow from ever hitting its target! A version of this seemingly Carrollian scenario was actually observed experimentally at the U.S. National Bureau of Standards. The experiment involved, instead of an arrow, a transition of one atomic energy level into another. It was found, in agreement with quantum theory, that looking for the decay too frequently (by spectroscopic means, in this case) tends to inhibit it!

Bohr emphasized that when we are asking a question of nature we must also specify the experimental apparatus that we will use to determine the answer. In classical physics we do not have to perennially take into account the fact that in answering the question (doing an experiment) we alter the state of the object. We can ignore the interaction of the apparatus and the object under investigation, at least in principle. For quantum objects like electrons this is no longer the case; the very act of observation changes the state of the electron in a way that drastically alters its subsequent evolution.

Particle and wave are what Bohr called complementary descriptive concepts, meaning they exclude each other. Bohr's principle of complementarity asserts that there exist complementary pairs of properties of the same object (such as position and momentum), one of which, if known, to some accuracy will exclude precise knowledge of the other. We may therefore describe an object such as an electron in ways which are mutually exclusive, without logical contradiction: for instance, as a wave of definite de Broglie wavelength and momentum, or as a particle of definite position, or sometimes as a wave packet

[605] Indeed, the particle does not even *possess* these attributes simultaneously, and any assumption to the contrary leads to predictions at variance with both quantum mechanics *and* experiment, as we discuss below.

with fuzzy, but approximately defined, values for both momentum and position. The contradiction is eliminated because the experimental arrangements that determine these descriptions are similarly mutually exclusive.

Thus, two crucial points about the quantum world emerge from the Copenhagen interpretation:

(1) Quantum reality — or, more precisely, its classical phase-space manifestations — is statistical, not deterministic. Even after *the experimental arrangement bas been specified for measuring some quantum property with utmost precision, individual measurement outcomes are generally unpredictable. The microworld is empirically knowable only as statistical distributions of measurements, and these distributions can be predicted and verified by physics. The attempt to form a mental picture of the position and momentum of a single electron consistent with a series of measurements results in the* fuzzy *electron. This is a human construct, attempting to fit the quantum world into the limitations of macroscopic observations, sense-perceptions and mental conceptualizations.*

(2) It is meaningless to talk about the physical properties of quantum objects without precisely specifying the experimental arrangement by which one intends to measure them. Quantum reality is in part an observer-created reality — although observing apparata are themselves subject to its laws. The idealized classical physical world unfolds itself according to immutable laws independent of the experimenter, who may watch the physical process much as the audience watches a play in a theater. In quantum theory the observed structure of a microscopic system is inherently dependent upon the nature of its interaction with the 'observing' macro-system — which, as noted above, could be human, artificial or natural[606]*.*

In summary, at the level of observable attributes of a microscopic system, the Copenhagen interpretation of the quantum theory rejected determinism, accepting instead the statistical nature of reality; and it also rejected

[606] In the early decades of quantum mechanics, it was supposed by some practitioners (such as Wigner) that *human consciousness* somehow plays a special role in quantum measurement. However, the following two lines of investigations have gradually made it quite clear that *any* entanglement of the micro-system wavefunction with that of a macroscopic object is a form of quantum measurement. **Von Neumann** pioneered the theoretical modeling of mechanized (automated) measurement, while **Everett** systematically described measurement interactions without wavefunction collapse in his 'Many Worlds' interpretation of quantum mechanics.

> *objectivity — accepting instead that material reality depended in some sense on how we choose to observe it. After hundreds of years of holding sway in the Western mind, the world view of classical physics fell — although causality, determinism and objective reality survive, albeit at a more abstract, holistic level of mathematical description. Thus, from the very substance of the universe — the atom — the physicists learned a new lesson about reality*[607].

***Einstein**, however, was unconvinced. Distressed by the indeterminism of the new quantum theory, he disputed that the theory gave a complete and objective description of nature. But that objection was not the main one that stood in the way of his accepting the theory's picture of reality. A principle of physics that he held even more dear than determinism was the* principle of relativistic local causality *— that distant events cannot instantaneously influence local objects without any mediation.*

*Together with **N. Rosen** and **B. Podolsky** he produced (1935) an argument (known as the* EPR paradox[608]*) which endeavored to show that quantum theory violated local causality. The EPR argument seemed to indicate that quantum theory had either to violate the principle of local causality or be*

---

[607] In the *Many-World* interpretation objectivity and determinism are retained, though at the heavy price of renouncing *either* the separate objectivity of any system smaller than the entire universe, *or* the ontological reality of a single universe (as opposed to an infinite ensembles of *possible* universes).

[608] **Nathan N. Rosen** (1909–1992, USA and Israel). Collaborated with Einstein at Princeton during 1935–1937 on the foundations of Quantum Mechanics, gravitational lenses, and the singularity-free solution of the gravitational-electromagnetic field equations.

Boris Podolsky (1896–1966, U.S.A.). Born in Taganrog, Russia; emigrated to the United States in 1913. Collaborated with Einstein during 1931–1935 at Caltech (Pasadena, CA) and at the Institute of Advanced Study, Princeton.

The EPR paper showed how quantum physics requires that a property, such as the polarization of a photon, could be measured at a distance by measuring the polarization of a second photon that had interacted with the first some time in the past. If it is deemed unacceptable that the polarization measurement could instantaneously influence the distant object, it follows (EPR claimed) that the first (now distant) photon must have possessed the measured property *before* the measurement was carried out. As the property measured can be varied by the experimenter adjusting the polarization – measurement apparatus, EPR concluded that all physical properties (in our example — values of polarizations in all possible directions) must be 'real' *before* they are measured, in direct contradiction to the Copenhagen interpretation.

incomplete; the EPR team concluded that quantum theory had to be incomplete.

Bohr himself considered the EPR paper as an 'onslaught that came down upon us like a bolt from the blue'. He made valiant efforts to refute the new challenge, commenting: 'They (EPR) do it smartly, but what counts is to do it right'.

For over thirty years physicists debated the conclusions of the EPR article. Then, in 1965, ***John Bell*** *proposed a (doable) EPR-type thought experiment (involving an entangled pair of particles), the outcome of which — assuming it verified the predictions of quantum mechanics — would require a choice between two physical interpretations: either the world was not describable in terms of a classical-physics set of variables (abandonment of physical realism), or it was nonlocal (i.e. instantaneous observations or other disturbances at distinct spatial locations are not independent). Bell derived a mathematical formula — an inequality — which holds classically, is violated in quantum mechanics, and could be checked experimentally.*

Variants of the experiment were repeatedly performed starting in the 1970s; and Bell's inequality — and thus by implication the central assumption used in its proof (that both locality and physical realism hold in the microworld) — was found to be violated. The world, it seems, is either not locally describable, or not classically objective. Either alternative — a nonobjective or nonlocal reality — is somewhat unpalatable, but perfectly consistent. A deeper analysis of the Bell thought-experiment shows that regardless of which of the two interpretations of reality we choose, relativistic local causality is preserved, i.e. influences cannot be transmitted instantaneously, or indeed faster than the speed of light in vacuo[609]*.*

---

609 The local causality principle, which Einstein insisted upon, is thus *weaker* than the *locality* assumption. In fact, if Bell's inequality is violated (as all experiments have hitherto demonstrated), there exist *instantaneous statistical correlations* between the results of various potential polarization measurements on the two entangled EPR photons, however far they have flown apart. However — as is well known even in classical physics — correlation does not imply causation; more specifically, one can prove that the Bell quantum correlations do not allow an observer measuring one of the photons to thereby send an instantaneous message (through the collapsing joint wavefunction of the two photons) to the observer who subsequently measures some polarization component of the other photon. Such a superluminal communication scheme — which is possible in some modified, nonlinear-Schrödinger equation versions of quantum mechanics — are whimsically known as "Bell Telephone".

Contrary to what EPR believed, the Hilbert space description of reality used in quantum mechanics can be complete without violating relativistic local causality; in fact, quantum field theory — the marriage of quantum mechanics and special relativity — is not only locally causal, but fully local when described as interacting operator–valued fields: local wave equations hold for all quantum fields (such as the electromagnetic fields, the electronic Dirac field, etc.), although the value of such a field at any point in spacetime should be understood as a Hilbert–space operator *rather than a real number. Hilbert-space* correlations *of observables, though, are still nonzero even outside the light cone, just as in the non-relativistic quantum description of EPR-type experiments.*

In retrospect, although EPR misconstrued the implications of quantum mechanics for the principle of local causality, their thought experiment led to a refined understanding of these implications. In addition, the EPR/Bell analyses are the lithmus test against which all extensions or generalizations of quantum mechanics are tested, and continue to inspire high-precision experiments to probe the foundations of quantum reality.

1926–1935 CE **William Francis Giauque** (1895–1982, U.S.A.). Chemist. Won the 1949 Nobel prize in chemistry for pioneer work in the field of very low temperatures. He was first to achieve (1933) a temperature close to $-273\,^{\circ}$C, the absolute zero, by applying the new principle of *cooling by adiabatic demagnetization* which he and **P. Debye** discovered independently (1926). From information gained at these low temperatures, he accurately predicted the existence of two *isotopes of oxygen* O^{17} and O^{18}, eventually resulting in abandonment of the oxygen-16 standard for atomic mass (1961) and its replacement by carbon-12 standard. In 1935 he succeeded in the magnetic cooling of helium to a temperature of $0.1\,^{\circ}$K.

Giauque was born in Canada, in Niagara Falls, Ontario. He was professor at the University of California, Berkeley (1934–1981).

Cooling by adiabatic demagnetization: there are elements which, when in a crystal lattice, can form ions whose outer shells are only partially filled. The unpaired electron spins give rise to independent ionic magnetic moments (paramagnetism).

Gadolinium, iron, chromium, and cerium are examples. When these elements are chemically combined with a large number of nonmagnetic molecules or radicals, the individual magnetic ions are so far removed from other magnetic ions that their magnetic moments behave almost independently, like the atoms of an ideal gas, even though they vibrate about equilibrium positions in the lattice. The paramagnetic salt Gadolinium sulfate octahydrate $[Gd_2(SO_4)_3 \cdot 8H_2O]$ is an example in which one magnetic ion is surrounded by many nonmagnetic atoms and is therefore, magnetically, very dilute.

Pierre Curie, and later **Léon Brillouin**, established the dependence of the magnetization M of such materials on the ratio $\frac{H}{T}$ (H — applied external magnetic field; T — absolute ambient temperature) in the form $M = C\frac{H}{T}$ for small values of $\frac{H}{T}$. This is known as *Curie's law* and C is called the *Curie constant*. The larger the Curie constant, the smaller the value of $\frac{H}{T}$ that is needed to produce a given magnetization.

The nature of the method of magnetic cooling is made clear by comparing it with a mechanical analogue:

Suppose that it is desired to cool a gas by means of mechanical work. The gas is in a piston–equipped container, and is initially in thermal contact with a heat bath at temperature T_1. In the first step of the cycle, the gas is *isothermally compressed* from volume V_0 to a volume V_1. In this process work is done on the gas, but since it can give off heat to the bath its temperature is not changed. In the second step, the gas is thermally insulated (e.g., by removing the bath) and is allowed to expand adiabatically back to $V = V_0$. In this process the gas does work at the expense of its internal energy and, as a result, its temperature falls to some value $T_2 < T_1$.

One can then complete the cycle by re-attaching the gas container to the heat bath, allowing it to absorb heat at fixed volume until it returns to temperature $T = T_1$. This cycle can be repeated to continually cool (extract heat from) the gas–container's environment.

The method of *magnetic cooling by adiabatic demagnetization* is very similar: The system of interest is a magnetic sample (e.g., Gadolinium sulfate) initially in thermal contact with a heat bath at temperature T_1. In practice this heat bath is liquid helium near $1\,^\circ$K, and thermal contact of the sample with the bath is established by heat conduction via helium gas at low pressure. A magnetic field is now switched on, until it attains some value H_1. In this process the sample becomes magnetized and energy is released in orienting the magnetic moments of the ions along the direction of the magnetic field (lowering of entropy, increase of order).

During the magnetization, the sample gives off heat to the bath, as the ion's magnetic potential energy lowers. The sample remains at temperature T_1 after equilibrium has been reached. The sample is then thermally insulated (e.g., by pumping off the helium gas which provided the contact with the bath) and the magnetic field is reduced to a lower value H_2. While the first step of *isothermal magnetization* is an "entropy squeezing" operation, like compressing a gas, the second step, namely the *adiabatic demagnetization*, takes place at *constant entropy*.

For the entropy to remain constant, a "disorder-increasing" process like demagnetization, in which orientations of ionic magnets are *randomized*, must be compensated by a "disorder decreasing" process, which can only be a drop in temperature. Thus, the temperature of the sample drops to $T_2 < T_1$. The sample is then put in contact again with the heat bath (still at $H = H_2$) and allowed to absorb heat from it, until the sample has returned to $T = T_0$. If this process is repeated several times, the continual absorption of heat from the sample's environment can result in the attainment of temperatures as low as $0.01\,^\circ$K. Indeed, temperatures close to 10^{-6} °K have been achieved by elaboration of this method. In the 1990's, other cooling methods — using combinations of lasers, RF, magnetic fields and gravity — were developed. The latest low-temperature record (2004) using such techniques is about 0.5 pico-Kelvins.

1926–1938 CE **Llewellyn Hilleth Thomas** (b. 1903, England). Physicist. Discovered a relativistic kinematic phenomenon, according to which a spinning *and* orbiting relativistic mass (electron, say) exhibits a precession of its axis of spin, such that the ratio of the precessional period to the orbital period[610] is $2c^2/v^2$. The effect is known as '*Thomas precession*' and is a special case of the more general '*Wigner rotation*'[611] (Wigner, 1939): an accelerated frame *rotates*, relative to an inertial frame, even in the absence of torques as measured in the instantaneous inertial frame. A comoving observer will

610 This expression is modified when $\frac{v}{c}$ is of order unity; it is valid as it stands for $v \ll c$.

611 *Wigner's rotation*: Consider 3 STR reference frames S, S' and S'', with S and S' related by a Lorentz transformation $L(\boldsymbol{v}_1)$, and S' and S'' related by $L(\boldsymbol{v}_2)$. If the velocity of S'' relative to original system S is $\boldsymbol{v}_3$, S'' is *not* obtained from S by $L(\boldsymbol{v}_3)$ alone. Rather, we find that $L(\boldsymbol{v}_3) = RL(\boldsymbol{v}_2)L(\boldsymbol{v}_1)$, where R is a 3D space rotation. With $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$ not parallel, $R \neq I$ and the final system S'' is *rotated* relative to S (*Wigner's rotation*). This rotation is the origin of the *Kinematical Thomas precession* which is manifested as a spin-orbit coupling terms in atomic and nuclear physics. Because of the presence of the *Wigner rotation*, the $L(\boldsymbol{v})$ ("pure boosts") themselves do not form a group – but together with the Lie group of 3D rotations (SO(3)), the set of boosts $L(\boldsymbol{v})$ *do* form a Lie group: the 4D Lorentz group (denoted SO(3, n)), of which SO(3) forms a subgroup.
Explicitly, $L(\boldsymbol{v}) = I - \sigma \operatorname{sh}\theta + \sigma^2(\operatorname{ch}\theta - 1)$, where I is the unit tensor in 4

observe no centrifugal or Coriolis effects, yet an external observer would find that the frame, and any body at rest in it, is rotating.

An application of the Thomas precession is encountered in the fine structure of atomic levels, where it causes the magnetic field, as seen by the electron, in its instantaneous inertial frame, to be half as effective at causing the electron's spin to precess. When this result became known, it surprised many, including **Goudsmit**, **Pauli** and even **Einstein** himself.[612]

Thomas suggested (1938) a modification in the design of cyclotrons such that the magnetic field should be varied in azimuth (i.e. round the perimeter of the orbit), as well as in the radial direction. This AVF (Azimuthally Varying Field) concept has been realized in the '*spiral ridge cyclotron*', where especially strong magnetic field regions are produced by spiral sectors built into the pole faces. This provides extra focusing action to overcome the defocusing effects of the radial field variations.

1926–1939 CE **Alexander Aitken** (1895–1967, New Zealand and Scotland). Mathematician. Influential researcher in statistics, numerical analysis and the theory of determinants and matrices; *Aitken's δ^2 process* and *Aitken's iterative interpolation* in numerical analysis, are named after him. Showed how invariant theory came under the theory of groups.

Aitken was born in Dudedin, New Zealand. His university career was interrupted by WWI; he enlisted (1915) and served in Gallipoli, Egypt and

---

dimension, $\operatorname{ch}\ \theta = \frac{1}{\sqrt{1-\left(\frac{v}{c}\right)^2}} = \gamma(\boldsymbol{v}), \quad \operatorname{sh}\theta = \frac{v}{c}\gamma, \ \ v = |\boldsymbol{v}|$, and,

$$\sigma = \begin{bmatrix} 0 & 0 & 0 & -\lambda \\ 0 & 0 & 0 & -\mu \\ 0 & 0 & 0 & -\nu \\ \lambda & \mu & \nu & 0 \end{bmatrix},$$

with (λ, μ, ν) the direction cosines of $\boldsymbol{v}$. The parameters of the above–defined Wigner rotation are: $R = R(\boldsymbol{e}, \psi)$, $\boldsymbol{e} = \frac{\boldsymbol{v}_2 \times \boldsymbol{v}_1}{|\boldsymbol{v}_1 \times \boldsymbol{v}_2|}$, $\psi = 2\tan^{-1}\left\{\frac{\sin\phi}{\tau + \cos\phi}\right\}$, where $\boldsymbol{e}$ is a unit vector in the direction of the axis of rotation and ψ is the *Wigner angle*. Here, $\tau = \sqrt{\frac{(\gamma_1+1)(\gamma_2+1)}{(\gamma_1-1)(\gamma_2-1)}}$ $\big(\gamma_1 = \gamma(v_1),\ \gamma_2 = \gamma(v_2)\big)$ and ϕ the angle between $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$. For a more detailed analysis see **A. Ben-Menahem**, "Wigner's rotation revisited", Am J. Phys. **53**, 62–66, 1985.

612 A gravitational variant of Thomas precession is known as "geodetic precession" and is one of the GTR effects being investigated in the relativistic gyro (gravity Probe B) experiment, launched into orbit in 2004.

France, being wounded at the battle of the Somme. His war experience was to haunt him for the rest of his life. Aitken came to Edinburgh, Scotland (1923) and studied for a Ph.D. under **Whittaker**, to whose chair he was appointed in 1946. He spent the rest of his life there.

Aitken had an incredible photographic memory; he knew π to 2000 places[613] and could instantly multiply, divide and take roots of large numbers. But his memory was also a problem for him. For most people memories fade in time which is particularly fortunate for the unpleasant things that happen. However, with Aitken memories did not fade and his horrific memories of the battle of the Somme lived with him as real as the day he lived them. These memories have contributed to the ill health he suffered and eventually led to his death.

1926–1939 CE **Eugene Paul Wigner** (1902–1995, Hungary, Germany and U.S.A.). Influential mathematician and physicist whose contributions had a decisive impact on modern theoretical physics, especially in quantum mechanics and nuclear physics.

In 1926 he was first to apply *group theory* to quantum mechanics. In 1927 he created the concept of *parity*[614] for atomic states and formulated

---

613 Before the days of computing machines there was a kind of human competition in seeing how far one could calculate π. In 1873, **Shanks** carried this out to 707 decimals; it was not until 1948 that it was discovered that the last 180 of them were wrong. In 1927, Aitken had memorized those 707 digits for an informal demonstration to a student society and naturally was chagrined in 1948 that he had memorized something erroneous. When π was calculated anew to 1000 decimals Aitken rememorized it, but had to suppress his earliest memory of those 180 erroneous digits which he could not forget! For this reason, Aitken found it much harder to recite the *second* 500 digits.

614 For all isolated atomic or nuclear systems, *parity* is defined as the multiplicative sign acquired by their wavefunction upon reflection of all coordinates w.r.t. the origin: *even* or positive parity for a "+" sign, *odd* or negative parity for a "−" sign. The parity of any state remains unchanged throughout its time evolution, provided that the Hamiltonian of the system is unchanged by the reflection of the coordinates (*conservation of parity*). The concept of parity was later extended to quantum field theories. The parity of a field or a system of particles is not just a matter of whether the relevant wavefunction is an even or odd function of spatial position: in analogy with angular momentum, particles and their fields often also possess *internal* parity. Thus, the *electric* and *magnetic* field transform as *polar* and *axial* vector fields, respectively:

$$\boldsymbol{E}(\boldsymbol{r},t) \longrightarrow -\boldsymbol{E}(-\boldsymbol{r},t)$$

$$\boldsymbol{B}(\boldsymbol{r},t) \longrightarrow \boldsymbol{B}(-\boldsymbol{r},t)$$

the *law of conservation of (or, equivalently, invariance under) parity*. In 1932 he evolved the concept of invariance under time reversal, that marks the behavior of subatomic particles[615]. In 1936 he worked out the theory of neutron absorption which later proved important in nuclear fission and the operation of nuclear reactors.

His book on group theory (1931) served as a basis for research on the molecular structure and band theory in solids.

With his Hungarian compatriots **Leo Szilard** and **Edward Teller**, Wigner helped persuade **Albert Einstein** (1939) to write the historic letter to President F.D. Roosevelt that set in motion the U.S. atomic bomb project. During WWII, he helped **Enrico Fermi** construct the first atomic pile.

Wigner was born in Budapest to a Jewish family. He received his higher education at the Technische Hochschule in Berlin. In 1930 he moved to the United States, and spent most of his academic life at Princeton University as a professor of mathematical physics (1938–1971). In 1963 he won the Nobel prize in physics.

1926–1944 CE **John von Neumann**[616] (1903–1957, Hungary and U.S.A.). A phenomenal mathematician (both pure and applied) who made major contributions in quantum physics, computer science, game theory and meteorology. About 20 of his 150 papers are on physics. The rest are distributed evenly throughout pure mathematics [set theory, logic, topological

---

the *pseudoscalar pi*–meson fields have intrinsic parity values of (−1), etc. In the spirit of *Noether's theorem*, one may view the conservation of the parity quantum number either as a conservation law *or* as a symmetry law. (The theorem refers to continuous symmetry groups, and thus does not strictly apply to discrete symmetries such as parity — although it can be modified to accommodate them.) Electromagnetic, gravitational and strong nuclear forces conserve parity; the world of physics was astonished when it was discovered in the 1950's that the *weak nuclear* force *violates* this symmetry.

[615] Again, with the exception of (some forms of) the weak nuclear interactions.

groups, measure theory, ergodic theory, operator theory (*von Neumann's algebras*)] and applied mathematics [statistics, numerical analysis, shock waves, flow problems, hydrodynamics, aerodynamics, ballistics, problems of detonation, meteorology, games and computers].

Von Neumann's thought processes were rapid, and his associates often found it difficult to keep up with his rapid flow of ideas. He was also a linguist, and could converse in 7 European languages. He preferred general to special problems, and rarely worried about mathematical elegance[617]. He got to the root of the matter by concentrating on the basic properties (axioms) from which all else follows. His insights were illuminating and his statements precise.

His book "*Theory of Games and Economic Behavior*" (1944, jointly with **Oskar Morgenstern**) had a significant influence upon economics. In the framework of their theory, the authors modeled the behavior of individuals in economic and adversarial situations. An individual's choices are ranked according to some payoff function, which assigns a numerical worth to the consequences of each choice.

Within game theory, individuals behave rationally: they choose the action that yields the highest payoff[618]. (Real people may not be consistently

---

617 In connection with a long-winded but straightforward proof, he is quoted as saying that he *did not have the time to make the subject difficult*.

618 Beginning in the second half of the 20^{th} century, powerful computers have been pressed into service to simulate of *social behavior of groups* in an overall effort to understand the *dynamics of social dilemmas*. A social dilemma involves a group of people attempting to provide themselves with a common good in the absence of central authority. The computer experiments gloss over the complexities of human nature, but it is believed that they can help elucidate some of the principles that govern interaction of many participants. The results indicate that overall cooperation cannot generally be sustained in groups that exceed a *critical size*. The size depends on how long individuals expect to remain part of the group as well as on the amount of information available to them. Moreover, both general cooperation and defection can appear *suddenly and unexpectedly* (nonlinear phenomena!). These results can serve as aids for interpreting *historical trends* and as guidelines for constructively reorganizing cooperations, trade unions, governments and other group enterprises.

To study the evolution of social cooperation, methods were borrowed from *statistical thermodynamics*. This branch of physics attempts to derive the macroscopic properties of matter from the interaction of its constituent molecules and other quanta.

Diversity strongly affects the dynamics of social dilemmas. A heterogeneous group can display two different types of diversity: variations around a common rational, but they do behave that way when presented with simple choices and straightforward situations.) In 1929 he gave *Hilbert spaces* their name, their first axiomatization and their present highly abstract form.

Neumann's war effort convinced him of the need for high-speed computers. He was instrumental in the development of *MANIAC* (Mathematical Analyzer Numerical Integrator And Computer). In computer theory, he did much of the pioneering work in logical design, in the problem of obtaining reliable answers from a machine with unreliable components, the function of *memory*, machine imitation of *randomness*, and the problem of constructing automata that can reproduce their own kind. These contributions were important in the development of the hydrogen bomb.

Neumann was born in Budapest to a Jewish family. Many anecdotes, from childhood on, tell of his phenomenal speed in absorbing ideas and solving problems, and of his equally phenomenal memory. He received his high school education at the *Minta*, the famous Budapest school, known for its high standards, liberal teacher-pupil relations and competitive training for its science students[619]. He studied chemistry at the University of Berlin and at

---

average or segregating into factions. Relations within subgroups may powerfully influence the evolution of cooperation, especially in large *hierarchical organizations*.

The study of social dilemmas provides insight into a central issue of behavior: how *global cooperation* among individuals confronted with conflicting choices can be secured. Recent studies (1994) have shown that cooperative behavior can rise *spontaneously* in social settings, provided that the groups are small and diverse in composition and that their constituents have *a long outlook*. Even more significantly, when cooperation does appear, it does so *suddenly and unpredictably* after a long period of stasis.

The fall of the Berlin wall and the breakdown of the centralized Soviet Union into many autonomous republics are examples of abrupt global defections from prevailing social compacts. The member countries of the European union currently face their own social dilemma as they try to secure supranational cooperation.

Hopefully, nonlinear dynamics will play an ever growing role in solving problems in the social sciences.

619 Most of the other famous expatriate Hungarian scientists, such as: **Edward Teller** (b. 1908), **Leo Szilard** (b. 1898), **George Polya** (b. 1888), **Theodore von Kármán** (b. 1881), **Eugene Wigner** (b. 1902), **Michael Polanyi** (b. 1891) and **Georg von Hevesy** (b. 1885) also graduated from this school. All eight were of Jewish middle class stock. All left Hungary as young men; all proved unusually versatile and made major contributions to 20^{th} century science and technology. Two among them eventually won Nobel prizes (see Table 5.6).

the Technische Hochschulle in Zürich. In 1926 he received both a diploma in chemical engineering and a Ph.D. in mathematics from the University of Budapest. He accepted a chair at Princeton University in 1931. In 1933 he was appointed the first professor of mathematical physics at the newly formed Institute of Advanced Study at Princeton. In 1954 his health began to deteriorate, and he died after a prolonged illness.

Game theory — Analysis of Conflicts and Cooperation

(A) Overview and history

Game theory, one of the most useful branches of modern mathematics, was anticipated in 1921 by ***Émil Borel****, but it was not until 1926 that* ***John von Neumann*** *gave his proof of the* minimax theorem*, the fundamental theorem of game theory. On this cornerstone he built almost single-handedly the basis structure of the theory. His classic work (1944),* Theory of Games and Economic Behavior*, written with the economist Oscar Morgenstern, created a tremendous stir in economic circles. Since then game theory has developed into an amalgam of algebra, geometry, set theory, and topology, with applications to competitive and cooperative situations in business, warfare, politics, biology and economics. It has been employed by folks as diverse as philosophers, political scientists, arms-control negotiators and evolutionary biologists.*

Game-theoretic analysis has insidiously penetrated the literature of macro- and microeconomics, international trade, labor, public policy, natural resources and development. Recurring themes include: threatening, bluffing, punishing, rewarding, building reputations, signaling one's unobservable "type" and sustaining cooperation in apparently noncooperative environment through repeated interactions. Answers through Game Theory have been sought to such questions as: "What is the nation's optimal strategy in the Cold War Game?"; "Is the Golden Rule the best strategy for maximizing happiness payoffs in the Great Game of Life?"; "How can a scientist best play the Induction Game against his formidable opponent, Nature?"

The theory of games in intended mainly as a theory of rational behavior *in practical situations that involve conflicting interests and in which the outcome* *is determined by the "best" strategies chosen by intelligent opponents. The players may be commercial rivals engaged in a competition, union leaders and management in an industry trying to reach a labor contract, campaign managers of candidates trying to get elected to a political office, military generals in an army trying to win a war, attorneys in a lawsuit trying for the best settlement for their clients, and so on; The theory of games finds applications in all situations in which parties involved have opposing goals, use their best strategy*[620]*, and yet cannot completely dominate the final outcome.*

In the life sciences, game theory is used as a mathematical tool for understanding the behavior of a species and how it evolved and interact with other species.

A game[621] *begins with, and is centered around, a specified set of decision makers who are called "players". Each player has some array of resources at his disposal, some spectrum of alternative courses of action (including attempts to communicate and collaborate), and some inherent system of preferences or utility concerning the possible outcomes. Outside the game model all players are alike — the theory refuses to distinguish among them. This is known as the principle of* external symmetry*. In such game models it will be always assumed that the identified players are rational, conscious decision makers having well-defined goals and exercising freedom of choice within prescribed limits. What they do with that freedom is a question for the solution theories to answer, not the rules of the game. The answers will generally fall far short of a deterministic prescription of behavior. Despite this essential element of free will, the rules of the game may nevertheless severely restrict the player's behavior.*

Virtually all game models involve a special kind of uncertainty that is caused by not knowing what other players are going to do: this is called strategic uncertainty*. Some games also allow random moves, by players or by nature, thus bringing the factor of* risk *(uncertainty with known probabilities) into the player's calculations. Historically, game theory has operated for the*

---

620 *Strategy*: a programmed way of behavior in pairwise contests. In the context of *chess*, for example, or war, strategy suggests a nicely calculated sequence of moves. The term *two-person* means that two players with conflicting interests are making use of their ingenuity to outwit each other. *Zero sum* means that any loss of one player is the gain of another.

621 The word "*game*" was an unfortunate choice for a technical term. The usual sense of the word has connotations of fun and amusements, and of removal from the mainstream and the major problems of life. These connotations should not be allowed to obscure the more serious role of game theory in providing a mathematical basis for the study of conflict, competition and cooperation.

most part under the assumption of complete information: all the players know all the rules and can make all necessary calculations[622].

The modern history of Game Theory goes back to the 18th century: ***James Waldegrave*** *(1684–1741, England) provided (1713) the first known minimax mixed strategy solution to a two-person game.* ***Augustin Cournot*** *(1838) discussed the special case of duopoly and utilized a solution concept that is a restricted version of the Nash equation.* ***Francis Edgeworth*** *(1881) proposed the contract curve as a solution to the problem of determining the outcome of trading between individuals. The concept of the core is a generalization of Edgeworth's contract curve.*

Zermelo *(1913) asserted (Zermelo's Theorem) that chess has only one individually rational payoff profile in pure strategies, i.e. chess is strictly determined.* ***Borel*** *(1921–1927) gave the first modern formulation of a mixed strategy along with finding the minimax solution for specific two-person games.* ***John von Neumann*** *(1928) proved that every two-person zero-sum game with finitely many pure strategies for each layer is determined, i.e. when mixed strategies are admitted this variety of game has precisely one individually rational payoff vector.*

Game theory continued its rapid development after WWII; The game now known as the Prisoners Dilemma was introduced at the Rand Corporation in California (1950) and in the same year ***John Nash*** *made important contributions to both non-cooperative game theory and bargaining theory. He proved the existence of a type of strategic equilibrium — the Nash equilibrium for non-cooperative games. The first explicit application to evolutionary biology was made by* ***R.C. Lewontin*** *(1961).*

(b) Theoretical background

We consider non-cooperative zero-sum games:

A zero-sum game is one in which the pay-offs to all the players add up to zero (similarly for a constant-sum game). Such games can be completely specified by a rectangular array of numbers (known as the game or payoff matrix) together with certain conventions on how to read it. The entries a_{ij} of this matrix represent the pay-offs to one of the players, call him R. Since

622 Since 1957, progress has been made in extending the theory to game-like situations in which the rules are incompletely known, such as forecasting of demand (i.e. unknown preferences).

the game is zero-sum, the pay-offs to the other player, C *are* $-a_{ij}$. *The index* i *conventionally ranges over* R*'s strategies (i.e. rows of the matrix), while* j *ranges over* C*'s strategies (i.e. columns of the matrix).*

To be more specific, it is assumed that player R *has a choice of* m *moves, which may be identified as* $R_1, R_2, ..., R_m$. *After he has selected a move, player* C *(column), makes his own move (based on whatever knowledge characterizing the game, and on whatever strategy or algorithm) among several alternatives* $C_1, C_2, ..., C_n$. *The moves of the two players are then compared and the winner declared according to the rules of the game. The payoffs, which are assigned numerical values, are generally presented in the form of an* $m \times n$ *matrix* $A = [a_{ij}]$ *such as the following:*

$$\text{player } R \quad \overset{\text{player } C}{\begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ & & \dots & \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{bmatrix}}$$

Each row of the matrix corresponds to one of the m *possible moves of player* R, *while each column corresponds to one of* n *possible choices* C *may move for his own move. The element* a_{ij} *represents the payoff to* R *when he selects move* R_i *and* C *selects move* C_j. *Positive amounts correspond to payments* C *makes to* R *(or benefit occurring to* R *at the expense of* C*), while negative amounts represent amounts or benefits player* R *makes or loses to player* C.

An important question that arises in the theory of games is whether one can determine a best move for players who wish to maximize their gains *or at least* minimize their losses, *i.e. whether one player should prefer one move over another to maximize his resulting advantage.*

To illustrate, let us consider the following example, in which we propose to determine the best move for each player.

R *and* C *agree to play a game: First* R *chooses a number from a set* $\{1,2,3\}$, *then* C *(not knowing the choice of* R*) chooses a number from the set* $\{1,2,3,4\}$. *The numbers are then compared by a referee who determines the winner and announce the reward or penalty according to the following* payoff matrix *(ignore the circle and cross-hairs for now):*

$$\begin{array}{cc} & C \\ & \begin{array}{cccc} 1 & 2 & 3 & 4 \end{array} \\ R \begin{array}{c} 1 \\ 2 \\ 3 \end{array} & \begin{bmatrix} 4 & 2 & 3 & 9 \\ 5 & 6 & \textcircled{5} & 7 \\ 6 & 8 & 4 & 3 \end{bmatrix} \end{array}$$

Assuming that both players wish to maximize their profits, the best move for each player is determined by the following rationale. First consider the game from R's point of view:

- *If I choose the first row, I am sure to win at least \$2, no matter what C will do. If I chose the second row, I'm guaranteed at least \$5 and if I choose the third row, I will gain at least \$3. These minima are* $\{2, 5, 3\}$*; so my best move is to choose the maximum of these minima — i.e.* $\underset{i}{max}\ \underset{j}{min}\ [a_{ij}] = 5$. *I therefore select the second row.*

  C, unaware of R's choice, argues as follows:

- *If I choose the first column, I will lose at most \$6; likewise \$8 in the second column, 5 in the third, and \$9 in the fourth column. Since I'm interesting in minimizing my losses, I must choose the minimum of the maxima;* The maxima are $\{6, 8, 5, 9\}$, *i.e.* $\underset{i}{max}\ \underset{j}{min}\ [a_{ij}] = 5$. *Therefore I select the third column.*

Thus R would play row 2 while C would play column 3. *Those choices guarantee R to win* 5 *dollars – the amount that C loses in the game.*

As long as either player uses his optimal strategy he is sure to receive a payoff equal to or better (from his perspective) than 5.

Note that the intersection of the second row and the third column indicated in the above matrix is the element that holds the minimax = maximin. In other words, the element $a_{23} = 5$ *which determines the winning of R (and the loss of C) has the unique property of being the minimum in its row and the maximum in its column. Such an entry is called a saddle point and the numerical value* $V = 5$ *associated with it is the value of the game. In this case the game matrix A is said to be strictly determined.*

If $V = 0$ *the game is called fair (e.g. with* $A = \begin{bmatrix} 0 & 2 & 4 \\ -2 & 0 & 2 \\ -4 & -2 & 0 \end{bmatrix}$, $V = a_{11} = 0$).

The mode of play of R and C in this case is known as pure strategy with R having a dominant strategy. It appears that the solution of a strictly determined game is easy to find, since each player can determine his opponents strategy and make his moves accordingly. However, most payoff matrices do not have saddle-points and the theory must be extended. i.e. one must consider general conditions under which games have values but players do not have good pure strategies. Consider, for example, the following pay-off matrix that has no saddle point,

$$A = \begin{bmatrix} -1 & 7 \\ 6 & -2 \end{bmatrix}$$

If players choose to play this game only once, there exist no professional advice for them at this stage and they will have to use their own rational thinking as to what strategy is best for them.

But suppose that the game is played more than once. A reasonable approach for player R in the above game is to choose row 1, since he has a chance of winning \$7 or may at worst lose \$1 in some cases. If he uses this strategy too often and plays it most of the time, his opponent can foil him by choosing column 1 and thus receive \$1 from him instead of loosing \$7 to him. It is thus reasonable for R to sometimes play row 2 so as to win \$6 at best or loose \$2.

Thus, C would be advised to chose column 1 if his opponent selects row 1 and select column 2 if R chooses row 2 This would work very nicely for C if he knew in advance precisely what R plans to do – which he generally does not.

How then can each player outsmart his opponent? The only way for them is to mix their strategies so as not to establish any pattern at all. The mixed strategies will keep R from winning two much, and protect C from losing too much, in the long run.

Let us consider a version of a game known as two-finger Morra; there are two players (R and C). Each player holds up either one or two fingers. If they hold up the same number of fingers, R gets the sum (in dollars) of the digits, and if they hold up a different number, C gets the sum. R's pay-off matrix is

$$\begin{array}{ccc} & & C \\ & & \begin{array}{cc} \text{1 finger} & \text{2 finger} \end{array} \\ R & \begin{array}{c} \text{1 finger} \\ \text{2 finger} \end{array} & \begin{bmatrix} 2 & -3 \\ -3 & 4 \end{bmatrix} \end{array}$$

Neither R nor C has a dominant strategy, and the maximin of R (-3) in not equal to the minimax of $C(2)$. This means that the game is not solvable in terms of pure strategies.

Suppose that R will show 1 finger for a fraction p_1 of the time and 2 fingers for a fraction p_2 of the time, such that his average pay-off will be $(2p_1 - 3p_2)$ if C shows 1 finger and $(-3p_1 + 4p_2)$ if C shows 2 fingers. But this only holds if C does adopt pure strategy. However, if C adopts a mixed strategy of his own, say with probabilities $[q_1, q_2]$, the average pay-off to R will be $(2p_1 - 3p_2)q_1 + (-3p_1 + 4p_2)q_2$ where $q_1 + q_2 = 1, p_1 + p_2 = 1$. The expected value of the game, $E(P, Q)$, can be written conventionally as the matrix product

$$E(P,Q) = [p_1, p_2] \begin{bmatrix} 2 & -3 \\ -3 & 4 \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \end{bmatrix} = PAQ^T$$

Where P is a row vector of probabilities that the row player selects for his strategies, and Q^T is the column vector of probabilities the column player selects for his own strategies. The object of the row-player is to choose P so as to maximize his expected pay-off (PAQ^T) given that the column player can choose any Q^T; while the column player tries to minimize it, given that the row player van choose any P.

This is just a generalization of the former maximin and minimax of pure strategy cases. For any given vector P, R sees what happens when C picks the $Q = Q^*(P)$ that does R worst damage (=least benefit) and subsequently picks that P such that, when $Q = Q^*(P)$ is selected by C, will do R the least harm (or most good). This strategy for R is achieved by the equality $2p_1^* - 3p_2^* = -3p_1^* + 4p_2^*$ yielding $p^* = \left[\frac{7}{12}, \frac{5}{12}\right]$.

Player R should therefore play one finger with probability $\frac{7}{12}$. If R adopts this strategy his expected pay-off is $2p_1^* - 3p_2^* = -\frac{1}{12}$ whatever C does.

So the best R can guarantee himself via his statistical strategy, is to expect to make on the average a small loss[623] *from every play of the game.*

The strategy for C is given by the solution of the equation $2q_1^* - 3q_2^* = -3q_1^* + 4q_2^*$, namely $Q^* = \left[\frac{7}{12}, \frac{5}{12}\right]$. C's expected loss is then $2q_1^* - 3q_2^* = -\frac{1}{12}$ i.e. a gain of $\frac{1}{12}$.

As long as R plays his best strategy, the 7 : 5 mixture, he holds his average loss per game to at most $\frac{1}{12}$ of a dollar. As long as C plays his best mixture, the 7 : 5, he ensures an average win per game of at least $\frac{1}{12}$ of a dollar. Had

623 Pay-offs are always given as payments from C to R even when the money (or benefit) actually goes that way, in which case the payment to R is indicated by a minus sign.

the pay-off matrix been $\begin{bmatrix} 1 & -2 \\ -7 & 8 \end{bmatrix}$, *the best strategy for* R *would be the mixture 5:1 and that of* C $5:4$, *with* $E(P,Q) = -\frac{1}{3}$.

In the general case of 2×2 *nonstrictly determined game matrix* $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ *one has*[624] $(a,d) > (b,c)$ *or* $(b,c) > (a,d)$, *where the strategies of the players* R *and* C *are* $P = [x, 1-x]$ *and* $Q = [y, 1-y]$ *respectively, the expected value of the game is*

$$E(x,y) = [x, 1-x] \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} y \\ 1-y \end{bmatrix}$$
$$= (a+d-b-c)xy + x(b-d) + y(c-d) + d$$
$$= (a+d-b-c)(x-x_0)(y-y_0) + E(x_0,y_0),$$

where

$$x_0 = \frac{d-c}{a+d-b-c} \text{ is a solution of } \quad ax_0 + c(1-x_0) = bx_0 + d(1-x_0)$$

$$y_0 = \frac{d-b}{a+d-b-c} \text{ is a solution of } \quad ay_0 + b(1-y_0) = cy_0 + d(1-y_0)$$

The explicit value of the game is

$$E(x_0,y_0) = [x_0, 1-x_0] \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} y_0 \\ 1-y_0 \end{bmatrix} =$$
$$= ax_0 + c(1-x_0) = \frac{ad-bc}{a+d-b-c}$$

From the algebraic form of $E(x,y)$ *it is clear that* R*'s choice of the (probabilistic) strategy,* $x = x_0$ *assures him of a maximal expectation of* $E = E(x_0,y_0)$, *no matter what* C*'s strategy is. But whereas in the case of pure strategy he was guaranteed a maximum payoff, here he selects a mixed strategy that will guarantee him the maximum expectation or maximum average winning in the long run. This is* R*'s optimum strategy. On the other hand, if* C *chooses the strategy* $y = y_0$, *no strategy of* R *can increase* C*'s average loss beyond* $E(x_0,y_0)$.

Thus the mixed strategy $y = y_0$ *is optimum for* C, *since it corresponds to* $E(x_0,y_0)$, *the minimum expected payoff to* R.

Note that $E(x,y)$ *has a saddle-point at* $x = x_0$, $y = y_0$, *since* $\Delta = E_{xx}E_{yy} - E_{xy}^2 = -(a+d-bc)^2 < 0$. *In this sense, the case of mixed strategies is a*

[624] In this notation $(x,y) > (z,w)$ means $min(x,y) > max(z,w)$.

generalization of the simple case of pure strategies: the equal minimax and maximin are associated with an expectation function $E(x, y)$ rather than with the payoff itself.

Mixed strategy introduced an all-important aspect of game theory: to be effective, the mixing must be done by a randomizing device. It is easy to see why nonrandom mixing is dangerous; Suppose that in two-finger Morra, R mixes by using the pattern $\{1\ 1\ 2\ 1\ 1\ 1\ 2\ 2\ 1\ 1\ 2\ 2\}$. C catches on and plays to win every time. R can adopt a subtler mixing pattern, but there is always a chance that C will discover it. If he tries to randomize in his head, unconscious biases creep in. The only way to achieve optimal strategy is to use a randomizer (die or machine).

Von Neumann proved that in every matrix game, regardless of size, there exists at least one optimal strategy for each player. This fundamental proposition is called the minimax theorem. It states that for all matrix orders $[\boldsymbol{x} = (x_1, x_2, \dots, x_n); \quad \boldsymbol{y} = (y_1, y_2, \dots, y_n)]$

$$\underset{\text{for all } \boldsymbol{x}}{\textit{maximum}} \left[\underset{\text{for all } \boldsymbol{y}}{\textit{minimum}}\ E(\boldsymbol{x}, \boldsymbol{y}) \right] = \underset{\text{for all } \boldsymbol{y}}{\textit{minimum}} \left[\underset{\text{for all } \boldsymbol{x}}{\textit{maximum}}\ E(\boldsymbol{x}, \boldsymbol{y}) \right]$$

Most two-person board games, such as chess and checkers, are played in a sequence of alternating moves that continues, until either one player wins or the game is drawn. Since the number of possible sequences is vast and so is the number of possible strategies, the matrix is much too enormous to draw. Even as simple a game as ticktacktoe would require a matrix with tens of thousands of cells, each labeled 1, -1 or 0.

If the game is finite (each player has a finite number of moves and a finite number of choices at each move) and has perfect information (both players know the complete state of the game at every stage before the current move), it can be proved (von Neumann was the first to do it) that the game is strictly determined. This means that either there is at least one best pure strategy that always wins for the first or for the second player, or that both of the players have pure strategies that can ensure a draw.

Example 1: Aerial Warfare

White repeatedly sends two-plane missions to attack one of Blue's installations. One plane carries bombs, and the other (identical in appearance) flies *cover for the plane carrying the bombs. Suppose the lead plane can be defended better by the guns of the plane in the second position than vice versa, so that the chance of the lead plane surviving an attack by Blue's fighter is 80 %, while the chance of the plane in the second position surviving such an attack is only 60 %. Suppose further that Blue can attack just one of White's planes and that Blue's sole concern is the protection of his installation, while White's sole concern is the destruction of Blue's installation. Which of White's planes should carry the bombs, and which plane should Blue attack?*

Let White's payoff be the probability of accomplishing the mission. Then

$$A = \begin{bmatrix} 0.8 & 1 \\ 1 & 0.6 \end{bmatrix}, \qquad p_1 = \frac{0.4}{0.6} = \frac{2}{3}; \quad p_2 = \frac{0.2}{0.6} = \frac{1}{3}$$

Thus always putting the bombs in the lead plane is not White's best strategy, although this plane is less likely to be shot down than the other. In fact, if White always puts the bombs in the lead plane, then Blue will always attack this plane and the resulting probability of the mission succeeding will be 0.8. On the other hand, if White adopts the optimal mixed strategy and puts the bombs in the lead plane only two times out of three he will increase his probability of accomplishing the mission by $\frac{1}{15}$*, since the value of the game is:*

$$v = \frac{2}{3} \cdot \frac{8}{10} + \frac{1}{3} \cdot 1 = \frac{13}{15}$$

By the same token, Blue's best strategy is to attack the lead plane only one time out of three and the other plane the rest of the time.

Example 2: The Prisoner's Dilemma

Two prisoners kept in separate cells are asked to confess a joint crime. If both confess, both remain in jail for 9 years. If only one confesses, he will instantly be freed (as witness for the prosecution), while the other gets sentenced to 10 years. If none of them confess, both will be sentenced for one year, pending investigation. Writing the pay-offs as -n (for n years in prison), we get for R

$$\begin{array}{ccc} & & C & \\ & & \textit{confess} & \textit{keep quiet} \\ R & \begin{array}{c}\textit{confess} \\ \textit{keep quiet}\end{array} & \left[\begin{array}{c} -9 \\ -10 \end{array}\right. & \left.\begin{array}{c} 0 \\ -1 \end{array}\right] \end{array}$$

The value of the game is -9 *(saddle point), indicating that the best policy for both* R *and* C *is to confess which is worse than* $(-1, -1)$ *if both keep quiet. Most people would regard the latter as the 'best' solution but the self-interest of the two 'players' leads to an outcome which is disastrous for both.*

This game has exercised an overwhelming fascination upon game theorists and psychologists. It encapsulates some of the major dilemmas in conflict situations and also models problems as diverse as nuclear disarmament*, predator/pray competition, "arms races" in evolutionary biology,* wage negotiation*, and the controversy of* whooping cough vaccinations*. The first dilemma is what should be the player's objective – to do what is best for* him *as an individual, or* him *as part of a group? This conflict is between* individual rationality *which would lead one to confess, and* group rationality *which would suggest keeping quiet. Which tendency predominates depends very much on the individuals involved, and their previous experience with other people, including each other. This obviously explains psychologist's interest in the game.*

The second problem is whether to think of Prisoner's Dilemma as a one-off game or as one that will be played repeatedly*. In a one-off game it seems best to confess, because there is no reason to build up ones opponent's trust in oneself. If, however, the number of games to be played is* not known *by the players the 'keep silent' strategy should be played all the time!*

Example 3: Evolutionary Biological systems – battle of the sexes

Much of game theory is static in the sense that time does not enter explicitly and dynamic considerations, if any, are implicit. In certain situations, however, the underlying dynamics can be modeled by nonlinear differential equations *of the Volter-Lotka type.*

In our section on zero-sum games, It was shown that the expected value of the game for the case of mixed strategies was given by the mathematical expression

$$E(P, Q) = \sum_{ij} p_i a_{ij} q_j$$

with a_{ij} *the pay-off matrix and* $\{p_i\}$, $\{q_j\}$ *the strategies (probability patterns) of the two players. When applying the theory to evolutionary biological systems, one must interpret the relevant entities in accord with the following "dictionary":*

probabilities	$\longrightarrow$	*frequencies of phenotypes in the population, or of behavioral strategies for given phenotype*
pay off matrix	$\longrightarrow$	*Darwinian fitness; eventually manifested in the number of offsprings*
Realization of strategy	$\longrightarrow$	*phenotype (behavioral pattern determined by the genes or genotype)*
Pure strategy	$\longrightarrow$	*(e.g.:'produce only sons', 'produce only daughters' in the sex-ratio game.)*

Assume a population divided into n *phenotypes* $E_1, E_2, ..., E_n$ *with time-dependent frequencies* $x_1(t), x_2(t), \ldots, x_n(t)$. E_i *corresponds to a (pure or mixed) strategy, and its fitness* f_i *will be a function of the state* $\boldsymbol{x}(x_1, x_2, \ldots, x_n)$ *of the population.*

If the population is very large, and if the generations blend continually into each other, we may assume that the state $\boldsymbol{x}(t)$ *is a differentiable function of* t*. The fractional rate of increase* $\frac{\dot{x}_i}{x_i}$ *of the phenotype* E_i *is a measure of its evolutionary success. Following the basic ideas of Darwinism, we may express this success metric as the difference between the fitness* $f_i(\boldsymbol{x})$ *of* E_i *and the average fitness*

$$\overline{f}(\boldsymbol{x}) = \sum x_i f_i(\boldsymbol{x})$$

of the population (i.e., the so-called field of game theory). Thus we obtain

$$\dot{x}_i = x_i \left[f_i(\boldsymbol{x}) - \overline{f}(\boldsymbol{x}) \right], \quad i = 1, 2, ..., n.$$

This model does not explicitly treat sexual reproduction, which – together with competition, cooperation and conflict, is implicitly encoded within the f_i functions.

Consider a linear game with n strategies (i.e phenotypes) and pay-off matrix U. The pay-off for a "strategist" (category of phenotype) with genotype–determined strategy vector $\boldsymbol{p}^i$ in a field $\boldsymbol{p}^j$ opponents is

$$a_{ij} = \boldsymbol{p}^i \cdot U\boldsymbol{p}^j$$

and the fitness $f_i(\boldsymbol{x})$ of the phenotype E_i is the superposition (mean) expressed by

$$f_i(\boldsymbol{x}) = \sum_j a_{ij}x_j = (A\boldsymbol{x})_i$$

where A is the $n \times n$ fitness pay-off matrix. The differential equations for the linear game are then

$$\dot{x}_i = x_i\left[(A\boldsymbol{x})_i - \boldsymbol{x}A\boldsymbol{x}\right], \qquad i = 1, 2, 3, ..., n$$

In the case $n = 2$, by setting $x = x_1$ and $1 - x_1 = x_2$ we obtain

$$\dot{x} = x(1-x)\left[(A\boldsymbol{x})_1 - (A\boldsymbol{x})_2\right].$$

If $a_{ij} = -a_{ji}$ hold for all i and j, the game is a zero-sum game. In that case $\dot{x}_i = x_i(Ax)_i$.

Conflicts among animals (especially with heavily armed species) are often settled by displays rather then all out fighting, with escalated contests rare. The following thought experiment explains the high frequency of conventional contests, and with it evolutionary stability*, in terms of game theory.*

Consider a conflict between males and females concerning their respective share in parental investment*.*

In many species, raising an offspring requires a considerable amount of time and energy. Each parent might attempt to reduce its own share at the expense of the other. The outcome might depend on which sex is in a position to desert first. Whenever fertilization is internal, for example, females risk being deserted even before giving birth to the offspring. The game is still further "rigged" against females by the fact that they produce relatively few, large gametes, and males many small ones. Females are thereby much more committed and can less afford to lose an offspring. Thus males are in many cases in a better position to desert. They can invest the corresponding gain in *time and energy into increasing the number of their offsprings with the help of new mates*[625]*.*

The female counterstrategy is "coyness", i.e. the insistence upon a long engagement period before copulation. Rather than undergoing a second costly engagement (for which it might be too late in the mating season), males would do better to stay faithfully home and help raise their offspring. Roughly speaking, in a population of coy females, males would have to be faithful.

Among faithful males, it would not pay a female to be coy, however: the long engagement period is an unnecessary cost. Thus the proportion of "fast" females would grow. But then "philandering" males will have their chance and spread. Females, therefore, would do well to be coy. The argument thus runs full circle.

In order to model this game theoretically, let us assume that there are two phenotypes in the male population X*, namely* E_1 *("philandering") and* E_2 *("faithful"), with frequencies* x_1 *and* x_2*; and two phenotypes in the female population* Y*, namely* F_1 *("coy") and* F_2 *("fast") with frequencies* y_1 *and* y_2*. Let us suppose that the successful raising of an offspring increases the fitness of both parents by* G*. The parental investment* C *will be entirely borne by the female if the male deserts. Otherwise, it is shared equally by both parents. A long engagement period represents a cost* E *to both partners.*

If a "faithful" male mates with a "coy" female, the pay-off is $(G - \frac{C}{2} - E)$ *for both. A "faithful" male and a "fast" female skip the engagement cost and their pay-off is* $(G - \frac{C}{2})$*.*

But a "philandering" male meeting a "fast" female makes off with G*, while her payoff is* $G - C$*. Finally, if a "philandering" male encounters a "coy" female nothing much happens and their payoff for both is zero. The male (*A*) and female (*B*) payoff matrices therefore are*

$$A = \begin{bmatrix} 0 & G \\ G - \frac{C}{2} - E & G - \frac{C}{2} \end{bmatrix}; \quad B = \begin{bmatrix} 0 & G - \frac{C}{2} - E \\ G - C & G - \frac{C}{2} \end{bmatrix};$$

where: the rows of A *and columns of* B *are, in order,* E_1 *and* E_2*; whilst the columns of* A *and rows of* B *are the two female categories (*F_1 *and* F_2*).*

No pair of male and female phenotypes is evolutionary stable in conjunction. There does, however, exist a unique pair of mixed strategies $\boldsymbol{p}$ *and* $\boldsymbol{q}$

[625] The underlying assumption is that each individual's behavior aims – or is genetically programmed – to maximize his or her progeny. The genotypes *not* resulting in such a drive tend, of course, to have their frequencies severely curtailed over the generations.

(of males and females, respectively) in Nash equilibrium. It is given by the solution of

$$a_{11}q_1 + a_{12}q_2 = a_{21}q_1 + a_{22}q_2 \qquad (q_2 = 1 - q_1)$$

$$b_{11}p_1 + b_{12}p_2 = b_{21}p_1 + b_{22}p_2 \qquad (p_2 = 1 - p_1)$$

i.e. by

$$p_1 = \frac{E}{C - G + E}\,, \qquad q_1 = \frac{C}{2(G - E)}\,.$$

This equilibrium is not stable. If a fluctuation decreases the frequency of philandering males, then the payoff of the males will not change; each phenotype has the same payoff, which depends only on the state of the female population. One cannot expect the frequency of philanderers to return to p_1.

As to the female population, their payoff will even increase but "fast" females gain more than "coy" ones since their risk of being deserted decreases. It is only when the "fast" female population increases that the male payoff changes. Again, they increase: but philanderers gain more than faithful males; hence more philanderers, hence more coy females, hence fewer philanderers, and so on.

This looks like an oscillating system. The appropriate differential equations are

$$\begin{aligned} \dot{x} &= x(1-x)\left[\frac{C}{2} - (G-E)y\right] \\ \dot{y} &= y(1-y)\left[-E + (C+E-G)x\right] \end{aligned}$$

This resembles a Volterra-Lotka prey-predator system

$$[\dot{x} = x(a - by); \qquad \dot{y} = y(-c + dx)]$$

and, like it, is doomed to perpetual oscillations.

Example 4: The Voter's Paradox - or, is Democracy mathematically Sound?

In the following we review the applications of Game Theory to the social sciences from ***Condorcet*** *(1788) to* ***Arrow*** *(1951).*

Much of the economic and social behavior in which we are interested is either ***group behavior*** *or that of an individual acting for a group. Group preferences may be regarded either as derived from individual preferences by some process of aggregation or as a direct attribute of the group itself.*

Game-theoretic methods provide an intriguing alternative to treating a group as though it were a sentient individual: we can cast the members of the group as players in an internal organizational subgame, vying for control of the group's action in the larger game.

As early as 1785, the French mathematician ***Marie-Jean-Antoine-Nicolas Caritat*** *(****Marquis de Condorcet****) discovered that society often has collective preferences that, if held by an individual, would be dismissed as irrational.*

This is the famous Voter's Paradox: three individuals use simple majority rule to decide what to do as a group. Their personal preferences orderings are

First individual: $A > B > C$
Second individual: $C > A > B$
Third individual: $B > C > A$

In this example, if the choice is between policies A *and* B*, then the group will choose* A *by a* $2:1$ *vote. Similarly, they will choose* B *over* C*, and* C *over* A*. hence the preferences of the group are described by the relations*

$$A > B, \qquad B > C, \qquad C > A$$

But this relation is not transitive! Hence a group utility scale cannot be constructed. Given that all possible individual preferences are equally likely, the chance of intransitivity is $\frac{12}{3!^3} \approx 5.6$ *percent. This may not seem like much, but one must keep in mind that this percentage is only for the simplest case of three people and three alternatives. It turns out that the probability increase both as the number of alternatives increases and as the number of voters increase (being more sensitive to the number of alternatives) as the following table show:*

NUMBER OF ALTERNATIVES	NUMBER OF VOTERS					
	3	*5*	*7*	*9*	*11*	∞
3	5.6%	6.9%	7.5%	7.8%	8.0%	8.0%
4	11.1%	13.9%	15.0%	15.6%	16.0%	17.6%
5	16.0%	20.0%	21.5%	23.0%	25.1%	25.1%
6	20.2%	25.5%	25.8 %	28.4%	29.4%	31.5%
7	23.9%	29.9%	30.5%	34.2%	34.3%	36.9%
∞	100.0%	100.0%	100.0%	100.0%	100.0%	100.0%

Clearly, group preferences come solely from the preferences of the individuals, unless one wishes other considerations to enter. In either case there is one simple and compelling condition called the principle of unanimity or the ***Pareto*** *Principle: If every member of the group prefers x to y, then the group itself, in its corporate judgment, also prefers x to y.*

This principle, obvious thought it may appear, has some far-reaching logical consequences. In some settings it may even lead to transitivity for the group preferences relation, contrary to what the Voters' Paradox would lead us to expect.

Building upon Condorcet's Voters' Paradox and the Pareto Principle, ***Kenneth Arrow*** *(1951) astounded mathematicians and economists alike with his "impossibility theorem" - a landmark in the application of rigorous mathematical methods to the social sciences.*

The thrust of the theorem is that no mathematical function exists that satisfies all of a certain set of arguably reasonable or desirable properties (restrictions); These are: monotonicity, independence, unanimity (Pareto Principle) *and nondictatorship. An immediate corollary of this theorem is the statement that any conceivable democratic voting system can yield undemocratic result*[626].

626 Arrow's unsettling game-theoretic demonstration was commented on by **Paul Samuelson** (1952) in these words: "The search of the great minds of recorded history for perfect democracy, is the search for a chimera, for a logical self-contradiction. Now scholars all over the world – in mathematics, politics, philosophy, and economics – are trying to salvage what can be salvaged from Arrow's devastating discovery that is to mathematical politics what **Kurt Gödel**'s (1931) impossibility-of-proving-consistency theorem is to mathematical logic." Arrow's demonstration helped earn him the Nobel Prize in economics (1972). It is one of the earliest astonishing results in game theory.

Conflicts between individual and group behavior, already encountered earlier, has an interesting analogue in sociology *through the bizarre phenomenon of* altruism*, which is a particular challenge to theories of evolution by* natural selection*.*

An animal behaves in a altruistic *way if it promotes the welfare of another at the expense of it's own. This seems difficult to reconcile with the notion of survival value, but it occurs nevertheless — and indeed quite frequently. The alarm call which warns a flock but attracts the attention of the predator upon the caller, is a common example. True, a group may benefit from altruistic traits among its members: it reduces the probability of extinction of the group. But selection at the group level is, as a rule, slow and much less effective than on the level of the individual: if a mutant gene, promoting altruistic behavior reduces the fitness of it's carrier, it will tend to be eliminated in spite of the boost it provides for the group. One must therefore find explanations in terms of* gene selection *and individual survival values. One such explanation is* kin selection: *a gene complex programming altruistic acts which benefit* relatives *may spread because it occurs, with a certain probability, amongst relatives whose overall (familial) reproductive success is thereby increased.*

Apart from this genetic *explanation there is a* strategic *explanation, which claims that in certain situations an altruistic act may increase the reproductive success of the individual performing it;* Game-theoretical *considerations show that conflicting interests can lead to the evolution of stable and apparently cooperative traits of behavior (e.g., wolves refrain from dealing the killing bite if their opponent offers his throat in a gesture of surrender). This strategic explanation relies on the notion of* frequency-dependent fitness: *the fitness of an individual may depend on what the* others *are doing.*

Finally, an economic *explanation relies on the notion of* reciprocal altruism; *e.g. unrelated young male baboons team up – while one of them mounts a female, the other one fights off its consort. The roles are reversed on a later occasion.*

Consider the voting system consisting of a plurality election *followed by a runoff between the top two vote getters out of three candidates. Suppose the votes of 17 voters distribute as follows:*

Class	Number of votes	Preferences (Best to worse)		
I	6	A	B	C
II	5	C	A	B
III	4	B	C	A
IV	2	B	A	C

If all the voters vote sincerely, and do not change their preference rankings, A (with 6 votes) and B (also with 6) will end up in the runoff, which A will win, 11 votes to 6.

Now imagine that the preferences are the same, except that the last class of voters elevate A from second choice to first choice:

Class	Number of votes	Preferences (Best to worse)		
I	*6*	*A*	*B*	*C*
II	*5*	*C*	*A*	*B*
III	*4*	*B*	*C*	*A*
IV	*2*	*A*	*B*	*C*

On the first ballot, A (8 votes) and C (5 votes) make the runoff. But A then loses, 8 votes to 9, because B's 4 supporters switch to C. Thus A's increased support has perversely torpedoed his victory! We witness here a situation where a candidate may be hurt if he receives additional votes: more votes can make a winner a looser! Similar situation arises in a straightforward plurality election without a runoff when public announcement of how candidates fared in a preelection are made.

Other methods of voting, such as the "Hare voting system"[627]*, are also not immune to perverse results. It can be shown that in the Hare system, a candidate who wins in two separate districts can loose in a combined tally of the two districts!*

---

[627] Advocated by **Thomas Hare** (1806–1891). English reformer and barrister. Best known for his proposed election system, giving each class of votes in the electorate a representation in proportion to its numerical strength (1858). Defined a *quota* as the greatest integer less then $\left[1+\frac{V}{n+1}\right]$, where V is the number of voters and n the number of open seats. Each voter lists a number of m candidates in his own order of preference. The first -choice votes are tabulated and the candidates who achieve the quota are the winners.

If, however, a candidate does not meet the quota, the least popular candidate on the first-preference list is eliminated and his/her supporters transfer their votes to the next higher choice from bottom. If this transfer causes another candidate to meet the quota, he is elected. If seats remain unfilled, the process continues until all the seats are filled. If at any point there is an open seat but no surplus of votes to transfer, the process continues until the candidates with lowest number of votes is eliminated and his supporters simply transfer their votes to their next-higher choice who still is in the race. The idea is that no vote should be wasted.

1926–1946 CE **Douglas Rayner Hartree**[628] (1897–1958, England). Applied mathematician. Developed ingenious approximation methods for the calculation of atomic wavefunctions of many-electron atoms[629]. He also applied his methods of numerical analysis to problems in ballistics, atmospheric physics, hydrodynamics and control of chemical engineering processes. Much of his work was of importance to Britain's war effort (1939–1945). Hartree was one of the first (1945) to use the electronic computer (ENIAC = Electric Numerical Integrator and Calculator) as a general-purpose computer.

Hartree was born in Cambridge and received his higher education there. During 1929–1937 he held the chair of applied mathematics at the University of Manchester. From 1946 until his death Hartree was Plummer professor of mathematical physics at Cambridge University.

1926–1949 CE **Pascual** (**Ernst**) **Jordan** (1902–1980, Germany). Physicist. Founded, with **Max Born** and **Werner Heisenberg**, quantum matrix mechanics. In 1949, Jordan suggested a cosmological model of '*creation out of nothing*', such that the sum of the mass-energy in the universe is *always* zero.

Jordan was a professor of theoretical physics in Rostock, Germany (1929–1944) and after 1947 in Hamburg.

---

628 For further reading, see:

- Hartree, D.R., *The Calculations of Atomic Structures*, John Wiley & Sons: New York, 1957, 181 pp.

629 In the *Hartree approximation* (1928) it is assumed that each electron moves in a central field that can be calculated from the nuclear potential and the wave functions of all the other electrons, by assuming that the charge density associated with an electron is (-e) times its position probability density. The Schrödinger equation is then solved for each electron in its own central field. Clearly, the approximation neglects correlations between the position of the electrons, since the entire wave function for all electrons is assumed to be a simple product of one-electron functions (but antisymmetrized in spin and spatial dependence, to confirm to Pauli's exclusion principle). From the atomic wave-functions it is possible to calculate the average distribution of negative electronic charge as a function of distance from the nucleus, which in turn determine the self-consistent electrostatic potential in which each electron orbital evolves. These charge distributions are of great importance in the theoretical calculation of macroscopic properties of matter.

Table 5.6: The magnificent Hungarians (1832–1994)

When Nobel Laureate Enrico Fermi was asked if he believed in extraterrestrials, he replied: "They are already here... they are called Hungarians!" The following list of 33 scientists, mathematicians and engineers provides the answer: [(∗) = Jewish]

Name	Life-span	Years of peak activity	Nobel prize	Field	Detail
Janos Bolyai	1802–1860	1832		Mathematics	Non-Euclidean hyperbolic geometry
Joseph Petzval	1807–1891	1840		Optics	Precision optical systems

Quaternions and Spinors: Hamilton to Pauli[630] *(1843–1927)*

If one tries to define three–dimensional vector division by seeking a vector $\boldsymbol{C}$ *such that* $\boldsymbol{B} \times \boldsymbol{C} = \boldsymbol{A}$ (or $\boldsymbol{C} \times \boldsymbol{B} = \boldsymbol{A}$), *for two given vectors* $\boldsymbol{A}$ and $\boldsymbol{B}$, *one discovers that this operation is:*

(I) well-defined only when $\boldsymbol{A} \cdot \boldsymbol{B} = 0$*;*

(II) non-unique, on account of the identity $\boldsymbol{B} \times \boldsymbol{C} = \boldsymbol{B} \times (\boldsymbol{C} - \alpha \boldsymbol{B})$.

It was this effort, to extend 3*-dimensional vector analysis to include both multiplication and division, which led* **Hamilton** *(1843) to invent a new division algebra for quadruples of numbers.*

Hamilton considered a 4*-dimensional real vector space with abstract unit base elements* $\{e_0, e_1, e_2, e_3\}$. *A general vector in this space, known as a quaternion, is written in the form*

$$q = q_0 e_0 + (q_1 e_1 + q_2 e_2 + q_3 e_3) = q_0 e_0 + \boldsymbol{q}.$$

with $q_0, \boldsymbol{q}$ *real.*

Quaternions obey the rules of ordinary algebra w.r.t. addition and scalar (in this case, real number) multiplication. With the definitions

$$e_1^2 = e_2^2 = e_3^2 = -e_0, \quad e_1 e_2 = -e_2 e_1 = e_3,$$

$$e_0^2 = e_0; \quad e_2 e_3 = -e_3 e_2 = e_1,$$

$$e_3 e_1 = -e_1 e_3 = e_2, \quad e_k e_0 = e_0 e_k = e_k, \quad k = 1, 2, 3$$

the product of two quaternions assumes the form

$$pq = (p_0 q_0 - \boldsymbol{p} \cdot \boldsymbol{q}) e_0 + p_0 \boldsymbol{q} + q_0 \boldsymbol{p} + (\boldsymbol{p} \times \boldsymbol{q}).$$

This reduces to the ordinary vector cross-product for $p_0 = q_0 \equiv 0$, *if we ignore the invariant part (scalar product) of the total product. If on the*

---

[630] For further reading, see:

- Cartan, E., *The Theory of Spinors*, Dover, 1966, 157 pp.
- Altmann, S.L., *Rotations, Quaternions and Double Groups*, Dover, 2005, 317 pp.

other hand $p_2 = q_2 = p_3 = q_3 \equiv 0$, $e_0 = 1$, $e_1 = \sqrt{-1}$, *it reduces to the complex multiplication of* $p_0 + ip_1$ *and* $q_0 + iq_1$.

Quaternions can thus be viewed as 4-dimensional numbers forming a vector space generated by unity $(e_0 = 1)$ *and three other base vectors, each of the latter being an independent square root of* -1. *We shall soon see that this number system provides a description of rotation in 3-dimensions, just as ordinary complex numbers do in 2 dimensions.*

This is achieved at the cost of sacrificing the law of commutative multiplication (since $e_1e_2 = -e_2e_1$, *etc.).*

Division of quaternions is realized through the definition of the inverse quaternion

$$q^{-1} = \frac{q_0e_0 - \boldsymbol{q}}{q_0^2 + q_1^2 + q_2^2 + q_3^2},$$

yielding $qq^{-1} = e_0$. *Thus, quaternions form a non-commutative division algebra over the real numbers.*

The further useful definitions

$$\boldsymbol{n} = \frac{q_1e_1 + q_2e_2 + q_3e_3}{\sqrt{q_1^2 + q_2^2 + q_3^2}} \qquad (\boldsymbol{n}^2 = -e_0),$$

$$q_0 = h\cos\frac{\varphi}{2}, \qquad \sqrt{q_1^2 + q_2^2 + q_3^2} = h\sin\frac{\varphi}{2},$$

$$h = \sqrt{q_0^2 + q_1^2 + q_2^2 + q_3^2}$$

reduce every quaternion to the standard form

$$q = h\left(\cos\frac{\varphi}{2}e_0 + \sin\frac{\varphi}{2}\boldsymbol{n}\right).$$

It then follows that

$$q\boldsymbol{r}q^{-1} = \mathfrak{R}\cdot\boldsymbol{r}, \qquad \text{for all} \quad \boldsymbol{r} = x\boldsymbol{e}_1 + y\boldsymbol{e}_2 + z\boldsymbol{e}_3$$

where $\mathfrak{R}$ *is a q-dependent orthogonal, real* 3×3 *matrix that represents a rotation of the axes by an angle* φ *about the axis* $\boldsymbol{n}$ *relative to the fixed axes* $\{\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$.

In fact, it turns out that one can set up a $2{:}\,1$ *correspondence between unit modulus* $(h = 1)$ *quaternions and the continuous Lie–group of finite* *rotations, in the sense that for every pair* $\pm q$ *of unit-modulus quaternions we can generate a distinct rotation about the axis* $\boldsymbol{n}$ *defined above, by an angle*

$$\varphi = 2\tan^{-1}\left\{\frac{1}{q_0}\sqrt{q_1^2+q_2^2+q_3^2}\right\}$$

[e.g. $q = \frac{e_0+e_3}{\sqrt{2}}$ *represents a rotation by* 90° *about the* z*-axis].*

So far we have not specified the nature of the abstract base elements $\{e_0, e_1, e_2, e_3\}$, *except through their 'multiplication table'. We saw, however, that in two limiting cases they can assume either the role of unit vectors in the 3-dimensional Euclidean vector space* $\mathbb{R}^3$ $(e_1 = \boldsymbol{e}_1,\ e_2 = \boldsymbol{e}_2,\ e_3 = \boldsymbol{e}_3)$ *or unit complex numbers in* $(e_0 = 1,\ e_1 = i)$.

Another interesting case arises when we represent the base elements as 2×2 *matrices such that:*

$$e_0 = \begin{bmatrix}1 & 0\\ 0 & 1\end{bmatrix} \equiv I,$$

$$e_1 = -i\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix} \equiv -i\sigma_1,$$

$$e_2 = -i\begin{bmatrix}0 & -i\\ i & 0\end{bmatrix} \equiv -i\sigma_2,$$

$$e_3 = -i\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix} \equiv -i\sigma_3,$$

where $\boldsymbol{\sigma} = \{\sigma_1, \sigma_2, \sigma_3\}$ *later became known as the* 3 *Pauli matrices (in the context of quantum mechanics). These* e_i *matrices obey the quaternionic laws of multiplication. The Pauli matrices are Hermitian*[631] $(\sigma_i^\dagger = \sigma_i)$ *and traceless.*

Keeping this in mind, we can write the standard form of a unit-modulus quaternion as

$$q(\boldsymbol{n}, \varphi) = I\cos\frac{\varphi}{2} - i\sin\frac{\varphi}{2}(\boldsymbol{\sigma}\cdot\boldsymbol{n}),$$

---

631 $A^\dagger \equiv$ transpose of the element–wise complex conjugate of A, for any complex matrix A.

where

$$\boldsymbol{\sigma}\cdot\boldsymbol{n} = \begin{bmatrix} n_3 & n_1 - in_2 \\ n_1 + in_2 & -n_3 \end{bmatrix}$$

and $(\boldsymbol{n}, \varphi)$ *are, as before, the (real) parameters of a rotation of the axes about the unit vector* $\boldsymbol{n}$ *with an angle* φ.

Any such rotation can be decomposed into 3 successive rotations by Euler angles (α, β, γ) *about the respective fixed-space axes* $\{\boldsymbol{e}_z, \boldsymbol{e}_y, \boldsymbol{e}_z\}$, *and indeed we find that*

$$q(\boldsymbol{n}, \varphi) = q(\boldsymbol{e}_z, \alpha) q(\boldsymbol{e}_y, \beta) q(\boldsymbol{e}_z, \gamma) =$$

$$\begin{bmatrix} e^{-i\frac{\alpha}{2}} & 0 \\ 0 & e^{+i\frac{\alpha}{2}} \end{bmatrix} \begin{bmatrix} \cos\frac{\beta}{2} & -\sin\frac{\beta}{2} \\ \sin\frac{\beta}{2} & \cos\frac{\beta}{2} \end{bmatrix} \begin{bmatrix} e^{-i\frac{\gamma}{2}} & 0 \\ 0 & e^{+i\frac{\gamma}{2}} \end{bmatrix} =$$

$$\begin{bmatrix} \cos\frac{\beta}{2} e^{-\frac{i}{2}(\gamma+\alpha)} & -\sin\frac{\beta}{2} e^{\frac{i}{2}(\gamma-\alpha)} \\ \sin\frac{\beta}{2} e^{-\frac{i}{2}(\gamma-\alpha)} & \cos\frac{\beta}{2} e^{\frac{i}{2}(\gamma+\alpha)} \end{bmatrix} = \begin{bmatrix} q_0 - iq_3 & -(q_2 + iq_1) \\ q_2 - iq_1 & q_0 + iq_3 \end{bmatrix}$$

which is the most general 2×2 *complex, unimodular (unit–determinant) and unitary matrix. If we shift* φ *to* $\varphi + 2\pi$ *(or by any odd multiple of* 2π*),* $\mathfrak{R}(\boldsymbol{n}, \varphi)$ *remains the same while* $q(\boldsymbol{n}, \varphi)$ *changes its sign. Thus, the quaternions* $\pm q$ *represent the same 3D rotation, and the* $2 \leftrightarrow 1$ *correspondence between unimodular quaternions and 3D rotations is thereby established.*

Spinors in 3 Dimensions (Pauli)

We have seen that the relations $\boldsymbol{r}' = \mathfrak{R}\cdot\boldsymbol{r}$ *and* $\boldsymbol{r}' = q\boldsymbol{r}q^\dagger$ *(since* $q^{-1} = q^\dagger$ *– in other words q is* unitary*) represent the* same *rotation, if one uses the base quaternions (*$e_k = -i\sigma_k; \quad k = 1,2,3$*) as unit basis vectors in 3D space. The quaternion relation can be put in a convenient form that involves multiplication of* 2×2 *matrices:*

$$S' = USU^\dagger, \qquad S = \begin{bmatrix} z & x - iy \\ x + iy & -z \end{bmatrix}$$

Let U^i_j *denote the* (i,j) *element of the unitary matrix* $q(\boldsymbol{n}, \varphi)$. *Denoting the elements of S by* $S^{k\ell}$, *and carrying out the matrix multiplication, we find the explicit transformation equations (a bar represents complex conjugation)*

$$
\begin{aligned}
S^{11\prime} &= U_1^1\overline{U}_1^1S^{11} + U_2^1\overline{U}_1^1S^{21} + U_1^1\overline{U}_2^1S^{12} + U_2^1\overline{U}_2^1S^{22} \\
S^{21\prime} &= U_1^2\overline{U}_1^1S^{11} + U_2^2\overline{U}_1^1S^{21} + U_1^2\overline{U}_2^1S^{12} + U_2^2\overline{U}_2^1S^{22} \\
S^{12\prime} &= U_1^1\overline{U}_1^2S^{11} + U_2^1\overline{U}_1^2S^{21} + U_1^1\overline{U}_2^2S^{12} + U_2^1\overline{U}_2^2S^{22} \\
S^{22\prime} &= U_1^2\overline{U}_1^2S^{11} + U_2^2\overline{U}_1^2S^{21} + U_1^2\overline{U}_2^2S^{12} + U_2^2\overline{U}_2^2S^{22}.
\end{aligned}
$$

Now we recall that under a rotation of the axes $\mathfrak{R}$, *the components of a vector transforms as* $\boldsymbol{r}' = \mathfrak{R}\cdot\boldsymbol{r}$, *while the components of a second rank tensor* $\mathfrak{T}$ *(represented as a matrix) transform according to* $\mathfrak{T}' = \mathfrak{R}\cdot\mathfrak{T}\cdot\mathfrak{R}^T$. *We may then draw an immediate analogy to* $S' = USU^\dagger$, *and posit a two component complex entity* ξ *(analogous to a vector* $\boldsymbol{r}$ *in 3D) that transforms according to the law*

$$\xi' = U\xi,$$

or explicitly

$$\begin{bmatrix}\xi^{1\prime}\\ \xi^{2\prime}\end{bmatrix} = \begin{bmatrix}U_1^1 & U_2^1\\ U_1^2 & U_2^2\end{bmatrix}\begin{bmatrix}\xi^1\\ \xi^2\end{bmatrix}.$$

Let another entity

$$\eta = \begin{bmatrix}\eta^1\\ \eta^2\end{bmatrix}$$

transform according to the different law $\eta' = \overline{U}\eta$. *We can then form Cartesian (tensor) products which transform as:*

$$
\begin{aligned}
\xi^{1\prime}\eta^{1\prime} &= (U_1^1\xi^1 + U_2^1\xi^2)(\overline{U}_1^1\eta^1 + \overline{U}_2^1\eta^2) \\
&= U_1^1\overline{U}_1^1(\xi^1\eta^1) + U_2^1\overline{U}_1^1(\xi^2\eta^1) + U_1^1\overline{U}_2^1(\xi^1\eta^2) + U_2^1\overline{U}_2^1(\xi^2\eta^2),
\end{aligned}
$$

etc.

Comparing this, term by term, with the laws of transformation of S^{AB}, *we find that* $\xi^A\eta^B$ *transform in exactly the same way; here* $A, B = 1, 2$.

Since S *is also a* 3*D vector, we may call* ξ^A *and* η^B semi-vectors, *since the transformation law of* S *was* split *into two separate transformation laws*

$$\xi'^A = U_B^A\xi^B, \quad \eta'^A = \overline{U}_B^A\eta^B,$$

where U is a unitary 2×2 matrix $(U^{-1}=\overline{U}^T)$ and the summation convention is employed for repeating indices. In terms of the Euler angles, the transformation law of ξ (for example) is

$$\begin{bmatrix}\xi^{1'}\\ \xi^{2'}\end{bmatrix}=\begin{bmatrix}\cos\frac{\beta}{2}e^{-\frac{i}{2}(\gamma+\alpha)} & -\sin\frac{\beta}{2}e^{\frac{i}{2}(\gamma-\alpha)}\\ \sin\frac{\beta}{2}e^{-\frac{i}{2}(\gamma-\alpha)} & \cos\frac{\beta}{2}e^{\frac{i}{2}(\gamma+\alpha)}\end{bmatrix}\begin{bmatrix}\xi^1\\ \xi^2\end{bmatrix}.$$

The norm of ξ is defined as

$$\xi^1\overline{\xi}^1+\xi^2\overline{\xi}^2=\xi^{1'}\overline{\xi}^{1'}+\xi^{2'}\overline{\xi}^{2'}$$

and is invariant under rotations.

We can improve the above notation by using dotted index ($\dot{1},\dot{2}$, or $\dot{A},\dot{B}$ etc.) for the $\overline{U}$ – transforming semi–vectors, for then one may distinguish the two transformation laws at a glance. Thus for instance $\xi^{\bar{A}}=\bar{\xi}^{\dot{A}}$, where a dotted index[632] *is taken to mean that the spinor transforms via $\overline{U}$; it ranges over $(\dot{1},\dot{2})$, while A,B etc. take values $(1,2)$.*

---

[632] This notation was introduced in 1929 by **van der Waerden** (1903–1996) to accommodate 4-dimensional relativistic spinors and the action of rotations and Lorentz-transformations on them; in this case U is *not* necessarily unitary but is still unimodular (that is, $\det U=1$). In this application, there are *four* types of spinors and the algebraic notation requires both upper and lower indices, each dotted *or* undotted, with four types of transformation laws. Thus, similar to the practice in ordinary differential – geometric tensor algebra, one introduces covariant and contravariant components (of both dotted and undotted spinors). Raising and lowering of spinor indices is done by the skew-symmetric spinor metric (known as the *symplectic*)

$$\epsilon^{BA}=\epsilon_{AB}=\epsilon^{\dot{B}\dot{A}}=\epsilon_{\dot{A}\dot{B}}=\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}$$

which satisfies:

$$\epsilon_{AB}\epsilon^{BC}=\delta_A^C,\quad \epsilon_{\dot{A}\dot{B}}\epsilon^{\dot{B}\dot{C}}=\delta_{\dot{A}}^{C}=\delta_{\dot{A}}^{\dot{C}},$$
$$\epsilon_{AB}=-\epsilon_{BA},\quad \epsilon_{\dot{A}\dot{B}}=-\epsilon_{\dot{B}\dot{A}},$$
$$\xi^A=\epsilon^{AB}\xi_B,\quad \xi_B=\xi^A\epsilon_{BA},$$
$$\overline{\xi}^{\dot{A}}=\epsilon^{\dot{A}\dot{B}}\overline{\xi}_{\dot{B}},\quad \overline{\xi}_{\dot{B}}=\overline{\xi}^{\dot{A}}\epsilon_{\dot{B}\dot{A}}.$$

with δ_A^C, etc. representing the Kronecker delta. The scalar product of two

Having introduced spinors as building-block entities from which vectors can be constructed[633]*, one may ask whether one can construct a spinor from a given vector. The answer is that one* cannot *build a unique spinor from*

dotted or two undotted spinors may then be defined as

$$\phi_A\psi^A = -\phi^A\psi_A = \epsilon^{AB}\phi_A\psi_B = -\epsilon_{AB}\phi^A\psi^B,$$

$$\overline{\phi}_{\dot{A}}\overline{\psi}^{\dot{A}} = -\overline{\phi}^{\dot{A}}\overline{\psi}_{\dot{A}} = \epsilon^{\dot{A}\dot{B}}\overline{\phi}_{\dot{A}}\overline{\psi}_{\dot{B}} = -\epsilon_{\dot{A}\dot{B}}\overline{\phi}^{\dot{A}}\overline{\psi}^{\dot{B}}.$$

In particular we have

$$\phi_A\phi^A = [\xi_1 \quad \xi_2]\begin{bmatrix}0 & -1\\ 1 & 0\end{bmatrix}\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} = -\xi_1\xi_2 + \xi_2\xi_1 = 0.$$

In the 4D (Minkowski/STR) case the matrix $S = \boldsymbol{r}\cdot\boldsymbol{\sigma}$ is replaced with

$$S_{A\dot{B}} = c\,t\cdot I + \boldsymbol{r}\cdot\boldsymbol{\sigma} = \begin{bmatrix}ct+z & x-iy\\ x+iy & ct-z\end{bmatrix},$$

and its transformation law by

$$S'_{A\dot{B}} = U_A^C\, U_{\dot{B}}^{\dot{D}}\, S_{C\dot{D}} \quad ,$$

where U_A^C is the (A, C) component of a quaternion $q_0 - i\boldsymbol{q}\cdot\boldsymbol{\sigma}$ with complex $(q_0, \boldsymbol{q})$ (corresponding to complex Euler angles); the angles are *real* for pure 3D rotations, and *complex* for pure boosts (Lorentz transformation).

Returning to the case where U is both unimodular and unitary (representing 3D rotations), $\overline{\phi}^{\dot{1}}\psi^1 + \overline{\phi}^{\dot{2}}\psi^2$ invariant under the transformation, so we may identify, for any spinor, ϕ, $\phi_A = \xi_{\dot{A}}$, where ξ is a different spinor. Hence, only two types of indices arise for 3D rotations, but four kinds are needed to accommodate Lorentz transformations as well.

633 For any given spinor $\begin{bmatrix}a+ib\\ c+id\end{bmatrix} = \begin{bmatrix}u\\ v\end{bmatrix}$ with unit norm $(a^2+b^2+c^2+d^2=1)$, we may create the real unit vector $\left[2(ac+bd),\ \ 2(ad-bc),\ \ a^2+b^2-c^2-d^2\right]$. For example, $(0, 0, 1)$ is obtained from the spinor $\begin{bmatrix}1\\ 0\end{bmatrix}$ and also from $\begin{bmatrix}(1+i)/\sqrt{2}\\ 0\end{bmatrix}$. In general, from $u = u_0\cos\frac{\beta}{2}e^{-\frac{i}{2}(\gamma+\alpha)}$, $v = u_0\sin\frac{\beta}{2}e^{-\frac{i}{2}(\gamma-\alpha)}$, there emerges the vector $[u_0^2\sin\beta\cos\alpha,\ \ u_0^2\sin\beta\sin\alpha,\ \ u_0^2\cos\beta]$. Denoting $u_0^2 = S$, the length of the 3D position vector, the magnitude of the corresponding spinor must be $\sqrt{\overline{u}u+\overline{v}v} = \sqrt{S}$.

three given components of a single vector since a spinor is specified by 4 *real parameters, whereas a vector requires only* 3.

A simple geometrical description of a spinor can, however, be given, analogous to that of a vector. A vector can be visualized as an arrow of length R *and two polar angles* φ *(azimuth) and* θ *(colatitude) relative to some fixed axes.*

To visualize a spinor we may think of an axe, letting the handle *represent the magnitude* S *and direction* (θ, φ)*, just as the arrow does in the case of a vector. Once we have fixed these specifications, the axe still has one degree of freedom left, since it can still rotate about the axis of the handle.*

To fix this degree of freedom, we imagine a short line segment perpendicular to the handle at its tip and call it the blade*. The angular position is now measured as the angle* ψ *between the southbound local meridian [passing through the point* (θ, ψ) *on the unit sphere], directed from the north pole toward the south pole, and the blade itself.*

1927 CE **Eugène Freyssinet** (1879–1962, France). Civil engineer. Developed *prestressed concrete* and made it into a successful worldwide building material for bridges, shell roofs, airship hangars, concrete sea-going ships and mass-produced pylons.

1927 CE First actual transmission of television signals (New York to Washington) by the American Telephone and Telegraph Company.

1927 CE First transatlantic telephone service opened.

1927 CE **Bernardus (Dominicus Hubertus) Tellegen** (1900–1990, Holland). Engineer and inventor. Invented the *Pentode*: a 5-electrode electric vacuum tube. It was developed from the *tetrode* by inserting the fifth electrode, called the *suppressor grid* (or grid No 3) in order to avoid tetrode secondary emission which reduces plate current. The suppressor grid has negative voltage w.r.t. the other electrodes because it is connected directly to the cathode. When the electrons emitted from the cathode strike the anode plate, *secondary emission* will occur.

In the tetrode this secondary emission is attracted to the screen grid, creating a screen grid current. The negative voltage of the suppressor grid will push the secondary electrons back to the plate, thus eliminating the dip (kink) found in the voltage-current curve of the tetrode.

Consequently the pentode may be considered as a *constant-current device* over a wide range of plate voltages, with non-linear characteristics only below the knee of the curve.

Tellegen worked at the Phillips Research Laboratory and was a professor at the University of Delft.

1927–1928 CE **Warren Alvin Marrison** (1896–1980, U.S.A.) and **Joseph W. Horton** (U.S.A.) built the first clock based on a quartz crystal oscillator.

Marrison was born in Kingston, Ontario. After earning a Master's degree from Harvard (1921), he went to work for Western Electric in New York City, and then for Bell Laboratories in New Jersey (1925). During his career, he invented 65 patents.

Marrison and others demonstrated that the quartz oscillator used in this way was more accurate than the best existing mechanical clocks used in astronomical observatories as time standards. During the 1940s, time standard laboratories throughout the world switched from mechanical clocks to quartz. The fundamental standard of time remained the rotation of the earth relative to the stars, but quartz clocks confirmed that the earth was an unreliable timekeeper.

Today electronic watches, cell phones, computers and many other devices use the same timekeeping standard as Marrison's clock — the regular vibrations of a quartz crystal. The world's fundamental time standard, though, is now based on *atomic* clock.

1927–1929 CE **Martin Heidegger** (1889–1976, Germany). Metaphysical thinker. The founder of modern *existentialism*. Exercised a great influence on the philosophers of continental Europe, South America, and Japan. His work stimulated much that is original and compelling in modern thought.

Heidegger found the obscure and fragmentary writings of the *pre-Socratic* philosophers to be an agreeably, plastic sort of raw material for his speculations, which came to be expressed in an increasingly sibylline form.

His *Sein und Zeit* (1927), a 20^{th} century version of Kierkegaard's[634] anguished acknowledgment of the contingent and the irrational, was the most potent and influential presentation of the existentialism that dominated Europe in WWII and for some years thereafter.

[634] **Sören Kierkegaard** (1813–1855, Denmark). Religious philosopher and social thinker. Held that Christianity stands opposed to the world, to time, and to reason, and that the interminable paradoxes of life are the inevitable result of man's reflections.

Heidegger's work is an attempt to understand the nature of Being (*sein*). To this end he analyzed human existence (*Dasein*), because it is the form of Being we can best know. His extensive discussions of human existence emphasizes anxiety (*angst*), alienation and death. This particular kind of existence peculiar to human beings is what differentiates men from the inert material surroundings within which they find they have been arbitrarily 'thrown'; it is a condition characterized by anxious awareness of the future, and as containing both the necessity of choice and death, the cessation of being.

Most people distract their attention from the fact of death and extinction and trivialize their freedom of choice, satisfied to follow conventional routine. But authentic life is only possible if death is resolutely confronted and freedom exercised with a sense of its essentially creative nature.

The superficial, practical business of man has the effect of hiding Being from him, although it is always present and we can make ourselves 'open' to it. The basic mood of man is *anxiety*, and the fundamental structure of man is *concern*. Anxiety is caused by man's encountering the indeterminate and indefinable *nothingness*.

Man's life is oriented from a standpoint of his consciousness of death, which makes the difference in the choices an individual makes during life. Death is a singular experience in that each person must encounter his own, without any possibility of delegating it to another.

Man, being summoned by his consciousness to the numerous possibilities among which he may choose, experiences the frustrating awareness that whatever choice he makes leaves others behind. The realization of certain choices allows the unfulfilled choices to plague him with *guilt*. Guilt is an indelible quality of *Dasein*; human Beings always feel guilty.

However, despite his anxiety, guilt, finitude and the nothingness of the world, man's present existence can attain values by moving through time with *resoluteness* against his *background of historical fate*, i.e. gaining authentic existence by being prepared for anxiety.

In this state, which Heidegger calls *histericality*, the individual moves from the past into the future, being driven by the past and oriented by the future; the past is futural in the sense that it is not finished, because it holds future possibilities and things which bear repetition.

While Heidegger's philosophy itself is comprehensible and, in its psychological orientation, quite sensible — the method of presenting his philosophy is extremely abstract, complex and obscure: In his attempt to understand Being, he often sought philosophical enlightenment in the etymologies of words and the insights of poets, especially his favorite — **Friedrich Hölderlin** (1770–1843, Germany).

Heidegger was born in Messkirch, Baden-Württemburg, the son of a Catholic sexton. He entered the Jesuit order as a novice and later studied philosophy at the University of Freiburg under **Edmund Husserl**. Then became a professor at Marburg (1923–1927) and Freiburg (1927–1944), where he succeeded his old teacher.

Possessing a seductive classroom presence, he attracted Germany's brightest young intellects during the 1920's.[635] He was thus able to inspire gifted disciples who produced political theories very different from the ideology endorsed by the master. Yet troubling residues remain not far beneath the surface of their influential work[636].

In 1933, Heidegger cast his lot with National Socialism. He squelched the careers of Jewish students and denounced fellow professors whom he considered insufficiently radical. For years, he signed letters and opened lectures

[635] Many were Jews, who would ultimately have to reconcile their philosophical and, often, personal commitments to Heidegger with his nefarious political views. Four of his most influential students came to grip with his Nazi association and it affected their thinking: **Hannah Arendt** (1906–1975), who was Heidegger's lover as well as his student; **Karl Lowith** (1897–1973) returned to Germany in 1953; **Hans Jonas** (1903–1993) grew famous as Germany's premier philosopher of environmentalism; **Herbert Marcuse** (1898–1979) gained celebrity as mentor to the New Left. Why did these Heideggerians fail to see what was in Heidegger's heart and Germany's future? In his book "*Heidegger's Children*", **Richard Wolin** locates this paradox in the wider cruel irony that European Jews experienced their greatest calamity immediately following their fullest assimilation, and he finds in their responses answers to questions about the nature of existential disillusionment and junction between politics and ideas.
Another important student of Heidegger was **Hans-Georg Gadamer** (1900–2002), who elaborated on the subject of human understanding. In his book *Truth and Method* (1960) Gadamer argued that 'truth' and 'method' were at odd with each other. He maintained that people have a 'historically effected consciousness' (*wirkungsgeschichtliches Bewußtsein*) and that they are embedded in the particular history and culture that shaped them.

[636] Much of the damage that this intellectual poison – disseminated by Jewish and non-Jewish thinkers alike, all deeply influenced by Heidegger and ultimately Nietzsche – caused in post–WWII America, can be traced to failure to see the deep connection between German philosophy and the rise of Nazism. On this blinkered view, the only trouble with Weimar was that the wrong side just "happened" to win. According to **Leo Strauss** and his school, this enables a Weimar – like moral catastrophe to recur; the 1960's anarchy was one step down that road, while *post–modernism* and todays rampart moral relativism and appeasement of tyranny are another.

with "Heil Hitler!" He paid dues to the Nazi party until the bitter end. Equally problematic for his former students were his sordid efforts to make existential thought serviceable to Nazi ends, and his failure to ever renounce their actions.

Heidegger hailed Hitler as the great protagonist of a new European culture and leaned toward the socio-political views of the Third Reich. On the strength of these views he was made rector of Freiburg University (1933), but soon quarreled with his new masters, resigned and moved to Switzerland (1934).

Heidegger was an active and fanatic member of the Nazi party until the end of World War II. His involvement with the party and his support of its world-view are undisputed. Even more disturbing than his active participation in Nazism[637], Heidegger never attempted to account for his support of the Nazis outside of calling his involvement with them "a blunder".

Moreover, he never publicly condemned Hitler nor the horrible crimes of Nazi Germany against the Jews. In this light Heidegger stands as a great embarrassment for philosophers. The key focus of recent years, however, has been to decide whether or not his philosophy somehow reflects his political ideology, to see if *Being* and *Nazism* are somehow related. The most likely connection is his account of human beings.

If human beings are *Dasein*, meaning they have no common essence, then there is no reason to expect that a particular group of *Dasein* will respect the rights of another. The only sense of security a *Dasein* can attain, comes from their given society. Consequently, Heidegger's account of *Dasein* can lead to absolute nationalism. At this point we can only wait to see if Heidegger the philosopher can be salvaged from Heidegger the political figure; it might ultimately not be worth the effort.

After the war, Heidegger was prohibited from teaching until the ban was lifted in 1951.

---

[637] Heidegger used the phrase '*Verjudung*', coined by Hitler in his 'Mein Kampf'. He informed on **Staudinger** to the Gestapo and insisted that they take action against him. He also had great influence on a whole generation of young German students and mobilized them to the Nazi movement.

“We are constantly projecting ourselves into the future.”

1927–1931 CE **Georges Henri Lemaître** (1894–1966, Belgium). Astronomer and cosmologist. Proposed that the universe was created by an explosion of concentrated energy and may still be expanding. This became known as the '*Big Bang*' hypothesis. He inferred it from the instability of the static general-relativistic models of the universe. Thus (independently of **Friedmann**), he discovered the simplest family of solutions to **Einstein**'s field equations of relativistic gravitation (GTR) that describe the expanding universe.

Lemaître was educated as a civil engineer and served as an artillery officer in WWI. After the war he entered a seminary and in 1923 was ordained a priest. He studied at the University of Cambridge's solar physics laboratory (1923–1924) and then at the Massachusetts Institute of Technology, Cambridge, Massachusetts (1925–1927), where he became acquainted with the findings of the American astronomers **Edwin P. Hubble** and **Harlow Shapley** on the expanding universe.

In 1927, the year he became professor of astrophysics at the University of Louvain, he proposed his Big Bang theory, which explained the recession of the galaxies within the framework of **Einstein**'s theory of general relativity.

Models of the expanding universe had been considered earlier, notably by the Dutch astronomer **Willem de Sitter** (1872–1934) but Lemaître's theory — as modified (on the nuclear/particle physics side) by **George Gamow** (1904–1968) and by *inflationary* scenarios (1980's and 1990's), has explained much empirical data and thus became the leading theory of cosmology.

Cosmological solutions of Einstein equations

One can show that for a *homogeneous* and *isotropic* universe, the *pseudo-norm* line element ds^2 (proper–time interval squared) – encoding the space-time metric tensor – can be written as

$$ds^2 = c^2dt^2 - R^2(t)d\sigma^2, \qquad d\sigma^2 = \frac{dr^2 + r^2(d\theta^2 + \sin^2\theta d\varphi^2)}{(1+\frac{1}{4}\epsilon r^2)^2}$$

where ϵ can be always chosen 0 or ± 1. Here $R(t)$ is the *cosmic scale factor* as function of standard cosmic time, t; (r, θ, φ) are curved spherical coordinates on the spatial submanifolds ("slices") at fixed t, with the origin at $r = 0$. The range of r is $[0, 2)$, except when $\epsilon = 0$, for which case r may range from 0 to ∞.

This line element was first derived by **Howard Percy Robertson** (1903–1961, U.S.A.) and **Arthur Geoffrey Walker** (1909–2001, England), and is known as the

Friedmann–Robertson–Walker (FRW) metric (1935–1936). This metric holds for *every* homogeneous and isotropic spacetime, independently of whether Einstein's equations hold or not. In it, the scale factor $R(t)$ describes the universe's expansion. The true distance of a given galaxy from a galaxy fixed at the origin is $rR(t)$, where R increases with time [with $R(0) = 0$ for realistic solutions, where $t = 0$ at the initial Big Bang singularity]; r is a constant dimensionless parameter depending on the galaxy. If $\epsilon = 0$, the space is Euclidean, if $\epsilon = -1$ the space is "*hyperbolic*", while if $\epsilon = 1$, it is "*hyperspherical*". In the first two cases the universe is spatially infinite, and topologically a $t = const.$ "slice" of it is $\mathbb{R}^3$; while for $\epsilon = 1$ it is spatially finite, and constant-t slice is topologically 3-spheres (S^3).

We substitute the Friedmann–Robertson–Walker metric into Einstein's field equations

$$G_{\mu\nu} + \lambda g_{\mu\nu} = -kT_{\mu\nu}.$$

In the above equation $\mu, \nu = 0, 1, 2, 3$, $k = \frac{8\pi G}{c^2}$, G is the constant of universal gravitation, λ is the cosmological constant, $g_{\mu\nu}$ is the metric tensor, $G_{\mu\nu}$ is the Einstein tensor (related to the symmetric, rank-2 contracted (Ricci) curvature tensor), and $T_{\mu\nu}$ is the stress-energy-momentum tensor.

We then find for a pressure-free ("matter-dominated dust") universe that $R(t)$ must satisfy these two conditions:

$$M = \frac{4\pi}{3} R^3 \rho = \text{constant} > 0$$

with ρ the mass density in any of the locally-comoving (galaxy–centered) frames; and

$$\frac{1}{2}\left(\frac{dR}{dt}\right)^2 = \frac{GM}{R} + \frac{\lambda}{6} R^2 c^2 - \frac{1}{2}\epsilon c^2$$

(**Lemaître**, 1927).

The first condition means that the mass-energy of a sphere of radius R does not change as R increases with the expansion of the universe, i.e., no matter or energy is created out of nothing; instead, the density drops because of the expansion.

The second condition leads to a solvable ODE for $R(t)$[638]. Every solution of this equation represents a different model of the universe.

For *a static* universe

$$\frac{dR}{dt} = 0, \quad \epsilon = 1, \quad \lambda = \lambda_c = \frac{64\pi^2}{9k^2M^2}, \quad R_c = \frac{1}{\sqrt{\lambda_c}}$$

(**Einstein**, 1917).

Lemaître showed that this solution is unstable. Indeed, it is easy to show that if R (or λ) is slightly perturbed away from the value R_c (or λ_c), then $\frac{dR(t)}{dt}$, as calculated from the above ODE, will not remain zero but start increasing (or decreasing) with time at an ever faster rate. That is, the universe will either start expanding, or contracting, at a continuously accelerated rate.

Depending on the values of ϵ and $\lambda \neq 0$, there are two fundamental optional scenarios for an expanding universe:

- *Continuously expanding universe*: $\epsilon = 0,\ \lambda > 0$; $\epsilon = -1,\ \lambda > 0$; $\epsilon = 1,\ \lambda > \lambda_c$. The density of the universe tends to zero as $t \to \infty$ and its scale factor expands exponentially fast. This is the process thought to have occurred during the brief *inflationary period* in the particle physics era of the early universe (a small fraction of a second after $t = 0$). In the first case $R = R_0 \exp\left(\sqrt{\frac{\lambda}{3}}c\,t\right)$ in the zero–mass–density ($\rho \to 0$) limit (**de Sitter**, 1917].
- *Pulsating ("anti-de Sitter") universe*: $\epsilon = 0,\ \lambda < 0$; $\epsilon = -1,\ \lambda < 0$; or $\epsilon = 1,\ 0 < \lambda < \lambda_c$. The function $R(t)$ increases initially from zero up to a maximum value $R_{\max}$ and afterwards decreases to zero again.

For $\lambda = 0$ we have the following possibilities:

---

[638] Our universe at the present epoch is quite well approximated by a pressure-free self-gravitating dust, with galaxy clusters playing the role of 'dust particles'. It is only during the so-called 'radiation dominated' era (before the recombination of ionized matter into neutral hydrogen at ca 300,000 years after the Big-Bang) that pressure was cosmologically important. Exact Friedmann-Robertson-Walker solutions of Einstein's equations are also obtainable for the radiation-dominated universe. A pulsating universe *may* or *may not* "bounce" back from its final "Big Crunch" $R < 0$ singularity; if it does, the Big–Bang/expansion/contraction/Big Crunch cycle repeats ed infinitum, perhaps with random variations in each new repetition. Our present understanding of quantum gravity is too meager to tell what happens before a Big Bang (or after a Big Crunch) singularity.

1. The universe is pulsating if $\epsilon = 1$ (**Friedmann**, 1922).
2. The universe is continuously expanding if $\epsilon = 0$, or -1.

Thus, in this case, the spatial geometry of the universe is clearly correlated to whether the universe is expanding continuously or pulsating; it may be hyperbolic $(\epsilon = -1)$ or spatially Euclidean $(\epsilon = 0)$ and continuously expanding, or else it is hyperspherical $(\epsilon = 1)$, and pulsating. The universe is spatially *infinite* in the first case, and finite without boundaries in the second. (The case of a Euclidean universe $(\epsilon = 0)$, which is continuously expanding, is a limiting special case of the hyperbolic universe.)

The light which comes to earth from a galaxy follows a *null geodesic* along which $ds = 0$ and $d\theta = d\varphi = 0$. (in the Milky-Way centered frame). The Friedmann–Robertson–Walker line element equation then yields

$$0 = c^2 dt^2 - \frac{R^2(t) dr^2}{\left(1 + \frac{\epsilon}{4} r^2\right)^2}$$

or

$$\frac{dt}{R(t)} = \frac{-dr}{c\left(1 + \frac{\epsilon}{4} r^2\right)},$$

where the minus sign is employed to indicate that the light comes towards us, i.e., propagates to smaller r.

For galaxies whose light has taken a small fraction of the age of the universe to reach earth, the above relation leads directly to *Hubble's law* for the redshift (relative wavelength lengthening) of light arriving from a galaxy at current distance $d = R(t_0) r$ from earth:

$$c\frac{\Delta \ell}{\ell} \approx Hd - \frac{H^2 d^2}{2c}(1 - q), \qquad q = -\frac{R_0 \ddot{R}_0}{\dot{R}_0^2},$$

where ℓ is light wavelength, $R_0 = R(t_0)$, t_0 is the time that a light ray (that left the galaxy at time t) reaches earth, $H = \dot{R}_0 / R_0$ is the Hubble's "constant" at the present cosmic epoch, and q is the present–epoch (dimensionless) *deceleration parameter*.

Using the above cosmological–dynamics ODE of Lemaître together with the assumption $\lambda = 0$, we find:

$$q = \frac{4\pi G\rho}{3H^2}, \qquad \epsilon = \frac{8\pi G\rho R^2}{3qc^2}\left(q - \frac{1}{2}\right).$$

The universe, therefore, is spatially hyperspherical if $q > \frac{1}{2}$ (i.e., $\epsilon > 0$), hyperbolic if $q < \frac{1}{2}$ (i.e., $\epsilon < 0$), and flat if $q = \frac{1}{2}$. Since q is related to the density of the universe, there is a critical value of ρ corresponding to $q = \frac{1}{2}$, and given by $\rho_c = \frac{3H^2}{8\pi G}$.

If $\rho > \rho_c$ the universe is hyperspherical (finite) and pulsating, while for $\rho \leq \rho_c$ it is hyperbolic or flat and expanding forever. If we put $H = 50$ km/sec/megaparsec (approximately corresponding to the latest empirical value for the universe's age t_0) in the last formula, we obtain $\rho_c = 5 \times 10^{-30}$ gm/cm^3.

Refined cosmological observations since the mid-1990's have established that the cosmological "constant" λ is *small* and *positive* at the present epoch ($\lambda \approx 5 \times 10^{-53}$ meter^{-2}). (We know from particle physics and the success of the inflationary scenarios for the very early universe, that λ is actually *dynamical* and epoch–dependent).

Therefore, the above $\lambda = 0$ equations must be modified accordingly. It is also believed, based on these observations, that we live in a $\epsilon = 0$ universe. And yet, $\rho \approx 0.3\rho_c$; the balance of the spatial curvature needed to close the universe, is supplied by the cosmological constant (nowadays referred to as *dark energy*).

1927–1937 CE **Fritz Wolfgang London** (1900–1954, Germany and USA). Physicist. Contributed to the quantum theory of valence, and the theories of superconductivity and superfluidity.

With **Walter Heitler**[639] (1927) he derived the first quantum-mechanical model of the hydrogen molecule (H_2), their wave-equations forming the basis for valence-bond approach to *molecular quantum mechanics*.

With his brother Heinz London (1935), he discovered a phenomenological modification of Maxwell's electrodynamics for a superconductor; it included both infinite conductivity and the *Meissner effect*. The *London equation* states that the time-derivative of the superconducting current density $\boldsymbol{J}$ is proportional to the electric field: $\frac{\partial \boldsymbol{J}}{\partial t} = a\boldsymbol{E}$, which implies that in a superconductor, the current can be nonzero even if the electric field is zero; He was then able

[639] **Walter Heitler** (1904–1981, Germany and Switzerland) one of the pioneers of quantum field theory and quantum chemistry. A student of A. Sommerfeld in Munich (Ph.D. 1926). Escaped the Nazis to Dublin (1941–1948). Professor of theoretical physics in Zurich since 1949.

to show that the magnetic field is zero inside the superconductor, except for a thin skin layer near its surface[640].

London (1936) was first to point out that *superfluidity*[641] may be related to Bose statistics.

---

640 In a normal conductor and a Drude-type (classical) conduction model, the electric field $\boldsymbol{E}$ provides the force needed to keep the electrons moving with a drift speed $v_d = \frac{eE\tau}{m}$, where e and m are the charge and mass of an electron, respectively, and τ is a time proportional to the electron mean free time between collisions; Thus $\boldsymbol{J} = \sigma\boldsymbol{E}$, where the conductivity σ is directly proportional to the mean free path. In the superconducting phase, all the Cooper (electron) pairs (call their density n) have the same drift velocity $\boldsymbol{v}_d$, yielding a current $\boldsymbol{J} = 2ne\boldsymbol{v}_d$. Taking the time derivative and writing the electron acceleration as the electric force divided by the electron mass, we have

$$\frac{\partial \boldsymbol{J}}{\partial t} = 2ne\frac{\partial \boldsymbol{v}_d}{\partial t} = 2ne\left(\frac{e\boldsymbol{E}}{m}\right) = 2\frac{ne^2}{m}\boldsymbol{E} = a\boldsymbol{E}.$$

Taking the curl of both sides of the London equation, and using *Faraday's law* $\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}$ the *magnetic Gauss'– law* $(\boldsymbol{\Delta} \cdot \boldsymbol{B}) = 0$ and *Ampere's law* (with $\frac{\partial \boldsymbol{E}}{\partial t} = 0$) $\nabla \times \boldsymbol{B} = \mu_0\boldsymbol{J}$, we obtain: $\nabla^2\boldsymbol{B} = a\mu_0\boldsymbol{B}$. The only uniform magnetic field that satisfies this equation is $\boldsymbol{B} = 0$, which is Meissner's result.
If an external magnetic field is applied to the superconducting sample, the London theory predicts the $\boldsymbol{B}$ field will decay exponentially inwards of the sample's surface, with skin-layer thickness $\frac{1}{\sqrt{a\mu_0}}$. Note that the *London theory* is in full accord with quantum physics. Indeed, the expression for the current density in terms of the Cooper-pair macroscopic (complex) wavefunction $\Psi(\boldsymbol{r})$ and the vector potential $\boldsymbol{A}$ is known to be

$$\boldsymbol{J}(\boldsymbol{r}) = \boldsymbol{J}_0(\boldsymbol{r}) - \frac{2e^2n}{m}\Psi^*\Psi\boldsymbol{A}$$

where

$$\boldsymbol{J}_0(\boldsymbol{r}) = \frac{ne\hbar}{2mi}(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*)$$

Since Ψ is a pure phase $(\Psi^*\Psi = 1)$,

$$\frac{\partial \boldsymbol{J}}{\partial t} = -\frac{2e^2n}{m}\frac{\partial \boldsymbol{A}}{\partial t} = \frac{2e^2n}{m}\left(-\frac{\partial \boldsymbol{A}}{\partial t}\right) = \frac{2e^2n}{m}\boldsymbol{E}$$

(the gauge $A_0 = 0$ was assumed) and London's result again follows.

641 According to the quantum-mechanical treatment of the *Pauli Exclusion Principle*, a gas of a normal He^4 atoms, each with its two protons, two neutrons, and two electrons is described by a wave-function which is symmetrical w.r.t. Helium–atom exchanges; it obeys *Bose-Einstein statistics* (since the total num-

He was born to Jewish parents in Breslau (now Wroclaw, Poland) and was educated at the universities of Bonn, Frankfurt, Göttingen and Munich (Ph.D., 1921). He was a Rockefeller research fellow at Zurich and Rome and lecturer at the University of Berlin. During 1933–1936 he was a research fellow at the Universities of Oxford and Paris, but Nazi persecution caused him to leave Europe. In 1939 he emigrated to the United States, becoming a professor of chemical physics at Duke University (1939–1954).

1927–1942 CE **R.V.L. Hartley** (1890–1970, U.S.A.). Electrical engineer, inventor and applied mathematician. Made the first serious attempt to introduce a scientific measure of *information* in the field of electrical communica-

---

ber of fermions in each atom is even).

Since the He^4 atoms are *bosons*, they may in principle "*condense*" in the lowest per-atom quantum state of the system as absolute zero temperature is approached. In this state they would not carry out any *thermal* motion, but they would nevertheless not form a crystal lattice since the *zero-point energy* of the light helium atoms, according to the *uncertainty principle*, is larger than their very small *Van-der-Waals bond energy* in a lattice.

The vanishing viscosity of superfluid Helium-4 (i.e., the vanishing dissipative collisions between its helium atoms) would then be due to the impossibility to transfer energy from one atom to another if the thermal energy is smaller than the first energy excitation gap of the system. This is so because the energy of the many-particle system of the superfluid helium atom is quantized.

Thus, treating the system of Helium atoms as a degenerate (ground state) boson gas, the lowering of the temperature below a critical value (T_c) of several degrees–Kelvin condenses a macroscopic fraction of the helium atoms into the ground state, forming what is called a *superfluid*. The process is known as *Bose-Einstein condensation*. An atom of the rare He^3 isotope – containing one less neutron – is a *fermion*; but it was discovered (D. Osheroff *et al.*, 1970's) that at very low temperatures (a few *milli*-Kelvin), He^3 atoms form bosonic (Cooper-like) pairs; these condense, and therefore pure He^3 liquid, too, can become superfluid.

The dynamics of inter–atomic interactions in liquid (and thus also superfluid) phase helium is quite complicated. Beginning with the pioneering work of **E. Cornell** (1995), however, physicists have been able to use advanced cryogenics (in Magneto–Optical–Gravitational traps) to produce mesoscopic samples of Bose–Einstein Condensates (BEC's) comprising gases of alkaline atoms (e.g Rb or Cs). This new state of matter – being gaseous and thus weakly–interacting and easily analyzed via simple quantum mechanics – has remarkable electromagnetic and mechanical properties, with many possible technological applications.

tion. To this end he defined (1927) what we now call the information capacity of a message[642].

Hartley formulated (1942) a real integral transform that is fully equivalent to the Fourier integral transform, but dispenses with complex representation. It is known as the *Hartley transform*[643]. It has certain advantages over the traditional Fourier transform, especially in saving computer time.

1927–1942 CE **Bronislaw Kasper Malinowski** (1884–1942, England). Founder of *Social anthropology.* Known for his intensive studies of the culture of Southwest-Pacific and African natives, and for his contributions to the theories of human culture in general.

Malinowski was born in Poland and studied at the University of London. He taught there for many years, and at Yale University from 1939.

Author of *Argonauts of the Western Pacific* (1922), *Myth in Primitive Psychology* (1926), and *A Scientific Theory of Culture* (1944).

1927–1948 CE **George Alfred Léon Sarton** (1884–1956, Belgium and U.S.A.). One of the outstanding historians of science in modern times.

Embarked on a mission to make the history of science an articulate discipline, believing that this would provide a history of human thought and a better understanding of the nature of man. In this he intended to achieve the 'new humanism', a holistic and all-embracing synthesis based on appreciation of science in history.

He began a monumental *Introduction to the History of Science* (3 volumes, ca 6000 pp., 1927–1948), which only reached the third volume, and the year 1400.

---

642 He regarded the sender of a message as equipped with a set of symbols (the letters of the alphabet for instance) from which he selects symbol after symbol, thus generating a *sequence* of symbols. He then defined H, the *information* of the message, as the logarithm of the number of possible sequences of symbols which might have been selected; clearly $H = s\log n$. Here s is the number of symbols selected, and n is the number of different symbols in the set from which symbols are selected.

643 The Hartley transform reads:

$$F(\omega) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(t)[\cos\omega t + \sin\omega t]\,dt,$$

$$f(t) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} F(\omega)[\cos\omega t + \sin\omega t]\,d\omega.$$

Sarton's legacy, in addition to the subject's professional identity, lay primarily in his bibliographies, documentation and fact finding (15 books, over 300 articles and notes, and 79 critical bibliographies).

Sarton was born in Ghent, E. Flanders, Belgium and educated in philosophy and the natural sciences. He obtained his doctor's degree in mathematics at Ghent University in 1911, and emigrated to the United States in 1915. His lifework at Harvard was financed by the Carnegie Institution. In 1912 he founded *Isis*, still a major journal in the subject. In the U.S.A. he created a learned society and established the identity of science history and its claim to a place in universities.

Sarton worked on the three volumes of his history for 37 years, finishing the last one, on the 14^{th} century, in 1948. He figured that dealing with the 15^{th} century alone would cost him 15 additional years, of which he said: "*At my age this would be tempting Providence*".

He then added:

"*Looking back to the dreams of my youth, the creation of a chronological survey of scientific efforts down to the* 20^{th} *century, to be followed by two series of complementary surveys.*

I may seem to have failed egregiously, for my Introductions stops five centuries short of the goal. The scholarly reader will agree with me that it is better to do something as well as one can than to do considerably more less well. Other scholars will complete my task and may be able to do it much better".

Worldview XLII: Sarton

* * *

"Early historians of science were tempted, in their ignorance and their bumptiousness, to consider the science of the 16^{th} and 17^{th} centuries as a continuation of ancient science, and so it was, but a continuation which would have been impossible or utterly different without the medieval gropings which intervened. Galilean physics is the climax of centuries of such gropings, and even the Newtonian fluxions and gravitation have medieval roots (whether Newton was explicitly aware of them or not does not matter much). The 17^{th}-century mathematicians were generally well acquainted with Greek mathematics down to Diophantos and Pappos, and they believed in good faith that they were taking up the work where those ancients had left it. They did not realize how much they owed to the slow incubation of ideas which was the medieval indispensable contribution. This was hidden from them because Renaissance scholars had tried to obliterate the Middle Ages; that obliteration, whether conscious or not, continued in the field of art and letters until the Romantic age, and in the field of science until our very own."

* * *

"The history of science describes man's exploration of the universe, his discovery of existing relations in time and space, his defense of whatever truth has been attained, his fight against errors and superstitions. Hence, it is full of lessons which one could not expect from political history, wherein human passions have introduced too much arbitrariness. Moreover, it is an account of definite progress, the only progress clearly and unmistakably discernible in human evolution. Of course, this does not mean that scientific progress is never interrupted; there are moments of stagnation and even regression here or there; but the general sweep across the times and across the countries is progressive and measurable. The history of science includes the most glorious, the purest, and the most encouraging deeds in the whole past."

* * *

"In order to explain 14^{th}-century thought, it is not enough to deal with 14^{th}-century authors; one must deal as well with many authors of earlier times

whose thought was still living in the 14^{th} century. It has already been remarked that though Archimedes was killed in 212 BCE, his spirit is still living today. As a matter of fact that particular spirit was not much in evidence in the 14^{th} century, but older ones, those of Hippocrates of Cos, Plato, Aristotle, Euclid were going strong. Medieval men were not chronologically minded, they spoke of Hippocrates and Aristotle in the same way as of their own contemporaries, and those ancient sages were indeed to that extent their contemporaries."

* * *

"The scientific results of the past may generally be neglected, for they have been incorporated into later ones; the scientific achievements, however, can never be superseded, and they keep their value eternally. Mathematicians have no technical reasons for reading Euclid, but they will never cease to admire him, and their appreciation of his genius is bound to increase together with their own knowledge."

* * *

"The history of science is to a large extent a history of rationalism, rationalism in action. It is a history of the gradual emancipation of men from superstition and ambiguities, a history of the growth of light in dark or darkened corners, a history of our salvation not only from lies but also from other evils, from servitude and intolerance. The medieval part of that history is meager in tangible results, but such results are not always a fair measure of the efforts. The difficulties which the medieval heroes of thought had to overcome were immense. Results are the fruit of all preceding efforts, not only of the latest ones. The triumph of modern science was partly due to medieval efforts.

Great men were not rarer in the 14^{th} century than in the 20^{th}, but the old institutions (the church and the empire) were shaking and the new institutions (universities, parliaments, etc.) not yet sufficiently well established."

* * *

"One universal characteristic of mystical thinking is the distrust of intellectualism. The great weakness of mysticism, always and everywhere, is its individualism. It is necessarily and paradoxically dogmatic, for the mystic, however sincere and convinced he may be, cannot give his reasons. His conviction cannot be communicated to others, except if they are exactly in the same

mood. He cannot completely justify himself; he can only oppose dialectical dogmatism with his own intuitive dogmatism.”

* * *

“The Greeks laid stress upon truth and beauty; the Romans upon strength and usefulness. The ruin of science, begun by Roman utilitarianism, was in danger of being completed by Christian piety which considered scientific research not only useless but pernicious.”

* * *

“From the point of view of the history of science, transmission *is as essential as* discovery*. If the results of Ptolemy’s investigations had been hidden instead of published, or if they had been lost in transit, they would be almost as if they had never been.*

Now, the question “How did Ptolemy’s knowledge came down to us?” opens up the study of medieval science and justifies it. If there were no other reason to study medieval science than to find out how ancient knowledge was handed down to us, that reason would be sufficient”.

* * *

“In the beginning astrology was a sound body of knowledge, based upon a premise, which proved to be erroneous, but which was not unreasonable, namely, that planets and stars can and do influence human events. Thus, a scientific study of planetary motions would enable one to interpret and to foretell these events.

It is easy enough to understand the growth of that fallacy if one realizes the appeal which periodical phenomena have never ceased to make upon people of all kinds, whether educated or not. Symmetry and periodicity form the very substance of science and also of art, and the more intricate, the subtler they are, the more impressive once they have been discovered. We may assume that even at the very dawn of civilization, the more thoughtful men had been awed by the extraordinary periodicities in the motion of the stars, of the moon, and the sun. And, by and by, as they discovered the more complicated periodicities involved in the apparently erratic displacements of the planets, their awe and trust in cosmic harmony increased in proportion. Thus were *the astrological assumptions naturally introduced. They received an extraordinary confirmation from two terrestrial phenomena which exhibited similar periodicities and were immensely impressive because of their universality, of their complexity, and of their mathematical rigor: the tides of the sea and the menstruation of women. Both phenomena were explained by planetary influences; the explanation was essentially right in the first case and wrong in the second. That error was a very pardonable one. And if some of the planets could thus affect the bodies of women nay, their very souls, was it unreasonable to assume that they might influence as well the destinies of men? These theories, being erroneous, were naturally sterile and unprogressive; as they could not progress, they deteriorated, and as they blocked the stream of thought, they gathered around them all the superstitions which it carried."*

* * *

"The historian of science can not devote much attention of the study of superstition and magic, that is, of unreason, because this does not help him very much to understand human progress. Magic *is essentially unprogressive, and conservative;* science *is essentially progressive. We can not possibly deal with both movements at once except to indicate their constant strife, and even that is not very instructive, because that strife had hardly varied throughout the ages. Human folly being once unprogressive, unchangeable, and unlimited, its study is a hopeless undertaking!*

The history of astrology*, however, must be carefully considered since a large part of it is so intimately connected with the history of science that it cannot be dissociated from it. This applies with even greater force to* alchemy*, for in this case there was considerably more scope for the continual integration of new experimental facts, which were valuable in spite of wrong interpretations: the alchemical facts outlasted the alchemical structure, and many of them are now integral parts of our chemical knowledge."*

* * *

"To take a step forward in the right direction is always a great thing, and the first steps are always the most difficult and the most creditable. We forget it but too often, and our histories are full of injustice, because we are almost always too generous toward those who made the last steps and reaped the result to all antecedent efforts, and too little generous to those who made the first and least profitable steps."

* * *

"A large part of our knowledge and of our technique was attained, not at all in a logical way, but by the method of trial and error, which works well, but is exceedingly slow. The whole history of thought points to the conclusion that some errors at least were unavoidable, that is, mankind could learn how to avoid them only by making them. Thus we were spared some errors only because our ancestors had made them before us. Indeed, these medieval scientists are our direct ancestors; if they had been such idiots, how could we be so clever? It is extremely probable that if we had been living under the same circumstances as they, we should not have proceeded much faster. The progress of science is on the whole, an accelerated one; thus, in any retrospective survey, we must expect the progress to become slower and slower as we penetrate more deep by into the past. And above all we must remember that science could not progress along certain lines without traversing vested interests and prejudices and without hurting the feelings of the community. To proceed in the face of such opposition has always required a great deal of intellectual courage. There were many more such sensitive lines in the Middle Ages than now, and thus there was a far greater need for that particular kind of heroism. In the whole sweep of history there is nothing more impressive than the spectacle of noble men who had the spirit to fight unreason and ignorance and who did not hesitate, not only to renounce material advantages, but even to jeopardize life and happiness in order to increase the amount of beauty, justice, *and of* truth *which is the essential part of our patrimony."*

* * *

"And this is the very spirit of science — the continual alteration of experimental research, of mathematical elaboration, of theoretical deduction and discussion suggesting new experiments. Or, in other words, the continual alterations of analysis and synthesis: analytical investigations without synthetic attempts must necessarily degenerate into crude empiricism and into superstition; synthetic constructions without periodic experimental contact must necessarily degenerate into a sterile dogmatism. Science is not a being, but a becoming."

* * *

"There are no discontinuities in the intellectual life of the world if we take into account the achievements of all peoples in every direction. Whenever a

nation dropped out of the race, another was ready to take up the torch and to continue mankind's eternal quest."

* * *

"Science slowly emerges from philosophy and religion, chemistry from alchemy, astronomy from astrology."

1927–1950 CE **Barbara McClintock** (1902–1992, US). Geneticist. Revolutionized the field through her observation in maize genetics that genes are not stable — thus overturning one of the main tenets of heredity laid down by **Gregory Mendel**. This had enormous implications and explained, for example, how resistance to antibiotic drugs can be transmitted between entirely different bacterial types. McClintock novel ideas were not accepted for many years. She won, however, the Nobel Prize in Physiology or Medicine (1983), the 5th woman to be so honored.

McClintock was born in Hartford, CT and received a Ph.D. in botany (1927) from Cornell University – where she stayed (1927–1935). Later held posts at the University of Missouri (1936–1941) and the Carnegie Institute, New York (1941–1992).

She showed (1927–1931, with **Harriet Creighton**) that genes can change their position on a chromosome ('*jumping genes*'[644]) from generation to generation. This would explain how originally identical cells take on specialized

[644] She observed that the patterns on twin sectors of maize seedlings were the inverse of one another, and that pigmentation of certain kernels did not correspond to their genetic makeup. Realizing that a single cell divided into sister cells, one gained what the other had lost, she deduced that *not all genes behave in the same way: some genes can switch others on and off*, moving from one place to another on the chromosome, or even 'jumping' from one chromosome to another. These jumping genes act as regulators and were later discovered in bacteria and fruit flies.

functions as skin, muscle, bone, and nerve cells, and also how evolution could give rise to multiplicity of species.

In the 1940's she showed how genes in maize are activated and deactivated by 'controlling elements' — genes that control other genes and which can be copied from chromosome to chromosome. She presented her work in a symposium in 1951, but its significance was lost on the attendees, who mainly worked with bacteria. It was not until the 1970's, after the work of **Jacob** and **Monod**, that her work began to be appreciated.

1927–1956 CE **Bernhard Zondek** (1891–1966, Germany and Israel). Gynecologist and endocrinologist. Discovered gonadotrophine. Developed the first reliable hormonal pregnancy test [1927, with **Selmar Aschheim** (1878–1965)] and the assistance of his brother **Herman Zondek** (1887–1979).

Zondek was born in Wronke, Germany. He was trained in medicine at the University of Berlin, becoming a professor (1926–8) and Director of its Department of obstetrics and Gynecology (1929–1933). He left Nazi Germany (1933) to become Professor at the Hebrew University, Jerusalem (1934–1966).

During this period he discovered that the anterior pituitary gland produced hormones called gonadotrophins, which in turn stimulated other endocrine glands, such as the ovary, to release their hormones. This work provided important evidence of control mechanisms in reproduction, which has had widespread significance in the development of medical and social attitudes towards questions of fertility, infertility, contraceptions and abortion.

1927–1957 CE **Otto Neugebauer** (1899–1990, USA). A foremost historian of premodern science. Made important contributions to the history of mathematics and astronomy. His coverage of Egyptian and Babylonian science and its transmission to the Hellenistic world released the surprising sophistication of certain areas of early science.

Many of his discoveries have revolutionized earlier understandings. He thus showed that Babylonian strength in algebraic and numerical work reveals a level of mathematical development in many aspects comparable to the mathematics of the early Renaissance in Europe (in contrast to the relatively primitive Egyptian mathematics). In the realm of astronomy, too, Neugebauer discovered an unexpected sophistication which he ascribed to a competent mathematical approach rather than to the result of millennia of observations (as used to be the interpretation).

Neugebauer was born in Austria to Jewish parents. He emigrated to the USA (1940).

1927–1958 CE **Ludwig Mies van der Rohe** (1886–1969, Germany and USA). Architect and teacher. One of the founders of the *modern movement* *in architecture*; won fame for the clean, uncluttered design of his buildings of brick, steel, and glass. The sparse appearance of his buildings illustrated his motto: "*Less is more*".

Mies was born in Aachen (N. Rhine – Westphalia), Germany. He built his first steel-framed building in 1927. In 1929 he designed the German pavilion at the Barcelona exhibition, with its marble walls reaching out beyond the building, its hovering roof slab, and its great expanse of glass. In 1930 he became director of the Bauhaus school in Dessau, but closed the school in 1933 as a protest against the Nazis.

In 1938 he emigrated to the USA and was appointed director of the school of architecture at the Illinois Institute of Technology. He is said to have based his attitudes to architecture and the teaching of it on Thomas Aquinas' proposition: '*Reason is the first principle of all human work*'.

The curriculum at his school was designed to teach general principles with a strong emphasis on construction, encouraging general rather than specialized solutions. This approach contrasted with most other contemporary schools of architecture in which the aim was to engender individuality of expression.

Mies' buildings are models of structured clarity and simple geometry. They had enormous influence on his contemporaries and indeed on many present-day architects, who respect his handling of the high-rise skeleton-frame tower block, exemplified in the twin towers on Lake Shore Drive (Chicago, 1948–51) and the Seagram building (New York, 1954–8).

1927–1960 CE **Abram Shmulovich Besicovitch** (1891–1970).
Karaite[645] mathematician. A geometric analyst of extraordinary power[646].

[645] *Karaism* — a sect that broke away from Judaism in 760 CE. They bear the name *Karaim*, "Scripturalists", believers in the Bible only, excluding later traditions. They claimed that the original intentions of the Holy Book were lost in the countless laws built on top of the biblical words. Their belief was that each Jew had a right to explain the biblical statements in accordance with his own views, without regard to the "official" explanation offered by the scribes and their followers.

[646] The following anecdote may serve as a typical example of his sharp wit: One day, during his lecture at Cambridge, the class chuckled at his fractured English. Besicovitch turned to the audience and said: "*Gentlemen, there are fifty million Englishmen speak English you speak; there are two hundred million Russian speak English I speak*". The chuckle ceased.

One of the founders of the theory of *fractals* (*Hausdorff-Besicovitch dimension*), on which he published a series of path-breaking papers during 1928–1937. In 1927, Besicovitch solved the *Kakeya problem*[647], proposed in 1917 by **Soichi Kakeya** (1886–1947, Japan). [It required to find a figure of least area in which a segment of unit length could be turned through 360° by a continuous movement.] Known for his work on *almost periodic functions*.

Besicovitch was born in Berdyansk, Russia. He was taught by **Markov** at St. Petersburg. He left Russia (1924) and worked with **Harald Bohr**. In 1927 he moved to Cambridge. His wife remained in Russia and the marriage was dissolved (1928). He then married (1930) the 16 year old daughter of a previous girlfriend.

1928 CE **Alexander Fleming** (1881–1955, Scotland). Bacteriologist. Discovered *penicillin* at St. Mary's Hospital, Paddington, London. (It was made stable enough for medical use only in 1943.) Shared the Nobel prize for physiology or medicine (1945) with **Howard Walter Florey** (1898–1968, England) and **Ernst Boris Chain** (1906–1979, England) for isolating and purifying penicillin for general clinical use.

1928 CE **Otto Paul Hermann Diels** (1876–1954, Germany) and **Kurt Alder** (1902–1958, Germany). Chemists; developed a synthesis known as the *Diels-Alder reaction*[648]: a technique for combining atoms into molecules that is useful in forming many compounds, especially synthetic rubber and plastics. For this they were awarded the Nobel Prize for Chemistry (1950).

---

[647] For a time it was believed that a hypocycloid of area $\frac{\pi}{8}$ was the desired figure. However, Besicovitch proved that Kakeya's problem has no solution by showing that there are figures of arbitrary small area having the Kakeya property.

[648] *Alkanes* are those hydrocarbones in which adjacent carbon atoms are joined together by a *stable single bond*. They are called *saturated hydrocarbons* because the carbon atoms are covalently bonded to as many hydrogens as the carbon-backbone connectivity allows. They have the general formula C_nH_{2n+2} (e.g. Methane CH_4, Ethane C_2H_6 etc.)

Alkenes contain two carbon atoms joined together by a *double bond*, and therefore two hydrogen atoms less than the corresponding alkanes. They are *unsaturated*, having the general formula C_nH_{2n} (e.g. Ethylene C_2H_4).

Dienes contain two double carbon bonds (e.g. Butadiene C_4H_6). Because of the *unstable* double bond, Alkenes and Dienes are chemically more active and form *addition compounds* with H_2, Cl_2, Br_2, HCl, HBr, H_2SO_4, etc.

In the Diels-Alder reaction, a conjugated diene reacts with an alkene:

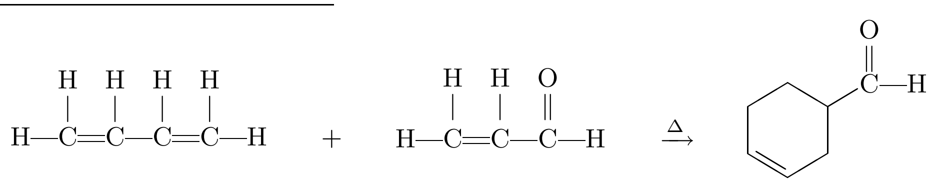
Reactions that create new carbon-carbon bonds are very important in organic synthesis because only through such reactions can small organic molecules be converted into larger ones. The Diels-Alder reaction is a particularly important reaction because it creates two new carbon-carbon bonds in a manner that results in a *formation of a cyclic molecule* (*aromatic compound*).

1928 CE **Chandrasekhar Venkata Raman** (1888–1970, India). Physicist. Observed experimentally the existence of displacement (lowering or raising) of frequencies in the electromagnetic radiation scattered by a molecule, known as the *spontaneous Raman effect* or *Raman scattering*. The effect had been predicted (1923) by **Adolf Smekal** (Germany) and involves at least three quantum states, and three transitions among them, in a molecule or a radical. The magnitude of the frequency change, and its dependence upon the properties of the absorbing species, constituted a compelling proof for the veracity of the quantum theory which had, at the time, only recently emerged.

The *Raman effect* is related to molecular vibrations and rotations and to electron orbitals. When a gas sample (for example) is illuminated with monochromatic radiation of frequency ν_0, it is observed that the radiation scattered in a direction at right angles to that of incidence, contains, in addition to the primary frequency component ν_0 (which is the result of coherent *Rayleigh scattering* of the incident radiation), secondary radiation components of frequencies $\nu_0 \pm \nu_s$, where ν_s corresponds to a frequency of the vibrational or rotational spectrum of the molecule. This is called *Raman scattering*[649].

Its quantum-mechanical interpretation is as follows: suppose that a molecule is initially in a (ground or excited) vibrational and/or rotational

---



where Δ signifies the addition of heat.

[649] The Raman effect can be explained in the framework of classical physics on the basis of the polarizability of the electron orbitals of molecules: A light wave with frequency ν_0 incident upon an isotropic molecule induces in this molecule an electric *dipole moment* $M_i = \alpha E_0 \sin(2\pi\nu_0 t)$, where α is characteristic of a specific molecule and is called *polarizability* (it is a measure of the deformability in the electron orbitals), and E_0 is the amplitude of the electric field vector of the impinging light. Assume that α is not constant but changes linearly with the intra-molecular atomic positions as the atoms in the molecule *vibrate* against each other with the frequency ν_s, or as optically anisotropic molecules *rotate* around their center of gravity. By setting $\alpha = \alpha_0 + \alpha_1 \sin(2\pi\nu_s t)$ and inserting

state[650], and also in some electronic-orbital configuration (ground state or excited). When an electron in the molecule absorbs a photon of frequency ν_0 it transitions to an excited electronic state (with the atomic-nuclei quantum state unchanged). If the excited state is not a metastable one, there is a virtually immediate re-radiation of a photon.

The molecule may return to the initial state, emitting radiation of the same frequency as the incident light; this is *Rayleigh scattering*. The molecule may, however, return to *another* vibrational or rotational level immediately above or below the initial level, with the emitted radiation having the frequency $\nu_0 - \nu_s$ or $\nu_0 + \nu_s$, respectively; this is the quantum explanation of *Raman Scattering*[651]. The Raman effect has been observed for both vibrational and rotational spectra; for the latter the selection rule for the electronic-orbital sector of the transition is $\Delta\ell = 0, \pm 2$ (compared to $\Delta\ell = \pm 1$ in the vibrational case)[652].

---

the expression into the equation for M_i, we obtain

$$M_i = \alpha_0 E_0 \sin(2\pi\nu_0 t) + \frac{1}{2}\alpha_1 E_0 \left[\cos 2\pi(\nu_0 - \nu_s)t - \cos 2\pi(\nu_0 + \nu_s)t\right].$$

While the first term represents an induced dipole moment that vibrates with the exciting frequency ν_0 and thus causes the classical *Rayleigh scattering*, the two terms in brackets are responsible for radiation of two light waves, the frequencies of which are shifted against that of the exciting wave by $\pm\nu_s$. This is the *Raman effect*, which is very important in molecular physics.

650 Vibrational and rotational states are orbitals of the *atoms* within a molecule, i.e. they are solutions of the Schrödinger equation for the nuclear-position wavefunction. Since electron motions are much more rapid than those of atoms (because nuclei are much heavier), the *Born-Oppenheimer* approximation allows one to first solve for the electron's wavefunctions with nuclei held fixed, and then use the dependence of the electronic energy levels upon nuclear positions to derive *effective* inter-atomic potentials — which are in turn used to set up and solve the nuclear-position wave equation.

651 Such a transition involves changes of *both* the electron wavefunction *and* the nuclear-positions wavefunction. (ν_s is a frequency characteristic of the vibrational or rotational transition.)

652 The effect had been predicted earlier by **Kramers**, **Heisenberg**, **Schrödinger** and **Dirac**. In fact it was seen by **Lommel** (1878), but discounted as noise.
At first, the effect was difficult to put to actual use because one needed strong sources (usually Hg discharges were used) and large samples. Often the ultraviolet from the source would further complicate matters by decomposing the specimen. And so it is not surprising that little sustained interest was aroused by the promising practical aspects of the Raman effect.

The $\nu_0 + \nu_s$ spectral component of the Raman effect depends on the initial molecular state being *excited* in its atomic-nuclear-positions sector; such vibrational and rotational excitations occur naturally due to thermal fluctuations.

The Raman effect provides a direct method for the investigation of the structure of molecules and molecular fragments in solid, liquid and gaseous state. It permits measurements of their natural vibration frequencies, and (through the transition selection rules) helps in studying the symmetries of molecules, intramolecular forces, molecular dynamics etc.

The Raman spectra characterize a molecule with such precision that their analysis can be used for determining the composition of mixtures of molecules when the ordinary methods of chemical analysis fail to provide needed results.

Raman was born in Tiruchirappali, Tamil Nadu, India. He received his bachelor degree at Presidency College, Madras (1904). During 1907–1917 he was employed as a civil servant in a finance department in Calcutta. In his spare time he cultivated his interest in acoustical problems and their relevance to the theory of musical instruments, and worked irregular hours in the laboratory of the Indian Association for the Cultivation of Science. In 1917 he became professor of physics at the University of Calcutta.

His most renowned contribution came in 1928 when he telegrammed his letter to *Nature* describing '*A New Type of Secondary Radiation*', for which he was awarded the Nobel prize for physics (1930). From 1933 onwards he lived and worked in Bangalore, where he founded the *Indian Academy of Science* (1934), and later directed the *Raman Research Institute* (1948).

The situation was changed dramatically when *laser* light sources became a reality. *Raman spectroscopy* is now a unique and powerful analytical tool; the laser is an ideal source for spontaneous Raman scattering. It is bright, highly monochromatic, and available in a wide range of frequencies.

In 1962, **Eric J. Woodbury** and **Wan K. Ng** fortuitously discovered a related effect known as *stimulated Raman scattering*, where part of the incident energy (at the wavelength 6943 Å in their experiment) was shifted in wavelength and appeared as a *coherent* scattered beam at 7660 Å. It was subsequently determined that the corresponding frequency shift of about 45×10^{12} Hz was characteristic of one of the vibrational modes of the molecule of nitrobenzene (the scatterer used by them).

By the turn of the 21^{st} century, active and passive photonic-device products became available that utilize intense *pump lasers* to provide the initial-frequency photons; the stimulated longer-wavelength lightwaves, present to begin with but amplified, *near-infrared telecommunication* signals propagating in ordinary optical fibers, with the fiber medium itself providing the scatterer molecules.

He was a prolific writer (there are more than 500 articles bearing his name), and a key figure in the foundation of modern Indian science. Along with **Ramanujan**, **Tagore**, **M. Gandhi** and **S. Radhakrishnan**, he was conspicuous in the flowering of Indian culture in the first part of the 20^{th} century. The astrophysicist S. Chandrasekhar (1910–1995) was his nephew.

1928–1933 CE **Raymond (Edward Alan Christopher) Payley** (1907–1933, England and USA). Mathematician. Made important contributions to the theories of *Fourier series*, *Fourier transforms*, *quasi-analytic functions* and related topics.

Paley was educated at Eton. From there he entered Trinity College, Cambridge where he was taught by **Hardy**. He then collaborated with **Littlewood**, **Zygmund** and **Polya**. In the United States he worked with **Norbert Wiener**[653].

While skiing near Banff he was killed by an avalanche. Thus ended the meteoric career of a brilliant mathematician who had the potential to rise to the level of the great mathematicians with whom he collaborated.

1928–1931 CE **Jesse Douglas** (1897–1965, USA). Mathematician. First to prove the existence of a surface of minimal area bounded by a contour (the *Plateau problem*, 1873; first posed by Lagrange in 1760 and studied by Riemann, Weierstrass and Schwarz).

Before Douglass' solution only special cases had been solved.

Douglass studied at Columbia College (1920–1926). Visited Princeton, Harvard, Chicago, Paris and Göttingen (1926–1930).

1928–1937 CE **Jerzy Neyman** (1894–1981, Poland and U.S.A.). Statistician. Produced the *Neyman-Pearson* system of hypothesis testing[654]: a set of

653 Payley-Wiener condition: A necessary and sufficient condition for a square-integrable function $A(\omega) \geq 0$ to be the Fourier spectrum of a causal function is the convergence of the integral

$$\int_{-\infty}^{\infty} \frac{|\ln\, A(\omega)|}{1+\omega^2}\, d\omega < \infty$$

654 Based on the *Neyman-Pearson lemma* which states (verbally) that an hypothesis is not invalidated because it makes observed events improbable; there must be a realistic alternative hypothesis that does better.

While the structure of this lemma is too restrictive for the result to have much *practical* significance, it does have enormous importance from a conceptual standpoint.

criteria for maximizing efficiency in the design of tests which is the foundation of modern *quality control*.

Faulty items found in an inspected sample may be ineradicable errors or a signal to close down and reset a machine. The theory then looks at the cost and risk of stopping a good machine and compares it to the cost and risk of running a bad one, to obtain the best criterion and sample size.

In 1934 Neyman tackled the problem of using random samples in *human populations*. He proposed a general principle: to take linear combinations of data items and balance them, first to eliminate bias and then to minimize variance. This provides rules for deciding how intensively to sample, and where.

In 1937 he formulated the classical theory of *confidence intervals*.

1928–1937 CE *Antisemitism in Austria* soared to unprecedental levels; violent antisemitic riots. Dr. Seipel, leader of the clericals and Prime minister, preceded to profess his hatred of the Jews. The Archbishop of Vienna endorsed the appeal to boycott Jewish merchants (1928). Governmental discrimination against appointment of Jews to the civil service continued.

By 1933, Jews were virtually eliminated from the university life. An edict was promulgated forbidding Jews to practice medicine in Austrian hospitals. In May 1934, a new Austrian constitution established a fascist-corporatist state on Christian principles. Chancellor **Dollfuss** was shot to death by Nazi storm troopers in Vienna (1934).

By the end of the year only 12 Jewish teachers in the Vienna elementary school system remain of a former total of 5000. Nearly 60,000 out of the 176,000 Vienese Jews were registered (1936) in the welfare department as applicants for relief. As of July 1937, Jewish doctors were not allowed to practice privately. The elimination of "Jewish influence" in education, the theater, the press, the arts, and the sciences was now achieved (1937).

On March 11, 1938 Vienna becomes the second largest city of the Third Reich; the fate of the Jews was finally sealed.

1928–1938 CE **Paul Adrien Maurice Dirac** (1902–1984, England). Distinguished physicist. A major contributor to relativistic quantum mechanics and quantum statistics, and the originator of the concept of antimatter.

Egon Sharpe Pearson (1895–1980, England; son of **Karl Pearson**) contributed to the theory of *statistical inference* and developed the concepts of *likelihood ratio* test of an hypothesis.

In 1926, while still a graduate student, he derived his own version of quantum mechanics, lagging only a few months behind Born and Jordan. In this same year he formulated, independently of **Fermi**, what is known today as Fermi-Dirac statistics. His major work was presented in 1928: he discovered a first-order partial differential wave equation for a free particle, which is invariant under the Lorentz transformation and incorporates spin in a natural way. This *Dirac equation* is consistent with the *Klein-Gordon equation*, and Dirac suggested the former as the fundamental relativistic wave equation for the electron – for which the Klein-Gordon equation is not sufficient[655].

He found that his new linear equation is a matrix equation of rank 4, the wave-function solutions of which are 4 component *spinors*. The associated algebra is the *Clifford algebra* in 4 dimensions, and each spinor component also obeys the Klein-Gordon equation.

Dirac's equation — when interpreted as a first – quantized (Schrödinger) wave equation — showed that there must be states of *negative energy*. The latter conclusion did not seem to correspond to physical reality. In a later paper, in 1929, Dirac suggested that a deficiency of an electron is one of these (otherwise completely *filled*) states, would be equivalent to a positively charged particle.

According to this idea, the vacuum is not empty, but rather contains an infinite sea of completely-filled negative energy states; localized energy, such as a high-energy photon, can occasionally knock one of these electrons into a positive energy state. To an observer, this would appear as the materialization, out of the vacuum, of a pair of particles — an ordinary electron, and a "positive electron" — a hole in the sea of negative, otherwise — filled energy

---

[655] One of the motivations at that time to reject the Klein-Gordon equation as a fundamental quantum-mechanical wave equation, was that the Born probabilistic interpretation seemed to lead to probability distributions that can go negative, clearly a nonsensical result. Soon, however, Dirac's own work on antimatter led to *second quantization* (nowadays called *field quantization*), in which there is a distinction between a particle's *field equation* on the one hand, and the *Schrödinger wave equation* of the whole (multiparticle) system on the other. Thus, in quantum electrodynamics — a second-quantized theory — we distinguish between Maxwell's equations (the photon's field equations) and the Schrödinger equation. When all this became clear, the Klein-Gordon equation was restored to grace as a valid equation, on equal footing for some (integer–spin, bosonic) particles with the Dirac equation (which holds for fields of spin-$\frac{1}{2}$ fermions). The Klein-Gordon equation follows from the Dirac equation, since the former is simply the quantum-mechanical version of Einstein's STR kinematical relation $p_\mu p^\mu = m^2c^2$, obeyed by *any* free particle of rest mass m.

levels. Similarly, an electron can *annihilate* its positive counterpart, by dropping from positive to negative energy (emitting radiation in the process) and re-filling a negative level.

This picture — while literally true for quasiparticles in conducting solids, for which the positive quasiparticles is the *hole* familiar from semiconductor physics[656] — requires some modifications in the more elegant field–quantization picture later adopted, in which the *Dirac sea* of negative–energy states is dispensed with. In the modern picture, fermions and anti–fermions are treated on equal footing, with a manifest *charge–conjugation* discrete symmetry between them.

Dirac's theory was confirmed when **C.D. Anderson** obtained a cloud chamber photograph with tracks showing the existence of *positrons*. Thus, an apparent fatal flaw of Dirac's theory turned into the successful prediction of *antimatter*. This development made it clear that the successful marriage of STR and quantum-mechanics requires a new foundation of the latter — in which particle numbers are not conserved, and even the vacuum is a complex many-body system[657]. Dirac's theory emerged triumphant.

Dirac also (1933) raised the question of what corresponds in the quantum theory to the *Lagrangian* method in classical theory. He pointed out that the function $K(\boldsymbol{x}_2, t_2;\ \boldsymbol{x}_1, t_1)$ which carries the wave function $\psi(\boldsymbol{x}_1, t_1)$ at time t_1 to the wave function $\psi(\boldsymbol{x}_2, t_2)$ at time t_2, is analogous to $e^{\frac{i}{\hbar}S}$, where $S(\boldsymbol{x}_2, t_2;\ \boldsymbol{x}_1, t_1)$ is the classical *action*.

This function S was first introduced by **Hamilton**, and was computed from the classical trajectory $\boldsymbol{x}(t)$ linking the coordinate $\boldsymbol{x}_1$ of the classical particle at the instant t_1 to the coordinate $\boldsymbol{x}_2$ at time t_2; the related **Hamiltonian** enables one to describe the classical evolution as a canonical transformation developing in time. Hamilton's action is obtained by integrating the Lagrangian of the system over the yet unknown classical path from the point with the coordinate $\boldsymbol{x}_1$ at instant t_1 to he point with the coordinate $\boldsymbol{x}_2$ at time t_2,

$$S = S(\boldsymbol{x}_2, t_2;\ \boldsymbol{x}_1, t_1) = \int_{t_1}^{t_2} L\left[\dot{\boldsymbol{x}}(t), \boldsymbol{x}(t), t\right]\, dt.$$

---

656 However, in the condensed–mater case there is less symmetry: no STR (the lattice frame is preferred!); no actual negative energies expending to $-\infty$ (just a valence band); and electrons have different effective mass than holes.

657 At first, Dirac erroneously identified the 'positive electron' with the proton! It is now accepted, on very strong theoretical and experimental grounds, that the mass and spin of any particle are exactly equal to those of its anti-particle (*CPT theorem*).

The *principle of least action* then states that the classical path $\bar{\boldsymbol{x}}(t)$ chosen by the system out of *all* possible paths is that for which S is extremal. This condition of extremum leads, mathematically, to the path-equation $\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{\boldsymbol{x}}}\right) - \frac{\partial L}{\partial \boldsymbol{x}} = 0$, where L is a priori *known* [e.g. for a single particle of mass m, moving in a potential $V(\boldsymbol{x}, t)$, we have $L = \frac{m}{2}\dot{\boldsymbol{x}}^2 - V(\boldsymbol{x}, t)$].

During 1937–1938 (and later, 1973–1979), Dirac proposed a new cosmological theory ("large number theory") based on the notion that there are some very large dimensionless numbers in physics with hitherto unknown significance, which are approximately equal to one another. These numbers (all of which are of the order 10^{40}) are:

(1) The ratio of the electromagnetic force between a proton and an electron to the gravitational force between them.

(2) The square root of the number of particles N in the observable universe.

(3) The age of the universe, in units of the time required for light to traverse the classical 'electron radius'.

Dirac suggested that this coincidence expresses some fundamental (although still unexplained) truth, and that therefore all three numbers should be equated.

It then followed that one or more of the 'constants' $\hbar$ (Planck's reduced constant), G (gravitational constant), e (the fundamental charge unit), c (velocity of light in vacuo), m_e and m_p (electron and proton masses) must vary over cosmic time-scales. In order to avoid the reformulation of atomic and nuclear physics, Dirac chose G as that fundamental 'constant' that varies with time. This requires that $G(t)$ *decrease* with time like t^{-1}, where t is time elapsed since the Big Bang in any frame of reference at rest relative to the local Cosmic Microwave Background Radiation. [In GTR, G *must* be kept fixed and unalterable, since there is no mechanism within the theory for G to depend either on the distribution of matter or time. In the *Brans–Dicke* (scalar–tensor) modification of GTR, in which the *strong* equivalence principle is relaxed, the effective G is a function of the scalar field, and so may depend on time (or even space). In modern inflationary and/or higher–dimensional QFT versions of Big–Bang cosmology, G, m_e, m_p and (to some extent) e may vary with cosmological epoch; $\hbar$ and G (in most theories) may not.]

Thus, Dirac's cosmology requires that GTR be replaced with some other field theory of gravitation, which he never supplied. Previously, **Eddington** tried unsuccessfully to explain the fine-structure constant $\left\{\frac{e^2}{4\pi\epsilon_0\hbar c} \approx \frac{1}{137}\right\}$ and other dimensionless parameters.

Dirac's theory is now in conflict with observations on two counts. First, his relation $t = \frac{1}{3}H_0^{-1}$ (H_0 is Hubble's constant at the present epoch) leads to an age of the universe that is too small. Second, recent observations (1981) have shown that $\frac{1}{G}\left|\frac{dG}{dt}\right| \leq 6 \times 10^{-11}$/year, and even as small a value for $\frac{1}{G}\left|\frac{dG}{dt}\right|$ as this bound, if extrapolated backwards over billions of years, is unacceptable: it predicts a surface temperature of the earth 10^9 years ago, that reach that of *boiling water*, which in turn, preclude the evolution of life to its present form.

Carter (1974) gave an entirely different explanation for the coincidence of large numbers: perhaps, at epochs much before these numbers approximately coincided, the physical conditions were such that life, and especially intelligent life like man, could not yet exist! Therefore, the coincidence of Dirac's large numbers is just a *necessary prerequisite* for man to appear in the universe. This is a version of the "*anthropic principle*".

Dirac was born in Bristol. His mathematical ability manifested itself at an early age. At the school he attended in Bristol, he was given rather advanced books on mathematics to study independently. His father, a Swiss by birth who was the French master at the same school, encouraged his son to develop his mathematical ability. He wished him to also become fluent in French, to the extent that, according to the son's report, the elder Dirac refused to speak to him unless he was addressed in the French language. This may have fostered Dirac's pronounced tendency to seldom speak, and to choose his words with utmost care. He avoided company, preferring to work alone. His main leisure pastime was solitary walks.

Toward the practical end of earning a living, Dirac studied engineering at the University of Bristol. The use of approximations that he acquired in these studies had a strong influence on his later work: it strengthened his confidence in the intuitive approach to problem solving. He came to believe that a theory expressing fundamental laws of nature could be constructed solely on the basis of approximations, guided by intuition rather than exact knowledge of the actualities. He declared that the actual phenomena were too complex ever to be pinned down in a precise way; a physicist must be satisfied to work with only approximate knowledge of reality.

Dirac's study of theoretical physics began only after he received a degree in electronic engineering, failed to find work in this field, and, aided by a grant, entered St. John's College, Cambridge. From R.H. Fowler, his faculty supervisor, who had collaborated with Niels Bohr in his pioneering work in atomic physics, Dirac learned the current state of that science. Dirac was awarded the Nobel prize for physics in 1933.

Dirac taught at Cambridge after receiving his doctorate there, and in 1932 was appointed Lucasian professor of mathematics, the chair once held by Isaac Newton. He served in that capacity until 1968, shortly after which he moved to the United States. In 1971 he was made professor emeritus at Florida State University, Tallahassee, FL.

Dirac had no school or following and had produced (like Einstein) very few students. He had essentially no collaborators and once, when asked about this, had remarked that "the really good ideas in physics are had by only one person".

The Dirac Equation

The development of quantum mechanics took place historically through the wave-mechanics of ***Schrödinger****, based on the pioneering work of* ***de Broglie****, and simultaneously through the matrix mechanics of* ***Heisenberg****,* ***Born*** *and* ***Jordan****. The latter scheme was concerned chiefly with the literal observables of an atomic system, such as the spectral lines obtained in transitions between pairs of states or the particle velocities and positions. The two approaches were unified in the work of* ***Dirac****, who based quantum mechanics on the classical mechanics of Poisson, Hamilton and Jacobi, with a new interpretation of Hamilton's 'canonical'* variables.

The successful representation of electron spin by the matrices of ***Pauli****, paved the way for many advances in quantum mechanics. However, the theory was still inadequate for dealing with fast-moving particles, because the Schrödinger equation is not invariant under the Lorentz transformation of STR.*

In order to derive a relativistic Schrödinger-like wave equation[658] *for an electron interacting with an electromagnetic field (atomic and/or external), one must first derive a suitable Hamiltonian function for a particle of rest mass*

[658] At that time, prior to the discovery of second (field) quantization, no distinction was made between probability – amplitude wave-equations and field equations.

m, and charge e, free or in an external electromagnetic field characterized (in a particular gauge) by a vector potential $\boldsymbol{A}$ *and scalar potential* ϕ*. The classical Lorentz-covariant Hamiltonian is*

$$H = \sum_{i=1}^{3} p_i \dot{q}_i - L \quad , \quad p_i = \frac{\partial L}{\partial \dot{x}_i}$$

with $x_i(t)$ *the spatial particle trajectory in a particular inertial frame, where* $\boldsymbol{p}(t)$ *is the canonical (not mechanical) 3-momentum and the Lagrangian is*

$$L = -mc^2 \left(1 - \frac{v^2}{c^2}\right)^{1/2} + e(\boldsymbol{v} \cdot \boldsymbol{A}) - e\phi.$$

This leads to

$$H = e\phi + c\left[(\boldsymbol{p} - e\boldsymbol{A})^2 + m^2c^2\right]^{1/2},$$

or,

$$(H - e\phi)^2 - (\boldsymbol{p} - e\boldsymbol{A})^2 c^2 = m^2 c^4.$$

With the usual quantum mechanical correspondence

$$\boldsymbol{p} \to \frac{\hbar}{i}\boldsymbol{\nabla}, \qquad H \to \hbar i \frac{\partial}{\partial t},$$

the relativistic wave equation for a charged particle devoid of intrinsic angular momentum (spin) becomes:

$$\left[\left(\frac{\hbar}{i}\frac{\partial}{\partial t} + e\phi\right)^2 - \left(\frac{\hbar}{i}\boldsymbol{\nabla} - e\boldsymbol{A}\right)^2 c^2\right]\psi = m^2c^4\psi \ ,$$

with $\psi(\boldsymbol{x}, t)$ *complex wave function. This is the Klein-Gordon equation for a charged scalar particle under the influence of an external EM field. For* $e = m = 0$ *(photon), the Klein-Gordon equation simply reduces to Maxwell's electromagnetic wave equation.*

The Klein-Gordon equation was first discovered by Schrödinger, but was almost immediately rejected by him for two reasons: firstly, it possesses negative-frequency solutions, which are also (by $H \to \hbar i \frac{\partial}{\partial t}$*) negative-energy solutions. This is not really fatal, since one can discard all such solutions, although this is a suspiciously artificial procedure, and leads to problems with causality.*

A more serious objection is that it would lead to negative probabilities in Born's interpretation of the wave function.

Dirac sought to avoid both problems by finding a wave equation with a differential operator linear in $\boldsymbol{\nabla}$. That is, he sought to replace

$$\left[(\boldsymbol{p} - e\boldsymbol{A})^2 + m_e^2 c^2\right]^{1/2}$$

with

$$\boldsymbol{\alpha} \cdot (\boldsymbol{p} - e\boldsymbol{A}) + \beta m_e c,$$

in such a way that the squares of both operators coincide. Clearly, such an equality cannot be valid if the quantities $\boldsymbol{\alpha}$ and β are regarded as an ordinary vector and scalar, since squaring both expressions and equating coefficients of similar terms leads to the contradictory requirements

$$\alpha = (\alpha_1, \alpha_2, \alpha_3), \quad \alpha_1^2 = 1, \quad \alpha_2^2 = 1, \quad \alpha_3^2 = 1, \quad \beta^2 = 1,$$

$$\alpha_1\alpha_2 + \alpha_2\alpha_1 = 0, \quad \alpha_1\beta + \beta\alpha_1 = 0,$$

$$\alpha_2\alpha_3 + \alpha_3\alpha_2 = 0, \quad \alpha_2\beta + \beta\alpha_2 = 0,$$

$$\alpha_3\alpha_1 + \alpha_1\alpha_3 = 0, \quad \alpha_3\beta + \beta\alpha_3 = 0.$$

However, it is possible to satisfy these equations if α_1, α_2, α_3 and β are not numbers, but rather 4×4 anticommuting matrices (called Dirac matrices[659]*):*

[659] This is only one of an infinite number of matrix representations for $\boldsymbol{\alpha}$, β; however, the matrices *must* be at least 4×4 (in 4 dimensions, the *Clifford algebra* can only be implemented using at least 4×4 matrices). The three 2×2 Pauli matrices are the simplest realization of a Clifford algebra in *three* dimensions. In D spacetime dimensions, the Dirac matrices must be at least 2^n by 2^n, where n is the largest integer not greater than $D/2$. In our 4 spacetime dimensions, 2×2 Dirac matrices are allowed *if* the fermion has zero rest mass (*Weyl spinors*). *Neutrinos* were once thought to be massless. Now, these spin $-1/2$ *leptonic* fermions are known to have small but finite masses, but — due to peculiarities of the weak nuclear forces that endowed them with their rest-masses a fraction of a second after the Big Bang – must still be described by (several copies of) a Weyl spinor. But charged leptons (e.g electrons) are described as Dirac spinors, with 4×4 Dirac matrices.

$$\boldsymbol{\alpha} = \left\{ \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \\ 0 & -i & 0 & 0 \\ i & 0 & 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{pmatrix} \right\}$$

$$\beta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$$

The corresponding Dirac equation for a charged particle in an electromagnetic field then assumes the form

$$H\psi = \left[c\boldsymbol{\alpha} \cdot \left(\frac{\hbar}{i} \boldsymbol{\nabla} - e\boldsymbol{A} \right) + \beta mc^2 + e\phi \right] \psi = \hbar i \frac{\partial \psi}{\partial t},$$

where the quantum Hamiltonian matrix-differential operator on the L.H.S. acts on both the position dependence and the discrete index of the four-component, complex Dirac–spinor wavefunction,

$$\psi = \begin{bmatrix} \psi_1 \\ \psi_2 \\ \psi_3 \\ \psi_4 \end{bmatrix} \quad ; \quad \psi_a = \psi_a(\boldsymbol{r}, t), \qquad a = 1, 2, 3, 4.$$

The Dirac equation is equivalent to 4 simultaneous, linear, first-order differential equations in the components of ψ. It has been solved exactly for several important problems, including that of the hydrogen (or any hydrogen–like) atom with infinitely–massive nucleus, and an electron in any plane EM wavepacket. In the special case of a free particle

$$\psi = \exp \left[\frac{i}{\hbar} (\boldsymbol{p} \cdot \boldsymbol{r} - Et) \right] \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ c_4 \end{bmatrix},$$

with $E^2 = -\boldsymbol{p}^2 c^2 = m^2 c^4$ and two of the four complex constant c_a components being independent per given value of $\boldsymbol{p}$ and given energy sign. This represents the two possible spin states ("spin up", ↑, and "spin down", ↓) of an electron (or positron) relative to any given rest-frame spatial direction. Thus, the

Dirac equation actually predicts the existence of electron spin[660]. *Better yet: in the non-relativistic* $(|\boldsymbol{p}| \ll mc)$ *regime in a weak external magnetic field, the Dirac equation predicts the electron spin gyromagnetic ratio of* $g_e = 2$ *— very close to the empirical value, which before Dirac was totally inexplicable (the orbital ratio has the classical value of* 1 *in Dirac's theory, in agreement with experiment). For the hydrogen atom, Dirac's equation correctly predicts the fine structure of line spectra (due to the spin-orbit magnetic coupling also predicted by semiclassical relativistic electrodynamics; and also due, in part, to the STR velocity dependence of mass).*

Substituting the above representation for ψ *into the Dirac equation (with* $\boldsymbol{A} = \phi = 0$*) we obtain a system of* 4 *simultaneous homogeneous, linear algebraic equations, whose solubility condition is:* $E = \pm(p^2c^2 + m^2c^4)^{1/2}$. *From this we conclude that the permissible energy values for a free particle in Dirac's theory range from* mc^2 *to* $+\infty$ *and from* $-mc^2$ *to* $-\infty$. *The first of these results is of course just what we expect for a free relativistic particle*

660 A *Weyl* spinor has only *one* spin state when moving at extremely relativistic speeds ($|\boldsymbol{p}| \gg mc$), and correspondingly it needs only *two* Dirac components; such is the case for *neutrinos.* These spin $-1/2$ fermions have very small masses, so they are usually emitted (and absorbed) traveling vary near light–speed, and spinning clockwise relative to their direction of motion. If one could slow them down substantially — or chase them in a frame in which they are at rest — one would, of course, observe them to occur in *both* spin states (if all else fails, one could then use a *magnetic field* to rotate them – like neutron, neutrinos are electrically neutral but have magnetic dipole moments – or, overtake them. So they will now appear to spin *counter–clockwise* relative to their direction of motion!)

This apparent paradox can be resolved by noting that, in any quantum field theory in which a Weyl spinor acquires mass, there is a certain probability (especially at non-relativistic speeds) for a neutrino to turn into an *anti*-neutrino (or vice versa) — and antineutrinos (at near-light speeds) are *always* observed to spin *counter*–clockwise relative to their velocity direction. This postulated weak inter–conversion of matter and antimatter may partly explain cosmological *baryogenesis* — the phase transition (a fraction of a second after the Big Bang) which generated a small (ca 1 part in 10^{10}) *excess* of matter over antimatter.

Subsequently, the *antimatter* annihilated almost entirely with matter, leaving only radiation and the small *matter* excess: the universe we observe today.

In some extensions of the Standard Model of particle physics, the existence of counter–clockwise–spinning ("right handed"), low–mass neutrino states, is due in part to a quantum mixing between *massless*, *left*-handed neutrinos moving at light–speed, and *ultra-heavy*, *right*–handed, Weyl spinor neutrinos.

— that its total energy can have any value greater than or equalling its rest energy. But the second allowed energy band is quite puzzling, since it implies the existence of states of negative energy!

Furthermore, there is nothing to prevent — and indeed the theory requires — the occurrence of transitions between states of positive and negative energy. These rather remarkable features of Dirac's theory led him to predict the positron (e^+), which was indeed discovered in 1932 *by* ***Anderson***, *but not really understood until the advent of quantum electrodynamics (QED) in the* 30*'s and the* 40*'s.*[661]

1928–1941 CE **Frank Whittle** (1907–1996, England). Engineer, inventor and fighter pilot. Father of the jet age. The leading pioneer in the development

[661] QED results when the coupled Maxwell and Dirac equations are second-quantized. According to QED, a positron propagating *forward* in time can be interpreted as a *negative energy electron* propagating *backward* in time (!) — and yet, overall the theory does obey STR's local causality. The small deviations of empirical results from Dirac's predictions – e.g. for g_e – have been explained to very high accuracy by QED effects ("radiative corrections"), such as *vacuum polarization* due to virtual e^+e^- pairs.

It is ironic that the two reasons for the original rejection of the Klein-Gordon (KG) equation, were invalid! for the negative energy solutions occur in Dirac's equation as well, and turn out to be necessary to describe *antimatter*; while the negative-probability problem disappears when one second-quantizes the KG equation.

Today, the KG is used as a field equation for fundamental *scalar* and other integer–spin (bosonic) quantum fields, while the Dirac equation is used for fundamental *spinor* (fermionic) fields (such as the spin $-1/2$ neutrinos, electrons and quarks). Hypothetical fundamental spin $-\frac{3}{2}$ fermions — the so-called *gravitinos* of *supergravity theories* — are described by the Rarita–Schwinger equation, which is essentially the Dirac equation for a field $\psi_{\mu a}(x)$ with both a spacetime *and* a Dirac index, and with a few additional auxiliary conditions. The *spin-statistics theorem* of Quantum Field Theory states that local causality requires that integer-spin fields (such as scalars, photons non-abelian gauge fields and gravitons) describe *bosons* (i.e. obey Bose-Einstein quantum statistics), while half-odd-integer-spin fields (such as electrons, neutrinos, quarks, protons) describe *fermions* (i.e. their associated particles obey Fermi-Dirac statistics and the Pauli Exclusion principle).

of the turbojet engine. This engine powered Britain's first jet plane in 1941 and became the model for the first U.S. turbojet.

Whittle was born in Coventry, England, the son of an inventor. He joined the Royal Air Force when he was 16 and distinguished himself already in 1928 with his first patent, after the Air Ministry rejected his jet engine proposals.

Whittle's basic patents lapsed in 1935 because he did not have enough money to pay patent fees. Later that year, a group of engineers became interested in his work and, with the British government and Whittle, formed *Power Jets Ltd*, to produce engines. Whittle had joined the RAF in 1924 as an apprentice, later training as a fighter pilot.

During 1937–1946 he worked on jet propulsion. In May 1941, the Gloster E 28/39 first flew with the Whittle engine. Both the German and the US jet aircraft were built using his principles. He retired from the RAF (1948) and took up a university appointment in the USA.

While others (e.g. the British Rolls-Royce Co.), made many billions off his invention — which revolutionized transportation in the 20th century — the inventor himself was merely granted the lump sum of $100,000. Even in his own country he never received the recognition he deserved. The jet age started without Whittle.

1928–1952 CE **Felix Bloch** (1905–1983, U.S.A.). Distinguished physicist. Among the first to apply quantum theory to solid state physics, particularly to the magnetic properties of matter. Discovered (with **Edward Mills Purcell**) the phenomenon of nuclear magnetic resonance (1946), and developed it as a means of studying solids and liquids by measuring the magnetic behavior of their atomic nuclei. For this work they were both awarded the Nobel prize for physics (1952).

Bloch was born in Zürich, Switzerland, to Jewish parents. He studied first at the Federal Institute of Technology in Zürich and in 1927 under **Heisenberg**, at Leipzig, where he became a lecturer in physics (1932). He left Germany in 1933 and in 1934 went to Stanford University where, apart from a period during WWII, he remained as a professor of physics (1934–1971). In 1954–5 he took leave to become director of CERN, Geneva. His main contributions to quantum physics were:

- Modern theory of electrical conduction in metals (1928). Developed and applied methods for solving the Schrödinger equation of an electron in periodic structure (metallic lattice). Introduced *Bloch theorem*; *Bloch wavefunctions*; and *Bloch wavenumber*. Showed that the *electrical resistance* of a metal is mainly due to imperfections in the arrangements of its constituent atoms. Investigated the conductivity of metals at low temperatures and determined the dependence of spontaneous magnetization upon temperature (1930).

- Measured the magnetic moment of the *neutron* (with **L.W. Alvarez**, 1939); devised methods of polarizing neutrons, separating them according to the direction of their intrinsic spin (neutron beams).
- Solved several problems concerned with the properties of *ferromagnetic* materials (such as iron). These materials are divided into small mesoscopic regions called *domains*, in each of which the magnetization points in a different direction. Bloch showed which factors influenced the formation of the boundaries (or 'walls') between these domains, and calculated their thickness and dynamics.
- Introduced the model of '*spin waves*' in magnetic materials, which has proved extremely valuable in understanding how magnetic properties deteriorate when the temperature of the material is raised.
- First successful NMR experiment with bulk matter; *Bloch equations* (1946).

1928–1968 CE **George Anthony Gamow** (1904–1968, Russia and U.S.A.). Distinguished astrophysicist. One of a handful of scientists who made a distinctive mark on 20^{th} century science:

- Developed the quantum theory of radioactivity (1928) including the *tunneling effect*[662].

[662] An important quantum-mechanical phenomenon (directly observable), also called *barrier penetration* – which is responsible for such physical phenomena as field emission of electrons from metals, nuclear fusion in the solar core, and α-particle radioactivity. The particle wave-function acquires an exponentially decreasing spatial dependence — the matter-wave analogue of optical *evanescence*. This, in turn, makes it possible for a particle with insufficient *classical* kinetic energy for passing over a potential barrier, to occasionally penetrate it nonetheless, with a computable, finite probability per "attempt". Our sun *could not shine* without quantum tunneling, since its core temperature is too low for thermal energy alone to allow fusing protons to overcome their mutual Coulomb repulsion at sufficient rates.

In 1933, **Clarence Melvin Zenner** (1905–1994, USA) first explained the electrical breakdown of insulators in terms of tunneling effects [known as *Zenner effect* or *Zenner breakdown* and put to use in the *Zenner diode*]. A very similar effect occurs in the *Esaki diode* (1957), where an external electric field is applied across a thin film of insulator separating heavily doped p-type and n-type semiconductors.

- Originated (with **Edward Teller**) the *liquid-drop model* of atomic nuclei (1928–1929).
- Postulated (with **Fritz Houtermans**) that the sun's radiant energy derives from thermonuclear processes (1929), i.e., that *nuclear fusion* is the primary source of energy in stars.
- Formulated the Gamow-Teller theory of *beta decay* (1936) and the theory of internal structure and energy source of red giant stars (1942).
- Sorted out the role played by neutrinos in the supernova explosions of stars.
- His application of nuclear processes to cosmology led him to become a leading advocate of the '*Big-Bang*' theory of the origin of the universe[663]. Already in the late 1930's he applied his wide knowledge of nuclear physics to stellar evolution studies and in work concerning the mass-luminosity relationship for stars.

As early as 1946 Gamow and his collaborators began theoretical research regarding the origin of the elements during the first 4 minutes of the expansion of the universe, hypothesizing that the elements were created by neutron capture[664]. By 1948, Gamow had coined the term 'Big Bang' for the cosmological model that described the Universe as beginning in a highly dense, compact fireball, whose explosive expansion we are still witnessing through the recession of the distant galaxies.

Gamow's work on big-bang cosmology led him to predict the *cosmic abundance of Helium* and the presence of a low-temperature *cosmic microwave*

---

663 Einstein himself did *not* believe in the existence of singularities in nature [*Ann. Math.* **40**, 922, 1939]. On the subject of the *big bang*, Einstein's last words were: "One may… not assume the validity of the equations for very high density of field and matter, and one may not conclude that the 'beginning of explosion' must mean a singularity in the mathematical sense" [A. Einstein and N. Rosen, *Phys. Rev.* **48**, 73, 1935]. Modern Quantum Field Theorists concur; for example, in *string theories* Einstein's GTR is but a long-wavelength approximation, to be replaced by an effective, non-local field theory at epochs approaching the Planck scale (times of order 10^{-43} sec after Big Bang). These effective field theories avoid the far-past singularities which **S. Hawking** and others proved must afflict *any* GTR-based cosmology (under reasonable assumptions).

664 Expounded in a paper by **A**lpher, **B**ethe and **G**amow (1948), in which Hans Bethe's name was borrowed for comical effect.

background radiation[665]. [The latter prediction was confirmed observationally by **Arno Penzias** and **Robert Wilson** (1965); light-element abundance predictions based on Big Bang models have also been brilliantly confirmed by astrophysical and cosmological observations.]

- First to suggest (1954) a three–nucleotide–symbol for genetic coding scheme; it was inaccurate, but later acknowledged as a key milestone in the development of molecular biology. The correct DNA genetic code — which indeed utilized codons three nucleotides long — was worked out by **M. Nirenberg** *et al.* in the 1960's.

Gamow was born in Odessa, Russia. He was educated in the USSR, studied nuclear physics at Göttingen, Germany (1928) and spent some time in Cambridge at the Cavendish Laboratory (1929), where **Rutherford** asked him to calculate the energy required to split the atom. He then emigrated to the United States (1933). Became a professor of physics at George Washington University (1934–1956), and later professor of physics at the University of Colorado (1956–1968).

1928–1960 CE **Georg von Békésy** (1899–1972, Hungary and U.S.A.). Physicist. Established a new theory of hearing based on waves formed by fluids in the *cochlea* of the inner ear. This auditory mechanism replaced a theory put forward by **Helmholtz** (1857), and won Von Békésy the Nobel Prize for physiology in 1961.

He showed that the tympanic membrane is almost critically damped, that the middle ear is nonlinear, and that receptions in various regions of the cochlear duct are sensitive to different frequencies of vibrations. He was first to suggest (1960) that the *inner hair cilia* in the cochlea were the transducers

[665] This radiation, which bathes the earth almost exactly isotropically from all directions in the universe, corresponds at the current epoch to the microwave radiation of a black body at a temperature of 2.7 °K. The only plausible explanation for the origin of this radiation is that it is the remnant of an early phase in the expansion of the Universe – the so-called *recombination era* (ca 3×10^5 years after the Big Bang). The near–visible photons of that epoch – when electrons combined with photons to form neutral hydrogen and the universe became transparent to EM radiation and also matter–dominated gravitationally – spread throughout space and lost their energy through the adiabatic cosmic expansion (i.e through red–shifting), so that the corresponding temperature dropped – from about 3000 °K at recombination to its present value of 2.7 °K.

which convert an acoustic signal into a neural signal (traveling along a nerve fiber), and all recent evidence has fully confirmed that hypothesis.

Békésy became interested in hearing as director of the Hungarian Telephone System Research Laboratory (1923–1946), and was later Senior Research Fellow in psychophysics at Harvard.

Mechanics of Hearing (1561–1991)

"Anyone familiar with how extraordinarily various systems have been refined during 200, 000, 000 *years of mammalian evolution by natural selection, has to sit up very respectfully indeed in front of well attested evidence of anything so potentially valuable to an animal's survival as an auditory response curve which, around its peak, becomes more and more sensitive as sound levels get lower and lower. Immediately one is tempted to puzzle over what special sort of mechanism might have evolved to allow such an advantageous increase of sensitivity at low stimulus level".*

James Michael Lighthill, *J. Vib. Acoust.* **113**, 1–13 (1991)

Four hundred years had to pass from the first application of the scientific method to the subject before man could gain some basic knowledge of the structure and auditory mechanism of the human ear. This is not surprising in view of the complexity of the inner ear and the strong dependence of its physiology upon acoustic principles and phenomena that were not fully understood before the end of the 19^{th} *century.*

The first period (1561–1772) is marked by the efforts of Italian physicians and anatomists to 'map' the anatomy of the ear: ***Gabriele Fallopio*** *(1523–1562) gave the first modern description of the organs of the inner ear (1561). His contemporary* ***Bartolomeo Eustachi*** *(1520–1574) published a treatise on the organ of hearing in which he rediscovered the* Eustachian tube *(named after him although it was discovered some* 2000 *years earlier by* ***Alcmaeon of Crotona****), the* tympanic membrane *and the* cochlea *(1564).*

Giulio Casseri *(1522–1616) wrote a book on the anatomy of voice and hearing in which he discussed the physiology of hearing. The Italian anatomist* ***Antonio Maria Valsalva*** *(1666–1723) provided (1704) the first detailed description of the physiology of the ear, and* ***Antonio Scarpa*** *(1747–1832) discovered in* 1772 *the semicircular canals, vestibule and the internal structure of the cochlea.*

During the second half of the 19^{th} *century, physicists and physiologists began to harness acoustical theory to investigate the passage of sound through the ear. Chief among these was* ***Helmholtz*** *(1857–1864), who proposed a* resonance theory of hearing, *based on the argument that the transverse fibers of the* basiliar membrane *in the cochlea of the inner ear act as* tuned resonators *(1857). In* 1864 *he advanced the theory that the pitch (frequency) is detected by a series of resonators of different sizes in the cochlea, and that overtones and beats based on different frequencies, determine the quality of the perceived sound. In* 1870, ***Galtz*** *recognized that the vestibular process is for maintenance of* directional equilibrium *and is not involved in hearing. In 1886,* ***William Rutherford*** *(1839–1899) discovered that tiny hairs in the cochlea are set in motion and thus convey sound.*

The first practical commercial electrical hearing aid was patented in 1902 *by* ***Miller Reese Hutchinson*** *(U.S.A.).*

On other fronts of the science of hearing, the pioneering work of ***W.C. Sabine*** *(1898–1900) laid the foundation of the* acoustics of buildings and rooms; *The first systematic explorations of* binaural hearing *were made by the physicist* ***Irving Langmuir***, *while working on the detection of submarines during WWI. The physicist* ***Harvey Fletcher*** *(1884–1981, U.S.A.) first used precise and effective electronic apparata in studies of sound and hearing (1923–1929). At Bell Laboratories, he led a wide range of experiments on speech, hearing and sound reproduction, using vacuum-tube electronics, microphones, headphones, amplifiers and loudspeakers.*

Like the eyes, the ears perform two functions — they detect sound and gather information about the position and movement of the body. But unlike the eyes, two separate receptors are involved — the so-called cochlea *is sensitive to sound, and the* semicircular canals *and vestibule detect movement.*

As with vision, the body faces the problem of converting an external stimulus into a code understood by the brain. Sound is produced by waves of alternating-sign pressure fluctuations spreading out from a source, rather like ripples on a pond. These waves can pass through solids, liquids and gases. Sound reaches the ears by the vibration of molecules in the air (or in water, if the listener is diving).

Before nerve impulses are produced in response to sound, the vibrations are first converted into the mechanical movement of 3 *tiny bones, the last* *of which sets up a wave in a tube (cochlea) filled with liquid. Rows of tiny nerve cells respond to this wave movement by firing off signals which carry information about the amplitude, phase and frequency content of the incoming sound. This* 3-*stage auditory system gives humans a dynamic range of* 10^{14} *from the softest to the loudest detectable signal. The frequency range of the human ear is between* 20–20,000 *Hz (although it is significantly narrower, in actual fact, for most individuals).*

Many animals can detect sound of far higher frequencies than those detected by humans. (Some bats can produce and detect frequencies up to 120,000 *Hz.) Humans are most sensitive to sounds between* 1000 *and* 6000 *Hz, the range in which speech sounds fall. In this region, the ear can distinguish between two different pitches separated by* 2 *to* 6 *Hz, and between two clicks when the second follows the first after only* 10 *milliseconds.*

The anatomy and physiology of the ear is briefly as follows: The external ear consists of a funnel-like structure (auricle) which helps direct the air pressure changes down into an S-shaped canal that leads inward for about 27 *millimeters. Without the auricle one could not hear very well (and would not have any place to hang one's glasses!). The auditory canal (meatus) leads to the diaphragm, or eardrum (tympanic membrane). Thus, the meatus acts like an organ pipe with one closed end, and sets up a standing wave whose fundamental wavelength is four times its length, or about* 108 *millimeters.*

Since the speed of sound is 354 *m/sec at body temperature, the frequency is* 3280 *Hz. The meatus*[666] *provides an amplification of* 5–10 *dB for frequen-*

[666] During the 1920's, when routine measurements of sound amplitudes first became practical, the wide dynamic range of magnitudes made it customary to plot data on a logarithmic scale. **Harvey Fletcher** introduced (1923) a definition of a *sound-pressure level* (s.p.l) relative to an arbitrary reference standard, $L = 10\log_{10}\left[\frac{(p^2)\text{ave}}{p^2_{\text{ref}}}\right]$, the resulting number having the units of *decibels* (db). This definition implies that $L = 0$ at the level $p^2 = p^2_{\text{ref}}$ and $L = 1$ (dB) for $p^2 = 10^{1/10}p^2_{\text{ref}} = 1.2589P^2_{\text{ref}}$. In general, a second pressure level exceeds the first by 1 dB unit if there is an increment of 0.1 in the logarithm to base 10 of their corresponding *mean square pressures*. The mean square pressure may correspond either to the acoustic pressure, to that of one frequency component, or to a band of frequencies.

The above definition is sometimes written in terms of an *intensity level* in the form $10\log_{10}\frac{I}{I_0}$, where $I = \frac{\langle p^2\rangle_{\text{ave}}}{2\rho_0 c}$ is the *sound intensity* (acoustic energy flow per unit area per unit time), and ρ, c are respectively the mass density and speed of sound in air at the ambient temperature and pressure; the denominator $z = \rho_0 c$ is the acoustic impedance. The reference intensity is usually chosen to be $10^{-12}\ \frac{\text{watt}}{\text{m}^2}$ which is about the threshold of human hearing at *cies between 2000–5000 Hz, and this frequency range is the region in which the ear is most sensitive.*

While the outer ear helps direct the miniscule air-pressure changes (as small as 10^{-9} atmospheres) down into the ear canal with some initial amplification, the problem still confronted by the ear is how to convert (transduce) air-motion into some other physical excitation that will stimulate the nerves to send messages on to the brain. This is done in two steps: in the first step

---

1000 Hz. [Note that if the actual intensity doubles $(I = 2I_0)$, the ear hears an increase of $10 \log_{10} 2 = 3$ dB, whereas if the intensity increases tenfold, there is an increase of 10 dB.]

The following auditory conditions are parametrized by the corresponding sound intensity (in $\frac{\text{watt}}{\text{m}^2}$) and dB level as heard by our ears: *human breathing* (10^{-11}, 10); *rustling of leaves*, or *whispers* (10^{-10}, 20); *two person conversation* (10^{-6}, 60); *vacuum cleaner* (10^{-4}, 80); *accelerating motorcycle* (at 5 meters: 10^{-1}, 110); *rock concert* (1, 120); *threshold of pain* (100, 140); *large rocket launch vehicle* (10^7, 190).

Some amusing comparisons can be constructed from these figures: since a human shout generates a power of 10^{-5} watts, the acoustic power generated by all the world's population shouting at once is about 10^5 watts. This power is emitted by a single large jet transport at take-off! Also, the total energy radiated by the combined shouts of the Wembly cup final crowd during an exciting soccer game is about that required to fry one egg! Finally, a 40 W light bulb illuminating an area of 1 cm^2 at distance of 1 cm produces the same power as 1500 bass voices singing fortissimo.

In the human ear, the range of acoustic intensities at the threshold of *audibility* on the one hand and the threshold of *pain* on the other, spans over 14 orders of magnitude; no single mechanical instrument is capable of such a vast dynamic range [*Analogy*: imagine a balance sensitive enough to weigh a single human hair with reasonable precision. If this same balance had the wide range of the human ear, it could also weigh an aircraft-carrier.] Note also that at the threshold of hearing, the vibration *amplitude* is about 10^{-9} cm at 1 KHz, that is, only some 10^{-3} of the mean free molecular path length in the surrounding air, or 0.1 of the Bohr atomic radius (*detail*: assume a displacement of the tympanic membrane $y = A \sin \omega t$ with $u = \dot{y} = A\omega \cos \omega t$; $I_0 = \frac{(p^2)_{\text{ave}}}{2z} = 10^{-12}$ watt/m^2; $(p^2)_{\text{ave}} = z^2 (u^2)_{\text{ave}} = \frac{1}{2} z^2 A^2 \omega^2$. Hence $A = \frac{2}{\omega}\sqrt{\frac{I_0}{z}}$, with $\omega = 2\pi \times 10^3 \,\text{sec}^{-1} = 6280 \,\text{sec}^{-1}$, $z = \rho_0 c = 450 \,\text{kg}\,\text{m}^{-2}\text{s}^{-1}$, yields $A = 1.5 \times 10^{-11}$ meters. Since one atmosphere is equal to $p_0 = 10^5 \frac{\text{Newton}}{\text{m}^2}$, and I_0 corresponds to a peak-to-trough pressure change of $\Delta p \simeq 4\sqrt{I_0 \rho_0 c} = 8 \times 10^{-5} \frac{\text{Newton}}{\text{m}^2}$, we find that $\frac{\Delta p}{p_0} \approx 10^{-9}$ at the threshold of audibility].

the vibrations of the tympanic membrane are converted into vibrations in the liquid, in which receptors are located.

Under normal circumstances the efficiency of vibration transfer from air to liquid is less than 0.1 *percent. The ear gets around this by using three small bones (ossicles)*[667] *of the so-called middle ear, which form a bridge connecting the eardrum to the inner ear and function to transmit vibrations between these parts. Because of the lever action of the bones, the force delivered to the last bone is* 1.4 *times greater than that applied to the tympanic membrane.*

The force delivered by the shapes is further increased because the surface area of the membrane is about 25 *times that of the oval window, which is where the bone applies its movement. Overall, then, the construction of the middle ear serves to amplify the air vibrations by* 35 *— a very clever mechanical structure indeed!*

The inner ear consists of a complex system of intercommunicating chambers and tubes called the labyrinth. The parts of the labyrinth include a cochlea[668] *that functions in hearing, and three semicircular canals that function in providing a sense of equilibrium. A bony chamber, called the vestibule, which is located between the cochlea and the semicircular canals, contains membraneous structures that serve both for hearing and equilibrium.*

If one cuts the cochlea tube lengthwise, it is seen that it is divided into two major compartments by the basiliar membrane; the two compartments interconnect. When the stapes pushes the membrane of the oval window, the fluid in the two compartments is compressed, so much so that the membrane covering the round window[669] *at the other end of the tube bulges out. The motion of the fluid sets the basiliar membrane into motion. A standing wave*

---

[667] The auditory ossicles (*malleus*, *incus*, *stapes*) never grow, and keep their size invariant throughout life. The malleus vibrates in unison with the eardrum, and causes the incus to vibrate, which in turn passes the movement onto the stapes. Vibration of the stapes at the *oval window* of the inner ear causes motion in a fluid within the inner ear.

[668] The total length of the uncoiled cochlea is about 35 mm. Its coiled diameter is about 1.5 mm. Its two galleries are filled with *perilymph fluid*. The partition between the galleries consists of 3 membranes of which the basiliar membrane is the lowest one. The partition between the galleries is filled with a highly viscous substance called the *endolymph*.

[669] The role of the *round window* is to relieve any pressure of the perilymph fluid due to *mass movement* of the fluid (caused by low-frequency thumps) from the oval window. High-frequency clicks do not produce a mass movement of perylimph, but cause the whole partition between the galleries to move.

is established in the membrane, the characteristics of which are determined by the frequency of the sound.

The location of nodes and antinodes of the vibrating basiliar *membrane will depend on the frequency of the exciting vibration in the fluid, while the displacement at each point along the membrane will depend on the spectral amplitude of the corresponding frequency.*

Thus, receptors that are linked up along the length of the basiliar membrane could "read" the frequency and amplitude of a given Fourier component of an incoming sound signal from the amplitude pattern formed along the axis of the membrane.

The basiliar membrane *is not as simple as we have implied: At its upper surface is located the* organ of Corti *which stretches from the apex to the base of the* cochlea. *Its receptor cells, which are called* hair cells, *are arranged in rows, of which there is a total of* 23,500 *in each ear. Above these cells is a* tectorial membrane *that is attached to the bony shelf of the cochlea and passes like a roof over the receptor cells, making contact with the tips of their hairs.*

As sound vibrations pass through the inner ear, the hairs shear back and forth against the tectorial membrane, *and the mechanical deformation of the hairs stimulate the receptor cells, thereby initiating a* nerve impulse *from the hair cells, along the sensory fibers to the* cochlear nerve, *which later forms the* auditory nerve. *Various receptor cells, however, have slightly different sensitivities to such deformation of their hairs.*

Thus, a sound that produces a particular frequency of vibration will excite certain receptor cells, while sound involving another frequency will stimulate a different set of cells. The inner hair cells are less sensitive than the outer row and therefore require greater mechanical stimulation before discharging. This arrangement therefore adds a further dimension of intensity discrimination. The auditory nerve carries auditory information to the temporal lobe of the auditory cortex, *passing through the* thalamus *on the way. Both ears send information to the cerebral hemispheres.*

In recent decades (1970–1990) great progress has been made in our knowledge of the macro- and micromechanics of the cochlea. First, experiments have shown that waves propagated along the basilar membrane are indeed dispersive; ***William Rhode*** *(1971, University of Wisconsin, U.S.A.) used surgical procedure allowing two small* Mössbauer sources *(measuring time-variation of Doppler shifted frequencies of source-emitted gamma rays) of diameter* 0.06 *mm, and* 1.5 *mm apart, to be implanted on the basilar membrane of a live squirrel monkey. Another Mössbauer source was placed on the point of the eardrum which is in direct contact with the handle of the malleus bone in the middle ear.*

Thus, when the ear was stimulated acoustically by a pure tone, the sinusoidal vibrations of both *the basilar membrane and the malleus — which drives it — could be determined in both amplitude and phase. From the amplitude ratio and the phase difference, the* group velocity *U could be evaluated at each frequency as a function of a coordinate x_r along the basilar membrane. It was found that, for any given frequency ω, U tended to* zero *at a different location, thus permitting the energy to "pile up" at a characteristic, frequency-dependent position $x_r(\omega)$! In other words, each Fourier component of an acoustic signal will propagate along the cochlea as far as its characteristic place.*

How is the basilar membrane able to achieve this feat of frequency selectivity? Experiments (1978) have shown that the mechanical behavior of the basilar membrane in vivo *is highly anisotropic, to the extent that neighboring short sections of the membrane vibrate almost independently of one another. This results in a continuous variation in* stiffness *along its length by about four orders of magnitude. This massive increase in compliance from base to apex is primarily due to a gradual increase in width (from* 0.1 *mm to* 0.5 *mm) and a corresponding decrease in thickness.*

This property facilitates the dispersive behavior mentioned above, as it permits the traveling wave at a given frequency to undergo a progressive reduction in wavelength, and therefore in group velocity, to zero as the characteristic position is approached. Then its amplitude must build up in a way limited only by viscous dissipation, which allows a very sharp tuning in the basilar membrane vibrations. This is how the different frequency components of an acoustical signal "find their way" to different characteristic positions along the cochlea.

Nevertheless, even the modest level of energy dissipation by viscous action is now believed to prevent this remarkable mechanism of frequency selectivity (based on passive *mechanical properties of the basilar membrane) from entirely accounting for the extreme sharpness of tuning observed in the best recent measurements. Compelling evidence has been amassed to the effect that an* active feedback mechanism, *residing in the* outer hair *cells, produces a further sharpening of the basilar membrane's response at* low amplitudes.

Some 4000 *inner hair cells are stretched along the length of the human cochlea, and each sends a signal to the brain along a group of nerve fibers, which together form part of the complete auditory nerve. Each of these nerve fibers comes from a particular place along the cochlea and predominantly carries information about acoustic signals at frequencies for which that is the characteristic position. Indeed, electrophysiological measurements of the neural activity in one of those fibers show a level of response to acoustic signals which has a* very sharp maximum *at the corresponding frequency (1965–1974).*

In addition, there are 12, 000 *outer hair cells. These cells are endowed with efferent nerve fibers carrying to them (from more central parts of the nervous system) neural signals which can be presumed to control their function.*

Experiments using Mössbauer source implantation on the basilar membranes of guinea pigs (1982) have shown that the threshold sound (sound pressure level in db) required to generate vibrations of the basilar membrane (at a particular place where a Mössbauer source was implanted) decreases with the decrease of frequency.

In addition, the basilar membrane response has a very sharp maximum at the frequency for which that point is the characteristic position. The (also very sharp) tuning of auditory nerve fibers — that is, their sharp maximum of response to acoustic signals at a characteristic frequency for each fiber — is found to be fully matched by the sharp tuning of the basilar-membrane mechanism in the inner hair cells which simply converts vibration velocities into neural activity.

Experiments (1987) have revealed that pure tone signals are able to evoke from the ear an acoustic response, *taking the form of an* emission *of sound from it at the same frequency, known as the* otoacoustic emission. *This means that the low-level incoming acoustic signal stimulates in the cochlea an active process, utilizing metabolic energy, that gives rise to a* backward traveling wave. *This backward wave exerts a pressure on the oval window which, through the same linkage acting in reverse, causes the eardrum to generate a signal that enhances the weak external signal.*

How then is the otoacoustic emission generated? It is believed that the vibrations of the outer hair cells vibrations are the source of the positive mechanical feedback (1987–1989).

So far we mainly discussed that part of the ear which responds to acoustic signals. *The ear, however, is also designed to respond to* accelerations and rotations of the head; *the relevant sensors are used by the brain to control the position, attitude and movements of the body — much as* inertial navigation *systems do in human-engineered air, sea and space craft. The sense of equilibrium actually involves two senses — a sense of* static equilibrium *(stability of the head and body when these parts are motionless), and a sense of* dynamic equilibrium *(maintaining balance upon sudden motion or rotation).*

The organs of static equilibrium are located within the vestibule, *the bony chamber between the* semicircular canals *and the* cochlea. *They are the* utricle *and the* saccule. *The dynamic equilibrium is monitored by the three bony* semicircular canals.

These two groups of receptors all work in basically the same way — that is, there are hairlike nerve cells within the tubes that pick up the swirl of internal *fluid caused by tilting or rotational movement of the head. The* saccule *and* utricle *are simply short tubes in the same plane. The canals, on the other hand, are three tubes arranged at right angles to each other. In this way they can detect movement of the head in any plane*[670]*. Signals from these two groups of receptor organs are largely responsible for inflicting motion sickness on the occasional unfortunate traveler.*

Among other interesting features of the ear which determine its quality as an auditory sensor is the persistence of hearing*. In the optical case, persistence of* vision *is of the order of* 0.02 *sec. In the aural case, regardless of the original intensity, the sound level decays to threshold in about* 0.14 *sec after stimulation has ceased.*

1928–1968 CE **Maurits Cornelius Escher** (1898–1971, Holland). A most original, unique and imaginative artist who created images of the observed world through which he represented concepts of *groups*, *fractals*, *manifolds*, *non-Euclidean geometries* and *topology*.

Most of his life was spent in making various kinds of analytic compositions out of his subjects by means of graphic processes such as wood-engraving or lithography. He was at the same time photographer, architect and visionary, and his images are of equal interest to cognitive psychologists, mathematicians and laymen. Some of his works treat landscapes and natural forms in a fantastic fashion using distorted geometries. Others combine seemingly meticulous realism with paradoxical visual and perspective effects.

Scientists are fascinated by Escher's work because they recognize in it elements of the world with which they are familiar[671]. For them the plurality of Escher's world signifies neither absurdity nor chaos, but a challenge to look for new logical relationships between phenomena: the strangeness or absurdity that seems at first sight to be present in his work can, in the final analysis, be resolved and explained.

---

670 It is amazing how nature, via the process of evolution, created a dynamical system that man could not improve on, if he had to construct it himself on the basis of modern science and technology.

671 It is bizarre how very little of 20^{th}-century science has been assimilated into 20^{th}-century art. Besides Escher, the *topological sculptures of* **Henry Spencer Moore** (1898–1986, England) come to mind.

The main source of fascination in Escher's prints is in the obvious message they convey: *reality is wondrous and at the same time comprehensible.*

Escher was born in Leeuwarden, the capital of the province of Friesland in the northern part of the Netherlands. He spent most of his youth in the city of Arnheim, where he attended secondary school. He later went to Haarlem, on his father's advice, to study architecture; there he came under the influence of the Jewish artist **Samuel Jessurun de Mesquita**, (1868–1944) who advised him to drop architecture and pursue his education in the graphic medium under his guidance (1919–1922).

Escher lived in Rome from 1923 to 1935, being greatly fascinated by Italy and its cultural heritage. He traveled extensively throughout the country. The rise of fascism caused him to leave Italy in 1935 and travel in Switzerland and Spain. He returned to Holland in 1941, and stayed there for the rest of his life.

Radio Communication and the Fourth State of Matter

During the early years of the 19^{th} *century, several major discoveries were made concerning the properties of electric current. In 1800* ***W. Nicholson*** *(1753–1815, England) and* ***A. Carlisle*** *(1768–1840, England) discovered the phenomenon of electrolysis, in which the chemical bonds of certain compounds (known as electrolytes) are broken by the passage of a current.*

The laws of electrolysis were stated by ***Faraday*** *in* 1832, *and these could be explained most simply in terms of ionic migration. According to the ionic theory, an electrolyte consists of free positive and negative ions which move to opposite electrodes during electrolysis. This idea was applied successfully to many problems of physical chemistry by* ***Arrhenius*** *and others. As a result, it appeared probable that in certain substances chemical combination depends on the electrostatic attraction between opposite charges attached to different atoms or parts of molecules.*

Some of the most important advances in late 19^{th} *century physics came from the study of electrical conduction in gases. After* 1855, *improved vacuum techniques enabled* ***Plücker***, ***Hittorf*** *(1824–1914, Germany), and* ***Crookes*** *(1832–1919, England) to investigate the properties of cathode rays. In* 1897,

***J.J. Thomson** produced strong evidence in favor of the theory that cathode rays are beams of subatomic particles, now called electrons (and identical to the earlier–discovered negatively charged* beta rays *emitted by radioactive substances). The electron theory was rapidly applied in many branches of physics, and **Millikan**'s experiments (from* 1911 *onward) made it clear that the electronic charge is the fundamental unit of electricity.*

J.J. Thomson went on to analyze the positive rays occurring in discharge tubes and by 1912 *he had evolved a technique for separating ions of different atomic masses and charges (mass spectrometry). In isolating two stable isotopes of neon he provided part of the explanation of fractional atomic weights in chemistry. By this time both the massive positive ions and the much lighter electron had been identified; **E. Rutherford** (1911) adduced strong evidence indicating that electrons orbit oppositely–charged* nuclei *within neutral atoms. Although the details of atomic structure remained obscure until the maturation of the quantum theory in the 1920s. It was evident that the stability of atoms depends on electrostatic forces.*

*With the advent of radio communication, **Arthur Kennely** (1861–1939, U.S.A.) and **Oliver Heaviside** (1850–1925, England) tried to explain the perplexing observation that radio-waves could bend around the earth's curvature and get across the ocean. [Maxwell's theory seemed to predict that radio waves should sail off into space!]*

Both Kennely and Heaviside, neither knowing of the other's work, suggested in 1902 *that there was a layer of electrified gases high up in the earth's atmosphere that* reflected radio waves*. This was quickly found to be true, and that region of the atmosphere is known today as the* Heaviside layer*, or simply* the ionosphere*.*

The ionosphere consists of various layers of partially ionized gases — plasmas *— that reflect a certain range of radio frequencies. The altitudes of the different layers vary considerably from day to day, depending largely on the activity of the sun. Low, medium and high frequency radio waves are reflected at different altitudes, and thus allow long-range radio broadcasts to span oceans and continents. But very high frequencies (VHF) and ultra high frequencies (UHF), which are used for television broadcasts, are not reflected by the ionosphere. Thus, TV signals can only be sent as far as the horizon, unless they are relayed. The* aurorae *are thought to be caused by ions and electrons of the ionosphere that are excited to the point where they glow.*

By the 1920*'s, radio communication was big business. Large industrial research laboratories such as* General Electric *Laboratories were deeply engaged in investigating the basic physical phenomena of radio communication, and seeking ways to make better electronic equipment.*

It was at the GE Labs that **Irving Langmuir** *(1881–1957, U.S.A.) carried out basic studies of electrified gases in vacuum tubes (as did Crookes half a century earlier) and coined the term* plasma.

One of the prime differences between gases and plasmas is that plasmas can conduct electricity, and its constituent particles can exert electromagnetic forces on each other. A plasma as a whole is usually electrically neutral on average (although charged particle beams, generated in particle accelerators or even in simple vacuum tubes, are not neutral). Most plasmas consist of a mixture of free electrons, positive ions and neutral atoms. A plasma may be lightly ionized (neutral atoms outnumbering the electrons and ions), or it may be fully ionized (almost no neutral atoms). Free electrons and ions may carry bulk electrical currents, and both electrons and ions can be energized by electromagnetic fields or by injected particle-beams.

Plasma physics is the study of charged particles collected in sufficient numbers, so that the long-range Coulomb force is a factor in determining their statistical properties, yet low enough in density so that short–range forces due to nearest-neighbor particles are negligible in comparison with the long-range electromagnetic forces exerted by the many distant particles. It is the study of low-density ionized gases.

The most characteristic aspect of the plasma state — to wit, the long rang of the Coulomb (and other electrodynamic) forces and the consequent collective behavior of the charged particles — was known much earlier, and was probably first described by Lord Rayleigh, in 1906, *in his analysis of electron oscillations in the Thomson model of the atom.*

The term "fourth state of matter", often used to describe the plasma state, was coined by **W. Crookes** *in* 1879 *to describe the ionized medium created in a gas discharge. The term follows from the idea that as heat is added to a solid, it eventually undergoes a phase transition to a new state, usually liquid. If heat is added to a liquid, it eventually undergoes a phase transition to the gaseous state. The addition of still more energy to the gas results in the ionization of some of the atoms. At a temperature above* $100,000\,^\circ K$ *most matter exists in an ionized state — the fourth state. A plasma state can exist at temperatures lower than* $100,000\,^\circ K$ *provided there is a mechanism for ionizing the gas, and if the density is low enough so that recombination is not too rapid.*

Early researches into the nature of plasmas, from glow discharge tubes to the Heaviside layer, dealt essentially with plasma at rest. *When WWII ended, many physicists turned their attention to the nature of plasmas flow. This study is called* plasma dynamics.

During the late 30*'s and the War-torn* 40*'s, astronomers and physicists began to realize that the matter in the* universe *(stars, nebulae and galaxies)* *is made up almost entirely of plasma: from the ionosphere, a* 100 *km or so over our heads, out to the deepest reaches of the cosmos (outward in space and backward in time), plasma is by far the most common known form of matter. Planets and interstellar dust, made up of the more familiar forms of matter, constitute a minor portion of the universe's mass*[672]*. Yet this means that plasma must be artificially created in terrestrial laboratories in order to be studied, as we happen to inhabit a planet!*

Plasma physics generally involves the well-known physics of classical mechanics, electromagnetism, and nonrelativistic statistical mechanics.[673] *The challenge of plasma physics comes from the fact that many plasma properties arise from the long-range Coulomb and magnetic interactions, and therefore involve complex collective phenomena with many particles interacting simultaneously via, and with, long-range EM fields.*

---

[672] Nevertheless, it now appears quite likely that the universe also contains large quantities of *dark matter*, not yet directly observed or studied directly; and according to the successful Big Bang cosmological theory, dark matter is far more massive overall than visible matter – by about two orders of magnitude. Some of this dark matter is theorized to be novel not just in its *phase* (state) but even in the very elementary particles it is made of — such as neutrinos, 'strange' quarks, axions, heavy "supersymmetric partners" of known particles, black holes, etc. These are not made of electrons, protons and neutrons (and/or their antiparticles), as is all known (so-called *baryonic*) matter that is either observable from afar or can be examined directly.

Apart from these exotica, the observed matter – from the earth's vicinity to the farthest galaxies – seems to be not only baryonic but also overwhelmingly made of *matter* as apposed to *antimatter* (i.e. positrons, antiprotons, etc.). The latter are few and short-lived due to their rapid annihilation (by their normal-matter counterparts) into pure radiant energy (mostly photons and neutrons, ultimately).

However, modern cosmology asserts that, a fraction of a second after the Big Bang, the entire universe was a plasma, but with no nuclei – nor even nucleons; rather it consisted of equal (or almost equal) amounts of particles and antiparticles, as well as quanta that are *their own* antiparticles such as photons and other so-called gauge bosons. The mechanisms that ultimately gave rise to our present matter – dominated observed universe ($\sim 10^{10}$ electrons and nucleons per photon, and almost no antiparticles) are not yet fully understood; they are being studied at several accelerator laboratories around the world.

[673] Yet, STR relativistic effects are important in the sun, in many nuclear reactions and decays, in some aspects of chemistry and atomic physics, and in plasmas naturally produced by cosmic ray cascades; and also in modern klystron tubes and particle accelerating structures.

In its simplest form, a plasma is a collection of protons and electrons at sufficiently low density so that two-body (short-range) interactions are negligible. Many-body theory, or the many-body problem, is the proper framework for the study of the properties of such a medium. When a collection of cations (protons and other atomic ions) and electrons coexist in an equilibrium state, the properties of this state are described by equilibrium statistical mechanics with the appropriate Gibbs ensemble. However, most of the interesting features of plasmas occur for nonequilibrium situations.

Equations of Magnetohydrodynamics[674] (Magnetic Fluid Dynamics)

Consider the behavior of an (approximately) locally electrically neutral, conducting fluid in ambient, dynamical electromagnetic fields. It is described by a matter density $\rho(\boldsymbol{t}, t)$, a velocity profile $\boldsymbol{v}(\boldsymbol{r}, t)$, a pressure field $p(\boldsymbol{r}, t)$, a current density $\boldsymbol{j}(\boldsymbol{r}, t)$, a magnetic permeability μ and a real constant conductivity σ. We assume that the displacement current can be neglected (slow motions), that μ and σ are approximately non-dispersive and homogeneous, and that the fluid is non-relativistic and inviscid. The combined hydrody-

namical and Maxwell equations, under adiabatic conditions, then read:

$\dfrac{\partial\rho}{\partial t} + div(\rho\boldsymbol{v}) = 0$	*Equation of fluid mass continuity*	(1)
$\rho\frac{D\boldsymbol{v}}{Dt} \equiv \rho\left(\frac{\partial\boldsymbol{v}}{\partial t} + \boldsymbol{v}\cdot\nabla\boldsymbol{v}\right) = -\nabla p + (\boldsymbol{j}\times\boldsymbol{B})$	*Local conservation of linear momentum where* $(\boldsymbol{j}\times\boldsymbol{B})$ *is the magnetic (Lorentz) force per unit volume*	(2)
$\boldsymbol{j} = \sigma[\boldsymbol{E} + \boldsymbol{v}\times\boldsymbol{B}]$	*Generalized Ohm's law for a conducting fluid (Ohm's law in local co-moving frame)*	(3)
$\dfrac{1}{\mu}\ curl\ \boldsymbol{B} = \boldsymbol{j}$	*Ampere's law*	(4)
$div\ \boldsymbol{B} = 0,\ div\ \boldsymbol{E} = 0$	*Magnetic and Electric Gauss' law*	(5)
$curl\ \boldsymbol{E} = -\dfrac{\partial\boldsymbol{B}}{\partial t}$	*Faraday's law*	(6)
$\dfrac{DS}{Dt} = \dfrac{\partial S}{\partial t} + \boldsymbol{v}\cdot\boldsymbol{\nabla}S = 0$	*Isentropic flow,*	(7)

with $S(\boldsymbol{r},t)$ *the entropy density. This system (together with an equation of state* $S = S(\rho,p)$*), comprising 15 independent scalar equations in 15 unknown scalar functions, can be further reduced*[675]*. Indeed, combining (3) through (6) we obtain*

$$\frac{\partial\boldsymbol{B}}{\partial t} = curl(\boldsymbol{v}\times\boldsymbol{B}) + \frac{1}{\mu\sigma}\nabla^2\boldsymbol{B} \tag{8}$$

Combining (2) and (4) we further have

$$\rho\frac{D\boldsymbol{v}}{Dt} = -\nabla p - \frac{1}{2\mu}\nabla(\boldsymbol{B}^2) + \frac{1}{\mu}(\boldsymbol{B}\cdot\nabla\boldsymbol{B}) \tag{9}$$

Equations (1), (5), (7), (8) and (9) constitute (together with the equation of state) a system of 8 independent scalar partial differential equations in the 8 unknown scalar functions ρ, p, $\boldsymbol{B}$, $\boldsymbol{v}$, *under condition of isentropic*

---

675 Note that due to the approximations involved, Eqs. (3)–(4) are not exactly consistent unless *irrotational flow* is assumed. Indeed, (4) implies $div\ \boldsymbol{j} = 0$, consistent with strict local charge-neutrality; yet taking the *div* of (3) and neglecting a term of order $\frac{1}{c^2}$ yields $\mathrm{div}\,\boldsymbol{E} = -(curl\ \boldsymbol{v})\cdot\boldsymbol{B}$, which by the *electric* Gauss' law part of (5) contradicts strict charge neutrality.

flow.[676] *It can be shown that these equations permit the propagation of small perturbations as undamped hydromagnetic waves.*

676 Eq. (8) yields only *two* independent scalar PDE's, since taking the divergence of both sides results in an *identity* due to (5).

History of Creation Theories — II

Act V: *Expanding Pseudo Riemannian Universe and Big Bang Cosmology* *(1917–1983)*

Cosmology is the study of the large-scale structure of the Universe in space and time — what it is now, what it was in the past and what it is likely to be in the future. Since the only long–range forces at work among the galaxies and (as yet unknown) dark–matter particles that make up the material universe are those forces of gravity, the cosmological problem is closely connected with the theory of gravitation — in particular with its modern version as formulated in ***Albert Einstein****'s general theory of relativity. In the framework of this theory the properties of space, time and gravitation are merged into one harmonious and elegant picture.*

Thus, from 1917 *on, cosmology has again been in the foreground of interest in connection with the development of the general theory of relativity. It seemed as if this theory could bring us a decisive step nearer to the solution of the cosmological problem. The actual situation, however, was not so simple. The progress made was predominantly due to the amazing advance of astronomical knowledge beyond the realm of our galaxy into remote depths of the universe. Our 'neighborhood', until then confined to small parts of the galaxy, was extended thereby into the extragalactic space, to distances which possibly may no longer be considered negligibly small as compared with the dimensions of the whole universe. Cosmological theory responded to this enrichment of our observational knowledge:*

The general theory of relativity was published in 1916 *and its first application to our solar system had already been made before* 1920. *But only a very few bold mathematicians and astronomers had the idea of extending its consequences to the whole universe. The first people to construct models of an expanding universe were* **de Sitter** *(1917),* **Friedmann** *(1922)* and **Lemaître** *(1927). However, the majority of astronomers did not take these models seriously. The situation lasted until* **Hubble** *discovered (1929) the expansion of the universe. This indeed is the event which we must mark as heralding beginning of the new science of cosmology.*

The whole way of thinking about the origin, evolution and destiny of the cosmos was altered after that. For the first time the study of the universe as a whole ceased being the realm of subjective speculations and became the subject of scientific research. The great advancement of cosmology that followed *was due to systematic research involving both observations and theory. However, the phenomenon of the expansion of the universe was so enormous, so amazing, that many people disputed it. Many efforts were made to attribute the red shift of light from distant galaxies to causes other than the expansion of the universe. All these efforts failed and today there is no serious dispute of the reality of the expansion.*

The observational basis for our belief in the expansion of the universe and the evaluation of its density distribution is based upon the use of various standard candles (widespread luminous objects such as variable stars, supernovae etc. with known absolute magnitude), in conjunction with galaxy recession – velocity measurements. The latter are done by measuring red shifts.

- *The redshift: Observed systematic increase in wavelength λ of the spectral lines with cosmic source distances, considered to result from a recession of the light source. It is related to the source-observer distance r and the instantaneous speed of recession (at emission epoch t) by the approximate relation $\frac{dr}{dt} = c\frac{\Delta\lambda}{\lambda} = Hr$, where H is constant (Hubble law; requires GTR non-linear corrections for redshifts $z = \frac{\Delta\lambda}{\lambda}$ of order 1). This law for the general expansion of the universe (calibrated for the nearer systems with known distances), furnished a further possibility of estimating distances when only observed red-shifts are available. In this way our knowledge concerning the distribution of matter in space and time was widened step by step through a great variety of methods of measuring or estimating distances (the so-called 'cosmic distance ladder').*

When the problem of cosmology was revived in connection with the theory of General Relativity, the surveyed part of the observable universe extended to distances of nearly 3×10^{21} km, containing in its volume about 10^8 galaxies, each consisting of some 10^{11} stars. This was an empirical background very different from that on which astronomy had to rely when it first attempted to tackle this complex problem.

Experimental evidence, based on this vast reservoir of matter, has shown that beyond a certain distance positive values of $\frac{\Delta\lambda}{\lambda}$ prevail, indicating a general recession of the more distant galaxy clusters which definitely no longer belong to the cluster of which our galaxy is a member. Hence, a general expansion of the universe is indicated. Moreover, observations disclose that to the first approximation, this expansion is isotropic (as viewed from any observatory at rest relative to his local cluster).

In addition, theoretical considerations show that no stable solution of the cosmological problem is expected to yield a static world in which gravitating matter fills the universe with a fixed average density. A universe at rest, filled *with gravitating matter, is not possible. This conclusion is common to both GTR and Newtonian gravity.*

Newtonian Cosmology

Assume the universe to be an infinite Euclidean space filled by galaxies, which will be treated like the molecules of a fluid distributed uniformly (on average) through space. Assume at first that Newtonian physics holds; we also impose for philosophical reasons, the cosmological principle — which states that the universe appears, on average, identical to two observers residing in any two of its galaxies. This principle is an extension of the Copernican notion — that earth is not privileged — to the cosmos at large. It follows that the mass–density ρ and the hydrostatic pressure p are functions of the time t only. Moreover, it also follows from this principle that — in any inertial frame with its spatial origin within any galaxy and co-moving with it — the mean hydrodynamical streaming velocity field $\boldsymbol{v}(\boldsymbol{r})$ of all other galaxies must be a homogeneous linear function of the space coordinate vector $\boldsymbol{r} = (x_1, x_2, x_3)$.

Furthermore, such a cosmos expanding (or contracting) symmetrically in all directions (i.e. isotropically) corresponds to a trajectory $x_i(t) = x_i^0 R(t)$, for any galaxy (or center–of–mass of local galaxy cluster) relative to any given galactic frame as described above; here $R(t)$ is a universal scale factor, while x_i^0 are constants that, however, depend on the galaxy whose trajectory is traced (and also on the galaxy where our observer sets up his comoving metrical frame).

The expansion is described by the equations:

$$v_i = \frac{dx_i}{dt} = x_i^0 \frac{dR}{dt} = x_i \frac{\dot{R}}{R}.$$

We thus obtain a law of expansion corresponding to that derived from the observed red-shift of the galaxies but with the "constant" H actually depending on the emission epoch t.

So far the considerations have been of a purely kinematical nature; they have not taken into account of the fact that all matter in the universe is gravitating. The following equations thus have to be satisfied:

- *Local conservation of mass:* $\frac{\partial \rho}{\partial t} + \mathrm{div}(\rho \boldsymbol{v}) = 0.$

- *Local conservation of linear momentum:* $\frac{\partial}{\partial t}(\rho \boldsymbol{v}) + \mathrm{div}(\rho \boldsymbol{v}\boldsymbol{v}) + \rho\,\mathrm{grad}\,\phi = 0$ *where* ϕ *is the Newtonian gravitational potential; and no term depending on the hydrostatic pressure*[677] *enters, since* $p = p(t)$.
- *Poisson's equation:* $\nabla^2\phi = 4\pi G\rho$.

If we impose the cosmological principle and restrict consideration to the case of isotropic expansion, namely $v_1 = ax_1,\ v_2 = ax_2,\ v_3 = ax_3,$ *it then follows from the above equations that* $a = \frac{\dot{R}}{R} = -\frac{1}{3}\,\frac{\dot{\rho}}{\rho},\ \ \frac{d}{dt}\left(\frac{\dot{\rho}}{\rho}\right) = 4\pi G\rho + 3a^2.$ *In these equations,* $\dot{\rho} = 0$ *entails* $a = 0$ *and* $\rho = 0$. *Hence, it is impossible to construct a Newtonian universe in which gravitating matter remains at rest; it is also impossible to let matter stream in such a way that the density remains constant.*

Now, due to the cosmological principle, the gravitational potential must be such that its derivatives $\frac{\partial\phi}{\partial x_i} = 0$ *for* $x_i = 0$ *(no preferred direction!). Consequently, the representation of* ϕ *by power series in* x_i *must begin with terms of at least the second order. In fact the above system of differential equations, along with* $\boldsymbol{v} = a(t)\boldsymbol{r}$, *imply*

$$\phi(x) = \frac{2\pi G\rho(t)}{3}(x_1^2 + x_2^2 + x_3^2)$$

up to an additive constant.

This quadratic potential with a time–dependent "spring constant" is an exact solution to the above equations of self gravitating flow.

In any of our galactic comoving inertial frames, the gravitational force upon a unit test-mass at position $\boldsymbol{r}$,

$$-\nabla\phi(\boldsymbol{r}, t) = -\frac{4\pi G\rho(t)}{3}\,\boldsymbol{r},$$

is readily seen to be the Newtonian gravity force due to a spherical radius – $|\boldsymbol{r}|$ *ball of galaxies, centered at the frame's galaxy-origin; the test mass lies on this ball's boundary sphere, and galaxies external to it exert no net force upon the test mass.*

---

677 In our dilute–gas fluid approximation of the universe, "pressure" stems from the random motions of galaxy clusters relative to their local comoving galactic frames. Cosmologists refer to these as *peculiar motions*. Strictly speaking the R.H.S of the streaming–motion law $\boldsymbol{v}(\boldsymbol{r}) = \frac{\dot{R}}{R}\boldsymbol{r}$ should have a random peculiar–motion term added to it.

This "screening", or cancellation, of the gravitational effects of galaxies outside such a ball is well known – Newton himself derived it; but it is problematical in its cosmological application, for the outside galaxies extend to infinity and the relevant integrals diverge. This problem can only be resolved within the General Relativistic (GTR) formulation of cosmology.

But since the screening assumption is vindicated in GTR, we will adopt it within the Newtonian cosmology, as well.

Introducing the trajectory $\boldsymbol{r} = \boldsymbol{r}_0 R(t)$ for a general galaxy in any one of our frames into the equation of motion[678]

$$\frac{d^2\boldsymbol{r}}{dt^2} = -\frac{GM(r)}{r^2}\,\frac{\boldsymbol{r}}{r}\,,$$

for a galaxy at the surface of a radius - r sphere ($r = |\boldsymbol{r}|$) containing mass $M(r)$, the differential equation for R follows: $\frac{d^2R}{dt^2} = \frac{-GM}{R^2}$, where $M = \frac{4}{3}\pi\rho R^3$ is a constant; it is the mass contained in a volume of one of our expanding spheres of radius $r = r_0 R(t)$ with $r_0 = 1$. The mass remains unchanged within any expanding volume with the galaxies upon its surface fixed relative to that surface.

The differential equation immediately yields the integral $\frac{1}{2}\dot{R}^2 = \frac{GM}{R} + h$, where the constant of integration h may be negative, positive, or zero. Accordingly, we obtain various types of expansions which may be called "elliptic", "hyperbolic", and "parabolic", since the character of the solutions closely resembles solutions obtained in the theory of rectilinear motion of two gravitating bodies.

From the preceding general discussion it follows that the dynamical problem of an expanding or contracting universe always gives rise to a singularity when, for $R = 0$, ρ becomes infinite. The singularity can be removed by amending Poisson's equation for the gravitational potential by an additional term.

If the quadratic gravitational potential $\phi(\boldsymbol{r}, t)$ derived above is supplemented by a term with the new constant λ:

$$\phi = \frac{2\pi G}{3}\,\rho(t)r^2 - \frac{\lambda}{6}\,r^2 = \frac{1}{2}\,\frac{GM(r)}{r} - \frac{\lambda}{6}r^2\,,$$

[678] The equation results *either* from the above "screening" assumption or (equivalently) it can be derived from the equation for $\frac{d}{dt}\left(\frac{\dot{\rho}}{\rho}\right)$, which was itself derived above from local conservation laws, the Poisson equation, and the (isotropic) cosmological condition.

the ordinary differential equation for the scale factor $R(t)$ *(with all other assumptions left unchanged) becomes*

$$\frac{d^2R}{dt^2} = -\frac{GM}{R^2} + \frac{\lambda}{3}R$$

and yields the integral

$$\frac{1}{2}\dot{R}^2 = \frac{GM}{R} + \frac{\lambda}{6}R^2 + h = \left(\frac{4\pi G\rho}{3} + \frac{\lambda}{6}\right)R^2 + h \; .$$

The singularity $\rho \to \infty$, *which formerly occurred for* $R = 0$, *does not appear now, provided* λ *is chosen* > 0, $h < 0$, *and the mean cosmic density is suitably small* $(\rho < \frac{\lambda}{4\pi G}$ *at any given epoch* $t)$.

In this case the equation $\frac{GM}{R} + \frac{\lambda}{6}R^2 + h = 0$, *corresponding to the case* $\dot{R} = 0$, *yields in general two solutions, say,* $R = R_1$ *and* $R = R_2$, *where* $R_1 < R_2$. *For* $R > R_2$, *real solutions exist for which R, coming from infinity — corresponding thus to a contracting universe — approaches the limit* $R = R_2$, *where* $\dot{R}$ *becomes zero. The contraction comes to a standstill at a finite value of* ρ *and changes into an expansion; at this turning point the new repulsive force (characterized by the cosmological constant* λ*) just balances the attraction due to the gravitational attraction.*

According as λ *and* h *are chosen to have various sign combinations and the appropriate density regimes are chosen, a variety of solutions results. But only the case, just mentioned, corresponding to* $\lambda > 0$, $h < 0$, *and* ρ *small enough, yields solutions which are free from singularities and hence do not necessitate the assumption that the universe has to pass through a phase of infinitely large densities, pressures and temperatures. But it must be emphasized that such regular solutions are obtainable only by introducing the ad hoc hypothesis of a new, and otherwise not motivated, universal long–range repulsive force in the universe.*

The constant λ *is the Newtonian manifestation of the GTR cosmological constant. Its introduction, however, is rather ad hoc within the Newtonian framework. In the Einsteinian universe, on the other hand, it is the observed smallness of* λ *which is "unnatural" especially when quantum effects are considered; and this smallness is one of the deep outstanding puzzles of our current models of particles and fields.*

Studies of the CMBR (Cosmic Microwave Background Radiation) and its anisotropies support the assumption of uniform matter density; while galactic surveys indicate (if the evidence in favor of a hierarchic structure is disregarded) a more or less uniform distribution of luminous (non-dark) matter in space in accordance with the equation $\log N_m = 0.6\ m +$ *const., where*

N_m is the number of galaxies brighter than the limiting magnitude m. If the unit volume is taken sufficiently large to smooth out local irregularities in the distribution, the resulting number of star-systems per unit volume is roughly constant at all distances and in all directions. Spreading the non-dark matter, concentrated mainly in stars, evenly over the whole space, a constant value of ρ for the density of matter is obtained[679].

The widely accepted current theory for the origin of the universe is the Big Bang theory. We accept, based on many pieces of evidence, that the universe started with a huge explosion from a superdense and superhot stage. Theoretically, if GTR is accepted without modifications, the universe must have started from a mathematical singularity with infinite density ($R(t) \to 0$ as $t \to 0$). Further, the derivative of R is infinite at this time; that is, the initial explosion happened with infinite velocity. However, it is virtually certain that classical GTR requires major modifications for t less than the Planck time ($\sim 10^{-43}$ sec), so singularities predicted by GTR, are not very worrisome for theorists.

The Big Bang was not an ordinary explosion of the familiar kind, where material is ejected from some central point into a pre-existing space. Here, space itself is created by the explosion, and there is, no central point! The

[679] Strictly speaking, observations do *not* unconditionally agree with the hypothesis of an expanding universe filled with matter of a constant mean density ρ. Nevertheless, the cosmological models of the universe have hitherto been developed on this assumption. Otherwise, the problem would still defy all our efforts to find a solution. In fact, all cosmological problems are approached by making the *postulate* that the observed phenomena (averaged over distance scales typical of galaxy super-clusters) are representative of the universe at large; only with this bold extrapolation can we obtain a truly cosmological theory. Cosmologists' faith in this postulate is greatly buttressed by the remarkable degree of observed isotropy of the Cosmic Microwave Background Radiation (to several parts of a million). This cosmological *principle*, precisely stated, is:

Every observer, wherever placed in the universe, describes the observed (large-scale) phenomena identically, and observes itself to inhabit an isotropically expanding universe in which matter is evenly distributed.

This postulate (which also includes the statement that the *microscopic constants* and laws of nature are the same for observers in any galaxy) brings to conclusion a development in science which had its beginning with Copernicus and Kepler. In much the same way as they removed the earth, and thus man as well, from the central position which he had hitherto claimed for himself in his restricted picture of the world, the cosmological principle deprives the picture of the entire universe of any features that tend to grant to man (or even his local galaxy super-cluster!) any privileged or central position.

material blasted out in the Big Bang is spread out uniformly over the entire *spatial extent of the observable universe, and every point in this universe appears to be the center of the explosion.*

How did this theory evolve? Einstein had first formulated his model of a static, finite universe in 1917, two years after developing the general theory of relativity. But he soon saw the flaws of this model. A static, closed universe could not remain static, because its own gravitation would cause it to collapse. This was a problem not only for his theory, but any theory of gravity, including Newton's. As the poet Edgar Allen Poe had noted seventy years earlier, unless a body of matter rotates, it will collapse under its own gravity — only rotation stabilizes bodies such as the galaxy and the solar system. But Einstein ruled out a rotating universe on philosophical grounds.

First, he believed that rotation itself is relative, like all other motion, and the universe's putative rotation would have to occur relative to a frame external *to it, an impossibility by definition.*

Second, rotation implies a central axis, but such an axis would be a distinct direction in space, different from all others — this contradicted his belief that space is the same everywhere and in every direction.

Clearly, Einstein reasoned, something prevents the collapse of the universe — something like the centrifugal force of rotation, but not rotation itself. This force must somehow increase with distance: it had never been observed on earth or in the solar system, but it must be strong enough at cosmological distances to overcome gravity. He introduced a new term into his equations of gravity, the "cosmological constant", a repulsive force whose strength increases proportionally to the distance between two objects, just as the centrifugal force in a rigidly rotating body increase proportionally to distance from its axis of rotation. But this new force, he reasoned, must act in all directions equally, like gravity, so it does not disturb the rotational symmetry of the universe.

To preserve his conception of a static universe, Einstein set the cosmological constant to a level that would exactly balance gravity, so that its repulsive force neutralized the tendency of the universe to collapse.

In 1924 new observations changed the picture radically. For a decade, astronomers had been measuring the spectra of stars in nearby galaxies. In nearly all cases, the spectra shifted slightly toward the red. Scientists had long known the simplest explanation for these redshifts is that the galaxies are moving away, shifting the frequency of light to the red (the Doppler shift; an analogous phenomenon makes the pitch of a train whistle rise as it approaches and fall as it recedes). It seemed strange that, rather than moving randomly, the galaxies seemed to mostly be moving away from each other and from us.

Carl Wirtz, *a German astronomer, put all the forty-odd observations together in* 1924 *and noted a correlation — the fainter the galaxy the higher its redshift, thus the faster it is receding. Assuming that fainter galaxies are more distant, then velocity increases with distance. The conclusion was tentative, since the distances to the galaxies were uncertain. But the American astronomer* ***Edwin Hubble*** *and his assistant* ***Milton Humason*** *soon began to systematically examine Wirtz's findings. Hubble had developed a new way of measuring the distance to a galaxy, based on the known intrinsic brightness of certain peculiar stars called Cepheid variables. Word soon filtered through the astronomical community that Hubble's data seemed to confirm the relation between redshift and distance.*

The news was of immense interest to a young Belgian, ***Georges Henri Lemaître***. *Lemaître received his doctorate in physics in* 1920, *and shortly thereafter entered a seminary to study for the priesthood. While at the Seminary of Maline, he became fascinated with the new field of general relativity, and after being ordained in* 1923, *went to England to study under Eddington. He then spent the winter of* 1924–1925 *at Harvard Observatory, where he heard Hubble lecture and learned of the growing evidence for the redshift-distance relation.*

Over the next two years Lemaître developed a new cosmological theory. Studying Einstein's equations, he found, as others had before him, that the solution Einstein proposed was unstable; a slight expansion would cause the repulsive force to increase and gravity to weaken, leading to unlimited further expansion; or a slight contraction would, vice versa, lead to collapse. Lemaître, independently reaching conclusions achieved five years earlier by ***Alexandr Friedmann***, *showed that Einstein's universe is only one special solution among an infinity of possible cosmologies — some expanding, some contracting, depending on the value of the cosmological constant and the "initial conditions" of the universe.*

Lemaître synthesized this purely mathematical result with Wirtz's and Hubble's tentative observations, and concluded that the universe as a whole must be expanding, driving the galaxies apart. And if the universe is expanding, then any of the cosmological scenarios that led to expansion could be a valid description of the universe. Cosmic repulsion and gravity are not delicately balanced within a static large–scale cosmos; rather the combined effect of repulsion and relative galactic motions predominate in an expanding universe.

Lemaître put forward his hypothesis of an expanding universe in a little-known publication (1927), and within two years his work and Friedmann's had become widely known and accepted in the tiny cosmology fraternity. By *this time (1929) Hubble had published the first results showing the redshift–distance relation, apparently confirming Lemaître idea of an expanding universe.*

This was not yet the Big Bang, though. The solutions of the equations of general relativity derived by Friedmann, and later by Lemaître, only showed that many solutions led to universal expansion. Some solutions did indeed produce a singularity — a collapse into, or an expansion from, a universe of zero radius. If the universe were dense enough, and repulsion weak, the universe would collapse to a point. But if the repulsive force were strong (or the mean cosmic density small enough), there would be no singular state: the universe could be diverging from a state near Einstein's balance, moving away faster and faster with the passage of time; or it could have contracted from an indefinitely large radius in the infinite past to a minimal radius, and then begin expanding. These nonsingular solutions would imply a universe of infinite age. Indeed not all possible solutions are spatially finite, closed hyperspheres, as Einstein envisioned — some are infinite in spatial extent.

In general when equations describing physical reality produce singularities — solutions involving infinite values for observable quantities — it is a sign that something is wrong, since scientists assume that only measurable, finite quantities should be predicted. So initially the solutions without singularities attracted the most attention.

This, then, was as far as general relativity alone could take the cosmological problem.

In 1928, ***James Jeans****, one of the most prominent astronomers of the time, revived Boltzmann's old arguments about the "heat–death" fate of the universe. The second law of thermodynamics, Jeans reasoned, shows that the universe must have begun from a finite time in the past, and must move from a minimal to a maximal entropy. Incorporating Einstein's equivalence of matter and energy, Jeans argued that entropy increases when matter is converted to energy, because energy is more chaotically dissipated. Thus the end state of the universe must be the complete conversion of matter to energy. "The second law of thermodynamics compels the materials in the universe to move ever in the same direction along the same road, a road which ends only in death and annihilation", he gloomily wrote.*

At the same time ***Eddington*** *was reaching a similar conclusion. Curiously enough, he begins his book* The Nature of the Physical World *with philosophical premises similar to those used by Giordano Bruno's enemies three centuries earlier. Like Bruno's persecutors, Eddington was viscerally repelled by an infinite universe: "The difficulty of an infinite past is appalling", he writes. "It is inconceivable that we are the heirs of an infinite time of preparation". He too concludes that the second law implies a beginning in time. He was not* *pleased by this idea either, but felt that it follows naturally from Boltzmann's laws.*

Lemaître, hearing his former teacher's views in March of 1931, was deeply impressed. He had been viewing his recent mathematical work in a philosophical light; Einstein's ideas of a hyperspherical space showed that a finite universe was again conceivable.

But if the universe is finite in space, then it should be finite in time as well, Lemaître argued (and the GTR equations support this latter inference for weak enough repulsion). Thus the nonsingular solutions that Lemaître had found — in which the universe has no beginning — were unacceptable. The only ones that corresponded to Lemaître's philosophical views were closed in space and *limited in time. Eddington had given him a further rationale for looking at the singular solutions — the second law indicates that the universe must have originated in a state of low entropy.*

From these two philosophical premises, Lemaître developed his concept of the "primeval atom", the first version of the Big Bang. At a 1931 *meeting of the British Association of the Evolution of the universe, he put forth these ideas for the first time. Beginning from the idea that entropy is everywhere increasing, he reasoned, quantum mechanics (developed in the twenties) shows that as entropy increases, the number of quanta — individual particles in the universe — increases.*

Thus, if we trace it back in time, the entire universe must have been a single particle, a vast primeval atom with zero radius. He identified this instant with the singularity of some relativistic solutions. Just as uranium and radium nuclei decay into subatomic particles, so this giant nucleus, as the universe expanded, explosively split up into smaller and smaller units, atoms of the eventual size of galaxies decaying into atoms that later become suns, and so on down to the scale of actual, present-day atoms.

During WWII cosmological research was suspended, along with other peacetime pursuits, as scientists were drawn into the war effort. By the war's end, though, the field was transformed. Prior to the war the creation of elements that compose the universe had been a speculative theoretical subject — too little had been known of nuclear reactions. Now, with the successful production of atomic bombs — the creation of the elements was no longer a hypothesis, but a technological fact. The fuel for one of the bombs unleashed on Japan was itself a created element — plutonium — generated from uranium.

Nuclear piles (reactors) and the A-bombs had transformed common elements into new and exotic elements and isotopes, which scientists found in analyzing the fallout from the bombs — especially that of the Trinity test in *the New Mexico desert. And the vast expansion of nuclear research that grew out of the Manhattan Project continued to yield data about nuclear reactions.*

To one of the Manhattan Project scientists, ***George Gamow****, the detonation of an A-bomb constituted an analogy for the origin of the universe: if an A-bomb can, in a hundred-millionth of a second, create elements still detected in the desert years later, why can't a universal explosion lasting a few seconds have produced the elements we see today, billions of years later, throughout the cosmos?*

In a paper in the fall of 1946, Gamow put forward his idea, a second version of the Big Bang. Unlike Lemaître, he took as observational verification of his hypothesis the abundance of the elements; but like him, Gamow assumed that this abundance could not have been produced by any process continuing in the present-day universe.

Gamow proceeded (1948) to investigate the characteristics of the superdense condition of the first moments of the universe. He concluded that the temperature must have been enormous at this stage. Under these conditions, the protons and neutrons must have formed the various chemical elements. The theory satisfactorily explains the formation of deuterium and helium. Perhaps it might also explain the formation of all the elements up to uranium, by progressive fusion with protons and neutrons to yield more and more complex nuclei.

It soon became clear, however, that since there is no stable nucleus with mass number 5, the formation of the elements just after the Big Bang must have stopped at helium. Thus, cosmic nucleosynthesis was necessarily restricted to light elements, up to helium[680] *^4_2He.*

After this failure, the theory was put aside altogether. The next theory about the formation of the chemical elements was the B^2FH theory, so named after ***G. Burbidge****,* ***M. Burbidge****,* ***W.A. Fowler*** *(1911–1995; Nobel prize, 1983) and* ***Fred Hoyle****. According to this theory, all the elements beyond*

---

680 It was later shown that the isotopes of *Lithium*, as well, have present-day cosmic abundances that can be accounted for by the cosmological *nucleosynthesis* reactions which the Big Bang theory predicts to have occurred during the first few minutes of the universe.

The isotopes thought to have been largely created at that epoch are: ^1H (proton); ^2H (deuterium); ^3He; ^4He; ^6Li; and ^7Li. Some of the higher-mass isotopes (created in exploding stars) catalyze the fusion of hydrogen into Helium in the nuclear combustion within later generations of stars, but the accumulated impact of stellar fusion upon the cosmic helium abundance (which is $\sim 25\%$ by mass) is calculated to be small.

^{1}H (proton) have been formed in stellar interiors. In particular, the heavier elements were formed during supernova explosions.

***Edwin E. Salpeter** had already shown (1952) that three nuclei of helium $^{4}_{2}He$ may combine to produce carbon, and other heavier elements may similarly be formed by addition of further helium nuclei, in the interiors of stars rich in helium, where temperatures may reach $10^8 K$. Still heavier elements may be formed during the final stages of stellar evolution, when a supernova explosion may occur.*

*The B^2FH theory was very successful. However, as **Hoyle** and **Taylor** realized (1964), it could not account for the amount of helium observed in stars, which constitutes 25% of their mass. According to the theory of nuclear reactions in stellar interiors, only 1–4% of the amount of matter locked up in stars would be helium if this element were produced entirely inside stars — and this is 6–25 times less than the spectroscopically observed amount. This result made **Hoyle** revisit the formation of elements in the Big Bang theory.*

*Thus, in 1967, **R.V. Wagoner**, **Fowler** and **Hoyle** calculated once again the amount of helium which may be formed in the early universe, and came to the same conclusion as **Gamow** and his collaborators.*

The situation is similar for deuterium, which is observed to have a cosmic abundance of 2×10^{-5}. This amount is much more than the amount expected to form in stars, because deuterium is not expected to survive for very long in stars. The deuterium we observe today, therefore, must have been formed in the early universe.

There are therefore two ways by which the elements of matter were formed. The first way, the cosmological one, produced only the light elements (mainly deuterium and helium) during the first four minutes after the Big Bang. The elements heavier than helium were formed later on, in the interiors of stars. This secondary process for generating elements started as soon as the first stars were formed ($t \sim 10^9$ yr after the Big Bang), and continues today.

Another indication in support of the Big Bang theory is the estimated age of the universe. Independent estimates, based on the expansion of the universe, the age of the oldest stars in the galaxies, or the age of terrestrial rocks based on the lifetimes of radioactive elements, give numbers of the same order of magnitude. All three methods agree that the age of the universe is between 10 and 20 billion years. If the universe did not have a beginning, there would not be an a priori reason for such a good agreement between these three different calculations.

Finally, an important piece of evidence for the Big Bang is the cosmic microwave background radiation. This radiation comes to us from all directions with almost uniform intensity (isotropically), and corresponds to the *radiation from a black body at a temperature of approximately 2.7°K. The radiation does not appear to be clumpy — unlike the distribution of matter; furthermore, the (parts per million) deviations from isotropic flux seem to be well explained by inflationary cosmology*[681]*. The only credible explanation for this radiation is that it consists of the photons which filled the universe during the "radiation dominated era", early in cosmic history, and became largely decoupled from matter during the "recombination era" ($t \approx 3\times10^5$ years after the Big Bang) — when the electron-proton plasma of the universe combined to form transparent, neutral hydrogen. These photons have since (during the $t > 3 \times 10^5$ yr "matter dominated" era we are still in now) undergone a cosmological redshift due to universal expansion, with their wavelengths thus stretched to their current value ($\sim 3\ mm/2.7 \sim 1$ millimeter by Wien's Law). No other plausible explanation has thus far been suggested. The powerful combination of* quantum theory*, GTR, and* nuclear *and* particle physics *allows detailed quantitative calculations — such as the abundances of light elements — that can be compared with empirical observations.*

To recapitulate, we note that the basic evidence in support of the Big Bang theory is:

- *Solutions of Einstein's equations (themselves well-confirmed in independent, solar–system and astrophysical tests).*
- *The observed helium, deuterium and lithium cosmic abundances.*
- *The agreement between the various independent estimates of the age of the universe.*
- *The cosmic microwave background radiation.*

None of the above-listed arguments in support of the Big Bang theory became immediately accepted. In particular, the solutions of Einstein's equations referred to homogeneous and isotropic models of the universe. So the question arises, what happens if the universe is not entirely homogeneous and isotropic after all? is it possible, in that case, to avoid the mathematical singularity and the initial explosion, by accepting (for example) that the universe has

[681] A variant of the Big Bang theory, developed in the 1980's, involving a brief reheating episode – a fraction of a second after the initial $t = 0$ instant, well before nucleosynthesis – in which the universe expanded exponentially. This event was powered by the energy released when a super cooled vacuum converted to its true ground state.

some rotation? (In Newton's theory, a rotating star which collapses does not form a singularity — unlike the collapse of a non-rotating star.)

Much effort has been expended by mathematicians to answer this question in the framework of GTR. The most important advances were made by ***S.W. Hawking*** *and* ***Roger Penrose***[682] *(1969), who showed that* any *reasonable model of the universe which has the observed characteristics of (approximate) homogeneity and isotropy, must start from a singularity. This theorem, which does not require absolute homogeneity and isotropy, is one of the most important achievements in the field of relativity.*

We see, therefore, that the general theory of relativity leads to an initial singularity of the universe. Would this change if we were not using Einstein's theory? Several competing theories have been developed[683]*, including the Brans-Dicke scalar-tensor theory and (more fundamentally) various*

682 The Hawking-Penrose theorem holds under the following assumptions: (1) The general theory of relativity holds. (2) The total energy density is locally positive. (3) There are no closed timelike or lightlike geodesics (i.e. no time paradoxes). (4) Space is not everywhere flat along all timelike or lightlike geodesics (it is unlikely that this is not the case). (5) There is at least one closed spacelike surface.

Since the assumptions on which the theorem is based are not very restrictive, there is little doubt that they apply to the actual universe.

683 Cosmologists have speculated that if we add the non-relativistic *kinetic energy of the expansion* of the observable universe, the *rest mass* energy of all masses in it and its *Newtonian potential energy* (which is negative), the resulting sum is:

$$E = \sum_i \frac{1}{2} m_i v_i^2 + \sum_i m_i c^2 - \sum_i \sum_j \frac{G m_i m_j}{2 r_{ij}} \approx 0,$$

to a high degree of accuracy. [The summations $\sum$ refer to all particles in the universe and r_{ij} is the distance between any two particles.]

This seems to be *roughly* true for the known (luminous) matter – which led **P. Jordan** (1949) to introduce the assumption that the sum of the mass-energy in the universe is *always* zero. Since the universe expands, however, the potential and kinetic energy terms both become smaller. For the total mass-energy of the universe to remain zero, Jordan then assumed that new matter is created, at appropriate distances and with appropriate velocities. This theory is essentially a revival of the old view that the universe has been created *ex nihilo*. The theory cannot explain the microwave background radiation and other observational data and is not relativistic. The *steady–state cosmology* of Hoyle Bondi and Gold is a variant of brans–Dicke theory (thus generally covariant) which allows for such continuous creation, but it fails to account for the CMBR or light–element nucleosynthesis.

string-theory-inspired modifications of GTR. However, so far none of them has managed to replace general relativity. Whenever observational tests were carried out in order to distinguish between relativity and another theory, relativity was vindicated. Consequently, most researchers today work on GTR cosmology, rather than on other competing theories.

It is quite likely that the singular beginning of the Universe is avoided via quantum mechanical phenomena. Such phenomena were very important when the age of the universe was of order 10^{-43} *sec (Planck time), but we cannot yet calculate their effects since we lack a theory of gravity.*

Objections concerning the formation of helium, lithium and deuterium, arise from doubts as to whether the observed abundances are universal or not. Much effort has been devoted to detecting stars with a helium abundance well below the generally accepted value (~25%). It seems, however, that the "exceptions" observed are not due to reduced helium content but rather to peculiarities in the spectra of certain stars. Besides, the most recent satellite observations confirm the idea that the observed deuterium has primordial origin, rather than having been formed in more recent stages of the evolution of the universe.

The objections with respect to the age of the universe are based on the uncertainties involved in the various methods of calculating or bounding it. However, despite some false alarms in the early 1990's, the best cosmological estimates for the present age of the universe–based on data gathered by the Hubble Space Telescope – have converged on a figure of $\sim 1.4 \times 10^{10}$ *yr, exceeding the age of that of the oldest known stars or galaxies. Other theories, like the theory of continuous creation, claim that there is an infinite number of galaxies older than this limit (although they may be too distant for us to observe) – but, again there is no evidence that such is the case.*

Finally, attempts were made to attribute the microwave background radiation to other (non-cosmological) effects. Observations, however, have shown the amazingly high degree of isotropy of this radiation and therefore, any non-cosmological origin of it is highly unlikely. Indeed, if this radiation were due to galaxies or stars, its anisotropy would be much higher. It is particularly significant that it has a black-body spectrum, something which would be very unlikely if it were non-cosmological in origin. And finally, even the minute deviations *of the CMBR from strict isotropicity, seem to be explainable in terms of the Big Bang scenarios known as* inflationary cosmology.

Is the universe spatially finite or not? In principle, we can answer this question by calculating the "deceleration parameter" $q = \frac{4\pi G\rho}{3H^2} = \frac{\rho}{2\rho_c}$ *from* *the redshift of the galaxies of known distances and by using the GTR correction to Hubble's Law (r = galaxy's distance at emission)*

$$c\frac{\Delta\lambda}{\lambda} \approx Hr + \frac{H^2r^2}{2c}(q-1).$$

If $q \le \frac{1}{2}$ the universe is spatially infinite, otherwise it is finite[684].

In practice it is very difficult to measure the distances of the farthest galaxies, so the calculation of q from the above equation is very inaccurate; *the observational data are not yet accurate enough to show any meaningful deviation from $c\frac{\Delta\lambda}{\lambda} = Hr$. We may only say that $1.5 > q > 0$, so this method cannot yet be used in practice to answer the question of whether the universe is finite or not. Furthermore, the above redshift-distance relation assumes that the cosmological constant, λ, vanishes — yet recent (1990's) observations indicate that the cosmic expansion is actually somewhat* accelerating, *meaning that λ must be nonzero and positive. However, the redshift equation can easily be modified to account for finite λ.*

To answer the question of whether the universe is open or closed in view of these difficulties, we must determine the density ρ and examine if it is above or below the critical density ρ_c.

We may then say that if $\rho > \rho_c$, the gravitational attraction of the matter in the universe would be enough to decelerate its expansion (were it not for the cosmological constant), and to eventually stop it and cause a contraction — leading to a pulsating universe or a "Big Crunch".

On the other hand, if $\rho \le \rho_c$ the gravitational attraction is inadequate to stop the expansion which will continue forever, whether $\lambda = 0$ or $\lambda > 0$. [This phenomenon is similar to the ejection of a particle from a celestial body: the escape velocity from a body of mass M is $v^2 = \frac{2GM}{r}$. If we set $v = Hr$ from Hubble's law, and $M = \frac{4\pi}{3}r^3\rho$, we obtain $\rho_c = \frac{3H^2}{8\pi G}$ as above.]

An independent determination of the average galactic mass density leads to a value of $0.12\rho_c$ for the density of luminous matter. To this we must add intergalactic gas and dust, intergalactic stars, possible exotic matter (made of particles other than electrons, protons and neutrons), small black holes, brown dwarves, etc., so-called dark matter *as well as the effect of λ ("dark energy"). The* inflationary *versions of the Big Bang theory suggest that ρ has been naturally tuned to be very close to ρ_c in the first fraction of a second after the initial explosion, which explains why ρ/ρ_c is roughly of order unity.*

[684] This formula should be corrected for the cosmological constant as discussed below.

Also, the recent (1990's) evidence for positive cosmological constant suggests that the universe is spatially open, although just barely.

1929 CE **José Ortega y Gasset** (1883–1955, Spain). Philosopher and essayist. In his works he purported to find patterns of development in European history by which the present could be explained or its ills exposed. This approach to historical situations was also an extension of his philosophical concern with the interrelationship of individuals and their circumstances.

Ortega claimed life to be more important than thought; because life is ever-shifting and mutating, a proper understanding of man demands the abandonment of the immobile concepts postulated by logical theory and the development of mobile thinking processes.

To him, the conceptual reality posited by idealism is not reality at all; reality is to be found in history, especially in personal history (i.e. in individual autobiographies). Thus, history considered through reason is the proper approach to reality; the two are co-existent components of truth.

Hence, reality does not consist in *Being*, but rather in *Becoming*, for what does the rational consideration of history demonstrate except the eternal evolutionary processes in nature? Consciousness is historical, but the importance of history is not exhausted with the past. Historical knowledge is valued as a preparation for the future.

His key works are: *The Theme of Our Time* (1923), *The Revolt of the Masses* (1929) and *Leibniz and Evolution of Deductive Theory* (1959).

Ortega was born in Madrid. After an early Jesuit education, he studied at the Central University of Madrid, graduating in 1902. Following further studies at the Universities of Leipzig, Berlin and Marburg he became professor of metaphysics at the University of Madrid (1910 to 1936). After the establishment of the republic (1931) he became a member of Parliament. Because of his opposition to the Franco regime he embarked on voluntary exile, living for a time in Buenos Aires and later settling in Lisbon.

In his *The Revolt of the Masses* (1929) and *Mission of the University* (1930), Ortega foresaw the ever-growing impact of science on Western culture and civilization. Beginning with the observation that from 1200 to 1800 *CE*, the population of the Western world remained almost constant, while in the last one hundred years the population in Europe and America has tripled in number, Ortega showed how out of this has risen the phenomenon of the *mass-man*. Can Western culture survive the encroachment of the mass-man? Can republican institutions survive this chaotic democracy? These are problems to which he sought a realistic solution.

Ortega addressed the question of the role of genius in science. To what extent are new ideas, and the whole progress of science, determined by the work of scientists of genius? Building on a similar idea of **Francis Bacon** (1620), Ortega asserts that genius is not necessary and that "*experimental science has progressed — thanks in great part to the work of men astoundingly mediocre, and even less than mediocre*".

Science accommodates and even needs the intellectually commonplace. According to this view, science proceeds, in certain areas at least, by addition of small if not tiny steps, and there are no real breakthrough[685].

[685] Some evidence *against* this idea comes from analysis (1990) of the use of the scientific literature. It turns out that 85 percent of papers in scientific journals are quoted in other papers once or not at all each year, while only 1 percent are quoted five or more times. This supports the argument that an extremely small proportion of the literature is dominant. However, it is not clear to what extent this dominant literature relies on the infrastructure created by lesser scientists. The question is less one of breakthroughs than of significant contributions.

Worldview XLIII: Ortega y Gasset

* * *

"Civilization becomes more complex and difficult in proportion as it advances. The problems which it sets before us today are quite intricate. The number of people whose minds are equal to these problems becomes increasingly smaller. This disproportion between the complex subtlety of the problems and the minds that should study them will become still greater if a remedy is not found, and it constitutes the basic tragedy of our civilization. By reasons of the very fertility and certainty of its formulative principles, its production increases in quantity and subtlety, so as to exceed the receptive powers of normal man. This has never happened in the past. All previous civilizations have died through insufficiency of their underlying principles. That of Europe is beginning to succumb for the opposite reason."

* * *

"In Greece and Rome it was not man as such that failed, but principles. The Roman Empire came to an end for lack of technique. When it reached a high level of population, and this vast community demanded the solution of certain material problems which technique alone could furnish, the ancient world started on a process of involution, retrogression and decay.

But today it is man who is the failure, because he is unable to keep pace with the progress of his own civilization."

* * *

"I do not believe in the absolute determinism of history. On the contrary, I believe that all life, and consequently the life of history, is made up of simple moments, each of them relatively determined in respect of the previous one, so that in it reality hesitates, walks up and down, and is uncertain whether to decide for one or other of various possibilities. It is this metaphysical hesitancy which gives to everything living its unmistakable character of tremulous vibration."

* * *

"We live with our technical requirements, but not by them. These give neither nourishment nor breath to themselves, they are not causae sui, but a useful, practical precipitate of superfluous, unpractical activities."

1929 CE **Max Knoll** (1897–1969, Germany) and **Ernst August Friedrich Ruska** (1906–1988, Germany). Physicists and inventors. Invented the *electron microscope*. Three years earlier they had set out to investigate the discovery made by **Hans Busch** (1884–1973) of Jena that when a beam of electrons passes through a wire-coil, which acts as a magnet, the beam can be focused. By 1933, Ruska's 'supermicroscope' achieved magnifications up to 12,000, and *a linear resolution*[686] well beyond that of the optical microscope. Ruska was awarded the Nobel prize for physics in 1986.

---

[686] The *linear resolution* of a microscope (**Abbe**, 1868) is the smallest distance of two object points that can still be discerned as being separate. It is given by the number $\frac{\lambda}{2n\sin\alpha}$, where λ is the wavelength of the light used, n is the refractive index of the fluid filling the space between the object and the objective lens, and α is half the angle of the lens subtended at the object. The *numerical aperture* $\{n\sin\alpha\}$ is a measure of the effective angular opening of the lens for gathering light from the object (with oil immersion numerical apertures up to about 1.6 are possible). For visible light with $\lambda = 5500$ Å, one then finds a linear resolution of 1700 Å for the minimum separation between resolved objects. This imposes a limitation on the ability to resolve specific detail in the image. This limitation is due to *diffraction effects*.

As the resolution of the light microscope is limited by the wavelength of light, efforts were made to utilize rays of shorter wavelength which can also be detected and used to form images. The fact that energetic electrons have extremely short de Broglie (quantum matter–wave) wavelengths has been put to practical use in *electron microscopes*. In these devices, electric and magnetic fields are used to focus electrons by means of electromagnetic forces that are exerted on moving charges. The resulting deflections are similar to the refraction effects produced by glass lenses used to focus light in optical microscopes. By using

1929–1935 CE **Bernhard Voldemar Schmidt** (1879–1935, Estonia and Germany). Optical instrument maker and inventor. Invented a telescope which is named after him. It uses a *spherical mirror* (not a parabolical reflector), and employs a spherically shaped correcting plate at the telescope aperture to compensate for spherical aberration; thus it is a combination of reflector-refractor system.

The *Schmidt-Cassegrain telescope* is the most popular among amateur astronomers because of its compact design and large aperture, and because the optics are completely enclosed. The effect of the correcting plate was to eliminate 'coma' (the optical distortion of focus away from the center of the image) and thus to bring the entire image into a single focus.

Schmidt was born on the island of Naissaar near Tallin, Estonia. He lost most of his right arm in a childhood experiment with gunpowder. He studied engineering in Göteburg, Sweden, and at Mittweida in Germany (1901), where he stayed making lenses and mirrors for astronomers. From 1926 he was attached to the Hamburg Observatory. He worked on the mountings and drives of the telescopes, as well as their optics. It was there that he perfected his lens and built it into the observatory telescope, specifically for use in photography (1932).

By replacing the parabolic mirror with a spherical one plus his correcting lens, Schmidt could produce an image that was sharply focused at every point on a curved photographic plate. In later models he used a second lens to compensate for the use of a flat photographic plate.

Schmidt's invention was of great importance to *optical astronomy*, as it provided extremely fine image definition over a field of several degrees. The best known Schmidt telescope is that on Mount Palomar, with an aperture of 120 cm and a focal length of 300 cm, used for photographic survey of the Northern sky (built, 1948).

---

electrons (with wavelengths of 0.05 Å or less, depending upon the voltage used to accelerate them) instead of visible light (with wavelengths near 5000 Å), the limitations on resolution imposed by diffraction effects can be largely overcome. Since the de Broglie wavelength for electrons accelerated through a potential difference V is $\frac{h}{\sqrt{2m_e eV}}$, accelerating potentials from 30 kV to several MV give extremely short wavelengths and also give the electrons sufficient energy to penetrate specimens of reasonable thickness. The resolution that is achievable by an electron microscope is limited by *lens aberrations* and by *scattering* in the specimen, so it is somewhat poorer than predicted on the basis of *diffraction* effects. Nevertheless, a linear resolution of 5 to 10 Å is possible with a 50-kV instrument, and 2 Å is possible with special, high-voltage microscopes. Magnifications range from about 10^3 to 10^5.

The *Schmidt-Cassegrain* (or catadioptric) telescopes use a combination of mirrors and lenses to fold the optics and form an image: Incoming light enters through the *aspheric Schmidt correcting lens*, then strikes the *spherical primary mirror* and is reflected back up the tube. The light is then intercepted by a small *secondary mirror* which reflects the light out of an opening in the rear of the instrument, where the image is formed at the eyepiece.

1929–1948 CE **Carl Ludwig Siegel** (1896–1981, Germany and U.S.A.). A distinguished mathematician. Most of his contributions are in number theory and functions of complex variable. Wrote books on Riemann matrices, geometry of numbers, transcendental numbers, symplectic geometry and analytic functions of several complex variables.

In 1929 Siegel extended *Waring's problem* to algebraic numbers. He also proved that if $P(x)$ is a polynomial with integer coefficients, than the Diophantine equation $y^2 = P(x)$ has at most a finite number of integer solutions (x, y), if $P(x)$ has at least 3 different complex roots. In 1932 he deciphered and extended Riemann's unpublished papers on the zeta function. This work resulted in the *Riemann-Siegel formula*, which proved to be useful for the computation of the zeroes of the *Riemann zeta function*.

Siegel was born in Berlin. He came to Göttingen in 1919 and left in 1940 for the United States, where he became a professor of mathematics at the Institute of Advanced Study, Princeton, NJ.

1929–1952 CE **Alexandr Osipovich Gelfond** (1906–1968, Russia). Mathematician. Originated basic techniques in the study of transcendental numbers and advanced the theory of interpolation and approximation of functions of complex variable. In 1929 he *conjectured* that if a_n and b_n $1 \leq n \leq m$ are algebraic numbers where $\{\ln a_n\}$ are linearly independent over $\mathbb{Q}$, then $b_1 \ln a_1 + b_2 \ln a_2 + \cdots + b_m \ln a_m \neq 0$ [proved in 1966 by **A. Baker**]. In 1934 he proved the *Gelfond theorem*, which states that a^b is transcendental if a is an algebraic number (different from 0 and 1) and b is an irrational algebraic number. This statement solves the 7^{th} Hilbert problem[687] (1900).

---

687 Thus it was finally shown that numbers such as $2^{\sqrt{2}}$, $(\sqrt{2})^{\sqrt{2}}$, $e^{-\pi} = (-)^i$ are transcendental.

An *algebraic number* α is a complex number that is a root of an algebraic equation $f(x) = 0$, where $f(x)$ is a polynomial over the field $\mathbb{Q}$ of rational numbers. Examples: $\alpha = \frac{1}{2} + \sqrt{11}$ is a root of $4x^2 - 4x - 43 = 0$; $\alpha = \frac{2}{1+\sqrt[3]{5}}$ is a root of $3x^3 - 3x^2 + 6x - 4 = 0$ $\big[$all the roots are $\alpha_k = \frac{2}{1+\rho_k \sqrt[3]{5}}$ where ρ_k, $k = 1, 2, 3$, are the three roots of unity: $\rho_k = \exp\left\{\frac{2\pi i}{3} k\right\}\big]$.

Gelfond was born in St. Petersburg to Jewish parents. He was a professor of mathematics at Moscow State University from 1931.

It can be shown that if x is the root of a polynomial with algebraic coefficients, then x is itself algebraic. A number that is not algebraic is called *transcendental*. It satisfies no algebraic equation with integer coefficients. It is not immediately clear that transcendental numbers exist. **Liouville** was first to construct some explicitly, for example, $\sum_{n=1}^{\infty} \frac{1}{2^{n!}}$. **Hermite** (1873) was first to prove that e is transcendental. **Lindemann** (1882) followed with the proof that π is transcendental (which showed that the quadrature of the circle was impossible).

It follows from Gelfand's theorem and Hermite's result that for $\alpha \neq 0$, α and e^{α} cannot both be algebraic. Consequently the functions e^{x} (for $x \neq 0$) and $\ln x$ $(x \neq 0, 1)$ have transcendental values for algebraic arguments x. This result is proved with the aid of complex analysis, which was the method used by **Gelfond** to show that e^{π} is transcendental. It is still not known whether e^{e} or $(e + \pi)$ or the Euler-Mascheroni constant γ are transcendental.

π, e and other transcendental numbers

Pi is transcendental.
The endless number cannot be expressed by any algebraic equation.
No pattern has been found in its digits,
Yet it cannot be proven in a finite amount of time that no pattern exists in an infinite number of digits.
Pi goes beyond our reality.
The nonexistence of humans would not preclude the existence of pi.
For the circle will always exist
In the shape and orbit of a planet,
In the path of a wave.
And where there is a circle, there is pi
Intrinsically embedded in it.
Pi is mysterious;
It evades all attempts of capture.
It is a line of digits like an endless snake that you can keep pulling at without ever reaching its tail.
Pi is perfect;
Each seemingly random digit is exactly where it belongs.
Whether a circle is as big as the universe,
Or as small as a quark,
Its diameter fits around its boundary exactly pi times.
Because pi is found in waves, every color, every sound is an expression of pi.
Because pi is found in circles, the moon, the sun, every planet, and every star is an expression of pi.
Because pi is found in each atom, pi is present in all physical sensation.
Pi is absolute beauty.

Eve Andersson (sweetie_pi@eveander.com)

The above computer-poetry summarizes succinctly the value of π in human culture. Yet one may still wonder why this number, representing the constant ratio of a circumference of every circle to its diameter, rose to such eminence? Clearly, it is the most famous ratio in mathematics – here on earth, and probably for any advanced civilization in the universe. But its real significance goes much deeper — Pi is fundamental to the way in which our universe functions; practically everything is dependent on π at some basic level: light, sound, energy, gravity, electromagnetic fields, matter itself... In fact, π is so central that it can be seen as a symbol of our universe.

Humans like to think that we live in a rational world. We like to take the often chaotic cosmos and discover or create order, so that we can understand it. Notwithstanding, π transcends rationality, and in doing so, it disturbs the order that we like to see. Even today, a small minority of people still try to prove that π is rational, although ***Lambert*** *was able to demonstrate the irrationality of π in 1776.*

In 1882 ***Lindemann*** *proved that π is transcendental*[688]*, finally putting an end to 2500 years of speculation. This means that π cannot satisfy any polynomial equation with rational coefficients. It further means that π cannot be expressed in any finite series of arithmetical or algebraic operations; using a fixed-size font, it cannot be written on a piece of paper as big as the universe. Lindemann's proof also showed the impossibility of squaring the circle.*

Lambert *(1776) also proved the irrationality of e and* ***Hermite*** *(1873) followed with the proof of its transcendentality. But it still remains unknown whether $\pi + e$ is transcendental. It is, however, known that πe is irrational and that e^π is transcendental (Gelfond, 1934).*

Other famous transcendental numbers of classical mathematics are:

- *Euler-Mascheroni constant*

$$\gamma = 0.577\,215\cdots = \lim_{n\to\infty}\left[1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{n} - \ln n\right].$$

(It was not proved to be transcendental, but is generally believed to be so by mathematicians.)

688 A real or complex number z is called *algebraic* if it is the root of a polynomial equation $z^n + a_{n-1}z^{n-1} + \cdots + a_1 z + a_0 = 0$, where the coefficients $a_0, a_1, \ldots a_{n-1}$ are all rational; if z cannot be a root of such an equation, it is said to be transcendental. The number $\sqrt{2}$ is algebraic because it is a root of the equation $z^2 - 2 = 0$; similarly, i, a root of $z^2 + 1 = 0$, is also algebraic.

- *Catalan's constant*

$$G = \sum_{k=0}^{\infty} (-1)^k \frac{1}{(1+2k)^2} = 1 - \frac{1}{9} + \frac{1}{25} - \frac{1}{49} + \dots .$$

  (Not proven to be transcendental, but generally believed to be so by mathematicians.)

- *Special values of the Riemann zeta function, such as* $\zeta(3)$.
- $\ln 2$.
- *Hilbert's number* $2^{\sqrt{2}}$; *proven to be transcendental [Gelfond, 1934].*
- e^{π}; *proven to be transcendental [Gelfond, 1934].*
- π^e *(Not proven to be transcendental, but generally believed to be so by mathematicians.)*
- $i^i \equiv e^{-\pi/2}$; *proven to be transcendental [Gelfond, 1934].*

1929–1954 CE **Andrei Nikolaevich Kolmogorov** (1903–1987, Russia). Distinguished mathematician. Made important contributions to the axiomatic foundations of probability theory through the use of the *Lebesgue measure* (1929).

During (1931–1933), Kolmogorov's research centered on analytical methods of probability theory: he formulated two systems of partial differential equations that bear his name. They describe transition probabilities for **Markov** processes in continuous time (forward and backward equations). These *Kolmogorov equations* are used in many applications to obtain the required probability distribution, especially in diffusion processes (e.g. population growth) and Brownian motion. This work marked a new phase in the development of probability theory and its implementation in problems of physics, chemistry, engineering and biology.

Kolmogorov made important investigations in topology (homological rings, nabla operator, nabla groups, continuous maps, duality law), information theory, function theory, functional analysis, turbulent flow of fluids and random stationary processes.

Kolmogorov was born in Tambov, Russia. In 1920 he started his studies at the Moscow state university in the faculty of physics and mathematics. After his graduation (1925) he stayed there as a research associate and was elected professor in 1931. In 1933 he became director of the Institute of Mathematics at the University. In 1939 Kolmogorov was elected an academician of the Academy of Sciences of the U.S.S.R. and later, an academician-secretary of the department of physical and mathematical sciences of the academy.

The KAM theorem

The combined work of ***Kolmogorov*** *(1954), his student* ***Vladimir I. Arnol'd****, and* ***Jürgen Moser*** *(1962–3) provided precisely defined mathematical criteria for determining whether (and which) perturbations can push a dynamical system into instability. The result is known as the KAM theorem.*

From Poincaré's work and that of his successors, mathematicians already had some sense that the phase-spaces of physical systems containing three or more bodies are characterized by an intricate interweaving of regular and chaotic regions. Yet some simple systems, such as the two–body (Kepler) problem is celestial mechanics, are integrable *(admit closed–form solutions), and their solutions are regular. In the solar system, for instance, one may reasonably regard inter–planetary interactions as weak perturbations to the (otherwise independent and Keplerian) motions of each planet about the sun. The question that remained was whether the feeble perturbations of the planets, compared with sun's overwhelming effect, are sufficient to lead to true instability.*

The KAM theorem assures us that motion in any dynamical system remains for the most part *regular, or quasi-periodic, if perturbations stay sufficiently small. Applied to our solar system, it means that any of a large set of initial conditions leads to quasi-periodic rather than chaotic orbits, provided the masses of the planets are sufficiently small compared with the sun's mass.*

An integrable *n-dimensional system is a system whose equations of motion can be reduced to n uncoupled one-dimensional (and in general non-linear) oscillators by means of a* canonical transformation *in $2n$-dimensional phase space is effected.*

The dynamics of a conservative, finite, lumped mechanical system can be described by the canonical system of ODE's (Hamiltonian equations of motion):

$$\dot{p}_k = -\frac{\partial H}{\partial q_k} \quad , \quad \dot{q}_k = \frac{\partial H}{\partial p_k} \qquad (k = 1, \dots, n),$$

where $\{q_j\}$ are generalized coordinates, $\{p_j\}$ are the corresponding canonically conjugate momenta, and H is the Hamiltonian function, given by

$$H(p, q, t) = \sum_{j=1}^{n} p_j \dot{q}_j - L$$

in terms of the Lagrangian $L(q, \dot{q}, t)$; $\{\dot{q}_j\}$ as functions of $\{q_k, p_k\}$ can also be obtained by solving $p_k = \frac{\partial L}{\partial \dot{q}_k}$ for the generalized velocities $\{\dot{q}_k\}$.

Such a dynamical system is in general not integrable*, that is, not explicitly solvable in the form*

$$p_k = f_k(t;\ p^0, q^0); \qquad q_k = g_k(t;\ p^0, q^0),$$

where $p^0 \in \mathbb{R}^n$, $q^0 \in \mathbb{R}^n$ are the initial conditions. There are exceptions to this general rule — among them the so-called integrable Hamiltonian systems*. A simple example of an integrable system occurs when the Hamiltonian is a function only of the p_k: $H(p, q, t) = K(p) \quad (p \in \mathbb{R}^n)$, known as the* normal form*. In this case*

$$\dot{p}_k = -\frac{\partial H}{\partial q_k} = 0; \qquad \dot{q}_k = \frac{\partial K}{\partial p_k};$$

thus all the p_k are constants, and we readily obtain the general solution in the form

$$p_k(t) = p_k^0 \qquad q_k(t) = \Big[\Big(\frac{\partial K}{\partial p_k}\Big)_{p=p^0}\Big] t + q_k^0,$$

so that we essentially have a generalized 'free particle' situation. Another standard example of an integrable system is a collection of n harmonic oscillators *with unit masses:*

$$H(p, q) = \sum_{k=1}^{n} \frac{1}{2}(p_k^2 + \omega_k^2 q_k^2).$$

Then

$$\dot{p}_k = -\omega_k^2 q_k; \qquad \dot{q}_k = p_k$$

where ω_k are the frequencies; this system admits the general solution

$$p_k = A_k \cos(\omega_k t + \phi_k); \qquad q_k = \frac{A_k}{\omega_k} \sin(\omega_k t + \phi_k)$$

$$q_k^0 = p_k^0 \frac{\tan \phi_k}{\omega_k}, \qquad A_k = \left[\left(p_k^0\right)^2 + \omega_k^2 \left(q_k^0\right)^2 \right]^{1/2}$$

Upon changing variables to polar 'action-angle' variables (I_k, θ_k) via

$$p_k = \sqrt{2\omega_k I_k} \cos \theta_k, \qquad q_k = \sqrt{\frac{2I_k}{\omega_k}} \sin \theta_k,$$

the Hamiltonian simplifies to $H(I, \theta) = \sum_{k=1}^{n} \omega_k I_k$, *which is the* normal form. *In these variables, the solution is*

$$I_k(t) = I_k^0; \qquad \theta_k(t) = \omega_k t + \theta_k^0 \qquad (k = 1, \ldots, n).$$

Note that the angle variables θ_k are only defined modulo 2π, i.e. $\theta_k' = \theta_k + 2\pi m_k$ (where for any k, $m_k = \pm 1, \pm 2, \ldots$) are all the same point in phase space. If $n = 2$, the motion is in 4-dimensional phase space, but it is restricted to a surface which satisfies the two conditions $p_k^2 + \omega_k^2 q_k^2 = 2\omega_k I_k$ $(k = 1, 2)$. The parametric equations of this surface are those of a 2-dimensional torus *embedded in $\mathbb{R}^4$:*

$$\begin{array}{ccc} \omega_k q_k = r_k \sin \theta_k; & p_k = r_k \cos \theta_k, & k = 1, 2, \\ r_1 = \sqrt{2\omega_1 I_1}, & r_2 = \sqrt{2\omega_2 I_2}, & r_1 > r_2 \end{array}$$

There are two distinct possible types of trajectories which may occur on this torus:

- (ω_1, ω_2) *are* rationally independent, *that is,* $m_1\omega_1 + m_2\omega_2 = 0$ *(with m_k : integers) has no solutions except $m_1 = m_2 = 0$ (example: $\omega_1 = \sqrt{2}$; $\omega_2 = 4$). The motion is then* quasi-periodic *and the trajectory is* dense everywhere *on the torus. These disjoint 2-tori (one per each (I_1, I_2) ordered pair) are called invariant tori; their union is the entire $\mathbb{R}^4$ space.*
  These frequencies are rationally *dependent, i.e. $m_1\omega_1 + m_2\omega_2 = 0$ has solutions for nonzero integers; e.g. $\omega_1 = \sqrt{2}$, $\omega_2 = \sqrt{18}$. The motion is then* periodic*; The trajectory will not visit some regions of the 2-torus.*

One can generalize this example to the case of the motions in a $2n$-dimensional phase-space which take place on disjoint, invariant n-tori.

A third example of an integrable system is the 'Kepler problem' in $\mathbb{R}^n$*, defined by the Hamiltonian*

$$H = \frac{1}{2}\sum_{k=1}^{n} p_k^2 - \left(\sum_{k=1}^{n} q_k^2\right)^{-1/2}.$$

This system is invariant under n *dimensional rotations and therefore has* $\frac{n(n-1)}{2}$ *angular–momentum type constants of motion:* $\kappa_{ij} = p_i q_j - q_i p_j$ $(1 \le i < j \le n)$.

The Kolmogorov-Arnold-Moser (KAM) theorem treats near-integrable system, with a Hamiltonian

$$H = H_0(I) + H_1(I,\theta) \qquad (I \in \mathbb{R}^N),$$

where H_1 *is taken to be periodic [i.e.* $H_1(I, \theta + 2\pi m) = H_1(I,\theta)$, $m = \{m_k\}$ *a vector of integers] and is required, in some sense, to be "small enough" (i.e.* $\|H_1\| \ll 1$ *for some norm). Hamilton's equations are then*

$$\dot{I}_i = -\frac{\partial H_1}{\partial \theta_i}; \qquad \dot{\theta}_i = \omega_i(I) + \frac{\partial H_1}{\partial I_i},$$

where ω_i *are the unperturbed frequencies, that is* $\omega_i = \frac{\partial H_0}{\partial I_i}$*. For most initial data (i.e. all except a set of small measure) Kolmogorov sketched a proof that the motion remains predominantly periodic or quasiperiodic, that is, confined to invariant tori; in other words the complement of the quasi-periodic motion (i.e. chaotic motion) has as small a Lebesgue measure as desired, provided* H_1 *is small.*

The KAM theorem is formulated by assuming that the Hamiltonian is analytic in a complexified domain of phase space, and that the unperturbed motion is non-degenerate; that is

$$\det\left(\frac{\partial \omega_i}{\partial I_j}\right) = \det\left(\frac{\partial^2 H_0}{\partial I_j \partial I_j}\right) \neq 0.$$

Clearly, an integrable system, by definition, cannot be chaotic. In general, when the perturbation H_1 *is large enough, the invariant tori are destroyed, and most initial–conditions data sets results in trajectories not limited to lower–dimensional submanifolds of* $2n$*–dimensional phase space.*

1929–1956 CE **Adolf Friedrich Johann Butenandt** (1903–1995, Germany). Biochemist. Isolated the first sex hormones (*estrone*, *androsterone* and *progesterone*), and determined their structure. In 1939 he shared the Nobel prize for Chemistry with **Leopold Ruzicka** (1887–1976), although he was forbidden by the Nazi regime to accept it. He discovered the first insect hormone, *ecdysone* (1956) and soon afterwards, *bombykol* — the scent produced by female silkworm to attract the males.

Butenandt was born in Lehe, near Bremerhaven, and studied medicine, biology and chemistry in Marburg and Göttingen. In 1936 he became head of the Kaiser Wilhelm Institute of Biochemistry in Berlin.

The Discovery of Planet Pluto (1906–1930)

The name Pluto comes from Pluton, an alternate Greek name for Hades, the god of the dead. The Romans borrowed and preserved without change almost all the myths about Hades and his underworld kingdom.

Pluto is the most distant known planet from the sun[689]*. Pluto and Neptune are the only planets that cannot be seen without a telescope. Both planets*

[689] Mean distance from the sun: 5914.3 million km; diameter: ca 2300 km; length of year: ca 248 earth years; rotation period: 6.4 earth days; *inclination* of orbit to the ecliptic: $i = 17^\circ$; *orbital eccentricity*: $e = 0.25$; *tilt* of spin axis to orbit: 177° (i.e. its north pole, defined by counterclockwise rotation, lies below the plane of its orbit); *density*: ca $2\ \frac{\text{gm}}{\text{cm}^3}$ (rocky material and ice).

A revolution in the understanding of Pluto began in 1978 when **James W. Christy** discovered that Pluto has a large satellite, which he names *Charon* (after his wife, *not* the Greek eponymous mythological figure that ferried the souls of the dead to the underworld dominion of Pluto). It revolves around the planet over a 6.4-day period, the same as Pluto's known period of rotation. Consequently, Pluto and Charon keep the same hemisphere facing toward each other, just as in the earth-moon system – in both cases as a result of tidal torques. The diameter of Charon was found to be 1186 km, while its orbital radius (about the Charon–Pluto center of mass) is 19640 km. Measurements of Charon's orbit revealed that the total mass of the Pluto-Charon system is about $\frac{1}{400}$ the mass of the earth.

Shortly after Charon was discovered, astronomers realized that twice during *were predicted mathematically prior to their actual discovery, based upon the gravitational perturbation they cause.*

*In 1905, **Percival Lowell** (1855–1916, U.S.A.), an American astronomer, made an elaborate mathematical study of the orbits of Uranus and Neptune. He then attributed the perturbations in their motions to the presence of an unseen planet beyond Neptune, and calculated its position. A systematic search for the planet by the staff of his private observatory (Flagstaff, Arizona — todays 'Lowell Observatory') failed to find it.*

*Fourteen years after his death, **Clyde William Tombaugh** (1906–1997; born in Streator, Illinois, a year after Lowell's own prediction) discovered **Pluto** on photographic plates which he took with a more powerful telescope at Lowell's Observatory (February 18, 1930).*

***Lowell** was born in Boston, a member of the distinguished Lowell family of Massachusetts*[690]*. Until* 1890 *he devoted himself to literature and travel in*

Pluto's 248-year circuit about the sun, the alignment between the earth and Pluto causes Charon's orbit to be seen edge-on. At those times, Charon appears to pass in front of Pluto (*transit*) or behind it (*occultation*) at 3.2 day intervals. These events are commonly known as *eclipses*. Fortunately for astronomers, they occurred close to Charon's discovery, in 1987. Due to the total occultation of Charon behind Pluto it became possible to resolve the individual spectra of the two bodies.

Careful timings of the transits and occultations can be translated into dimensions of the objects, provided one knows the distance between Charon and Pluto. This, combined with the new measurements of the total mass of the system, yielded the above–quoted estimate of Pluto's density.

A star occulted by Pluto in 1988 flickered before it vanished — revealing that the planet has a thin, hazy atmosphere, composed of methane, argon, nitrogen, oxygen and carbon monoxide. Pluto's equatorial surface is at a temperature of about 58° Kelvin; its surface is covered with frozen methane and a wispy atmosphere that may periodically precipitate snow.

Calculations of Pluto's orbital motion covering a period of 845 million years [**G.J. Sussman** and **J. Wisdom**, *Science*, 22 July 1988] indicate that Pluto's orbit is *chaotic* over long periods. It is most likely that Pluto formed in the outer solar system and that chaotic dynamics led to its current eccentric and highly inclined orbit. It may thus be a relic from the formation of the solar system.

Recently, (2000's) there has been a trend among astronomers to "demote" Pluto from the ranks of *bona fide* planets of Solar System.

690 His brother **Abbott Lawrence Lowell** (1856–1943) was president of Harvard University (1909–1933). His sister **Amy Lowell** (1874–1925) was an American poet and critic.

the far east. Afterwards he became best known for his belief in the possibility of life on Mars and the existence of canals there[691]*. In* 1894 *he completed the construction of his private observatory at Flagstaff, Arizona.*

Tombaugh *served at Lowell Observatory, and spent most of his academic career at the New Mexico State University.*

[691] The canal theory was put to rest by data received from U.S. spacecraft *Mariner 4* when it flew past Mars in July 1965. As to Martian life, the chemical and biological analyses performed, via robotics, by the *Viking I* and *II* lander spacecrafts (July 20, 1976 and Sept. 3, 1976), proved inconclusive. In 1996, an analysis of a meteorite discovered (1984) in Antarctica, strongly suggested that it had come from Mars, possibly bearing fossils of ancient organisms. Future missions to Mars may finally settle the question whether life exists, or has ever existed on the red planet.

Exploration and Discovery of the Solar System[692] ***(1610–2008 CE)***

From the dawn of history until the beginning of the 17th century the known universe consisted of only 7 heavenly bodies:[693]

Sun
Mercury
Venus
Moon
Mars
Jupiter
Saturn

plus the "fixed" stars with earth itself considered the universe's center, in accord with the Church–sanctioned Ptolemaic system.

[693] In *Genesis* **37**, 9 Joseph tells his brothers of a dream about "the sun and the moon and the eleven stars..." If we discount the above list of naked-eye bodies, Joseph must have included another naked-eye "fixed" stars. Candidates may be chosen from the list of brightest stars in the Northern skies, namely: *Sirius*, *Canopus*, α *Centauri*, *Vega* and *Arcturus*.

In 1610, ***Galileo Galilei*** *first pointed a telescope upon the heavens. By the end of the 17th century,* 9 *new bodies had been discovered and the heliocentric theory of* ***Copernicus*** *was widely accepted. The total number of known bodies had more than doubled, (now including planet earth) to* 17. *The new additions were:*

Callisto	*1610*	*Galileo Galilei*
Europa	*1610*	*Galileo Galilei*
Ganymede	*1610*	*Galileo Galilei*
Io	*1610*	*Galileo Galilei*
Titan	*1655*	*Christiaan Huygens*
Iapetus	*1671*	*Giovanni Domenico Cassini*
Rhea	*1672*	*Giovanni Domenico Cassini*
Dione	*1684*	*Giovanni Domenico Cassini*
Tethys	*1684*	*Giovanni Domenico Cassini*

Only 5 *new bodies (not including comets) were discovered in the 18th century (all by* ***William Herschel****), bringing the total to* 22*:*

Uranus	*1781*	*William Herschel*
Oberon	*1787*	*William Herschel*
Titania	*1787*	*William Herschel*
Enceladus	*1789*	*William Herschel*
Mimas	*1789*	*William Herschel*

The number of known bodies in the solar system increased dramatically in the 19th century, with the discovery of the asteroids (464 *of which were known by 1899), but only* 9 *more "major" bodies were discovered. The number of major bodies rose thereby to* 31 *(almost doubling the 17th century total):*

Neptune	*1846*	*Johann Gotfried Galle,* *Urbain Jean Joseph Le Verrier*
Triton	*1846*	*William Lassell*
Hyperion	*1848*	*William Cranch Bond*
Ariel	*1851*	*William Lassell*
Umbriel	*1851*	*William Lassell*
Phobos	*1877*	*Asaph Hall*
Deimos	*1877*	*Asaph Hall*
Amalthea	*1892*	*Edward Emerson Barnard*
Phoebe	*1898*	*William Henry Pickering*

In the 20th century (up to 1990), 40 more major bodies (and thousands of comets and asteroids) have been discovered (27 by the Voyager probes), more than doubling the count again to 71:

Himalia	*1904*	*C. Perrine*
Elara	*1905*	*C. Perrine*
Pasiphae	*1908*	*P. Melotte*
Sinope	*1914*	*S. Nicholson*
Pluto	*1930*	*Clyde W. Tombaugh*
Carme	*1938*	*S. Nicholson*
Lysithea	*1938*	*S. Nicholson*
Miranda	*1948*	*Gerard Kuiper*
Nereid	*1949*	*Gerard Kuiper*
Ananke	*1951*	*S. Nicholson*

Timeline

432 BCE — **Meton** introduced his calendar in Athens.

c. 270 BCE — **Aristarchos** of **Samos** estimated the distance and size of the sun and proposed that earth goes around it.

c. 250 BCE — **Erathosthenes** estimated the size of the earth.

c. 135 BCE — **Hipparchos** discovered the precession of the equinoxes and estimated the distance to the moon.

c. 46 BCE — **Julius Caesar** commanded the reform of the Roman Calendar.

c. 140 AD — **Claudius Ptolemaeus** (Ptolemy) wrote "*Megale Syntaxis tes Astronomias*" (known 1000 years later as "*Almagest*"), proposing his world system.

1543 — **Nicolaus Copernicus** published his theory of the solar system.

1582 — **Pope Gregory the 13th** commanded the reform of the calendar.

1609 — **Galileo Galilei** built the first astronomical telescope and observed for the first time craters on the moon, satellites around Jupiter and the moon–like apparent phases of Venus.

1609–1619 — **Johannes Kepler**, using **Tycho's** observations, formulated his first two laws of planetary motion (1609), and the third in 1619.

1686 — **Isaac Newton** established the *law of universal gravitation.*

1781 — **William Herschel** discovered planet *Uranus* with a mirror telescope of his invention.

1801 — **Giuseppe Piazzi** discovered main–belt–asteroid *Ceres.*

1807 — Discovery of main–belt asteroid *Vesta.*

1838 — **Friedrich Bessel** first measured the distance to a star (61 Cygni).

1839 Invention of *photography* by **L.J.M. Daguerre**.

1846 Discovery of a new, theoretically predicted planet — *Neptune*.

1930 Discovery of planet *Pluto*.

1957 Soviet Union launched the first man-made satellite, *Sputnik 1*.

1961 **Yuri Gagarin** became the first human to orbit earth.

1969 United States lands a man on the moon (*Apollo 11* mission)

1976 The U.S. *Viking 1* soft-landed on *Mars*; took pictures and searched for chemical signatures of life.

1977–1989 The U.S. *Voyager 1* and *Voyager 2* embark on a space odyssey which takes them to encounters with Jupiter, Saturn, Uranus, Neptune and beyond.

1989–1999 U.S. space probe *Magellan* sent on a mission to orbit *Venus* and map it, using a radar imaging system.

1989–1991 U.S. craft *Galileo* (with some European sub–systems) sent on a mission to orbit *Jupiter* and study its atmosphere, satellites and surrounding magnetosphere.

1990–1994 U.S. (HST); launched the *Hubble Space Telescope*; it returned high-resolution images of Mars and the other outer planets of the Solar system as well as deep–space imagery; its surveys of supernovae throughout the observable universe played a key role in refining and confirming the Big Bang cosmological theory, establishing the universe's age (14Gy) and discovering its residual *dark energy* (vacuum expansion). In 1994 the HST photographed the spectacular collision of a fragments of comet Schumacher–Levy with Jupiter.

1990–1995 U.S./European craft *Ulysses* sent on a solar fly-by mission to study the poles of the sun and the interstellar space above and below the poles. It used Jupiter for a gravity-assist boost to swing out of the ecliptic plane and onwards to the poles of the sun.

1995 Europe and U.S. Solar Probe *SOHO* (Solar and Heliospheric Observatory) was launched to study the sun's internal structure, by observing velocity oscillations and radiance variations, and to look at the physical processes that form and heat the sun's corona and that give rise to the solar wind — using imaging and spectroscopic diagnosis of the plasma in the sun's outer regions. SOHO was placed in a "halo orbit" around the *L1 Lagrangian point* (a point 1.5 million km away from us at which the gravitational pull of the earth balances that of the sun).

1996 NASA made a startling discovery that points to the *possibility* that a primitive form of microscopic life *may have existed* on Mars more than 3 billion years ago. As evidence, NASA presented a potato-size stone (designated ALH84001), a rare type of meteorite (recovered from Antarctica) that had its genesis on the planet Mars. The stone's Martian provenance was determined by its isotope ratios; it was likely ejected from Mars due to the impact of a asteroid, landing on earth thousands of years ago. Over the course of the preceding $2\frac{1}{2}$ years, a team of NASA researchers and outside collaborators used sophisticated techniques of physical chemistry and optics to minutely examine the meteorite; they uncovered mineralogical, chemical, and structural oddities which they interpreted as evidence for biological activity in Mars' distant past.

The stone's journey began some 16 million years ago when an asteroid slammed into Mars and hurled chunks of the planet into space. About 13,000 years ago at least one of those pieces plummeted onto the frozen wastes of Antarctica, where it was found on Dec 27, 1984.

1996 U.S. Asteroid Orbiter *NEAR* (Near Earth Asteroid Rendezvous) launched to the near–earth asteroid *433 Eros*. The spacecraft studied the asteroid for one year after entering orbit in Feb 1999.

1997 U.S. and Europe Saturn Orbiter and Titan Probe *Cassini – Huygens* was launched to explore the whole Saturnian system — the planet itself, its atmosphere, rings and magnetosphere, and some of its moons. Titan is especially interesting because its atmosphere is supposed to have properties very close to those of the terrestrial atmosphere in its pre-biotic phase.

1998–9 U.S. *Mars Surveyor Project*: spacecraft '*98 Orbiter*' (1998) studied the planet from polar orbit for about 2 years, using a variety of advanced instruments; '*98 Lander*' (1999) studied the environment at the Martian south pole, seeking to understand the planet's climate and soil. It was equipped with meteorological equipment to study the weather, and a robotic arm to dig trenches in the soil.

1999–2006 U.S. Comet Sample Return *Stardust*. Scheduled to rendezvous with Comet P/Wild-2 in 2004, study the object and collect material for analysis on earth. Capsule is scheduled to return in January 2006.

2007 NASA launched the probe *DAWN* via Delta II ion–engine rocket from Cape Canaveral (Sept 27). The DAWN will travel 5.1×10^9 km to asteroids *Vesta* and *Ceres*, reaching *Vesta* sometime in August 2011.

1930 CE, Aug. 13 ca 12^h:04^m GMT (07^h:04^m LT). A mysterious explosion over the Curucá River[694], in the upper reaches of the Amazon, West Brazil (near the border junction of Peru, Columbia and Brazil); ca 5 °S, 71.5 °W.

A glowing bolide arrived from a northerly direction and apparently exploded at low altitude (5–10 km) in the atmosphere over the Brazilian rain forest. The earthquake generated by the impact of the main detonation-wave was recorded at *La Paz* (1322 km away) at 07:05:03 LT, and the explosion was heard in cities 240 km away (Atalaia do Norte and Esperanca). At the source –

"... the sun turned blood red and a darkness spread overhead; a fine red dust (ash) began to fall onto the forest and into the river; several ear-piercing whistles then filled the air, becoming louder and louder; from the sky fell large balls of fire like thunderbolts; there were three distinct explosions, each causing tremors like earthquakes".

Astronomers estimated a yield equivalent of about one megaton TNT (about a tenth of the yield of the Tunguska event of June 30, 1908 in Central Siberia). They believe that the bolide originated in the comet *P/Swift-Tuttle* and that the fireballs were associated with its *Perseid meteroid stream*[695].

---

694 A tributary of the Rio Yavari, itself a large tributary of the Amazon River.

695 Huyghe, P., *Incident at Curucá*, The Sciences, March/April 1966, pp. 14–17.

Apart from the major *Tunguska explosion* (June 30, 1908) and the smaller *Brazilian explosion* (Aug. 13, 1930), at least three other similar events, albeit of smaller yield, are known to have happened over land:

British Guiana, Dec. 11, 1935
British Columbia, March 31, 1965
New Guinea, March 04, 1975.

Thus, it is quite feasible that bolide-earth encounters in the yield range 100–1000 KT take place ten times more often than astronomers and geophysicists had thought, with the earth subjected to 3–4 such events per century.

1930 CE

- Superconductivity was discovered in lead-bismuth alloys by **W.J. de Haas** and **J. Voogd**. This class of superconductors is called *type II*, and its members differ from *type I* superconductors in their magnetic properties, which involve *Abrikosov Flux tubes* penetrating the medium bulk.
- The *photographic flashbulb* was patented by a German inventor, **Johannes Ostermeir**. A small filament in the 'flash lamp' heated to ignite foil inside the bulb, providing a bright, smokeless, flash of light. This provided a much safer and more practical means of photographic illumination than did previous methods, which employed flash powder.

1930 CE **Vannevar Bush** (1890–1974, U.S.A.). Electrical engineer. Developed and built the first mechanical analog computer ('*differential analyzer*') designed to solve differential equations.

Bush was born in Everett, MA. He taught at Tufts University (1914–1917). After conducting submarine-detection research for the U.S. Navy, he joined the faculty of the Massachusetts Institute of Technology (MIT) at Cambridge in 1919. From 1930 he worked with a team at MIT to build the differential analyzer. This machine foreshadowed the electronic computers developed after WWII. During 1940–1948 he served as a high ranking government official in charge of scientific research and development. His famous "unfettered research" memorandum set the tone for generous U.S. government support for "Big Science" basic research in the post–war are – a policy that greatly benefited fields such as nuclear and particle physics, in particular.

1930 CE **Ernest Orlando Lawrence** (1901–1958, U.S.A.). Distinguished physicist. Invented the circular particle accelerator (cyclotron). It was the first non-electrostatic accelerator to reach high energies (ca 12 MeV for protons).

The principle of operation of the cyclotron[696]: positive ions from a central source are *repeatedly accelerated by an alternating electric field* applied across the gap between two D-shaped half-circles ("*dees*", diameter ca 90–230 cm). These ions describe spiral paths in a *perpendicular magnetic field* (ca 20,000 gauss) and are finally directed by a deflector plate onto a target.

With the cyclotron, Lawrence produced *technetium*, the first artificially produced element. He later contributed to chemistry, biology and *medicine* by producing new artificial elements (e.g. radioactive phosphorus and iodine) and also generated neutron beams used in cancer treatment. During WWII, he worked in the Manhattan project, in which he was in charge of developing the electromagnetic process for separating uranium-235 for the atomic bomb. Lawrence also invented the color-television picture tubes. The Lawrence Berkeley Laboratory at Berkeley; Lawrence Livermore National Laboratory at Livermore, CA; and element 103, Lawrencium, were named in his honor.

Lawrence was born in Canton, South Dakota. He was an assistant professor at Yale University (1921–1928) and became a full professor at the University of California, Berkeley, in 1930. He built the Radiation Laboratory at Berkeley in 1936 and won the Nobel prize for physics in 1939.

---

[696] In the non-relativistic approximation, the revolution frequency of a particle in a uniform magnetic field is independent of its kinetic energy. As the particle is accelerated via synchronized electric fields during short segments of its orbit, it travels faster, experiencing a magnetic deflection force proportional to its velocity. The centripetal acceleration is proportional to the square of its velocity; Newton's second law then becomes $\frac{mv^2}{r} = Bev$ or $m\omega^2 r = Be\omega r$. In these equations m is the mass of the accelerated particle, v its linear velocity, e its charge, r is the radius of revolution, B the magnetic field, and $\omega = \frac{v}{r} = \left(\frac{e}{m}\right) B$ is the angular velocity *which is independent of the speed or radius*, and fixed for a group of particles with fixed $\left(\frac{e}{m}\right)$ ratio. The time of revolution $t = \frac{2\pi}{B}\left(\frac{m}{e}\right)$ is thus also independent of the speed. If the frequency of the alternating potential difference between the "*Dees*" (the D-shaped halves of the cyclotron) is correctly adjusted, the ions emerge from each *dee* after exactly one-half cycle and are attracted into the opposite *dee*. The energy characteristic of the machine is limited by the diameter $2R$ of the *dees* and the magnetic field strength B: $E_{\text{lim}} = \frac{m}{2} v_{\text{lim}}^2 = \frac{e^2 B^2 R^2}{2m}$. Above 10 MeV for protons, the relativistic increase in mass begins to de-synchronize the revolution frequency with the oscillator frequency.

Big Science I — Particle Accelerators[697] *(1930–1971)*

High energy particle physics is the study of fundamental particles and their interactions, transmutations and associated fields. This involves probing short distances, which in turn is accomplished with probes of short de Broglie wavelength, i.e. high momentum and energy $(p = \frac{h}{\lambda})$. *"High energy" varies from a few keV (in the spectrometer of J.J. Thomson, in which he discovered the electron in 1897) to 100 GeV (in the spectrometer where the* Z^0 *particle was discovered in 1983) and beyond — a range of more than 8 orders of magnitude*[698] *which will continue to grow as accelerator technology marches on.*

Particle accelerators are devices used to accelerate charged elementary particles or ions to high energies. Particles are accelerated through their

[698] *Energy scales in modern physics*: a proton or electron accelerated through 1 Volt acquires a kinetic energy of $1 \text{ eV} = 1.602 \times 10^{-19}$ Joule. Thus: $\text{keV} = 10^3$ eV, $\text{MeV} = 10^6$ eV, $\text{GeV} = 10^9$ eV, $\text{TeV} = 10^{12}$ eV. The electron *rest-mass energy* is $E_0 = m_e c^2 = 0.511$ MeV, while the proton rest-mass energy is 938 MeV. The amount of rest–mass energy stored in 1 kg of matter is 9×10^{16} Joule [at a cost of 10 cents per kilowatt-hour, the energy stored in one kilogram of dirt – if it could be released – would be worth about 2.5 billion dollars!].

Energies of the order of eV are associated with outer electrons in atoms, keV — with inner electrons in heavy atoms, MeV — with neutrons and protons (nucleons) inside nuclei and released in fission, fusion and other nuclear reactions; 10^2 MeV to GeV's — with quarks inside nucleons, light quark-antiquark hadrons, heavy-lepton production, and nucleon-antinucleon production. Energies of order 10^2 GeV resolve the weak nuclear forces' range (via the uncertainty principle) and produce their mediating particles.

electromagnetic interactions. Only electrically charged particles that are relatively stable against spontaneous decay may be readily accelerated. The only particles that fit this description are the electron*, the* proton*, and relatively stable nuclei (heavy ions) plus their antiparticles. However, beams of charged* unstable *weakly–decaying particles (such as the* muon*) can be accelerated, stored and collided with targets and each other, since the highly relativistic energies of such beams result in time–dilation factors that render them stable enough*[699]*.*

Particle accelerators today — along with their attendant peripheral equipment, such as detectors*, and stand–alone detectors designed to study cosmic rays and exotic particles and decays — are some of the largest and most expensive instruments used by scientists. Accelerators all have three basic parts: a source of charged particles, a tube pumped to a high vacuum in which the particles can travel freely until they reach their target, and some means of speeding up the particles. The vacuum is needed so that the particles are not scattered by air molecules.*

Due to many innovative technological advancements in the field of accelerators, the maximum achievable particle energy has grown by many orders of magnitude over the decades since the early accelerators of 1930. Each new accelerator technique has reached a limit in the maximum energy within a few years, only to be overtaken by a new invention. The main stages of development were as follows:

1. Electrostatic machines (1–10 MeV; 1927–1933)

The success of the nuclear model of the atom, proposed in 1911 *by* ***Rutherford*** *and developed by* ***Niels Bohr*** *and others, served to emphasize the great difference in energy scale between atomic processes involving only the extranuclear electrons and nuclear processes proper. During the first* 20 *years of the* 20^{th} *century, the chief source of information about nuclei was natural radioactivity, as exhibited by the chemical elements of highest atomic and mass numbers.*

[699] Also, it is possible to form collimated *secondary* beams – composed of charged or neutral particles, whether stable or not – through in–flight radioactive decays of accelerator–produced collision products. Thus pion, kaon, neutrino, and other secondary particle beams are routinely created in accelerators and fission reactors, and used to induce further reactions.

In 1919 *Rutherford carried out some simple experiments to test whether the positively charged nucleus of a light element could be disrupted by bombardment with the alpha particles emitted from a radioactive preparation. This would require the alpha particles to penetrate the Coulomb field of repulsion exerted by the charge of the light nucleus, and it was known from scattering experiments that such penetration is unlikely. Nevertheless Rutherford was able to show that the element nitrogen, under alpha-particle bombardment, occasionally emitted protons, probably due to the reaction* $^{14}_{7}N + \ ^{4}_{2}He \rightarrow \ ^{1}_{1}H + \ ^{17}_{8}O$.

This hypothesis was verified by ***Patrick (Maynard Stuart) Blackett*** *(1897–1974, England), who in* 1925 *started his experiments with colliding atoms in a Wilson cloud chamber and took first photographs of nuclear reactions. Many basic discoveries were made with radioactive sources, but it was soon realized that particle accelerators would provide a much higher yield of nuclear reactions under more controllable conditions.*

Linear accelerators (linacs) accelerate charges along a straight line in an evacuated tube. In the case of electrostatic linac, the acceleration results from the force applied by a static electric field provided by a large potential difference. A particle of charge e *moving through a potential drop of* V *can gain kinetic energy* $E_k = eV$. *The high voltage (up to* 2 *MV) may be obtained by charging capacitors with a voltage multiplier circuit. In 1930, an international race was underway to produce the first artificial disintegration of the nucleus*[700]*. This goal was achieved at the Cavendish Laboratory, England: a huge voltage divider was built and used to linearly accelerate protons to kinetic energies of some* 800, 000 eV.

In 1932 ***John Douglas Cockroft***[701] *(1897–1967) and* ***Ernest T. S. Wal-***

---

[700] Already in the late 1920s, study of the structure, excitation, and disintegration of the nucleus awaited new technology. Calculations by **George Gamow** (1904–1968) based on the new wave mechanics, indicated that protons of relatively low energy could penetrate barriers of light nuclei. This, in turn, encouraged Cockroft and Walton to achieve proton-induced disintegration of lithium nuclei with a conventional voltage multiplier.

[701] **Cockroft** studied at Manchester University under **Horace Lamb**. After serving in WWI he continued his studies at Cambridge and then worked under **Rutherford** in the Cavendish Laboratory, where he collaborated with **P. Kapitsa** on the production of intense magnetic fields at low temperatures. In 1928 he returned to work on the acceleration of protons by high voltages with E.T.S. Walton. He became professor of Natural Philosophy at Cambridge in 1939. In 1940 he was appointed Head of the Air Defense Research and Development Establishment and in 1946 he became Director of the Atomic Energy Research Establishment at Harwell.

ton[702] *(1903–1995) in England were first to accelerate protons by means of an electrostatic generator and demonstrate possibilities for production of many types of reactions in light nuclei, such as*

$$ {}^{1}_{1}H + {}^{7}_{3}Li \rightarrow 2\,{}^{4}_{2}He + Q $$

with Q being the heat of (nuclear) reaction. For this feat of 'atom splitting' they were awarded the Nobel Prize in Physics for 1951. This provided also the first experimental proof (1927) of ***Einstein****'s equation $E = mc^2$.*

The maximum energy achievable in an electrostatic linac, of order 1 MeV, *is limited by electrical discharge. The brute force acceleration by direct current (DC) high voltage was further improved with the development of the* ***Van de Graaff*** *accelerator (1933).*

The rectifier circuit of the Cockroft-Walton system was replaced with an electrostatic charging belt. The effects of sparking were reduced by insulating the accelerating tube with compressed gases. Van de Graaff accelerators can produce kinetic energies of about 10 MeV. *Since kinetic energies of particles from nuclear decays are typically a few* MeV, *the machine can produce kinetic energies that are larger than those available from natural radioactive decays.*

2. RF Linear Accelerators (up to 50 GeV; 1928 to 1990s)

To reach very high energies, particles must be accelerated, stepwise, many times over. Conceptually, the simplest system is a linear accelerator *which uses* alternating electric fields *of high magnitude to push particles along a straight line.*

To achieve this feat, particles pass through a line of hollow metal tubes enclosed in an evacuated cylinder. An alternating electric field of constant frequency [usually in the radio (RF) or microwave range] is timed so that a particle is pushed forward each time it goes through a gap between two of the metal tubes. Since the velocity increases at each gap, the cylinder lengths must increase also. This new concept of RF acceleration was introduced in 1928 by the Norwegian physicist ***Rolf Wideröe*** *(1902–1996, Norway and USA) [but originated with* ***Gustaf Ising*** *(1883–1960) in 1924].*

[702] **Ernest Thomas Sinton Walton** went to the Belfast Trinity College (1922) and later to the Cambridge Cavendish Laboratory (1927). He became professor of Natural and Experimental Philosophy at Trinity College, Belfast (1947).

In his pioneering apparatus Wideröe passed electrons across two gaps. The voltage across both gaps was made to oscillate such that the electrons arrive at each gap when the voltage difference across it is a maximum. The electrons are accelerated in each of the two gaps. Let the gaps be separated by a distance d *under voltage difference* $V_{\max}$. *Then the total kinetic energy of the electron after the first gap is* $E = mc^2 + eV_{\max}$, *its momentum* p *is given by* $pc = \sqrt{E^2 - (mc^2)^2}$ *and its velocity is* $\frac{v}{c} = \frac{pc}{E}$. *To be accelerated in both gaps, the voltage oscillation frequency must be* $f = \frac{v}{d}$. *Substituting* $d = 1$ m, $V_{max} = 100$ kV *one finds* $f = 160$ MHz *— a radio frequency. Since the energy gain from each gap is* $eV_{\max}$, *the electron's overall gain in kinetic energy is* $2eV_{\max}$. *There is no limit in principle to the number of acceleration gaps that can be added.*

The RF acceleration technique is useful in practice largely because of a phenomenon called longitudinal phase stability: *in practice electrons travel in* bunches *of finite length and are collectively accelerated. Consequently, all particles do not arrive at the acceleration gap at the same time. Choosing the accelerating voltage* V_0 *to be* smaller *than the maximum voltage, particles that arrive* early *are accelerated by a* smaller *voltage difference, while particles that arrive* late *are accelerated by a larger voltage. Only particles in the* center *of the bunch are accelerated by* V_0. *But both late and early arrivals are always* synchronized *with the center of the bunch.*

The key ingredient in later improvements of the RF acceleration technique was a novel high-frequency power source: the Klystron *amplifier (1937–1940) can provide several megawatts at a frequency of a few gigahertz. One refinement of the RF technique is to accelerate relativistic particles using electromagnetic waves in a* wave-guide cavity. *Acceleration occurs in such a cavity when the* group velocity *of the wave is equal to the* particle velocity. *The phase and group velocities of the electromagnetic waves are adjusted by appropriate geometric shaping of the wave-guide cavity.*

Theoretically a linac of any energy can be built. However, RF technology required the availability of large RF power sources for the acceleration, and enormous technical problems had to be solved before linear accelerators became useful machines.

The largest linac in the world, at Stanford University (Stanford Linear Accelerator Center – SLAC), is 3.2 km *long. It is capable of accelerating electrons to an energy of* 50GeV *(*50 *billion, or giga, electron volts). Stanford's linac is designed to accelerate two beams of particle bunches (electrons and positrons), which "surf" on regions of a traveling TM* 01 *waveguide mode with oppositely-oriented longitudinal electric fields. The* e^+ *and* e^- *beams are then separated magnetically, made to curve around, and collided.*

Early SLAC experiments (1960's and early 1970's), which established the quark model, involved colliding linac-produced e^- beams with stationary protons and other fixed–target nuclei (e.g. in a liquid hydrogen bubble chamber).

3. Cyclotron and Synchrocyclotron (1929–1952)

Uniform static magnetic bend *charged particles around circular arcs, while uniform electric fields* speed them up. *When a charged particle of mass m and charge e is moving with velocity v along a circular path of radius r perpendicular to the magnetic field $\boldsymbol{B}$, Newton's second law of motion becomes $evB = \frac{mv^2}{r}$, $p \equiv mv = eBr$; hence $v = \frac{eBr}{m}$. In practice, the tracks are not simple circles, even if $\boldsymbol{v}$ is perpendicular to $\boldsymbol{B}$, because the particle loses energy and momentum via its accelerator-caused EM radiation; actual tracks are inward–spiraling helices. The expression $p = eBr$ shows that a decreasing momentum leads to a decreasing radius about the magnetic–field axis.*

A 500-GeV RF linear accelerator would have to be about 75 km long, with enormous construction, maintenance and power challenges and costs. It thus makes more sense to magnetically guide the charged particles into traversals of multiple closed, circular paths, along which their kinetic energies can be gradually increased via the synchronized application of RF fields. This required an altogether new approach, which eventually came in 1929 with the invention of the cyclotron *by* ***E.O. Lawrence***. *It made use of the RF technique pioneered by* ***Rolf Wideröe*** *(1928).*

Lawrence's idea was to accelerate ions or electrons stepwise, using a uniform magnetic field to move the particles in a spiral path which repeatedly crosses an accelerating gap in the plane of the spiral. An applied, radio-frequency electric field, synchronized in phase with the orbital frequency of the ions, is used to accelerate the particles on each trip across the gap.

In 1930, Lawrence's students, ***Niels Edlefsen*** *(1893–1971)* and ***Milton Stanley Livingstone*** *(1905–1986) built the first cyclotron: it was essentially a linac wrapped into a tight spiral.*

But instead of many tubes, the machine has only two flat D-shaped hollow vacuum chambers (called dees), placed between the poles of a magnet (actually a powerful electromagnet). The magnetic field is constant and is perpendicular to the trajectory of the charged particle. This configuration makes the charged particle move in semicircular *paths within each dee. The dees are connected* *to a source of alternating voltage, is synchronized so that whenever a charged particle is moving from dee* 1 *to dee* 2, *the electric field between the oppositely charged dees is maximum in a direction that will accelerate the particle. One-half cycle later, the charged particle is moving in the opposite direction from dee* 2 *to dee* 1 *and the electric field has been reversed to again align itself with the momentary direction of the particle's motion, so as to give it a maximum increase in speed.*

When inside the metal dees, each charged particle is within a conductor where the electric field is zero. As the beam particles gain energy and momentum from its trips between the dees, their orbital radius will increase, according to $p = eBr$. *As the particles gain energy, they will spiral out toward the other peripheries of the accelerator dees, until they gain enough energy to exit the accelerator.*

If the maximum radius is R *and if* $E_k \ll m_0c^2$ *(*$m_0 =$ *charged particle's rest mass), then relativistic effects may be neglected and* $E_k \approx \frac{p_{\text{max}}^2}{2m_0} = \frac{e^2B^2R^2}{2m_0}$. *For example if* $B = 1.3$ Tesla *a singly–charged particle species, and* $R = 11$ cm, *(the 1932 Lawrence-Livingstone machine) we find the cyclotron frequency* $f_{\text{cyc}} = \frac{\omega_{\text{cyc}}}{2\pi} = 20$ MHz *and* $E_k = 1.0$ MeV *for a proton with* $m_0 = 1.67 \times 10^{-27}$ kg. *Its rest energy is* $m_0c^2 = 938$ MeV.

In a cyclotron, the time (T) *between acceleration burst is the time for the particle to make one-half of a revolution. For a particle traveling at a speed* v *in a circle of radius* r, $T = \frac{\pi r}{v}$. *Therefore, the frequency (*ω_{cyc}*) of the oscillating voltage is chosen to be* $\omega_{\text{cyc}} = \frac{\pi}{T} = \frac{v}{r}$, *so that the voltage changes sign each half-revolution. This frequency is called the* cyclotron frequency.

For a non-relativistic particle the orbital frequency *(*ω_{orb}*) is a constant (independent of particle energy),* $\omega_{\text{orb}} = \omega_{\text{cyc}} = \frac{v}{r} = \frac{veB}{p} = \frac{eB}{m_0}$. *Hence, the particles may be accelerated each time they cross the gap by selecting* $\omega_{\text{AC}} = \omega_{\text{cyc}}$.

If, however, the particle's kinetic energy begins to become an appreciable fraction of its rest energy, the mass begins to increase significantly, in accordance with STR. As a result, ω_{orb} *will decrease when the particle is speeded up at a constant* B *field and the particle traversals of the dees will fall out of phase with the accelerating electric field.*

Indeed, **Hans Bethe** *and* **M.E. Rose** *(1911–1967) showed that a fixed-frequency cyclotron of the Lawrence-Livingstone design has a practical upper* *energy limit of about* 25 *MeV* *(for protons), owing to the said relativistic mass increase*[703].

[703] For a *relativistic* particle, $\omega_{\rm orb}$ depends on the particle speed because the momentum has Lorentz factor $\gamma = \left(1 - \frac{v^2}{c^2}\right)^{-1/2}$ via $p = \gamma m_0 v$; $\omega_{\rm orb} = \frac{veB}{p} = \frac{eB}{\gamma m_0}$. Thus, if $\omega_{\rm cyc}$ is kept fixed, particles cannot be accelerated to extreme relativistic energies because the γ factor becomes important.
This effect can be readily calculated; if

$$m_0 c^2(\gamma_1 - 1) = 2eV_{max}$$

is the energy gained per revolution, the increase of γ after the first revolution is $\delta\gamma = \gamma_1 - 1$.
This increase in γ causes orbital oscillation to be out of phase with the cyclotron oscillation by $(2\pi)\delta\gamma$ radians. In the next revolution, γ increases further by $(\delta\gamma)$ and the total phase difference of the orbital and cyclotron oscillations increases to $2\pi(1+2)\delta\gamma$. After N revolutions the phase difference is $2\pi\,\frac{1}{2}\,N(N+1)(\delta\gamma) \approx \pi N^2(\delta\gamma)$ When the phase difference is π, the particles are no longer accelerated because they arrive at the gap when the voltage has the wrong polarity. The maximum number of revolutions that the particles make while still being accelerated is

$$N_c = \sqrt{\frac{1}{\delta\gamma}} = \sqrt{\frac{m_0 c^2}{2eV_{max}}}\ ,$$

while the corresponding kinetic energy after N_c revolutions is
$E_k = N_c \cdot \delta\gamma \cdot m_0 c^2 = \sqrt{m_0 c^2 \cdot 2eV_{max}}$.
For $V_{max} = 150$ kV, the maximum kinetic energy for protons is about 17 MeV. For electrons, the maximum kinetic energy is much smaller, so that the conventional cyclotron is not useful for electron accelerations.
One may estimate the size of magnetic field and cyclotron frequency for any desired energy. Let p be the maximum momentum and E_k the maximum kinetic energy of the proton corresponding to a maximum radius R. Using the relations

$$E = m_0 c^2 + E_k, \qquad pc = \sqrt{E^2 - (m_0 c^2)^2} \approx \sqrt{2E_k m_0 c^2}$$

(for $E_k \ll m_0 c^2$), we find

$$B = \frac{1}{eR}\sqrt{2m_0 E_k}, \qquad v = \sqrt{\frac{2E_k}{m_0}}, \qquad \omega_{\rm cyc} = \frac{v}{R} = \frac{c}{R}\sqrt{\frac{2E_k}{m_0 c^2}}.$$

Thus for $E_k = 1$ MeV and $R = 22$ cm, one obtains $B = 0.65$ Tesla, $f_{\rm cyc} = \frac{\omega_c}{2\pi} \approx 10$ MHz.

A way to circumvent this limit was found (1945) independently by ***Edwin McMillan*** *(1907–1991) and* ***Vladimir Veksler*** *(1907–1966) who proposed to sustain the resonance by frequency-modulating the electric field. Under this arrangement, the RF oscillator that accelerates the particles around the dees is automatically adjusted to stay in step with the accelerated particle; as the particle gains mass, the RF frequency is lowered slightly to keep in phase with the slightly more sluggish orbital traversals*[704].

This means that the frequency of the field is varied synchronously with the inverse of the particle energy $(\gamma m_0 c^2)$*. Such a device is called a synchrocyclotron. Here there is no longer an advantage to having a very large voltage per turn as in a conventional cyclotron; the acceleration per revolution is usually chosen to be about* 10 KeV *per turn. Since there is a limit to how large of a magnetic field can be produced, the maximum energy achievable is limited by how big one can make the device: as the maximum energy of the synchrocyclotron increases, so must its size, for particles must have more space in which to spiral.*

4. Betatron and beta-synchrotron (up to 100 GeV; 1940–1947)

Electrons cannot be easily accelerated in a cyclotron, since the operating principle of this latter device is based in the constancy of the ratio e/m *of the electron. The relativistic variation of the mass of an electron with velocity becomes important at such low energies as to render the cyclotron useless for accelerating these particles (e.g. already at a kinetic energy of* 1 MeV,

---

704 Other remedies (suggested in the pre-WWII years) took advantage of the focusing action of *inhomogeneous magnetic fields* at the outer edge of the vacuum chamber, e.g. curvature of magnetic lines of force create a magnetic force on particles away from the central plane directing them back into the central plane. In 1938 **Llewellyn Hilleth Thomas** (1903–1992) suggested that the magnetic field should be varied in *azimuth*, that is, around the perimeter of the orbit, as well as in the *radial* direction. This "AVF" (azimuthally varying field) concept has been realized in the *spiral ridge cyclotron*, where especially strong magnetic-field regions were produced by spiral sectors built into the pole face: the magnetic field strength increases radially everywhere inside the vacuum chamber and is designed to satisfy the fixed-frequency condition into the relativistic region. At the same time the strong azimuthal field variations provide extra focusing action to overcome the defocusing affects of the radial field variation.

the electron has about 3 times as much inertia as an electron at rest). Even conventional synchrocyclotrons cannot be adapted to make allowance for such large increases in mass.

A machine whose operation is independent of relativistic considerations was in order. This necessity was the mother of the invention of the betatron, *a special circular accelerator for electrons, by* **Donald William Kerst** *(1911–1993) in 1940. The operation of the betatron involves simultaneously using a static (DC) magnetic field to hold moving electrons in a stable orbit, while the field also has an AC component that oscillates rapidly. The changing flux results in a tangential electromotive force (EMF) that accelerates the electrons along their orbit.*

The particles are injected with a certain initial velocity distribution from an electron "gun", tangent to a horizontal circular orbit of fixed radius within a ring-shaped vacuum chamber known as the "doughnut". This chamber is placed between the poles of a magnet whose field lines are approximately at right angles to the plane of the orbit. The magnetic field has a static component, known as the 'guide field', and a time-varying AC component (at a fairly low frequency, e.g. 60 *Hz) obtained by applying an alternating current to an electromagnet.*

The guide field keeps the electrons in a circular path, while the time-varying field creates an induced electric field *which accelerates the electrons (over a certain range of each cycle) due to changing magnetic flux through the orbit (Faraday's law). The main condition for successful operation of the betatron is the confinement of the orbital radius within strict limits despite the large difference between the initial and final electron energies. This is achieved by arranging for the magnetic field to vary* radially *in a suitable manner.*[705]

[705] The static magnetic field exerts a centripetal force on the orbiting electrons. From the time of injection the magnetic field varies. According to Faraday's law this results in a tangential electric field E_t, causing the electrons to accelerate. The static 'guide field' must be made radially inhomogeneous in order to force the electron into an orbit of approximately fixed radius R in spite of its increasing momentum. To find the type of function $B = B(R)$ required, we write Faraday's law in the form

$$-\oint d\boldsymbol{\ell} \cdot \boldsymbol{E} = 2\pi R E_t = \frac{d\Phi}{dt},$$

where E_t is the clockwise tangental E-field component and Φ is the magnetic flux through the radius-R orbit, and the EMF line integral is taken in the anticlockwise sense as viewed from above the doughnut. Hence the anticlockwise tangential accelerating force on an electron in a betatron is

$$\frac{dp}{dt} = \frac{d}{dt}(mv) = \frac{e}{2\pi R}\frac{d\Phi}{dt} \ .$$

with p momentum and e the (positive) magnitude of an electron's charge.
The condition that will ensure that the electrons pursue a circular path of fixed radius R while being accelerated is

$$\frac{mv^2}{R} = evB \ ,$$

where $m = m_0/\sqrt{1 - v^2/c^2}$ is the electron's relativistic mass and $B = B(R)$ is the magnitude of the magnetic field at the circular path (of radius R). Hence $mv = eRB$; combining with the EMF acceleration equation yield $eR\frac{\partial}{\partial t}B = \frac{e}{2\pi R}\frac{d\Phi}{dt}$. Integration w.r.t. time (recall R is by design t-independent) yields $B = \frac{1}{2\pi R^2}\Phi = \frac{\Phi}{2A}$, with $A = \pi R^2$ the area enclosed within the orbit.
The condition for a constant orbit of radius R, then, is that the magnetic field at the position of the orbit should equal half the average field (magnetic flux per unit area) through the orbit. This result is achieved by shaping the pole pieces of the magnet so that the flux density decreases with distance from the symmetry axis.
More extensive analysis shows that this orbit is *stable*, i.e. if electrons are displaced away from it, restoring forces will arise to move them back to the orbit (causing so-called *betatron oscillations* and *phase oscillations*). To extract the electrons after their acceleration, the condition $B = \frac{\Phi}{2A}$ may be violated by momentarily adding or subtracting some auxiliary flux that will cause the electrons to *spiral* in or out. While at a fixed radius R, the electron accelerated at a way such that its Kinetic energy rises at a rate

$$\frac{dE_k}{dt} = v\frac{d}{dt}(mv) \approx \frac{2\pi R}{T}\frac{dp}{dt} = \frac{2\pi R}{T}|eE_k|$$

where T is the time the electron takes to complete its current traversal of the circle. Since $v(t)$ increases asymptotically toward c after many traversals, T *decreases* asymptotically toward $2\pi R/c$.
A typical betatron that accelerates electrons to 100 MeV might have an orbit of radius $R = 1$ m, and a magnetic field at that orbit which changes at a rate of $100 \ \frac{\text{Webers}}{\text{m}^2\cdot\text{sec}}$ during the acceleration process. Hence the induced emf is about 628 V. An electron in this betatron acquires 628 eV each time it traverses a complete circle; it must take about $160,000$ revolutions before it has an energy of 100 MeV! The non-relativistic limitation on particle speed that affects the cyclotron, does not affect the betatron, since the electrons in the latter are *accelerated continuously* and need not (indeed do not) make each turn in precisely the same period of time.

In the betatron, there are small displacements of the particles due to collisions with the dilute gas inside the beam pipe. The accelerator must be designed to have electromagnetic restoring forces so that particles slightly out of orbit get pulled back into orbit. To this end a more general treatment of the problem shows that, with radial field variations of the form $B \propto r^{-n}$ $(0 < n < 1)$, *the electron beam executes* oscillations *in both the radial direction ('phase oscillations') and in the direction perpendicular to the orbit ('betatron oscillations'). These oscillations about the mean orbital radius are important in synchrotrons as well as betatrons, because their amplitudes determines the minimum size of the vacuum chamber. The machines have to be designed in such a way that oscillations are of* small *amplitude throughout the acceleration cycle, and this involves a proper choice of the index* n.

The betatron principle applies to particles of all speeds, and it enables electrons to be brought rapidly from the injection energy to energies of several MeV. When the designed maximum energy is reached, the orbit is artificially collapsed, usually by arranging for part of the magnetic pole assembly to reach saturation. The electrons then spiral inwards *to strike a target, which commonly consists of a tungsten rod. At the end of each acceleration cycle the target emits an intense burst of X-rays tangentially to the electron beam, produced by the* bremsstrahlung *process*[706].

Since the electrons in a betatron reach speeds close to c *(the speed of light in vacuum) early in the acceleration cycle, they circulate at nearly constant intervals of time during the major part of the cycle. It is then a comparatively simple matter to supply extra energy to the beam by applying an electric field of fixed frequency, as is done in the* beta-synchrotron. *The beam passes repeatedly through a tuned cavity forming part of the doughnut, and RF power is switched on in this cavity at a suitable moment in the cycle. Many electrons enter the cavity when it is at positive potential relative to the grounded internal surface of the doughnut and these receive extra energy, mainly expressed as a mass increase (their increase in* speed *is negligible). The process is repeated for all electron bunches possessing phase stability, and the final energy greatly exceeds the betatron limit.*

One notable (and unavoidable) feature of electron accelerators of the circular type is the emission of electromagnetic radiation from the beam itself.

---

[706] When the electron passes near a target nucleus, and is thus accelerated sideways and radiates X-rays or gamma rays. At the quantum level, *Quantum Electrodynamics* (QED) describes the process via a *Feynman diagram* involving a virtual photon exchange (between electron and nucleus) and the emission of a (real) photon by the electron. If the latter is virtual, it can decay into a real electron–positron pair – resulting in antimatter production, as routinely done at e^+e^- colliders such as SLAC and DESY.

Since the particles are continually accelerated toward the center of the orbit (even when not accelerated tangentially), they radiate according to nearly – classical laws, and an intense synchrotron radiation *is seen. The energy losses from this effect are not serious until the electron energy approaches the GeV scale. Electromagnetic theory predicts that the energy radiated per revolution*[707] *by a particle of rest mass* m_0, *charge* e, *velocity* $v \approx c$ *(ultra–relativistic* regime) *and orbital radius* r *is* $\Delta E \cong \frac{e^2}{3\epsilon_0 r}\left(\frac{E}{m_0c^2}\right)^4$, *with* ϵ_0 *the vacuum permittivity.*

Synchrotron radiation places a practical limit on the maximum energy of a betatron. A high energy electron machine is therefore made large $(\Delta E \propto \frac{1}{r})$ *in order to reduce synchrotron radiation.*

While merely a nuisance from the particle physicist's standpoint,, synchrotron radiation is nowadays being used as a well-controlled collimated X-ray source, with wide applications in medicine, chemistry, biology, material science, and condensed-matter physics. Thus old betatrons and storage rings (see below), no longer useful as nuclear or particle-physics probes, are outfitted with extra groups of magnets called "wigglers" to enhance *synchrotron*

---

[707] Classical electromagnetic theory states that the power radiated by an orbiting charge e as observed in the laboratory Lorentz frame is $P = \frac{2}{3c^3}\frac{e^2a^2}{4\pi\epsilon_0}$, (Larmor's Law), where the acceleration is $a = \frac{v^2}{r}$ (valid for a nonrelativistic particle); while for an ultra-relativistic particle, the Lorentz–transformation laws of radiated fields and power mean that the lab–frame energy lost per revolution is $\approx \frac{4\pi\alpha}{3}\frac{\hbar c}{r}\gamma^4$, where $\gamma = (1-\beta^2)^{-1/2}$, $\alpha = \frac{e^2}{4\pi\hbar c}$ (we work in an electromagnetic unit system in which $\epsilon_0 = 1$). On account of their small rest mass, synchrotron radiation is much more important for electrons than for protons, and must be taken into account in the design of the betatron.
Assuming $r = 1$ m, $E_k = 300$ MeV, we have for an electron $(m_e = 0.511\ \frac{MeV}{c^2})$

$$\beta \approx 1; \qquad \gamma = \frac{E}{m_ec^2} = \frac{E_k + m_ec^2}{m_ec^2} \approx 588; \qquad \Delta E = 730 \text{ eV}$$

For the proton $(m = m_p)$ at the same kinetic energy, the exact version of the above synchrotron radiation energy–loss formula (valid for any particle velocity) yields:

$$\gamma = \frac{E}{m_pc^2} = 1.3; \qquad \beta \equiv \frac{v}{c} = \frac{\sqrt{\gamma^2-1}}{\gamma} = 0.64; \qquad \Delta E = 5\times 10^{-9} \text{ eV}$$

The classical approximation we have been using for the synchrotron radiation is valid as long as a typical radiated photon has energy $\hbar\omega_{ph} \ll E_k$ in the laboratory frame. This is usually the case for both electron and proton machines.

radiation by decreasing the radius of curvature of the electron beam. The word's largest electron synchrotron is the Large Electron Project (LEP) at CERN, which has a radius of about 4 km and energy of 100 GeV.

5. High Energy strong-focusing proton synchrotrons (1000 GeV; 1952–1971)

By the last decades of the 20^{th} century, accelerators could produce precisely timed and collimated, nearly 'mono–energetic' beams of charged particles with energies ranging from a few MeV to several hundred GeV. Intensities can be as high as 10^{16} particles/sec (of order 10^9 per bunch), and the beams can be concentrated onto targets of only a few square microns in area. The particles that are most often used as primary projectiles are protons and electrons.

Two tasks can be performed well only by accelerators, namely: the controlled production of new particles and new quantum states, and the investigation of the detailed structure of subatomic systems.

Only a very few stable and free particles exist in nature — the proton, the electron, neutrinos, the photon and the graviton[708]*. Only a limited number of nuclides are available in terrestrial matter, and they are usually in the ground state. To escape the narrow limitations of what is usually available, new, unstable particles and nuclear states must be produced artificially. To create a state of mass m, we need at least the energy $E = mc^2$; Very often, considerably more energy is required, as well as high beam fluxes (luminosities). The expression $p = eBr$, valid for any circular accelerator, shows us that increasing the momentum proportionally increases the trajectory radius, for a given magnetic field. Therefore, high-energy circular accelerators, such as the* 1-TeV *Tevatron accelerator (at the Batavia, Illinois Fermilab facility) require a radius of about a kilometer. To increase the energy to* 20 TeV *will require a radius of* 13.5 *km!*

Obviously, no laboratory can afford a magnet having square kilometers of pole areas. Therefore, huge-radius accelerators keep the curvature of the charged particles path constant by utilizing dipole magnets placed at inter-

[708] Of those, the proton may yet prove, and the three neutrino species oscillate into each other over sufficiently long travel distances through vacuum or matter.

vals[709] *along the path. Since* $B = \frac{mv}{er}$, B *must increase as both* m *and* v *increase, for given* r. *The actual radii of these behemoth accelerators are larger than that calculated from* $p_{\max} = eB_{\max}r$, *because dipole bending magnets alternate with quadrupole and other focusing magnets to keep the particle beam from spreading.*

Beam Optics

Beams of particles typically travel multiple traversals around circular accelerators, with total distances exceeding $10,000$ *km. Thus they must be* collimated *by suitable "lens systems" that operate on charged particle beams in analogy to optical lenses (this is true even in linacs, and "single pass colliders" such as the SLC at SLAC, Stanford). In light optics, the path of a monochromatic light ray through a system of thin lenses and prisms can be found easily by using geometrical optics:*

Consider, for instance, the combination of a positive (converging) and a negative (diverging) thin lens, with equal focal length f *and separated by a distance* $d \ll f$. *This combination is always focusing, with an overall focal length given by* $f_{\text{comb}} \approx \frac{f^2}{d}$.

In principle, one could use electric or magnetic lenses for the guidance of charged particle beams. The electric *field strength required for the effective focusing of high-energy particles is, however, impossibly high, and only* magnetic *elements are used*[710]. *The deflection of a monochromatic (mono-energetic) beam by a desired angle, or the selection of a beam of a desired momentum, is performed with a* dipole magnet *(the optical analog is a prism).*

---

709 This method was first realized in the construction of the first proton synchrotron (1 GeV) in Birmingham, England by **Marcus Laurence Edwin Oliphant** (1901–2000; England and Australia) and his collaborators (1947): The orbital radius was kept nearly constant over a large part of the acceleration cycle, and magnetic guidance was used only in the later stages of acceleration. Thus, *ring-shaped magnets* represented the most efficient deployment of a given amount of magnetic material.

710 However, *electric quadrapole* electrostatic lenses are routinely used in *low*–energy (several eV) mass spectrometer, which are used to measure minute amounts of trace chemicals. In this case, the accelerated particle beams are complex mixture of ionized or excited molecules. Due to the low particle velocities involved ($v \ll c$), magnetic fields would not be effective at all, so AC quasi–electrostatic multipole fields are used to guide and separate the different molecular species.

The radius of curvature, ρ, is obtained by equating the centripetal force $\frac{mv^2}{\rho} = \gamma \frac{m_0 v^2}{\rho}$ to the Lorentz force evB, where v is the particle velocity in the plane of motion normal to the field B. This yields $\rho = \frac{p}{|e|B}$. Clearly, an ordinary dipole magnet bends particles in only one plane; and even in that plane, B must be non-uniform for focusing to be achieved (since ρ is otherwise uniform for a mono-energetic beam). Such considerations lead to the conclusion that no magnetic lens with properties analogous to that of an optical focusing lens can be designed.

However, ***E.D. Courant***, ***M.S. Livingstone***, ***H.S. Snyder***, *and* ***N. Christophilos*** *invented during 1950–1952 a system of magnets that can effect a 3-D focusing (known as* strong focusing[711]*) such that focusing occurs simultaneously in two planes perpendicular to each other. Strong focusing is especially important in a large-radius (high energy) machine where the particle path length is very long and where one needs to keep the magnet aperture as small as possible to reduce the costs of magnets.*

In the strong focusing technique, oscillations are greatly reduced by the introduction of magnets that alternately focus and defocus in the horizontal and vertical planes containing the local beam line (i.e one magnet focuses *in one plane and de-focuses in the other, then the next exchanges the roles of the two planes, and so on. The magnets can be combined to yield a net focusing effect.*

There are two ways of achieving this in practice: In the alternating gradient synchrotron *alternating magnet sections have the net effect similar to that of a converging lens system in optics. This feature results in a large saving of magnetic material (4000 tons as against 36,000 tons in the Dubna machine, say) but it also necessitates* extreme accuracy *in the fabrication and alignment of the magnetic sections.*

A second option is the quadrupole doublet system: *the magnet system is composed of two quadrupole magnets, where one is rotated around the central (beam) axis by 90° w.r.t. the other. This arrangement forms an essential element of all modern particle accelerators, and also of* beam lines *that lead from the accelerating machines to the experiment halls (where beams are collided with fixed targets or each other). With the aid of focusing devices, a beam can be transported over distances of many km with small intensity loss.*

---

[711] In contradistinction to the *phase stability* arrangement that is named *weak focusing*. In weak focusing, fringe magnetic fields, applying vertical and radial restoring forces on a particle slightly out of orbit, are provided by *shaping* the magnetic fields.

In a proton synchrotron, the energy for fixed radius is limited by the field strength of the bending magnets. Thus, a very high energy machine is made with high-field magnets and a large radius.

6. Storage Rings and Colliding Beams Machines (100 GeV; 1961–1971)

In order to collect a large number of accelerated particles, each output beam pulse from an accelerator can be magnetically guided into a circular ring, where the beam energy can be further increased via RF fields. This ring, called a storage ring, *contains magnetic dipole structures to keep the particles moving in a circle.* Large numbers of particles per bunch, *and short bunches, increase the probability of desired (and sometimes rare) interactions occurring when two counter-rotating beams (of the same or different particle type) are magnetically deflected into* interaction regions, *usually spaced regularly around the storage-ring perimeter.*

The storage ring consists of a vacuum pipe passing through a ring of dipole magnets *that maintain a constant field, so that particles circulate* continuously; *other magnetic devices, also spaced along the ring, are responsible for focusing the beam or beams. The storage ring usually doubles as a synchrotron, so that particles are both accelerated and* stored *in the same machine.*

Two storage rings that intersect at one or more places can be used to study the collision of two stored beams. Particle-antiparticle collisions may be studied with a single storage ring, with particles and antiparticles circulating in opposite directions. (e.g. electrons and positrons – e^+e^- – or protons and antiprotons).

For a colliding beam machine to work, the particles must be accumulated and stored in stable orbits for durations on the scale of hours *— compared to the few* seconds *they typically spend in the synchrotron acceleration process (hence the name 'storage rings'). This requires an* extremely high vacuum *compared to that needed in a synchrotron. In a storage ring, the magnets are continuously operating, whereas in the normal operation of a synchrotron they are pulsed briefly every few seconds. Also, the beams in a storage ring must be* focused *to a small cross-sectional area and contain a large number of particles.*

A major increase in useful energy was achieved with the colliding beam machines: *Two colliding ultra-relativistic protons, for instance (or an electron and positron), each with energy $E^* \gg m_0c^2$, have the same* center-of-mass *energy as a particle of energy* $E = 2\frac{(E^*)^2}{m_0c^2}$ *colliding with a stationary counterpart, where* m_0 *is the proton or electron rest mass. Colliding beams are therefore used to achieve the highest achievable center-of-mass COM collision energies. In general, colliding beams of accelerated particles can yield more COM-frame energy (for instance, to create new particles) than collisions in which one particle is at rest. To understand this, we consider the classical Newtonian (non-relativistic) completely inelastic collision of a particle of mass* m *moving at speed* v *(relative to a fixed laboratory frame of reference) with an identical particle at rest in the same frame. Conservation of linear momentum requires that the two particles move together after the collision with a common velocity* $\frac{1}{2}v$*. The law of conservation of energy then implies that kinetic energy converted during the collision to other forms of energy (e.g. heat, inelastic deformations, elastic vibrations etc.) is*

$$\frac{1}{2}mv^2 - \frac{1}{2}(2m)\left(\frac{v}{2}\right)^2 \equiv \frac{1}{2}\left(\frac{1}{2}mv^2\right).$$

Thus, only one-half of the initial translational kinetic energy has been converted to other forms of energy.

On the other hand, if two particles with equal and opposite momenta collide and stick together, they are motionless after the collision and all the initial translational kinetic energy is converted into other kinds of energy. Consequently, if one wants to convert, say, 1 MeV *of kinetic energy, there are two options (classically):*

- *Hit a particle at rest with an equal-mass particle of* 2MeV *kinetic energy*
- *Effect a head-on collision of two equal-mass each with a kinetic energy of* 1/2 MeV *particles*

For the first option one needs a 2-MeV *accelerator, but for the second option one needs only a* $\frac{1}{2}$-MeV *accelerator, i.e. the counter-moving particles in the colliding beams each need only* $\frac{1}{4}$ *of the kinetic energy of the particles bombarding a fixed target in the classical case. In the relativistic case, this ratio decreases rapidly below* $\frac{1}{4}$ *as the required energy increases – in fact it is* $1/\gamma$*, with* γ *being the time–dilation factor for each colliding–beam particle. Therefore, existing accelerators have been altered, and new ones designed and built, to provide head-on collisions.*

7. Use of accelerators in basic and applied science

In about twenty laboratories all around the globe, scientists operate various linear and curved synchrotron–type accelerators, both to induce and study inter–particle collisions and to generate powerful and precise pulses of radiation in the X-ray range, using 3rd generation synchrotron X-ray sources. The primary charged–particle beams and various secondary beams (produced from them or independently) – the latter including, but not limited to, synchrotron X-rays are used at experimental stations to perform novel experiments in five disciplines:

- *Fundamental Physics:*

Accelerators are used to explore atomic nuclei and elementary particles, thereby allowing nuclear and particle physicists to identify new elements, particles and interactions. Machines exceeding 1 GeV *are used to study stable and unstable fundamental particles and resonances. Several hundred of these particles have been identified. High-energy physicists have discovered, and will doubtless continue to discover, rules and principles that govern the classification, inter-conversion, composition and interactions of subnuclear particles. Such schema are as useful to nuclear and particle physics as the periodic table of the chemical elements is to chemistry. They permit scientists to study violent particle collisions that mimic the state of the universe a fraction of a second after the Big Bang; and to elucidate the symmetries and invariances governing the fabric of the universe at the smallest spacetime scales, as well as study astrophysical objects and radiations. The collisions effected in such research involve primary charged–particle beams from accelerators, as well as: (charged and neutral) secondary beams from decays and collisions in accelerators and nuclear reactors; laser beams; specially prepared bulk–matter samples (used at targets); and cosmic rays and other (known and conjectured) particles from space, such as neutrinos, gamma rays, WIMPs etc.*

- *Material Science and Molecular Structure:*

Using synchrotron X-radiation from electron accelerators, studies are made of the atomic structure of natural and artificial polymers using a variety of X-ray techniques, such as spectroscopy, diffraction and imaging.

- *Chemistry:*

Chemistry relates atomic and molecular structure of matter with the transformations occurring when different substances are brought in contact, heated, *pressurized, subjected to electric fields, etc. To go beyond the results of static analysis before and after a chemical reaction, chemists apply synchrotron techniques in absorption spectroscopy and diffraction as well as in surface scattering in order to follow a chemical reaction as it happens. Here, X-rays yield new insight into the kinetics of chemical reactions by obtaining time-resolved structural information directly from the reaction zone (in situ investigation).*

The highly monochromatic, collimated and brief X-ray pulses available from synchrotron sources allow time-resolved studies of extremely small samples even for poorly interacting compounds. This approach has, for instance, improved our understanding of the polymerization process *of the superconducting polymer, polysulphur nitride. In another experiment, the use of hard X-rays penetrating into the bulk of matter revealed details of the* hydration process *of Portland cement that are of some technological importance.*

Modern synchrotron radiation sources contribute to the progress of chemical analysis, directly yielding information about the kinetics of chemical reactions whilst substantially extending the detection limits.

- *Medicine:*

Novel imaging techniques that overcome the limitations of conventional X-ray sources. The small spotsizes of synchrotron X-ray beams allow Computed Micro Tomography (CMT) to be carried out. This non-destructive measurement yields 3-dimensional reconstructions of human tissues with spatial resolution in the micron range (10^{-6} m). *In absorption mode, the technique was used to image the diminution of* bone structure *with aging, while in-line holography setups allowed the monitoring of* coronary artery *plaque and trombosis.*

Also, X-ray based clinical research is performed in the fields of medical imaging and radiation therapy.

- *Molecular Biology:*

The basic principle of molecular biology is that the biological functions of an organism are governed by large and complex molecules, such as proteins, enzymes, lipids, nucleic acids, etc. To understand how these macro-molecules govern the processes of life, the determination of their three-dimensional spatial structures is essential.

The technique used for this purpose is X-ray diffraction. Scientists routinely perform structural analyses of biological molecules (e.g. the nucleosome core particle or *the Blue-tongue virus) and develop new techniques to study structural modifications as a function of time (the biological movie, e.g. of carbon monoxide photo-desorption from myoglobin).*

Synchrotron-radiation studies at SSRL (Stanford Synchrotron Radiation Laboratory, part of SLAC) have yielded important information about the toxicity of various mercury compounds found in fish from polluted habitats.

1930 CE *Woods Hole Oceanographic Institution* chartered as a private, non-profit organization devoted to scientific study of the world's oceans. On Dec. 31, its ship *Atlantis* was launched from the ship-building yards in Copenhagen, and sailed July 02, 1931.

1930–1931 CE **Subrahmanyan Chandrasekhar** (1910–1995, India and U.S.A.). Distinguished astrophysicist. Shared the 1983 Nobel prize for physics for his work on late evolutionary stages of massive stars. He calculated that a *white dwarf* can exist only if its mass is less than 1.4 solar masses (*Chandrasekhar limit*).

Chandrasekhar was born in Lahore, India, a relative of Venkata Raman (who won the Nobel prize for physics in 1930). Educated at the University of Madras and Trinity College, Cambridge University. Joined the staff of the University of Chicago (1938) and became a professor there in 1952. He did important work on radiative energy transfer in stellar atmospheres and convection on the solar surface.

1930–1941 CE **Juliusz Pawel Schauder** (1899–1943, Poland). Mathematician. Made important contributions to topology and the links of topology with the theory of semilinear and quasilinear elliptic partial differential equations (PDE). Named after him are: *Schauder fixed-point theorem*[712]*; Leray-Schauder fixed point theorem; Riesz-Schauder theorem; Schauder basis* in Banach space and *Schauder energy inequality* of PDE of hyperbolic type.

Schauder was born in Lvov to Jewish parents. He was drafted into the Austro-Hungarian army (1917) and fought in Italy, where he was taken prisoner. He then joined the Polish army in France before returning to Lvov to begin his university studies (1919). After obtaining his doctorate (1923) he taught both in a secondary school and at the University of Lvov.

During 1932–1933 he studied at Leipzig and with **Hadamard** in Paris. In 1941 the German army entered Lvov and the systematic murder of its Jews began. Schauder sent pleas for help to **Hopf** and **Heisenberg** saying that he had many important results but no paper to write them on. He was shot by the Gestapo in September 1943.

1930–1949 CE **Kurt Friedrich Gödel** (1906–1978, Austria and U.S.A.). Mathematician and logician.

He discovered a theorem which states that within any rigid logical mathematical system rich enough to contain arithmetic, there either exist propositions that cannot be proved or disproved on the basis of the axioms within that system, or the system's basic axioms give rise to contradictions.[713]

---

[712] Proved (1930) a major extension to Brouwer's (1910) fixed-point theorem for the case of infinite-dimensional topological space.

[713] The precise assumptions that underline Gödel's *incompleteness theorem* are these: if a formed system is (1) finitely specified, (2) large enough to include arithmetic, and (3) consistent — then it is incomplete.

Condition (1) means that there is a countable infinity of axioms, with a definite algorithmic procedure for listing them. We could not, for instance, choose our system to consist of all the true statements about arithmetic, because this collection cannot be finitely listed in this sense.

Condition (2) means that the formal system includes all the symbols and axioms used in arithmetic. The symbols are 0, ('zero'), S, ('successor of'), $+$, $\times$, and $=$. Thus, the number two is the successor of the successor of zero, written as the term $SS0$, and 'two plus two equals four' is expressed as $SS0 + SS0 = SSSS0$. It is instructive to see how these requirements might fail to be met. If we picked a theory that consisted of references to (and relations between) only the first ten non-negative numbers (0, 1, 2, 3, 4, 5, 6, 7, 8, 9), then Condition (2) fails and such a mini-arithmetic is complete. Arithmetic makes statements about individual numbers, or terms (like $SS0$, above). If a system does not have individual terms like this but, like Euclidean geometry, makes statements only

This "*Gödel's incompleteness theorem*" put an end to **Hilbert**'s dream of providing, for all of mathematics, a formal axiomatization that is both complete and absolutely consistent.

This discovery was revolutionary in a negative fashion, similar to **Galois**' proof of the impossibility of finite solvability for polynomials of degree higher than 4, and **Hamilton**'s relinquishing of commutative multiplication (for quaternions). But Gödel's theorem is even more 'destructive', for it undermines the very foundation of all pure mathematics[714]. Gödel's so-called

about points, circles, lines etc., then it cannot satisfy Condition (2). Accordingly, as **Alfred Tarski** first showed, Euclidean geometry is complete. There is nothing magical about the flat, Euclidean nature of the geometry either: the non-Euclidean geometries on curved surfaces are also complete. Similarly, if we had a logical theory dealing with numbers that used only the concept of 'greater than' without referring to any specific numbers, then it would be complete: we can determine the truth or falsity of any statement about numbers involving the 'greater than' relationship. The simplest system of formalized mathematical logic – involving relations such as "p and (q or s)" (the symbols referring to *True* or *False* statements) and axioms such as "(p and q) implies p"— has likewise been proven to be complete.

Another example of a system that is smaller than arithmetic is arithmetic without the multiplication, $\times$, operation. This is called *Presburger arithmetic* (the full arithmetic is called *Peano arithmetic*, after the mathematician who first expressed it axiomatically, in 1889). At first this sounds strange. In our everyday encounters with multiplication it is nothing more than a shorthand way of doing addition (for example, $2+2+2+2+2+2 = 2 \times 6$). But in the full logical system of arithmetic, in the presence of logical quantifiers such as 'there exists' or 'for any', multiplication permits constructions which are not merely equivalent to a succession of additions.

Gödel showed, as part of his doctoral thesis work, that *Presburger arithmetic* (**M. Presburger**, 1929) is complete: all statements about the addition of natural numbers can be proved or disproved; all truths can be reached from the axioms. Similarly, if we create another truncated version of arithmetic which does not have addition but retains multiplication, this is also complete. It is only when addition and multiplication are simultaneously present that incompleteness emerges. Extending the system further by adding extra operations (such as exponentiation) to the repertoire of basic operations, makes no difference. Incompleteness remains, but no intrinsically new form of it is found. Arithmetic is the watershed in complexity in mathematics.

714 On the other hand, it seems to safeguard the role of intuition in mathematics, since the theorem shows that doing mathematics cannot be reduced to mechanical symbol-manipulation.

"meta–mathematical" result was made possible by a novel method, discovered by him, of mapping statements *about* the mathematical axiomatic system into arithmetic statements *inside* that system. Gödel's theorem, with the essential incompleteness of knowledge it entails, has been likened to Heisenberg's uncertainty principle in physics[715].

Gödel's monumental demonstration that formal systems of mathematics have limits, gradually infiltrated the way in which philosophers and scientists viewed the world and our quest to understand it. Superficially, it appears that all human investigations of the Universe must be limited. Science is based on mathematics; mathematics cannot discover all truths; therefore science cannot discover all truths. Indeed, some scientists acknowledge that Gödel's incompleteness theorem places limits of our ability to discover the truths of mathematics and science, and therefore acts as a fundamental barrier to human understanding of the universe.

In 1938 Gödel demonstrated that one can safely assume **Cantor**'s continuum hypothesis as an *additional postulate* in set theory, i.e. he proved that the continuum hypothesis is consistent with the **Zermelo-Fraenkel** axioms.

In 1949, Gödel discovered a peculiar exact solution of Einstein's gravitational field equations[716], which leads to a model dust-filled universe that is homogeneous but anisotropic. In Gödel's universe, space-time appears normal locally, but in any sufficiently large region of space-time there exist closed timelike curves, which allow an event to affect its own causal past. Thus, in his model universe, a person could kill one of his ancestors, in time to prevent his own eventual birth! A number of such space-time solutions have since been found, and physicists are still unsure as to their physical significance. This circumstance highlights our as–yet incomplete understanding of gravity, and especially how it should be unified with quantum mechanics.

Gödel collaborated for some time with Albert Einstein in an effort to establish a unified field theory.

Gödel was born in Brünn (now Brno), Austria-Hungary, the second of the two children of Rudolf and Marianne Gödel. His father was a director of a textile factory and his mother descended from a family of weavers. Neither Kurt nor his brother enrolled in optional courses in the Czech language, and gave

[715] One of Hilbert's young students, **Gerhard Gentzen** (1900–1945) showed (1940) that it was possible to circumvent Gödel's conclusion and deduce all the truths of arithmetic – *provided* one allows a more powerful form of mathematical induction (*transfinite induction*) based upon **Cantor**'s ordinals.

[716] Gödel's universe: $ds^2 = -dt^2 + dx^2 - \frac{1}{2}e^{2\sqrt{2}\omega x}dy^2 + dz^2 - 2e^{\sqrt{2}\omega x}dydt$, where $-\Lambda = \omega^2 = 4\pi\rho$; ρ is the proper mass density of the pressureless dust, Λ the cosmological constant, and the natural ($G = C = 1$) system of units is used.

up their Czech citizenship after WWI becoming students at the University of Vienna.

Gödel enrolled there in 1924, intending to major in physics, but switched into mathematics in 1926, receiving his doctorate degree in 1930. He was a member of the faculty of the University of Vienna from 1930. He emigrated to the United States in 1940, and from 1953 served as a professor at the Institute of Advanced Study, Princeton, NJ.

Scientists on the consequences of Gödel's Theorem

"One may speculate that undecidability is common in all but the most trivial physical theories. Even simply formulated problems in theoretical physics may be found to be provably insoluble."

(Stephen Wolfram)

* * *

"Gödel proved that the world of pure mathematics is inexhaustible; no finite set of axioms and rules of inference can ever encompass the whole of mathematics; given any set of axioms, we can find meaningful mathematical questions which the axioms leave unanswered. I hope that an analogous situation exists in the physical world. If my view of the future is correct, it means that the world of physics and astronomy is also inexhaustible; no matter how far we go into the future, there will always be new things happening, new information coming in, new worlds to explore, a constantly expanding domain of life, consciousness, and memory."

(Freeman Dyson)

* * *

"Clearly then no scientific cosmology, which of necessity must be highly mathematical, can have its proof of consistency within itself as far as mathematics goes. In the absence of such consistency, all mathematical models, all theories of elementary particles, including the theory of quarks and gluons... fall inherently short of being that theory which shows in virtue of its a priori *truth that the world can only be what it is and nothing else. This is true even if the theory happened to account with perfect accuracy for all phenomena of the physical world known at a particular time.*

It seems on the strength of Gödel's theorem that the ultimate foundations of the bold symbolic constructions of mathematical physics will remain embedded forever in that deeper level of thinking characterized both by the wisdom and by the haziness of analogies and intuitions. For the speculative physicist this implies that there are limits to the precision of certainty, that even in the pure thinking of theoretical physics there is a boundary. An integral part of this boundary is the scientist himself, as a thinker."

(Stanley Jaki)

* * *

"It is by no means obvious that Gödel places any straightforward limit upon the overall scope of physics to understand the nature of the Universe just because physics makes use of mathematics. The mathematics that Nature makes use of may be smaller and simpler than is needed for incompleteness and undecidability to rear their heads. Yet, within science, it is the smaller individual problems that are at the mercy of computational intractability and undecidability."

(John D. Barrow, "*Impossibility*", 1999)

1930–1956 CE **Witold Hurewicz** (1904–1956, Holland and USA). Mathematician. Contributed to set theory and topology:

His main topics of research were: *topological embedding* of separable metric spaces into compact spaces of the same finite dimension (1930); *dimension theory* (1941) which presents the theory of dimension for separable metric spaces;

Discovered of *higher homotopy groups* (1935–1936) and *exact sequences* (1941). His work led to *homological algebra*.

Hurewicz was born in Lodz, Poland to Jewish parents. He was educated at the Universities of *Warsaw*, and *Vienna* (Ph.D. 1926) and held positions at the Universities of *Amsterdam* (1928–1936), *Princeton*, *North Carolina* (1939–1944), and *M.I.T.* (1945–1956).

Hurewicz died falling off a ziggurat (a Mexican pyramid) at Uxmal, after attending a conference outing at the International Symposium on algebraic topology in Mexico.

1930–1960 CE **Pier Luigi Nervi** (1891–1979, Italy). Engineer and architect. Influenced modern architecture through his imaginative use of *reinforced-concrete* structures that combined economy with great clear span structures. He experimented continually to find ways to push concrete construction techniques to new limits.

Nervi believed that the process of creating form was identical for both the technician and the artist.

During 1947–1961 Nervi was a professor of technology and construction in the faculty of architecture at Rome University.

Condensed-Matter Physics[717] — *from antiquity to quantum electronics*

Baryonic matter in the bulk[718] — *in macroscopic quantities that can be directly sensed by us — is an aggregate of a very large number of atoms. On earth, it appears in three basic states: gas, liquid and solid. In gases, the average distance between molecules is much greater than the molecular sizes, and intermolecular forces are on average much weaker than the forces which hold the atoms together inside molecules. Thus in gases, the molecules largely retain their individuality.*

In a solid, atoms and molecules are tightly packed and held in more or less fixed relative positions by electromagnetic forces. Consequently, the shape and volume of a solid remain essentially constant under a range of physical conditions characteristic of each particular specimen.

A liquid has intermediate properties; in it inter-molecular interactions are important, and position of neighboring molecules are highly correlated, but they can slide past each other, and far-away molecules are not correlated in position or quantum state.

---

[718] "Baryonic matter" is made up of protons, (optionally) neutrons, and electrons. Most baryonic matter in the observable universe is in the form of neutral or ionized atoms and molecules – including all known matter in our solar system. Under extreme conditions (Big Bang, while dwarf stars, neutron stars, accelerator experiments) baryonic matter can *break down* into quarks, leptons and other particles, or aggregate into star–sized atoms or even nuclei. Cosmology indicates that only a small fraction of matter in the universe is baryonic.

Solid state physics is the area of quantum physics which is concerned with the mechanical, thermal, electrical, magnetic and optical properties of solid matter; *condensed matter* physics is more general and covers liquids as well. Sometimes the distinctions are blurred: glass is really a kind of liquid, and the degenerate electron gases in a metal or white dwarf star, or the neutrons in a neutron star are also liquids.

In most solids, each atom (or molecule) is mostly affected only by its close neighbors. Moreover, the structure of solids usually exhibits (at least mesoscopically, and excluding impurities, dislocations, interstitial atoms, etc.) a regularity or periodicity due to a repetitive, three dimensional arrangement of atoms or ions, known as a *crystal lattice*. Therefore, to understand the structure of a solid, it is often necessary to study only the basic unit, or cell, of the lattice.

In a sense, the solid can be regarded as a large molecule, the forces between atoms being due to interaction between atomic electrons, and the structure of the solid being determined by those arrangements of nuclei and electrons which yields a *quantum-mechanically stable system*.[719]

The ways in which atoms are arranged in solid materials are determined primarily by the strength and directionality of the interatomic bonds. Qualitatively, we can understand why an atomic bond is strong or weak, directional or non-directional, from a knowledge of the *energetics* of the bonding electrons and their orbital shapes with respect to the positively charged ion cores. The more negative the bonding energy, the stronger the bond. Thus, a pronounced lowering of the *electron energies* results in a strong, or primary bond; a slight lowering of the energy results in a weaker, or secondary, bond.

Crystalline solids are classified according to five *primary* types of bonding: *molecular*, *ionic*, *covalent*, *metallic* and *pure semiconducting*. One is distinguished from another by the ways in which the bonding electrons are localized in space. All *secondary* bonding may be viewed in terms of weak *dipole* interactions.

Molecular solids (and liquids) consist of stable molecules or atoms that are bound by weak *Van der Waals attraction* such that they retain much of their individuality when brought into close proximity. The physical mechanism involved here is an attraction between *electric dipoles* [because of the fluctuating quantum-mechanical behavior of the electrons in a molecule, all molecules have a fluctuating electric dipole moment, even though for many of them, symmetry considerations require that it fluctuate about an average value of zero; the *interaction energy* results from induced correlations between

[719] Certain solids such as diamond really *are* one giant molecule — hence their strength.

moments of two molecules]. The resulting attraction energy is of the order of 10^{-2} eV, and the forces generally vary with the inverse 7^{th} powers of the intermolecular separation. Many organic compounds, inert gases and ordinary diatomic gases such as I_2, O_2, N_2, H_2 form molecular solids in the solid state. The weak bonding makes molecular solids easy to deform, and the absence of free electrons makes them very poor conductors of heat and electricity.

Ionic solids, such as NaCl (rock salt), consist of close regular 3-dimensional array of alternating positive and negative ions having a lower energy (enthalpy) than the separated ions. The structure is stable because the binding energy of the entire crystal due to the net electrostatic attraction exceeds the sum of the binding energies of the individual, well-separated ionic molecules. Ionic binding in solids is not directional because spherically symmetrical closed-shell ions are involved. Hence the ions are arranged like close-packed spheres with various packing schemes. The actual crystal geometry depends on which arrangement minimizes the energy, and this in turn depends principally on the relative sizes of the ions involved.

In the absence of free electrons to carry energy or charge from one part of the solid to another, such solids are poor conductors of heat and electricity. However, because of the strong electrostatic forces between the ions, ionic solids are usually hard and have high melting points, although they can be solvated – and often in almost ionic form – by polar solvent liquids such as water. Lattice vibrations can be excited by far-infrared energies, so that ionic solids show strong absorption properties in that spectral region, but are mostly transparent to visible radiation.

In covalent solids, atoms are bound by shared valence electrons – as in covalent bonds within molecules. The bonds are directional and determine the geometrical arrangements of atoms in the crystal structure. The rigidity of their electronic structure makes covalent solids hard and difficult to deform, and it accounts for their high melting points. Because there are no free electrons, covalent solids are not good heat or electrical conductors, either. Most covalent solids (diamond excepted) absorb in the visible spectrum and are therefore opaque.

*A metallic solid is a regular lattice of spherically symmetrical positive ions arranged like close-packed spheres, through which the conduction and valence electrons – those contributed from the outer shells of the individual atoms – move (**Bloch**, 1928). This type of solid exhibits a bond that is a limiting case of covalent binding, in which electrons are shared by all the ions in the crystal. As a result, metals are good electric and heat conductors, strong, yet ductile, and strongly reflect in the visible and radio parts of the spectrum.*

A semiconductor is like a metal, except the number of shared valence electrons per atom exactly fills the solid's valence band, so its conduction *band is empty. The energy gap between these bands, plus the Pauli exclusion principle, thus render electronical and thermal conduction very dependent upon impurity content.*

There are solids whose binding is a mixture of the above principal types. Such is the hydrogen bond, where a single hydrogen atom appears to be bonded to two distinct atoms, although (because neutral hydrogen has only one electron) it should form a covalent bond with only one other atom. The hydrogen bond is particularly important because its energy is only of order 0.1 eV ($\sim$ 6 *kcal/mole) and also because the hydroxyl group occurs so frequently in most biological systems. It is especially important in molecular genetics by virtue of controlling in part the possible pairings between the two strands of the DNA molecule (***F.H.C. Crick** *and* **J.D. Watson***, 1954).*

It is believed that the hydrogen bond is largely ionic in character. In the extreme ionic form the hydrogen atom loses its electron to another atom in the molecule and the bare proton forms the hydrogen bond. The small size to the proton permits only 2 *nearest-neighbor atoms, because the atoms adjacent to the proton are so close that more than* 2 *of them would get in each other's way. Thus the hydrogen bond connects only two atoms (belonging to two distinct molecules).*

Together with electrostatic attraction between the electric dipole moments of individual polar covalent–bonded molecules, the hydrogen bond is responsible for the striking physical properties of water and ice.

Departures from ideal crystal structure, so-called lattice imperfections, lead to many properties of solids which have practical consequences.

The history of man's efforts to unveil the 'mystery' of the solid state of matter can be divided into 5 *principal periods:*

(1) DESCRIPTION AND CLASSIFICATION, 315 BCE–ca 1600 CE;

(2) RECOGNITION OF INTERNAL GEOMETRICAL FEATURES, 1665–1800;

(3) OPTICAL, ELECTROMAGNETIC AND CHEMICAL PROPERTIES, 1801–1894;

(4) CLASSICAL ATOMIC MODELS, 1895–1931;

(5) QUANTUM-ELECTRONIC MODELS, 1930–present. We have grouped the first four stages under the single heading of classical studies.

A. Classical Studies (315 *BCE*–1931 CE)

Owing to their numerous applications for useful and decorative purposes, minerals[720] *(especially crystals*[721] *and gems) have attracted the attention of mankind for several thousands of years. Egyptian paintings of* 5000 *years ago show that minerals were used in weapons and jewelry, and in religious ceremonies: The breastplate of the high priests of the ancient Israelites were studded with four rows of gemstones (ca 1200 BCE).*

The oldest existing treatise on minerals is that written about 315 *BCE by* ***Theophrastos****, a Greek philosopher.* ***Pliny the Elder*** *of Rome, in his Historia Naturalis (77 CE), wrote about metals, ores, stones and gems.*

Other early writings about minerals were produced by the German scientists ***Albertus Magnus*** *(De Mineralibus, 1262) and* ***Georgius Agricola*** *(De Re Metallica, 1556).* ***Andreas Libavius*** *(1597), pointed out that salts present in mineral waters crystallize upon evaporation.*

The first important step in the study of crystals was made by ***Robert Hooke*** *in his Micrographia (1665), where he noticed the regularity of the minute quartz crystals found lining the cavities of flints. Independently, the Danish naturalist and physician* ***Nicolaus Steno*** *(Niels Stenson, 1631–1686) described various gems, minerals and fossils enclosed within solid rocks in his book De solido intra solidum naturaliter contento (Florence, 1669). He was first to discover that the angles between the faces of quartz crystals were the same even though the crystals had different shapes. At about the same time,* ***Erasmus Bartholinus*** *(1625–1692, Denmark, 1669) and* ***Christiaan Huygens*** *(1690) studied double refraction of calcite and Iceland-spar crystals.*

---

720 Natural, inorganic, solid constituents of the earth's crust. Most minerals also have definite crystalline forms.

Common minerals and organic gems are: *Sapphire*, *Ruby* (Al_2O_3 — hexagonal); *Topaz* ($Al_2F_2SiO_4$ — orthorombic); *Emerald* [$Al_2Be_3(SiO_3)_6$ — hexagonal]; *Opal* ($SiO_2{\cdot}nH_2O$ — amorphous); *Amethyst* (SiO_2 — hexagonal); *Turquoise* [$CuAl_6\{(OH)_2PO_4\}_4{\cdot}4H_2O$ — triclinic]; *Malachite* [$Cu_2CO_3(OH)_2$ — monoclinic]; *Azurite* [$Cu_3(CO_3)_2(OH)_2$ — monoclinic]; *Amber* [$C_{12}H_{20}O$ — amorphous]; *Diamond* (C — cubic); *Lapis Lazuli* [$Na_8(AlSiO_4)_6S_2$ — cubic]; *Alabaster* ($CaSO_4{\cdot}2H_2O$); *Ivory* [$Ca_3(PO_4)_2$]; *Pearl* [84–92% $CaCO_3$ + organic substances + water]; *Coral* (mainly $CaCO_3$ — hexagonal).

721 The word *crystal* is of Greek origin, meaning *clear ice*. The name was also applied to the clear transparent quartz (rock crystal) from the Alps, under the belief that it had been formed from water by intense cold. It was not until the 17^{th} century that the name was extended to other bodies. Quartz crystals from crowns have been preserved since 768 CE in Japan.

In 1695, ***Anton van Leeuwenhoek*** *(1632–1723) observed under the microscope that different forms of crystals grew from solutions of different salts. A French scientist,* ***Jean-Baptist Louis Romé de l'Isle*** *(1736–1790) suggested in* 1772 *that Steno's discovery could be explained only if the crystals were composed of identical units stacked together in a regular way. He described the process of crystallization, and classified crystals into six groups according to their symmetry properties. About* 1780, *chemists began to develop correct ideas about the nature of chemical elements and other substances. These ideas helped scientists understand the chemical makeup of minerals, but did not remove the mystery about crystal shape and internal structure.*

The science of crystallography *was founded in* 1801 *by* ***René Just Haüy*** *(1743–1821, France) in his* 4*-volume treatise* Traité de cristallographie. *There he showed that the arrangement of identical particles in a* 3*-dimensional periodic array could account for the fact that the index numbers of the direction of all faces of a crystal are exact integers* (law of rational indices). *During the* 19^{th} *century, most of the minerals known today were described, optically studied and chemically analyzed.*

The discovery of X*-rays in* 1895 *provided physicists with the tool they needed to study crystal structure, but it was not until June* 8, 1912 *that* ***Max von Laue*** *and his assistants developed an elementary theory of diffraction of* X*-rays by a periodic array of scatterers. They applied it to explain experimental observations of* X*-ray diffraction in crystals, and thus obtained clues to their internal structure. [At that time, scientists did not fully understand* either X-rays or *crystals, and the work of von Laue demonstrated both the wave nature of* X*-rays* and *that crystals are composed of a periodic array of atoms.] The first determinations of crystal structures by* X*-ray diffraction analysis were reported by* ***W.L. Bragg*** *in* 1913.

While all this was going on, the pre-quantum physics of the solid state was advancing along other avenues as well: In 1900, *the physicist* ***Paul*** *(****Karl Ludwig****)* ***Drude*** *(1863–1906, Germany) suggested for the first time that electrical and thermal properties of metals might be correlated, by assuming that metals contain* free electrons *in thermal equilibrium with atoms in the solid. In his model, he introduced the concept of* mean free path *for collision of the free electrons*[722] *and furnished a classical microscopic explanation of*

[722] In a typical metal such as copper or silver, the atoms are arranged in a systematic array to form a crystal. The atoms are in such close proximity that the outer, loosely bound electrons are attracted to numerous neighboring nuclei and, therefore, are not closely associated with any one nucleus. These conduction electrons are visualized as being free to wander through the crystal structure, or lattice. At absolute zero temperature, the conduction electrons encounter no

opposition to motion and the resistance is zero (assuming no crystal defects); this fact is understood in quantum mechanics, but has no *classical* explanation. At nonzero temperatures, the electron-deficient atoms (ions) possess kinetic energy in the form of vibration about equilibrium positions in the lattice; this vibrational energy is measured by temperature. There is a continual interchange of energy between the vibrating ions and the free electrons in the form of elastic and inelastic collisions. The resulting electron motion is random (for both thermal *and* quantum reasons), there is no net motion, and the net current is zero. Quantum – mechanically, the lattice vibrations are quantized into "quasiparticles" called *phonons* (sound quanta), absent at $0\,°$K, and in a perfect crystal electrons can only collide with phonons – they do not 'see' individual lattice ions. If a uniform external electric field $\boldsymbol{E}$ is applied, the electrons are accelerated; superimposed on the rapid random motion, there is a small component of *drift* velocity along $\boldsymbol{E}$. Classically, upon each inelastic collision with an ion, the electron loses most of its kinetic energy: it then accelerates again, gains a velocity component along $\boldsymbol{E}$, and loses its energy at the next inelastic collision. The time between collisions is determined by the random velocity component – typically much larger than the drift term – and the length of the mean free path. On average, the electron gains a directed drift velocity that is directly proportional to $\boldsymbol{E}$.

Thus, the classical theory of metals, as expounded by Drude, assumes a model in which some of the electrons are detached from their parent atoms and become free to move in the material in much the same way as an *electron gas*. When an electric field $\boldsymbol{E}$ is applied, these free electrons drift with an average velocity $\boldsymbol{v}_d$ and give rise to a current density $\boldsymbol{J} = -en\boldsymbol{v}_d$ where n is the number of free electrons per unit volume, each of charge $\{-e\}$. In this classical electron-gas model of conductors, an electron collides with the metal ions, and between collisions moves in accordance with the force produced by $\boldsymbol{E}$, such that the electron's velocity at time t *after the most recent collision* will be $\boldsymbol{v} = \boldsymbol{v}_0 - \left(\frac{e}{m_e}\right)\boldsymbol{E}t$. Here m_e is the electron's mass; $\boldsymbol{v}_d$ is then the *average* drift velocity between collisions. Since $\boldsymbol{v}_0$ is distributed randomly in direction, $\langle \boldsymbol{v}_0 \rangle = 0$ and $\boldsymbol{v}_d = \langle \boldsymbol{v} \rangle = -\frac{e\tau}{2m_e}\boldsymbol{E}$, where angular brackets indicate averaging over time and electrons, τ is the 'mean free time' between collisions, and the factor $\frac{1}{2}$ arises from the 'saw-tooth' shape of $\boldsymbol{v}(t)$. Substituting the expression for $\boldsymbol{v}_d$ into the equation for $\boldsymbol{J}$, one obtains $\boldsymbol{J} = \sigma\boldsymbol{E}$, where σ is known as the *conductivity* and the *resistivity* $\rho = \frac{1}{\sigma} = \frac{2m_e}{e^2 n\tau}$ is inversely proportional to τ, the average time between collisions (in copper $\tau = 5.4 \times 10^{-14}$ sec at room temperature, $T = 273\,°$K).

Many metals obey the above linear relationship between $\boldsymbol{J}$ and $\boldsymbol{E}$. For copper with an atomic weight of 63.6 and a density of $8.9\ \frac{\text{g}}{\text{cm}^3}$, by Avogadro's law, the density of atoms per mole cu is [3] is

$$n_a = \frac{6.022 \times 10^{23}\ \text{atoms/g–mole cu} \times 8.9\ \text{g/cm}^3}{63.6\ \text{g/g–mole cu}} = 8.43 \times 10^{22}\ electrons/cm^3\ .$$

Assuming there is one free electron per atom, and considering a current of $I = 4$

Ohm's law, still taught today (although supplanted by the quantum field theory). The foundations of the classical theory of ionic crystals were laid by **Erwin Madelung** *(1881–1972, Germany) in* 1909 *and by* **Max Born** *in* 1910. *In these crystals (e.g. rock salt: NaCl) the binding depends on the Coulomb electrostatic attraction between the singly charged ions (e.g.* Na^+ *and* Cl^-*), and equilibrium is achieved by a counteracting short-range repulsive force.*

In a classical model of the ideal rock salt crystal, the effective potential of the forces acting between the Na^+ *and* Cl^- *ions is* $U(r) = -0.29\frac{e^2}{r} + \frac{c}{r^9}$. *Here* c *is a constant which is determined from the equilibrium condition* $\left[\left(\frac{\partial U}{\partial r}\right)_{r=r_0} = 0\right]$. *The interaction potential then assumes the form*

$$U(r) = -0.29\frac{e^2}{r}\left[1 - \frac{1}{9}\left(\frac{r_0}{r}\right)^8\right].$$

From this, one evaluates the lattice energy (the total energy per mole of the crystal, equals to minus the energy per mole liberated upon forming the

Ampere in a copper conductor with a cross-sectional area of $A = 1\ \text{mm}^2$, we find $v_d = \frac{I/A}{n_a e} = 0.03\ \frac{\text{cm}}{\text{sec}}$.

The average drift velocity in a good conductor is thus very low compared to the random thermal electron velocities which are of the order of 10^5 m/sec at room temperatures. As temperature increases, random thermal motion increases, the time between energy-robbing collisions decreases, mobility decreases, and therefore conductivity decreases. It is characteristic of metal conductors that resistance increases with temperature.

The relation $\sigma = \frac{ne^2\tau}{2m_e}$ can be put into a more useful form by defining a measurable quantity, the *mobility* μ, given by the ratio of the drift velocity to the applied field, i.e. $\mu = \frac{v_d}{|\boldsymbol{E}|} = \frac{e\tau}{2m_e}$. Therefore $\sigma = ne\mu$. For conduction by positive carriers as well as negative carriers, the conductivity is given by $\sigma = nq_n\mu_n + pq_p\mu_p$, in which μ_n and μ_p are the mobilities of negative and positive carriers, respectively q_n and q_p are their charges (absolute values), and n and p are the numbers of these carriers per unit volume. The sign of the charge of a species of electric current carrier in a metal can be determined from measurements of the *Hall effect*. Measured values of the resistivity for copper show a *linear* dependence on the temperature.

In general, the classical theory of metals is *unable to predict correctly the linear relationship between the resistivity* ρ *and the temperature* T. However, calculations based upon modern quantum theory *can* account satisfactorily for this linear dependence.

crystal from widely separated Na^+ *and* Cl^- *ions). To this end, one considers that each* Na^+ *ion in the lattice has 6 neighboring* Cl^- *ions, each of which is bound to it by the* same spherically symmetric *interaction* $U(r)$.

One mole of an NaCl crystal has L Na^+ *ions, from each of which binding forces extend to each of its 6 neighbors. Hence the lattice energy, computed assuming an equilibrium distance* r_0 *between adjacent constituents, is* $E = 6LU(r_0) = -1.74\left(\frac{8}{9}\frac{e^2}{r_0}\right)$, *with* L *representing the Avogadro number. This energy is negative because it is* released *if the crystal is formed from its ions (stated otherwise — it is the energy needed to* break *the crystal apart into a state of zero potential energy).*

The lattice energy of any ionic crystal can be expressed by the general formula $E = C\frac{e^2}{a}$ *where* $a = 2r_0$ *is the* lattice constant. *The constant* $\alpha = 1.74$ *that appears in the above expression for* E *is known as the* Madelung constant *(1918) and is of central importance in the theory of ionic crystals; it determines the constant* c*. It is defined via the relation* $\frac{\alpha}{r_0} = \sum_j \frac{(\pm)}{r_j}$, *where* r_j *is the distance of the* j^{th} *ion from the reference ion and* r_0 *is the nearest-neighbor equilibrium distance. For an infinite line of ions of alternating signs, with the negative ion as the reference ion and* r_0 *as the distance between adjacent ions,*

$$\frac{\alpha}{r_0} = 2\left[\frac{1}{r_0} - \frac{1}{2r_0} + \frac{1}{3r_0} - \cdots\right] = \frac{2}{r_0}\log_e 2,$$

yielding

$$\alpha = 2\log_e 2 = 1.386\ldots.$$

In three dimensions, the summation is more involved: a direct summation leads to convergence problems unless one arranges to work with neutral or nearly neutral groups of ions, *by dividing an ion among different groups and using fractional charges. [Physically, it is equivalent to grouping of ions into units of higher electrical multipoles such as dipoles (potential* $\propto r^{-2}$*), quadrupole (potential* $\propto r^{-3}$*), etc.]*

In the sodium chloride structure, we obtain nearly neutral groups by considering the charges on cubes, *counting charges on cubic faces as shared between two cells* $\left(+\frac{1}{2}\right)$, *on edges as shared between four cells* $\left(+\frac{1}{4}\right)$, *and on corners as shared between eight cells* $\left(+\frac{1}{8}\right)$. *The first cube thus contributes*

$$6\frac{\frac{1}{2}}{1} - 12\frac{\frac{1}{4}}{\sqrt{2}} + 8\frac{\frac{1}{8}}{\sqrt{3}} = 1.46.$$

Taking into account the next larger cube enclosing the original cube, the next iteration yields $\alpha = 1.75$, *close to the accurate value of* 1.747 565 *for NaCl.*

When two species of atoms are bonded primarily with either ionic or covalent bonds, it is possible for them to form discrete molecules. When the primary bonds are satisfied completely within a subunit, the subunits must then be held together by a type of bond different from the primary bond.

In such molecular crystals, *subunits are held together with weak, secondary intermolecular forces. The largest class of molecular crystals is that in which covalently bonded molecules have weak intermolecular bonding. When the molecules are approximately spherical (because of molecular rotation), the crystal is usually a close-packed array of these molecules held together by non-directional forces. This occurs, for example, in crystals of* CH_4 *and* NH_3 *at low temperatures. To this class belong also crystals of the inert-gas atoms, whose outer shells are complete (He, Ne, Ar, Kr, Xe).*

All these solids are made of substances whose molecules are not polar. Since all valence electrons in these molecules are paired, covalent bonds between atoms of different molecules (or, for the inert case, between any *two atoms) are essentially impossible, and* the molecules retain their individuality. *They are bonded by the same intermolecular forces that exist between molecules of a gas or liquid, known as* Van der Waals force. *They are weak, and corresponds roughly to a force between two fluctuating, mutually-inducing* electric dipoles[723]. *The interaction energy between the dipoles is always negative (i.e. attractive), varies as the mean square* $\langle p^2 \rangle$ *of the dipole moment of the inducing molecule, and is inversely proportional to the* 6^{th} *power of the distance between the molecules.*

A molecule whose electronic distribution is perfectly symmetrical will yield a finite value for $\langle p^2 \rangle$ *even though* $\langle \boldsymbol{p} \rangle$ *is zero. That is, every possible instantaneous position that the electrons of the molecule can occupy, will*

---

723 Suppose that a given molecule possesses, at some instant, an electric-dipole moment $\boldsymbol{p}_1$. This molecule will then be surrounded by an electric-dipole field $\boldsymbol{E} = -\operatorname{grad}\left(\frac{\boldsymbol{p}_1 \cdot \boldsymbol{r}}{r^3}\right) = -\frac{\boldsymbol{p}_1}{r^3} + 3\left(\frac{\boldsymbol{p}_1 \cdot \boldsymbol{r}}{r^5}\right)\boldsymbol{r}$. This field will induce an instantaneous dipole moment $\boldsymbol{p}_2 = k\boldsymbol{E}$ in a second molecule, where k is the *polarizability* (dipole moment per unit electric field) of the second molecule. The mutual energy of interaction of the two dipoles, separated by displacement $\boldsymbol{R}$, is $U(R) = -\boldsymbol{p}_2 \cdot \boldsymbol{E} = \frac{\boldsymbol{p}_1 \cdot \boldsymbol{p}_2}{R^3} - 3\frac{(\boldsymbol{p}_1 \cdot \boldsymbol{R})(\boldsymbol{p}_2 \cdot \boldsymbol{R})}{R^5}$. Using the above expression for $\boldsymbol{p}_2$, we find $U(R) = -k(1 + 3\cos^2\theta)\frac{p_1^2}{R^6}$, where $(\boldsymbol{p_1} \cdot \boldsymbol{R}) = p_1 R \cos\theta$. This indicates the existence of an attractive *force* between the two molecules *varying as* R^{-7}.

lead to a dipole moment of some size and orientation for the molecule as a whole, and although these rapidly fluctuating instantaneous moments average to zero, their mean square *must have a finite, positive value.*

In conclusion, two non-polar molecules should exhibit a characteristic r^{-7} attractive force (the gradient of their $\sim r^{-6}$ interaction potential). The strength of this force in a given case depends both on the mean-square fluctuation of the electric-dipole moment and on the polarizability of the molecules. In general the range of variability of these parameters is narrow, and consequently the Van der Waals' interaction will be rather insensitive to the type of molecule involved, though it tends to increase with molecular or atomic geometric size.

B. The Quantum Physical Basis of Chemistry or "What is a Molecule?" (1927–1937)

"Carbon gives biology, but silicon gives geology".

Charles Kittel

Solid state physics is a natural extension of molecular physics and physical chemistry, which in turn are concerned with the structure, properties and interactions of molecules, so far as they are determined by physical methods. In this sense, solid state physics is a logical continuation of atomic physics proper.

Molecular physics is closely related to chemistry. The chemist attempts to determine the composition of a compound and its structure. He is also interested in certain characteristic quantities, such as the heat of formation of the molecule and the energy freed by its decomposition into its elements, or the rates at which reactions between molecules occur. Chemistry proper is not, however, able to explain the valency, stability and bonds in molecules. Neither can it answer questions such as: Why is NH_3 pyramidally shaped? Why does benzene (C_6H_6) have the form of a hexagon? Why can hydrogen atoms join together to form the molecule H_2, but never form H_3? Why do carbon atoms combine with 4 hydrogen atoms? Why are the spectra of molecules so complex when compared with atomic spectra, ranging from microwaves up to the ultraviolet?

These and many other questions could not be answered satisfactorily before quantum mechanics was developed. It was the development of this theory *since* 1927 *that furnished a basis for answering such questions via the theory of chemical bonding, molecular dynamics and spectroscopy, and other aspects of physical chemistry.*

Molecular physics determines the spatial geometry of the atoms in the molecule, its modes of rotation and vibration, its dissociation energies, the arrangement of the electrons in the orbitals of the molecule, the possibilities of exciting electrons, the molecule's interactions with EM radiation, and the rapid rearrangements of electronic configurations attendant upon inter-molecular collisions and reactions. The experimental methods used by physicists to deal with these problems, such as spectroscopy, various forms of molecular-scale microscopy and X-ray, neutron and electron diffraction are now used also by chemists, with the result that the demarcation lines between molecular physics, modern inorganic and organic chemistry and physical chemistry have almost disappeared.

Moreover, contemporary physics, chemistry and biology meet on the molecular level: molecular physics, chemical physics, theoretical chemistry and molecular biology are but different aspect of one common reality.

During the first stage of this development, scientists were eager to use the new quantum mechanics to establish the theory of the chemical bond. The main contributors were ***W. Heitler*** *and* ***F. London*** *(1927),* ***M. Born*** *and* ***R. Oppenheimer*** *(1927),* ***D.R. Hartree*** *(1928),* ***P.M. Morse*** *(1929),* ***J.E. Lennard-Jones*** *(1929),* ***E.A. Hylleraas*** *(1930, 1931),* ***J.C. Slater*** *(1930),* ***C. Zenner*** *(1930),* ***E. Teller*** *(1930),* ***Kronig*** *and* ***Penney*** *(1931),* ***H.E. White*** *(1931, 1937),* ***J.H. Van Vleck*** *(1933–1936) and* ***L.C. Pauling*** *(1928–1937).*

A molecule is a well defined collection of atoms that are attracted to each other such that the whole collection may be thought of as a single, stable dynamical and structural unit. The attractive interaction between two atoms is called a chemical bond. Clearly, the chemical bond must be something more specific than a simple attraction between atoms, or we would have to refer to all the water in a glass as a single molecule. It is really only a question of degree; but generally, if the attraction between two atoms is such that an energy of at least 10 kcal/mole (≈ 1 eV per pair of atoms) is required to move them an infinite distance apart – a chemical bond is said to exist between these atoms, and they usually may be considered as belonging to the same molecule.

Since electrons obey the laws of quantum mechanics, our understanding of their behavior must be based on a knowledge of these laws (in addiction to electrodynamics). The most important aspects of the quantum mechanical nature of electrons, atoms and molecules, are: the Pauli exclusion principle, *the uncertainty principle, the superposition principle, and the fact that nuclei are much more massive than electrons (and thus move much more sluggishly and can often be treated as semi classical masses holding each other via anharmonic "springs").*

When two or more atoms combine to form a molecule, the more tightly bound, or inner, electrons of each atom (which fill complete shell of their respective atoms) are practically undisturbed, remaining attached to their original nuclei. Only the outermost, or valence, electrons in the unfilled shells are affected, and they move under the resultant forces due to the ions (composed of the nuclei and inner shells), as well as their mutual electrostatic repulsion, the various quantum effects, and other (non-electrostatic and weaker) electromagnetic effects. These valence electrons are responsible for chemical bonding and for most physical properties of the molecule (but not its mass).

In principle, the Schrödinger Equation (SE) and the postulates of quantum mechanics are all that is required to calculate the properties of any molecule. In practice, however, the exact analytical solution of the SE for complicated molecules has not been achieved (and is probably impossible), and experiments are required to determine the structure and behavior of molecules. Various analytical and numerical approximation schemes, though, lead to some important valid conclusions.

Let the center of mass of the molecule be at rest, so its overall the translational kinetic energy is removed from consideration. The time-dependence of any stationary solution for the molecular wave function is taken to be $e^{-i\frac{E}{\hbar}t}$*, where* E *represents one of the permissible total energy values. Then, a system of* p *different nuclei of masses* M_α *and* q *electrons of mass* m *is governed by the following PDE for the complex spatial wavefunction* $\Psi(\{\boldsymbol{R}_\alpha\}, \{\boldsymbol{r}_i\})$*: (*$\boldsymbol{R}_\alpha$ *and* $\boldsymbol{r}_i$ *are nuclear and electronic positions, respectively)*

$$\sum_{\alpha=1}^{p} \frac{1}{2M_\alpha} \nabla_\alpha^2 \Psi + \frac{1}{2m} \sum_{i=1}^{q} \nabla_i^2 \Psi + \frac{1}{\hbar^2}(E - U)\Psi = 0,$$

where the overall potential energy is $U(|\boldsymbol{R}_\alpha - \boldsymbol{r}_i|)$ *if magnetic forces, external EM fields and spontaneous emission of photons are ignored.*

This represents a very complicated physical system, even if the potential energies considered are limited to those of electrostatic origin. If magnetic and electromagnetic forces are ignored, one can write

$$U = U_{ee} + U_{nn} + U_{ne} = \frac{1}{2} \sum_{k,k'} \frac{e^2}{r_{kk'}} + \frac{1}{2} \sum_{\alpha,\alpha'} \frac{Z_\alpha Z_{\alpha'} e^2}{r_{\alpha\alpha'}} - \sum_{\alpha,k} \frac{Z_\alpha e^2}{r_{k\alpha}}.$$

where

$$r_{kk'} = |\boldsymbol{r}_k - \boldsymbol{r}_{k'}| \,,$$

$$r_{k\alpha} = |\boldsymbol{r}_k - \boldsymbol{R}_\alpha|$$

and

$$r_{\alpha\alpha'} = |\boldsymbol{R}_\alpha - \boldsymbol{R}_{\alpha'}| \ .$$

Ordinary perturbation methods cannot be applied directly, because no solutions of an equation simpler than but comparable to the above are known (except in the single-atom case).

The best approximate method of dealing with the above is the Born-Oppenheimer approximation (1927). At the foundation of this treatment of molecular problems is the great disparity between electronic and nuclear masses. This enables one to separate the SE, and with it the problem, in two parts. First, the energy levels and the wave functions corresponding to the outer electrons moving under the influence of stationary ("clamped") protons (and their closely bound electron shell) are found. These electrons move much more rapidly than of the nuclei, and complete many cycles of their motion (classically speaking) during an interval in which the nuclei move only slightly.

The second step entails treating the quantum mechanical dynamics of the protons (and their rigidly attached closely bound inner electronic shells, if any) in an effective potential determined by the electronic wavefunction (treated as charge-density clouds). This potential consists of the electrostatic and magnetic energies of the nuclei and their shells, and the electronic energy obtained in the first (electronic) step of the approximation. This finally yields the rotational and vibrational energy states of the molecule.

The simplest example of a chemical binding that occurs in nature is the hydrogen molecule ion (also known as H_2^+ *molecule or ionized hydrogen molecule) where a single electron is shared between two protons. No exact solution to this '3-body problem' has been found, but most of the salient features of the molecular system can be established in an approximate way.*

In the Born-Oppenheimer approximation we substitute $\Psi = \psi_e \psi_n$ *into the SE, where the electronic wave-function* $\psi_e(\boldsymbol{r}_i, \boldsymbol{R}_\alpha)$ *[*$\boldsymbol{r}_i$ *are the electron position vectors and* $\boldsymbol{R}_\alpha$ *are the position vectors of the nuclei] is the eigenfunction of*

$$H_e = -\frac{\hbar^2}{2m}\sum_i \nabla_i^2 + U_{ee} + U_{en},$$

and $\psi_n(\boldsymbol{R}_\alpha)$ *depends only on* $\boldsymbol{R}_\alpha$*.*

The original SE then approximately decouples into the two equations

$$-\frac{\hbar^2}{2}\sum_{\alpha=1}^{p}\frac{1}{M_\alpha}\nabla_\alpha^2\psi_n + [U_{nn} + E_e(\boldsymbol{R}_\alpha)]\,\psi_n = E\psi_n,$$

and

$$-\frac{\hbar^2}{2m}\sum_{i=1}^{q}\nabla_i^2\psi_e + (U_{ee}+U_{en})\psi_e = E_e(\boldsymbol{R}_\alpha)\psi_e,$$

where E_e is the total electronic energy (the ground-state eigenvalue of the operator H_e). These equations reflect the approximation that the nuclei move in a field of an effective potential which is composed of the electronic energy, which varies adiabatically as a function of the internuclear distances, plus the internuclear potential $U_{nn}(\boldsymbol{R}_\alpha)$.

Consider the special case of H_2^+: The SE for the electron reads

$$H_e\psi_e = -\frac{\hbar^2}{2m}\nabla^2\psi_e - \left(\frac{e^2}{r_a}+\frac{e^2}{r_b}\right)\psi_e = E_e\psi_e$$

where r_a, r_b are the respective distances of the electron from proton a and proton b, and E_e in the energy of the clamped-nuclei electron orbital.

It is convenient to scale all distances to the first Bohr radius ($a_0 = \frac{\hbar^2}{me^2}$ = 'atomic unit') and all energies to the Rydberg. The above equation then becomes

$$H_e\psi_e = -\frac{1}{2}\nabla^2\psi_e - \left(\frac{1}{r_a}+\frac{1}{r_b}\right)\psi_e = E_e\psi_e.$$

Thus E_e, ∇^2, r_a, r_b and R are now dimensionless, and E_e is electronic energy in units of $\left(\frac{e^2}{a_0}\right)$ (in $\epsilon_0 = \frac{1}{4\pi}$ units). For fixed internuclear distance R, the effective potential energy of the molecule is: $U_{\text{mol}} = \frac{1}{R} + E_e$. Using the Rayleigh-Ritz variational method, the 'trial energy' $U_{\text{mol}} = \int \psi_e H_e \psi_e d\tau + \frac{1}{R}$ is minimized subject to the constraint $\int \psi_e^*\psi_e d\tau = 1$ ($d\tau$ is an electron-positron volume element).

As a 'trial wave-function' ψ_e, one uses a linear combination of the radially symmetric trial eigenfunctions of two virtual hydrogen atoms

$$\psi = \alpha\psi_a + \beta\psi_b, \quad \psi_a = \frac{\gamma^{3/2}}{\sqrt{\pi}}e^{-\gamma r_a}, \quad \psi_b = \frac{\gamma^{3/2}}{\sqrt{\pi}}e^{-\gamma r_b}$$

(with γ dimensionless). We then have the normalization relations

$$\int \psi_a^*\psi_a d\tau = \int \psi_b^*\psi_b d\tau = 1$$

and

$$\int \psi_a^*\psi_b d\tau = \int \psi_b^*\psi_a d\tau = S$$

(overlap integral). Straightforward substitution then yields two equations involving α and β:

$$(\alpha^2 + \beta^2) + 2\alpha\beta S = 1,$$

$$E_e(R) = (\alpha^2 + \beta^2) \int \psi_a H_e \psi_a d\tau + 2\alpha\beta \int \psi_b H_e \psi_a d\tau.$$

Since the Hamiltonian operator in the electronic sector is an even function *of the x, y, and z coordinates (components of $\boldsymbol{r} - \frac{1}{2}(\boldsymbol{r}_a + \boldsymbol{r}_b)$, the electron's position relative to the COM of the molecule), the energy eigenfunctions of the system must all be even or odd functions of these coordinates. That is, every nondegenerate energy eigenfunction must have the property that*

$$\psi_n(x, y, z) = \pm\psi_n(-x, -y, -z).$$

On the other hand, for degenerate *energy eigenfunctions, arbitrary* linear *combinations of even and odd functions of the coordinates are acceptable as eigenfunctions. Thus, the hydrogenic wave functions in which the electron is localized near one proton or the other, are good electronic wave-functions for large proton separation, and these wave functions are approximately degenerate.*

But when the nuclei separation decreases to a value where pure hydrogenic wave functions are no longer a good approximation, the degeneracy is lifted, and the correct electronic eigenfunctions must exhibit the required symmetry or antisymmetry with respect to $\boldsymbol{r}_a \leftrightarrow \boldsymbol{r}_b$. One then constructs two solutions: symmetrical

$$\alpha = \beta = \frac{1}{\sqrt{2(1+S)}}; \qquad E_e = \frac{\int \psi_a H_e \psi_a d\tau + \int \psi_b H_e \psi_a d\tau}{1+S};$$

and antisymmetrical

$$\alpha = -\beta = \frac{1}{\sqrt{2(1-S)}}; \qquad E_e = \frac{\int \psi_a H_e \psi_a d\tau - \int \psi_b H_e \psi_a d\tau}{1-S}.$$

Of these, the symmetrical solution corresponds to the lower energy level, *thus leading to the* ground state *of the molecule.*

Performing the necessary integrations, the explicit expression for $E_e(R)$ (the effective proton-proton Born-Oppenheimer potential) for the symmetrical *solution become*

$$E_e(R) = -\frac{1}{2}\gamma^2 + \frac{\gamma(\gamma-1) - J + (\gamma-2)K}{1+S}$$

where

$$S = \frac{\gamma^3}{\pi} \int d\tau e^{-\gamma(r_a+r_b)} = \left(1 + \rho + \frac{1}{3}\rho^2\right) e^{-\rho},$$

$$\rho = \gamma R, \qquad J = \frac{\gamma^3}{\pi} \int d\tau \frac{e^{-2\gamma r_a}}{r_b} = \frac{1}{R}\left[1 - (1+\rho)e^{-2\rho}\right],$$

$$K = \frac{\gamma^3}{\pi} \int d\tau \frac{e^{-\gamma(r_a+r_b)}}{r_b} = \gamma(1+\rho)e^{-\rho}.$$

Here, J is the integral describing the Coulomb attraction of proton b and the electron cloud centered about proton a. K is the exchange integral, having no classical equivalent and being a consequence of the fact that the electron in the molecular ground state is present near both protons (the same applies to S). Note that K is appreciable only if ψ_a and ψ_b overlap substantially.

Since E_e depends on the two variables γ and ρ, a minimization w.r.t. these two variables shows (numerically) that the energy minimum lies at the equilibrium distance $R_0 = 2.08$ atomic units (or 1.10 Å) and $E_0 = -0.5866\ \frac{e^2}{a_0}$. The corresponding dissociation energy of $H_2^+ \to H + H^+$ is calculated to be 2.24 eV, as compared with the experimental value of 2.65 eV.

The Born-Oppenheimer approximation of fixed nuclei can be similarly employed for the evaluation of the binding energy and equilibrium distance of the neutral hydrogen molecule H_2.

The Hamiltonian operator for the system can be divided into 3 parts: one relating to the motion of the center of mass, one to the electronic motion for a given proton separation, and the third to the relative motion of the protons under an effective potential energy consisting of their own mutual Coulomb energy and the electronic energy.

The Hamiltonian operator for the electronic motion is symmetrical in x (the coordinate measured along the direction of the line joining the two protons) so that the electronic eigenfunctions will again have even or odd parity w.r.t. x.

The case of the neutral H_2 molecule differs from the case of the ionized molecule in one important respect: the presence of two identical electrons in the neutral molecule requires the application of the exclusion principle. The electronic eigenfunctions must now not only exhibit either even or odd parity w.r.t. their separate space coordinates, but must also be antisymmetric w.r.t. an interchange of the space and spin coordinates of the two electrons.

Thus, the exclusion principle leads to a physical effect, namely an effective repulsion of the electrons if their spins are parallel (in addition to their electrostatic repulsion).

Let the two nuclei (protons) be denoted by a and b and the two electrons by 1 and 2. We then have the following electronic Hamiltonian in atomic units (after subtracting the motion of the center of mass):

$$H_e = -\frac{1}{2}(\nabla_1^2 + \nabla_2^2) + \frac{1}{r_{12}} - \left(\frac{1}{r_{a1}} + \frac{1}{r_{b1}} + \frac{1}{r_{a2}} + \frac{1}{r_{b2}}\right).$$

At large inter-nuclear distances R, the wave function should go over into the product of the separate atomic eigenfunctions, either becoming of the form $f(\boldsymbol{r}_{a1})f(\boldsymbol{r}_{b2})$ if electron 1 forms an atom with nucleus a, and 2 with b, or of the form $f(\boldsymbol{r}_{b1})f(\boldsymbol{r}_{a2})$, if the two electrons are exchanged.

A reasonable approach at finite *distance R will be to take a linear combination of two such products, and symmetry considerations lead to the choice of the symmetrical solution*

$$\psi(1,2) = \alpha\,[f(\boldsymbol{r}_{a1})f(\boldsymbol{r}_{b2}) + f(\boldsymbol{r}_{b1})f(\boldsymbol{r}_{a2})]$$

for the ground state *(with* antiparallel *electron spins, according to the Pauli principle). We are again neglecting all spin dependent interactions, except those resulting from the Pauli principle. The antisymmetric combination, would lead to a larger energy with no attraction and no formation of a molecule at all.*

We apply the operation $\int d\tau_1 \int d\tau_2 f^*(\boldsymbol{r}_{a1})f^*(\boldsymbol{r}_{b2})\cdots$ to the equation $H_e\psi = E_e\psi$ with the ansatz $f = \frac{\gamma^{3/2}}{\sqrt{\pi}}e^{-\gamma r}$, and use the abbreviations:

$$S = \int d\tau_1 f^*(\boldsymbol{r}_{a1})f(\boldsymbol{r}_{b2}) \qquad \textit{(overlap integral)}$$

$$\left.\begin{aligned} J &= \int d\tau_1 \tfrac{1}{r_{b1}}|f(\boldsymbol{r}_{a1})|^2 \\ J' &= \iint d\tau_1 d\tau_2 \tfrac{1}{r_{12}}|f(\boldsymbol{r}_{a1})|^2|f(\boldsymbol{r}_{b2})|^2 \end{aligned}\right\} \text{classical interaction integrals}$$

$$\left.\begin{aligned} K &= \int d\tau_1 \tfrac{1}{r_{a1}} f^*(\boldsymbol{r}_{a1})f(\boldsymbol{r}_{b1}) \\ K' &= \iint d\tau_1 d\tau_2 \tfrac{1}{r_{12}} f^*(\boldsymbol{r}_{a1})f(\boldsymbol{r}_{b1})f^*(\boldsymbol{r}_{a2})f(\boldsymbol{r}_{b2}) \end{aligned}\right\} \text{exchange integrals}$$

$$A = \int d\tau_1 f^*(\boldsymbol{r}_{a1})\left[-\frac{1}{2}\nabla_1^2 - \frac{1}{r_{a1}}\right] f(\boldsymbol{r}_{a1})$$
$$A' = \int d\tau_1 f^*(\boldsymbol{r}_{a1})\left[-\frac{1}{2}\nabla_1 - \frac{1}{r_{b1}}\right] f(\boldsymbol{r}_{b1}).$$

All the above integrals can be evaluated in terms of elementary functions. The final result has the form

$$E_e = -P(\rho)\gamma + Q(\rho)\gamma^2$$

where $\rho = \gamma R$ *and* P, Q *are known functions of* ρ. *The energy minimum is at* $E_e = -\frac{P^2}{4Q}$. *Numerical computations yield an equilibrium state at* $R = R_0 = 0.77$ Å, *against an experimental value of 0.742 Å. The energy is then* $E = -1.139\frac{e^2}{a_0}$ *as compared with* $2E_0 = -\frac{e^2}{a_0}$ *of two* separate *hydrogen atoms in the ground state.*

In polyatomic molecules, molecular orbitals are obtained by the superposition of the atomic orbitals. The situation becomes interesting when we mix orbitals with different directionalities, such as s and p states. The principle of superposition is based on the recognition that the addition of atomic orbitals will be most effective (producing the greatest bond energy) when the overlap of the electron wave-functions will be maximal. The process of mixing s*- and* p*-orbitals is called* hybridization.

The most striking example of its significance occurs in carbon. This element possesses 4 electrons in the L-shell, and since its valency is 4 we must suppose that these electrons are distributed among the states defined by $\psi(2s)$, $\psi(2p_x)$, $\psi(2p_y)$ *and* $\psi(2p_z)$. *The most stable configuration in this valence state will occur when the respective molecular orbitals exhibit* maximum overlapping *(**Pauling**, 1937).*

It therefore follows that to study the possible hybrid orbitals, we need only discover the conditions for maximum charge-cloud density in an assigned direction. This occurs when wave functions are used which contain 4 equal 'weights' of the constituents. If we write

$$\psi = c_1\psi(2s) + c_2\psi(2p_x) + c_3\psi(2p_y) + c_4\psi(2p_z),$$

then, since the separate wave-functions on the r.h.s. are mutually orthonormal, the contributions to $|\psi|^2$ *are in the ratio of* $c_1^2 : c_2^2 : c_3^2 : c_4^2$. *When these are equal we have* $c_1^2 = c_2^2 = c_3^2 = c_4^2 = \frac{1}{4}$ *which renders (with any arbitrary phase choice for* c_1*)*

$$c_1 = \frac{1}{2}, \quad c_2 = \pm\frac{1}{2},$$

$$c_3 = \pm\frac{1}{2}, \quad c_4 = \pm\frac{1}{2}.$$

Upon choosing $c_1 = \frac{1}{2}$, *there are four independent combinations of the remaining signs. These give the 4 wave functions*

$$\psi_1 = \frac{1}{2}\left[\psi(2s) + \psi(2p_x) + \psi(2p_y) + \psi(2p_z)\right],$$
$$\psi_2 = \frac{1}{2}\left[\psi(2s) + \psi(2p_x) - \psi(2p_y) - \psi(2p_z)\right],$$
$$\psi_3 = \frac{1}{2}\left[\psi(2s) - \psi(2p_x) + \psi(2p_y) - \psi(2p_z)\right],$$
$$\psi_4 = \frac{1}{2}\left[\psi(2s) - \psi(2p_x) - \psi(2p_y) + \psi(2p_z)\right]$$

where (ignoring the common radial factors),

$$\psi(2s) = 1, \qquad \psi(2p_x) = \sqrt{3}\sin\theta\cos\phi,$$
$$\psi(2p_y) = \sqrt{3}\sin\theta\sin\phi, \quad \psi(2p_z) = \sqrt{3}\cos\theta.$$

Now, the maximum of ψ_1 *occurs where*

$$\frac{\partial\psi_1}{\partial\theta} = \frac{1}{2}\sqrt{3}\{\cos\theta\cos\phi + \cos\theta\sin\phi - \sin\theta\} = 0,$$
$$\frac{\partial\psi_1}{\partial\phi} = \frac{1}{2}\sqrt{3}\{-\sin\theta\sin\phi + \sin\theta\cos\phi] = 0.$$

The solution is $\tan\phi = 1 \quad \left(\phi = \frac{\pi}{4}\right)$, $\tan\theta = \sqrt{2} \quad (\theta = 54^\circ 44')$. *Similarly, the maxima of the remaining wave functions occur at* $\phi = -\frac{\pi}{4}$, $\theta = 125^\circ 16'$ *for* ψ_2, $\phi = \frac{3\pi}{4}$, $\theta = 125^\circ 16'$ *for* ψ_3, $\phi = \frac{5\pi}{4}$, $\theta = 54^\circ 44'$ *for* ψ_4. *The corresponding vectors in these directions will be*

$$\boldsymbol{e}_1 = \boldsymbol{e}_x + \boldsymbol{e}_y + \boldsymbol{e}_z, \qquad \boldsymbol{e}_2 = \boldsymbol{e}_x - \boldsymbol{e}_y - \boldsymbol{e}_z,$$
$$\boldsymbol{e}_3 = -\boldsymbol{e}_x + \boldsymbol{e}_y - \boldsymbol{e}_z, \qquad \boldsymbol{e}_4 = -\boldsymbol{e}_x - \boldsymbol{e}_y + \boldsymbol{e}_z.$$

The angle between (say) $\boldsymbol{e}_1$ *and* $\boldsymbol{e}_4$ *is given by* $\cos\theta_{14} = -\frac{1}{3}$, *therefore* $\theta_{14} = 109^\circ 28'$. *It is the angle between the lines joining the centroid (carbon) to any two of the 4 H atoms bonded to the carbon; the 4 lines form the vertices of a regular tetrahedron. The hybridization scheme just described is known as* sp^3, *because all three* $2p$ *orbitals of the central carbon atom participate. The other possible hybridization schemes are:* sp^2 *(trigonal planar* symmetry, *as for the methyl radical* CH_3, *linear shape, as for* CO_2 *or acetylene* C_2H_2*), and schemes involving* s, p *and* d *orbitals (for 3*[rd]*-row central atom, e.g. phosphor and sulfur).*

The simplest stable molecule is that of hydrogen, H_2. *If we start with two ground state hydrogen atoms an infinite distance apart, electron 1 is in a* $1s$ *orbital around proton* a *and electron 2 is in a* $1s$ *orbital around proton* b. *As the distance between the two atoms decreases, we use a linear combination of the* $1s$ *atomic orbitals to construct a molecular* orbital *for which each electron is equally likely to be in the neighborhood of each proton.*

There are only two possible combinations that satisfy the condition that each electron be associated equally with each nucleus, one by taking the sum and the other *by taking the difference of the two* $1s$ *atomic orbitals. Addition leads to constructive interference between the two wave functions in the region between the two nuclei and results in increased electron density in this region. This orbital is called the* BONDING MOLECULAR ORBITAL.

In the opposite situation the two atomic orbitals undergo destructive interference in the region between the two nuclei, and the electron density is very low in this region (it is zero on a nodal plane bisecting the inter-nuclear line segment). This orbital is called the ANTIBONDING MOLECULAR ORBITAL.

The electronic SE can now be used to calculate the energy E_e *of the* hydrogen molecule, *which depends on the internuclear distance. The arbitrary fiducial zero of energy is taken to be the energy of the two hydrogen atoms when infinitely far apart.*

When the molecule is in the bonding state $(1s_a + 1s_b)$ *it will have an energy less than that of the dissociated atoms, i.e. it will be a stable entity. The molecule in this state has a dissociation energy* E_0 *and a bond length* R_0. *The antibonding orbital* $(1s_a - 1s_b)$ *yields a higher energy than that of the dissociated atoms for all* values *of* R.

Therefore, no stable molecule can exist in that state. In the bonding orbital, there is high electron density between the two protons, meaning that the electrons serve as the bonding agent. In the ground state, with both electrons occupying the same molecular orbital, they must have opposite spins.

The electrons in a molecular orbital that has a high density in the region between the two nuclei create a COVALENT BOND, *which results from an overlap of two atomic orbitals. A similar technique is used for diatomic molecules (such as* O_2, N_2*) containing many valence electrons. In this type of bond, known also as* HOMOPOLAR BINDING, *two electrons in the ground state are equally shared between two identical atoms in a manner described by a wave function which is symmetric in the space coordinates of the two electrons, but antisymmetric in the spins. Successive pairs of electrons (pooled from both atoms) similarly occupy successively higher molecular orbitals — both bonding* and *antibonding, in general. This "buildup" (aufbau) scheme holds for molecules involving two different atoms as well, and even for multi-atomic molecules.*

In diatomic molecules, electrons do not move in a central field of force, and therefore the orbital angular momentum operator $\boldsymbol{L}$ of an electron does not remain constant during its motion. However, because of the axial symmetry about the line (say, z axis) passing through the two nuclei, the component of $\boldsymbol{L}$ in the z direction is conserved (except for spin-orbit and inter-electron coupling effects), i.e. $L_z = m_\ell \hbar$; here m_ℓ is, as usual, quantized to $m_\ell = 0, \pm 1, \pm 2, \dots$. The sign of m_ℓ determines the sense of rotation of the electron about the z-axis, but since the energy is independent of this direction one need only give the absolute value, $|m_\ell| = \lambda$.

The different angular momentum states are denoted according to the following scheme: $m_\ell = 0$, $\lambda = 0$ (σ states); $m_\ell = \pm 1$, $\lambda = 1$ (π states); $m_\ell = \pm 2$, $\lambda = 2$ (δ states); $m_\ell = \pm 3$, $\lambda = 3$ (ϕ states). Thus, except for σ-states, all angular momentum states are doubly degenerate because of the possible signs of m_ℓ. In addition, in each of the above states the electron may have its spin up or down relative to the molecular axis. So, σ-states can accommodate two electrons with opposite spins whereas the remaining states, π, δ, ϕ can accommodate up to four electrons each, two with spin up and two with spin down.

For molecular orbital states of the electron, one uses the notation $\lambda n\ell m_\ell$, where $n\ell$ serves to indicate the atomic orbitals from which each of the molecular orbitals has been formed by linear combination. Each of these molecular orbitals corresponds to a different energy.

In the case of molecules composed of two identical nuclei, such as H_2, the aforementioned structural cylindrical symmetry is augmented by a further symmetry (or antisymmetry) of the electron probability amplitude under exchange. The shape of the molecular orbitals resulting from a linear combination of atomic orbitals will depend on the atomic quantum numbers.

When the charges of the two nuclei composing the molecule are different, the Coulomb interaction of each nucleus with its electrons is different and the molecule no longer has a center of symmetry. In general, only the unpaired electrons in the last unfilled shell in each atom will participate strongly in the chemical bond.

In the case of NaCl, for example, these are the $3s$ electron in Na and one of the $3p$ electrons in Cl. Since the Cl nucleus produces a stronger attractive field and its atomic shells are closer to it, the Chlorine's electronegativity is bigger than that of the Na atom, which means that the electronic charge of the bonding electron pair is displaced toward the Cl nucleus. This results in an uneven charge distribution, and hence an electric dipole moment of the NaCl molecule. The NaCl molecule may thus be considered as being composed of two ions held together by their Coulomb attraction. We express this situation by writing Na^+Cl^-.

This type of molecular bonding is called an ionic bond; in it the classical model yields an adequate approximation to the energetic state of the stable bond.

For most heteronuclear diatomic molecules, the situation is intermediate between pure covalent bond and pure ionic bond. The more ionic the bond, the larger the electronic dipole moment of the molecule.

For molecules with more than two atoms, the geometry of the molecule is determined quantum-mechanically. It was found experimentally that a bond between any two of its atoms occurs in the direction in which the respective atomic wave functions have maximum overlap.

Thus, consider the water molecule H_2O*: if for simplicity we ignore hybridization, the active ingredients in the oxygen atom are the two unpaired electrons, each with* $n = 2,\ \ell = 1,\ m_s = \frac{1}{2},\ m_\ell = \pm 1$*, i.e. (say) one O electron in the* p_x *state and the other in the* p_y *state (the remaining 2p-electrons of O are along the z-axis in* p_z *state, with their spins paired). The other active elements, [one (1s) per H atom] are located so that they couple with maximum wave-function overlap to the two respective unpaired electrons in O. The result is a molecule having, to the first approximation, a right-angle shape. The presence of the H atoms polarizes the motion of the p electrons of O such that the lobes nearer to the H atoms are larger than the far lobes. Also, the angle between the O–H bonds increases from* 90° *to* 104.5° *because of the repulsion among the O atom's two lone pairs (non-bonding electron pairs) and the two O-H bonding pairs.*[724]

Detailed calculations show that the hydrogen 1s-electrons are pulled toward the O atom, so that the centroids of the negative and positive charges do not coincide, producing a net electric dipole moment along the line bisecting the bent H-O-H angle.

A similar situation occurs in the ammonia molecule NH_3*, where the interaction is (again, ignoring the* sp^3 *hybridization) between the 3 unpaired* $(2p_x)$*,* $(2p_y)$ *and* $(2p_z)$*-electrons in the N atom and the 3 (1s)-electrons of the H atoms. The result is a trigonal pyramidal structure, with the N atom at the apex and the H atoms forming the base (the angles at the vertex of the pyramid between any two H atoms is* 107.3°*).*

The bonds of methane (CH_4*) can only be understood in terms of hybridization. First a slightly excited state of carbon, consisting of one 2s and three unpaired 2p-electrons, is mandatory to engage the four H atoms. But these four bonds would not have the same energy and the same directionality (2s is spherically symmetric).*

[724] The last two featured can also be understood in terms of an sp^3 (tetrahedral) hybridization of the oxygen orbitals.

To account for the experimental results, which indicate 4 bonds of the same energy and directionality, suitable solutions of the SE were found. By making 4 linearly-independent linear combinations of the four wavefunctions so-called hybridized wavefunction in the form

$$\psi_{1,2,3,4} = \frac{1}{2}\left[\psi(2s) \pm \psi(2p_x) \pm \psi(2p_y) \pm \psi(2p_z)\right]$$

we obtain suitable wave-functions with maxima pointing toward the vertices of a tetrahedron, as explained above.

Clearly, since s and p wave functions correspond to different values of the angular momentum, the hybrid wave-functions do not *describe states of well-defined electronic angular momentum.*

C. Quantum Theory of Solids and The Semiconductor (1930–1936)

The many and varied properties of solids have intrigued us for centuries. Technological developments involving metals *and* alloys *have shaped the course of civilizations, and the symmetry and beauty of naturally occurring, large single* crystals *have consistently captured our imagination. However, the origins of the physical properties of solids were not understood at all until the development of* quantum mechanics*. The application of quantum mechanics to solids has provided the basis for much of the technological progress of modern times.*

Quantum mechanics *provides a "technology" to analyze atomic systems, in order to calculate their energy levels, shapes and interactions and to predict the probability of transition from one state to another. When we consider the properties of matter in bulk, new problems arise because of the complicated interaction between atoms and molecules. Even in the gaseous state, intermolecular forces affect the behavior considerably, although it is possible to describe deviations from the gas laws in terms of simple two-body interactions. In the liquids and solid states, the close proximity of atoms gives rise to strong forces affecting many particles.*

At the same time, the fundamental rules of quantum mechanics *become important in dealing with vibrations of the crystal lattice and with condition of electrons in metals. Despite intense mathematical difficulties, solid-state physics has made great progress in accounting for several phenomena which received no classical explanation. Moreover, its results have great practical* *significance and wide implications in many fields of physical research, including deep and fruitful mathematical similarities to Quantum Field theories (QFT) of particle physics and cosmology.*

The quantum theory of solids includes the following topics:

- *Crystal's lattice vibrations — theory of phonons.*
- *Heat conduction, specific heats and thermal expansion coefficients.*
- *Metallic electric conductivity.*
- *Paramagnetism, diamagnetism, ferrimagnetism, and ferromagnetism.*
- *Band theory of solids and semiconductivity.*
- *Superconductivity.*

The classical Drude model (1900) was based on concepts borrowed from the kinetic theory, suggesting that electrons in a metal behave like molecules of a gas (at ordinary temperatures) and participate in thermal equilibrium according to the Maxwell-Boltzmann velocity distribution law. The greatest success achieved by Drude's theory consisted in the derivation of the Wiedemann-Franz law[725]*, which states that the ratio of thermal conductivity to electrical conductivity is given by the expression* $3\frac{k^2}{e^2}T$.

***Drude** (1863–1906, Germany) was also able to derive an expression for electrical conductivity, which is of some importance even today. However, a theory that was adequate for Newtonian particles was not expected to accommodate electrons, which since the 1920's were recognized as* quantum *entities, obeying* quantum *laws.*

Indeed, Drude's theory soon ran into conflict with experimental results: the hypothesis that every free electron should possess a mean kinetic energy of $\frac{1}{2}kT$ *per degree of freedom in a state of thermal equilibrium leads to a corresponding electronic contribution to the molar heat capacity of* $\frac{3}{2}R = 3$ *cal/mol deg which is in flat contradiction with the Dulong-Petit rule. This and other difficulties disappear only if it is assumed* ad hoc *that the number of free electrons is* considerably smaller *than that of atoms.*

*The first step toward the modification of Drude's theory was taken (1928) by **Arnold Sommerfeld** (1868–1951) with the new assumption that the electron gas in metals possesses the properties of a* highly degenerate Fermi-Dirac

[725] **Gustav Wiedemann** (1826–1899, Germany), **Rudolf Franz** (1827–1902, Germany).

gas. The SE for the free electron, $\nabla^2\psi + \frac{2m}{\hbar^2}E\psi = 0$, admits a de Broglie plane-wave solution for the electron's complex wave function $\psi = ce^{i(\boldsymbol{k}\cdot\boldsymbol{r})}$, where c is a complex normalization constant and $\boldsymbol{k}$ is the vector wavenumber; $\hbar = \frac{h}{2\pi}$ is the reduced Planck constant and m denotes the electron mass. The electron's vectorial momentum operator is defined by $\boldsymbol{p} = -i\hbar\boldsymbol{\nabla}$ and the SE yields $\boldsymbol{p}\psi = -i\hbar\boldsymbol{\nabla}\psi = \hbar\boldsymbol{k}\psi$; in other words, the wavefunction (Hilbert-space state vector) is a simultaneous eigenvector of the operators p_x, p_y, p_z with eigenvalues

$$\boldsymbol{p} = \hbar\boldsymbol{k} = m\boldsymbol{V},$$

where $\boldsymbol{V}$ is the velocity [in one dimension $p = \frac{h}{\lambda} = \hbar k$].

A free electron has only a kinetic energy E, and its *dispersion relation* (dependence of E on $\boldsymbol{k}$) is the parabola

$$E(k) = \frac{p^2}{2m} = \frac{\hbar^2}{2m}k^2$$

(also, the Planck relation $E = h\nu = \hbar\omega$ yields $\omega = \frac{p^2}{2m\hbar} = \frac{\hbar}{2m}k^2$). Since $|\psi|^2 = c^2$ is a constant, the probability density of detecting the single free electron is the same everywhere when it is in the pure $\boldsymbol{k}$ state Ψ. Note that the energy is a *continuous* function of k.

However, the gas of shared electrons is not actually free: ignoring inter-electron interaction (apart from the Pauli exclusion principle), the electrons still interact with the metal's lattice ions.

This causes the individual atomic valence orbitals to become spread over the entire metallic bulk, via superposition, into gigantic, macroscopic, molecular orbitals.

Identical atomic orbitals thus split into a very large ($\sim$ Avogadro's number per mole) shared orbitals, which are for all intents and purposes a continuum — called a *band*.

Since there is more than one atomic orbital involved, more than one electron band results. Bands are separated by finite energy gaps (band gaps); within a band, the dispersion relation is *not* parabolic.

Next, we present a simple-minded model illustrating how such electron bands arise. We begin by restricting the motion of a single electron to a segment $0 \leq x \leq a$. This can be thought of as a model for conduction electron in a one-dimensional metal crystal lattice, where we neglect interactions of these electrons with each other and with the positive ions and assume that the height of the potential barrier is much above the electron's kinetic energy.

The electron can move freely inside each repetitive unit cell of the lattice, assumed of size a, bouncing back and forth between the cell boundaries, but cannot escape to a neighboring cell.

This simplified model is physically relevant to electron condition only when a (possibly small) coupling is allowed between cells; such a coupling occurs because an electron has a finite probability to tunnel across the inter-cell potential barrier, so the conduction electrons — usually one or more per cell — mix and propagate throughout the lattice.

The back and forth motion of an electron inside any given cell — ignoring tunneling and the presence of other electrons — is accommodated by the solution of the SE,

$$\psi = Ae^{ikx} + Be^{-ikx}$$

with the approximate boundary conditions $\psi(a) = \psi(0) = 0$.

The probability amplitude (wavefunction) is thus no longer a propagating wave, but rather a standing wave $\psi = c\sin kx$ *where k, p, E may only range over the sets of discrete values*

$$k_n = n\frac{\pi}{a},$$

$$p_n = \hbar k_n = \frac{\pi n\hbar}{a},$$

$$E_n = \frac{p_n^2}{2m} = \frac{n^2\pi^2\hbar^2}{2ma^2}.$$

Also, we may choose the wavefunction phase convention so that

$$\psi_n = \sqrt{\frac{2}{a}}\sin\left(\frac{\pi n x}{a}\right)$$

on account of the per-cell total probability normalization

$$\int_0^a |\psi_n|^2 dx = 1.$$

The positive wavenumber (e^{ikx}) *term in* Ψ *corresponds to an electron moving in the positive x direction, while the* e^{-ikx} *term corresponds to an electron moving in the opposite direction. In accord with the superposition principle, the electron is doing both at once. Other mobile valence electrons have identical wavefunctions in other cells:* $ma \leq x \leq (m+1)a$, *with* m *ranging over* $\ldots, -2, -1, 0, 1, 2, \ldots$. *It turns out that due to inter-cell tunneling, each* $\Psi_n(x)$ *in each cell* m *acquires a phase factor* e^{iqx}, *where* q *is the Bloch wavenumber for the n-th band;* q *is continuous (unlike* k_n*)*

and ranges over $-\frac{\pi}{a} \leq q \leq \frac{\pi}{a}$, *since* $\Psi_n(x; q + \frac{2\pi}{a})$ *is just* $\Psi(x; q)$ *for a different band.*

The energy E_n *of the electron is not entirely kinetic, as is the case of the free electron, because of the potential energy due to the lattice ions and the resulting inter-cell tunneling effects;* $E_n = E_n(q)$ *depends on the Bloch wavenumber* q *for each band* n. *The expression for the energy in terms of* q *is complicated and depends on the geometry of the lattice. The important general result is that the range of values of the* n*-th band energy* $E_n(q)$ *has discontinuities or* gaps *such that near* $q = 0$ *the shape of* $E_n(q)$ *closely resembles that of a free particle. Therefore, the lattice significantly affects the motion of the non-bound electron only when* q *is close to* $n\frac{\pi}{a}$. *At intermediate values of* q, *the electrons move freely through the lattice.*

The above one-dimensional treatment can easily be generalized to three dimensions. Thus, for crystals having a cubic repetitive unit-cell which is a cube of side a, *the single-cell electron wavefunction (before inter-cell transmission is taken into account) is*

$$\Psi = \left(\frac{2}{a}\right)^{3/2} \sin\frac{\pi n_1 x}{a} \sin\frac{\pi n_2 y}{a} \sin\frac{\pi n_3 z}{a}$$

with energy levels $E = \frac{n^2\pi^2\hbar^2}{2ma^2}$, $n^2 = n_1^2 + n_2^2 + n_3^2$, *and* n_1, n_2, n_3 *are positive integers.*

When the cells are allowed to interact, $\Psi_{n_1,n_2,n_3}(x)$ *and* E_{n_1,n_2,n_3} *again become functions of a continuous Bloch wavenumber,* $\boldsymbol{q}$, *which is now a vector belonging to the* reciprocal momentum-space *unit cell:* $-\frac{\pi}{a} \leq q_j \leq \frac{\pi}{a}$, $j = 1, 2, 3$. $E_{n_1,n_2,n_3}(\boldsymbol{q})$ *are periodic band dispersion relations, with approximately parabolic shape near* $\boldsymbol{q} = 0$.

The simplest exactly-soluble quantum-mechanical model for electronic bands in a crystal lattice is the ***Krönig-Penney*** *periodic-potential model.*

In the band, the dispersion relations are not exactly *quadratic, and the electronic energy levels do not fill the whole range* $0 \leq E < \infty$, *but only certain* bands *in the range. However, when only a single, partially-filled band is important, the free box approximation is useful, since the band is always approximately quadratic near its bottom. The 'effective' electron mass is then calculated from the reciprocal of the band's curvature at the bottom,* $\nabla_{\boldsymbol{q}}^2 E$, *and may differ from the electron's physical (inertial and gravitational) mass. We may call this the 'quasi-free' approximation for the conduction electrons.*

For a small molecule, the molecular-orbital energy levels are widely spaced, but for a very large lattice (as is the case for electrons in a metal) successive levels are so close that they practically form continuous spectra (bands). We ask: how many mobile-electron energy levels are there in a small energy range

dE, when the lattice is very large? (For the time being we assume a quasi-free dispersion relation.)

In k-space $\frac{\pi}{a}(\xi, \eta, \zeta)$, each point with $\xi = n_1$, $\eta = n_2$, $\zeta = n_3$ (positive integers) represents an electron state. The total number of points lying inside a surface of a sphere of radius k give the number of different states associated with energies $\leq E$. We evaluate first the total number of states (including a factor of 2 for spin) in a volume of an octant of radius k,

$$N(E) = \frac{2a^3}{\pi^3}\frac{1}{8}\left(\frac{4}{3}\pi k^3\right) = \frac{2a^3}{3\hbar^3\pi^2}(2m^3)^{1/2}E^{3/2}.$$

The number of states with energy between E and $E + dE$ per unit volume of the lattice (a^3) is thus

$$\frac{1}{a^3}dN(E) = g(E)dE,$$

where

$$g(E) = \frac{1}{\pi^2\hbar^3}(2m^3)^{1/2}E^{1/2}$$

is the number of states per unit volume per unit energy interval, at the energy E (since each level can accommodate two electrons with opposite spins, the values of $N(E)$ and $g(E)$ were doubled).

If N, the total number of electrons per unit volume, is less than the total available number of energy levels in the band, the electrons will occupy all band energy levels up to a threshold level, called the Fermi level $\epsilon_F = E(N)$. From

$$N = \frac{2}{3\pi^2\hbar^3}(2m^3)^{1/2}\epsilon_F^{3/2}$$

we derive

$$\epsilon_F = \frac{\hbar^2}{2m}(3\pi^2 N)^{2/3}.$$

[Example: silver, density $= 10.5\frac{\text{g}}{\text{cm}^3}$ and atomic weight 108 g/mole has one free electron per atom. The total number of free electron per cm^3 is thus

$$N = \frac{6.02 \times 10^{23}\ \frac{\text{atom}}{\text{mole}} \times 10.5\frac{\text{g}}{\text{cm}^3}}{108\frac{\text{g}}{\text{mole}}} = 5.9 \times 10^{22}$$

free electrons/cm^3. The Fermi energy is $\epsilon_F = 5.5$ eV, taking the approximation that m is the physical electron mass.]

We can estimate the relative number of conduction electrons in a metal which are thermally excited to higher energy states; most of the excited electrons are in a range ΔE *above the Fermi energy* ϵ_F, *where* $\Delta E \cong kT$. *Assuming that* $kT \ll \epsilon_F$, *the number* ΔN *of excited electrons per unit volume can be calculated from* $\Delta N \simeq g(\epsilon_F)kT$. *The* fraction *of conduction electrons that is thermally excited is small. Simple algebraic manipulations then lead to the result*

$$\Delta N/N \simeq kT/\epsilon_F .$$

At room temperature $kT \simeq 0.025\ eV$ *and typically* $\epsilon_F \simeq 4\ eV$, *so that* $\Delta N/N \simeq 1/160$. *The* absolute *number of excited conduction electrons is, however, very large.*

An estimate can also be made of the relative number of electrons in the conduction band of an insulator or semiconductors at temperature T. *If in the Fermi distribution* $n(E)$ *we have* $E - \epsilon_F \gg kT$, *then*

$$n(E) = \frac{1}{exp\left[(E-\epsilon_F)/kT\right]+1} \simeq exp\left(-\frac{E-\epsilon_F}{kT}\right)$$

so that in such an energy range the Fermi distribution varies with energy like the Boltzmann distribution.

We know that $E - \epsilon_F = \frac{1}{2}E_g$ *at the bottom of the conduction band in an insulator. Thus the condition* $E - \epsilon_F \gg kT$ *is met* ($E_g \gg kT$ *for an insulator), so we can take*

$$n(E) = e^{-\frac{E_g}{2kT}}$$

as the number of electrons per state in the conduction band of an insulator.

Since the Fermi distribution falls in value by an order of magnitude in an energy range of about $\Delta E = 2kT$, *we get a good estimate of* ΔN, *the number of conduction electrons, by evaluating those in the range* $2kT$ *above the bottom of the conduction band. Since*

$$\Delta N = n(E)g(E)\Delta E,$$

we must now evaluate $g(E)$, *the density of states. Because* $g(E)$ *starts at zero at the bottom of the conduction band, a typical value over the range* $\Delta E = 2kT$ *is obtained by evaluating* $g(E)$ *at* $E = kT$. *Hence,*

$$\Delta N \simeq e^{-\frac{E_g}{2kT}} g(kT) 2kT.$$

Using our earlier results for a metal, $N = \frac{2}{3}\epsilon_F g(\epsilon_F)$ *and* $g(kT)/g(\epsilon_F) = \left(\frac{kT}{\epsilon_F}\right)^{1/2}$, *we have*

$$\Delta N/N \simeq \left(\frac{kT}{\epsilon_F}\right)^{3/2} e^{-\frac{E_g}{2kT}}.$$

This is the relative number of conduction electrons for an insulator. This fraction is much smaller than the corresponding result $\frac{kT}{\epsilon_F}$ *for a metal, partly because the density of states* $g(E)$ *is smaller near the bottom of the conduction band in an insulator than at the Fermi energy in a metal — but principally because of the occupation fraction* $e^{-\frac{E_g}{2kT}}$. *Let us take* $E_g = 6$ eV *as the gap in a typical insulator; at room temperature this factor is then* $e^{-\frac{E_g}{2kT}} = e^{-120} \approx 10^{-52}$. *Not only is the fraction* $\Delta N/N$ *insignificant, but the absolute number of conduction electrons is also negligible for an insulator. If, however,* $E_g = 1$ eV, *as for a semiconductor, then although* $e^{-\frac{E_g}{2kT}} \doteq 10^{-9}$ *gives a very small fraction, the number of conduction electrons is no longer insignificant.*

On the basis of the Fermi-Dirac theory, Sommerfeld worked out the thermal *properties of an assembly of electrons, obtaining quite good agreement with observations. In this sense, the Sommerfeld model was an*

important step in the development of the theory of metals. It was, however, less successful in explaining the electrical *properties of metals: it failed to explain why some elements are good electrial conductors and others are not.*

The next important improvement in understanding the physical properties of solids was the development of band theory. *This theory is based on a careful* quantum analysis *of the role of the* atomic lattice *centers in the solid. These centers were found to be far more important than assumed in the previous theories, in which they served only to balance electric charge and to act as scattering sites for the free conduction electrons.*

It was shown earlier that quantum theory provides the means for describing the energy levels of the electrons surrounding an atom. Mathematical complications for systems involving many atoms and many electrons are so great that they prevent a rigorous mathematical treatment. Nevertheless, the use of approximation methods makes it possible to obtain considerable insight into the behavior of complicated many-body systems.

It is of great interest, for example, to consider the behavior of many atoms brought together to form a solid. A useful approximation which bears on the *difference between conductors and insulators is the so-called band approximation, which was discussed earlier in connection with the solutions of the SE.*

*It was shown that the SE exhibits band structure as a direct result of the periodicity of the potential function (**R. de L. Kronig** and **W.G. Penney**, 1931). The qualitative existence of bands was first pointed out by **M.J.O. Strutt** (1927). Band theory was further extended by **F. Bloch** (1928), **L. Brillouin** (1930, 1931), **C. Zenner** (1934), **N.F. Mott** and **H. Jones** (1936).*

The ideas of these scientists can be summarized in the following qualitative manner: An energy band in a one-dimensional crystal is made up of a large number of waves of different energies moving with equal numbers in both directions. Thus each energy level corresponds to two Schrödinger waves, one traveling to the left and the other to the right. Since by the exclusion principle any particular wave function can be shared by two electrons having opposite spins, each energy level can accommodate two electrons (of opposite spins) traveling to the left and two electrons (of opposite spins) traveling to the right, and no more. Each energy level is thus a sort of two-way street by means of which an electron can travel with a particular energy and speed to the right or to the left with its spin either up or down.

Some crystals are insulators (nonconductors) of electricity; Absolutely pure silicon and germanium held at very low temperatures are quite good insulators. How can this be?

In insulators the energy bands lying above a certain energy are completely empty. Obviously, no electric current can flow as the result of an empty energy band. It turns out to be equally true that no current can flow as the result of a completely filled energy band since there is an electron going to the right for every electron going to the left. (If a very strong electric field were applied to the material, an electron might jump from the highest filled band to the lowest empty band and so become free to move.)

In conductors such as pure metals, a particular conduction band is only partially filled with electrons. In lithium, for example, there is only one valence electron per atom, so the lowest band is only half-full; the crystal should therefore be a conductor. [In the case of diamond, which is an insulator, there are 4 valence electrons per atom.]

When an electric field is applied to a conductor, some electrons going one way can transfer to slightly higher empty energy levels and travel in the other direction. Since more electrons will be traveling in one direction than in the other, an electric field can cause a net electric current to flow.

Metals are good conductors. Some substances obdurately remain insulators. A third class of materials, called semiconductors, *can conduct electricity when they contain certain impurities in very minute quantities. Silicon and germanium are semiconductors. The presence of small amounts of elements such as phosphorus, antimony, and arsenic, adds electrons to the empty bands. When there is no electric field applied, these electrons settle down four to a level, two traveling to the right and two to the left*[726]*. But if a small electric field is applied so as to force electrons towards the right (left), some electrons which initially were traveling to the left (right) jump into vacant levels of a shade higher energy and travel to the right (left).*

Another group of substances, including boron and gallium, also make semiconductors. They take away *electrons from a filled energy band, leaving the band in an "almost filled" condition. When an electric field is applied, some electrons traveling against the field will jump to vacant levels and travel in the direction in which the electric field urges them to go. When the mathematics of the "almost filled"energy band is worked out, it shows a behavior exactly like that we would expect from* positive charges *(= absence of negative charge) traveling through the crystal. Experiments confirms this mathematical picture.*

Thus, there is a real reason to think of the conduction in this "acceptor" type of semiconductors as due to holes *in the "almost filled" band — holes that act as free positive charges would act. The effective mass of holes is found to differ from that of electrons.*

Materials such as phosphorus, antimony, or arsenic, are called n-type *impurities or* donors *because of the negative electrons they add. Materials such as boron or gallium, removing electrons from filled bands and create holes that behave like positive charges and are free to move, are called* p-type *impurities, or* acceptors.

Electrons will normally enter the conduction band either by thermal agitation, or excitation via external bombardment by particles or radiation. The energy gap between the valence and conduction bands in semiconductors is no more than about 1 eV [1.14 eV for silicon and 0.67 eV for germanium]. Although the value of the Fermi distribution function (governing the relative population of an energy states in the conduction and valence bands) is small (since $kT \simeq 0.025$ *eV at room temperature), the number of available states in the conduction band is high. Hence the thermal excitation from the valence band into the conduction band occurs for a significant number of electrons,*

726 In the three-dimensional case, there is an almost continuous *shell* of electron momenta vectors sharing a single given energy (per given spin). This shell is spherical for isotropic lattices.

this number being the product of the mean number of electrons per quantum state and the number of quantum states per relevant energy interval.

Furthermore, the conductivity of a semiconductor increases rapidly with temperature; the number of excited electrons in silicon, for example, increases by a factor of about 10^9 *with a doubling of temperature from* $300\,^\circ K$ *to* $600\,^\circ K$. *Thus a semiconductor can be defined as a non-metallic covalent substance which possesses measurable conductivities, dependent upon the temperature and impurity levels.*

Photovoltaic (PV) cells — tapping solar energy (1839–1999 CE)

Introduction

The sun's energy is vital to life on earth, It determines the Earth's surface temperature and supplies virtually all the energy that drives natural global systems and cycles. Although some other stars are enormous sources of energy in the form of X-rays and radio signals, our sun releases 95% of its energy as visible light. Yet, visible light represents only a fraction of the total radiation spectrum; infrared and ultraviolet rays are also significant parts of the solar spectrum.

The sun emits virtually all of its radiation energy in a spectrum of wavelengths that range from about 2×10^{-7} *to* 4×10^{-6} m. *The majority of this energy is in the visible region. Each wavelength corresponds to a frequency and an energy; the shorter the wavelength, the higher the frequency and the greater the energy (expressed in eV, or electron volts).*

Photovoltaic cells convert light energy into electricity at the atomic level, *bypassing thermodynamic cycles and mechanical generators. Although first discovered in 1839, the process of producing electric current in a solid material with the aid of sunlight wasn't truly understood for more than a hundred years. Throughout the second half of the 20th century, the science has been refined and the process has been more fully explained. As a result, the declining cost of these devices has put them into the mainstream of modern energy producers. This was caused in part by advances in the technology, where PV* conversion coefficients *have improved considerably.*

*Most commonly known as "*solar cells*", PV systems are already an important part of our lives. The simplest systems power many of the small calculators and wrist watches we use every day. More complicated systems provide electricity for pumping water, power communication equipment, heat our kitchen and bathroom waters, and even light our homes and run our appliances. In a surprising number of cases, PV power is the cheapest form of electricity for performing these tasks.*

Today, solar cells power virtually all satellites, *including those used for communications, navigation, defense, and scientific research. The* computer *industry, especially transistor semiconductor technology, also contributed to the development of PV cells. Transistor and PV cells are made from* similar materials *and operate on the basis of similar physical mechanisms. As a result, advances in transistor research provide a steady flow of new innovations in PV cell technology.*

Photovoltaic cells are an up and coming alternative energy source. In the 1950s, when oil was thought to be able to last the world forever, scientists at NASA began researching and developing photovoltaic cells for use in space exploration. Power systems applications for earth were not explored until the 1970s, during the oil crisis. At that time scientists also started researching other forms of power systems in a race to find an economical and clean alternative to coal – and oil – burning power plants.

The first person to observe the photovoltaic effect was **Edmund Becquerel***, a French physicist, in 1839. As time progressed, so did interest in this newly discovered phenomenon. In the 1880's photovoltaic cells built from selenium were used to convert light into electricity, with a very poor efficiency of about 1% to 2%.*

The next remarkable development to affect photovoltaic technology was the invention of techniques to produce highly pure crystalline silicon (Bell Telephone Laboratories, 1954). Since then, other scientists have investigated the properties of crystalline silicon and have used it to make photovoltaic cells with acceptable efficiency levels. Early applications involved powering radio systems on orbital satellites.

The benefits of solar energy speak for themselves. It has been estimated that the solar energy available to be generated from the sun is nearly 10,000 times more than the total energy consumption of the world.

Advantages of photovoltaics also include:

- *Low maintenance*
- *No moving parts*
- *High mobility*
- *Effective for a variety of applications*
- *Environmentally friendly*
- *Working life of 20 to 30 years*

The use of silicon crystals in Photovoltaic cells makes them expensive. First of all, silicon crystals are currently assembled manually. Secondly, silicon purification is difficult and a lot of silicon is wasted. In addition, the operation of silicon cells require a cooling system, because performance degrades at high temperatures.

Research is underway for new fabrication techniques, such as those used for microchips. Alternative materials like cadmium sulfide and gallium arsenide are at an experimental stage.

Underlying Physical Mechanisms

Free electrons can be generated near surfaces (of metals, insulators and semiconductors) by four processes:

- *The interaction of photons with matter may cause* photon absorption *or scattering by either of three mechanisms: internal photoelectric effect, Compton effect and electron-positron pair production.*

In all three cases, an electron *is moving after the effect, so the moving electron can be used to detect the photon. At low energies the* photoelectric effect *is very strong, but its probability drops off rapidly at high energies. As photons increase in energy and momentum, the* Compton effect *becomes more important in scattering them out of the beam. Pair production does not begin until* 1.022 MeV, *but it becomes more and more effective after that. In toto, the transmitted intensity* I *is related to the incident intensity* I_0 *along an axis* x, *via the experimental absorption law* $I = I_0 e^{-\mu x}$, *where*

$$\mu = \mu_{\text{photoelectric}} + \mu_{\text{Compton}} + \mu_{\text{pair production}}.$$

The light absorbed in a semiconductor increases the total free carrier concentration and causes the transport of electrons from the valence band into the conduction band. The electron-hole pairs thereby generated are free quasi-particles and can take part in the semiconductor's conductivity [phototubes, photodiodes, photocathodes].

- *Secondary electron emission: If electrons impinge upon the surface of a solid, a certain fraction is reflected, whereas the rest penetrate into the solid and may cause emission of secondary electrons. This phenomenon is common to metals, semiconductors and insulators.*

- *Field-aided emission* by applying an electric field to the surface.

- *Thermionic emission:* heating the surface until some electrons have enough energy to escape the potential barrier [thermionic diodes].

Photoconductivity is the increase of conductivity due to a photon absorption, or otherwise stated — the decrease in electrical resistance when exposed to light. The effect is particularly strong in selenium, in metal sulfides, oxides and halides, as well as in germanium and silicon. The release of valence electrons by photoabsorption is called *internal photoelectric effect*, in contrast to the *external photoelectric effect*, which is the release of electrons from *metal surfaces* (Einstein 1905). The production of conducting electrons and holes by photoabsorption is possible in all insulator or semiconductor crystals. The majority of the good and practically important photoconductors, however, are semiconductors. Electronic semiconductivity, photoconductivity, and phosphorescence are three closely related crystal phenomena.

The application of an external electric field to the material results in the transport of both electrons and holes through the material and the consequent production of an electric current in the electrical circuit of the detector.

A *photoelectric cell* is a device that converts light into electricity. Two main types of photoelectric cell are in use today: the phototube and the solid-state photodetector.

The *phototube* is an electron tube in which electrons, initiating an electric current, originate through photoelectric emission. In its simplest form the phototube is composed of a cathode coated with a photosensitive material (known as a *photocathode*), and an anode. Light falling upon the cathode causes the liberation of electrons, which are then attracted to the positively charged anode, resulting in a flow of electrons (i.e., current) proportional to the intensity of the light. Phototubes may be highly evacuated, or filled with an inert gas at low pressure to achieve greater sensitivity.

In a modification called the multiplier phototube, or *photomultiplier*, a series of metal plates are shaped and arranged so that the photoelectric emission is amplified by secondary electron emission. The multiplier phototube is capable of detecting ionizing radiation of extremely low intensity; it is an essential tool for nuclear and particle research, astronomy, and space guidance systems.

Another important application is the *image converter:* The image of an object which emits only infrared or X-ray radiation is projected onto an infrared- or X-ray sensitive layer (photo-cathode). According to the varying intensity of the incident radiation, a varying number of electrons are emitted from the *photo-cathode. These electrons are electrically accelerated and concentrated on a fluorescent screen by means of electron optics. There, the electronic image excites fluorescence and thus creates a visible image of the infrared or X-ray object.*

The second type of photoelectric cell, the solid-state photodetector, has replaced the phototube for many applications because it is small, inexpensive, and uses little power. The simplest type of solid-state photodetector is the photoconductor — a semiconductor whose resistance changes when it is exposed to light — that is, to a flow of photons.

More stable and precise than a simple photoconductor is the photodiode: it is made by joining together an n-type and p-type semiconductors. In practice, the two types are often single silicon crystals doped with donor impurities on one side and acceptor impurities on the other. The region in which the semiconductor changes from p-type to an n-type is called a junction. The initial concentrations of electrons and holes on opposite sides of the junction results in the diffusion of electrons across the junction from the n-side to the p-side and of holes in the opposite direction, until equilibrium is established. The result of this diffusion is a net transport of positive charge from the p-side to the n-side.

Unlike the case when two different metals are in contact, the electrons cannot travel very far from the junction region because the semiconductor is not a particularly good conductor. The diffusion of electrons and holes therefore creates a double layer of charge at the junction similar to that of a parallel-plate capacitor. There is thus a potential difference across the junction which tends to inhibit further diffusion. In equilibrium, the n-side with its net positive charge will be at a higher potential than the p-side with its net negative charge. In the junction region, there will be very few charge carriers of either type, so the junction region has a high resistance. The junction region is also called the depletion region because it has been depleted of charge carriers.

A semiconductor with a p-n junction can be used as a simple diode rectifier. When an external potential difference is applied across the junction (by connecting a battery and a resistor to the semiconductor) such that the positive terminal of the battery is connected to the p-side of the junction, the diode is said to be forward biased. Forward biasing lowers the potential across the junction, thus enhancing the diffusion of electrons and holes as they attempt to reestablish equilibrium, resulting in current in the circuit.

If the positive terminal of the battery is connected to the n-side of the junction the diode is said to be reverse biased. This tend to increase the potential difference across the junction, thereby further inhibiting diffusion. Essentially, the junction conducts only in one direction, similar to a vacuum-tube diode.

In a photodiode, in the absence of illumination, a negligible dark current flows through the junction. When the p-n junction is illuminated, excess carriers are generated and the current rises in proportion to the light intensity, causing a voltage drop across the load resistor. Photodiodes are used as an electric eye in operating burglar alarms, traffic-light controls, and door openers. A light source (which may be infrared and invisible to the human eye) at one end of the circuit falls on the photocell located some distant away. Interrupting the beam of light breaks the circuit. This in turn actuates a relay, which energizes the burglar alarm or other circuit. Other common uses for photoconductors include light switching and dimming, and light meters for cameras.

It is observed that as the reverse bias is increased and reaches an extreme value, the current suddenly increases. In such large electric fields, electrons are stripped from their atomic bonds and accelerated across the junction. These electrons, in turn, cause others to break loose. This effect is called avalanche breakdown. Although such a breakdown can be disastrous in a circuit where it is not intended, the fact that it occurs at a sharp voltage value makes it of use as a voltage regulator known as a Zenner diode.

"Avalanche" diodes are used to amplify the signal from a light source. In these devices, a large reverse voltage is applied so that a photon-created electron in the conduction band gains enough energy to bounce against atoms in the semiconductor and thus liberate additional electrons. A large current is therefore produced when light strikes the diode. Phototransistors are also used to amplify light signals. Their construction is similar to conventional transistors except that one of the transistor's junctions is exposed to radiation. In bipolar phototransistors, it is the base-emitter junction that is exposed to radiation; in field-effect phototransistors it is the gate junction.

A solar cell (solar battery) *is a photodiode working under conditions of forward bias and converts radiant energy directly into electrical energy. It consists of a thin layer of p-type silicon on an n-type silicon base. The n- and p-regions are heavily doped so that the resistance of the cell is small. There is an optimum thickness of the p-region* (≈ 0.025 mm) *so that as much as possible light is absorbed near the junction. When a photon is absorbed in the p- or n-region, it can create a hole-electron pair. Usually the hole and electron quickly recombine, but in a solar cell the internal electric field in the depletion layer at the p-n junction (directed from the n-side to the p-side) can separate the hole and electron before they have a chance to recombine.*

The separation of the carriers produces a forward voltage across the barrier (forward, because the electric field of the photoexcited carriers is opposite the built-in field of the junction). The appearance of a forward voltage across the illuminated junction is called the photovoltaic effect.

Thus, the two sandwiched semiconductors function as a battery, creating an electric voltage at the surface where they meet (junction). It is this field that causes the carriers to move from the semiconductor bulk toward the surfaces and makes them available for the external electrical circuit. The application of an external voltage and a local resistance in series with the junction makes the charge carriers do work which has come directly from the energy of the incident radiation.

The light-emitting diode *(LED; or luminescent diode) is the reverse of a solar cell: the passage of a* forward *current through the p-n junction involves minority carrier injection of electrons into the p-region and holes into the n-region. The injected carriers recombine with the majority carriers of the respective region, their intensity decreasing with the distance from the p-n junction. In many semiconductors the recombination is nonradiative, i.e. the energy liberated in the recombination process is absorbed by the crystal lattice, that is, turns eventually into* heat. *However, in such semiconductors as* SiC, GaAs, InAs, GaP *and* InSb *the recombination is* radiative: *the energy of recombination is liberated in the form of photons. Because of that, a forward current flowing through the p-n junction made of such materials is accompanied by the emission of light from the junction region. LED are used in displays, and in flash lights.*

A special type of photodetector is the Charge-coupled device *(CCD). It contains an array of light detectors, each registering variations of light intensity as small changes of voltage. The unit has the form of a small capacitor, composed of metal oxide and semiconductor layers, capable of both photodetection and* memory storage. *When the subtle change of voltage (created by the photoconductive electrons) is applied to the metal layer (called the 'gate'), electron-hole pairs created in the semiconductor are separated and the electrons become trapped in the region under the gate. This trapped charge represents a small piece of a digital image known as a* pixel *(picture element). The complete image can be recreated by reading out a sequence of pixels from an array of CCD's.*

Modern computer systems incorporate auxiliary optoelectronic devices in their scanning *and* printing *peripherals. Consider, for example, the principles of operation of a scanner: As one presses the "scan" button on a typical hand-held scanner, a* light-emitting diode *(LED) illuminates the image beneath the scanner. An inverted, angled* mirror *directly above the scanner's window reflects the image onto a* lens *at the back of the scanner.*

The lens focuses a single line of the image into a charge-coupled device *(CCD), which is a component designed to detect minute changes of voltage. The CCD contains a row of light detectors. As the light shine onto these detectors, each registers the local amount of light as a voltage level that* *corresponds to a grey-scale value (black/white or color components). The voltages generated by the CCD are then sent to a specialized chip for gamma correction, a process that enhances the black tones in an image so that the eye, which is more sensitive to dark tones than to light ones, will have an easier time recognizing the image (with some scanners, gamma correction is performed as a software process).*

The single line of the image now passes to an analog-to-digital converter (ADC). In a grayscale scanner, the converter assigns 8 *bits to each pixel, which translates into* $2^8 = 256$ *levels of gray in the final digitized image. The A-D converter on a monochrome scanner registers only* 1 *bit per pixel (either on or off), representing, respectively, black or white.*

As the operator's hand moves the scanner, a hard rubber roller (the main purpose of which is to keep the scanner's path straight) also turns a series of gears that rotate the slotted disc. As the disc turns, a light shines through the slits and is detected by a photomicrosensor on the other side of the disc. Light striking the sensor throws a switch that sends a signal to the ADC converter. The signal tells the converter to send the line of bits generated by the converter to the PC. The converter clears itself of the data, and is ready to receive a new stream of voltages from the next line of the image.

Timeline

1839 **Edmund Becquerel** (France) discovered the *photovoltaic effect*: he observed that shining light on an electrode in an electrolytic cell increased the generation of electric current between the metal electrodes. His discovery, however, remained a curiosity of science for the next 65 years.

1873 **Louis May** and **Willoughby Smith** (England) discovered the *photoconductivity of selenium*.

1876 **W.G. Adams** and **R.E. Day** observed the *photovoltaic effect* in solid selenium.

1883–6 **Charles Fritts** (USA) described and developed the first *solar cells* made from selenium wafers. Fritts envisioned that solar cells may one day compete with the large electrical generating plants (which were just then being established in the United States), since solar cells were compact, self-sustaining and their fuel, solar energy, is both without limit, and without cost.

The fledgling solar cell industry of the 19th century, however, never developed as Fritts predicted. Most engineers at the time felt that Fritts' experiments violated the principle of conservation of energy. This bias within inside the engineering community inhibited any serious large scale research and development.

Fritts and other solar cell experimenters of the period *could not formulate a theoretical defense* against their colleagues' objections; they simply knew that these cells worked. Why they worked (i.e., the photovoltaic effect), however, could not be adequately explained by 19th century classical physics.

Researchers in photovoltaics were to remain the black sheep of the scientific community until *quantum mechanics* (which explained how solar cells worked) won general acceptance among scientists and engineers.

1887 **Heinrich Hertz** (Germany) discovered that ultraviolet light altered the lowest voltage capable of causing a spark to jump between two metal electrodes.

Selenium PV cells were adopted in the emerging field of *photography* for use in *light* measuring devices.

1890–1900 *The photoelectric effect*: By the year 1890 it was well-known that an isolated polished metal surface becomes positively charged when illuminated with ultraviolet light (UV). Presumably, the UV light somehow removed negative charges from the surface, leaving it with positive charge. This phenomena was named the *photoelectric effect*. **Lenard** (1900) showed that the ejected negative charge consists of *electrons* (discovered by J.J. Thompson in 1897).

1904 **Wilhelm Hallwachs** (Germany) discovered that a combination of copper and cuprous oxide was photosensitive.

1905 **Albert Einstein** explained the *photoelectric effect* in the framework of quantum physics.

1910 **Richard Willstätter** worked out the structure of *chlorophyll* ($C_{55}H_{72}MgN_4O_5$). It is the substance of plant leaves which, during *photosynthesis*, catalyzes the formation of carbohydrates from atmospheric CO_2 and H_2O through the action of *sunlight*, thus converting light into chemical energy — a living *solar cell*[727].

---

[727] *Photosynthesis* is a process by which the energy of sunlight is used to form molecules such as glucose from CO_2 and H_2O:

$$\text{energy } + 6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6 + 6O_2$$

Because this reaction produces O_2, a supply of oxygen built up in the atmosphere. This oxygen supply allowed primordial organisms to run the above reaction backwards (in which direction it proceeds *spontaneously*!) and oxidize the carbohydrates they devoured in order to obtain energy:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{ energy}$$

Those organisms who used the solar energy to change simple molecules into more complex ones are the ancestors of modern *plants*; those who ate carbohydrates and burned them to obtain energy are the ancestors of modern animals. As life evolved, it moved away from the above simple type of *organic chemistry* toward a more complex type of chemistry called *biochemistry*, in which highly specialized and complex molecules were "invented" by evolution to catalyze reactions, store and convert energy, build tissues, regulate structures and *heredity*; chlorophyll is an example of such an invented complex molecule.

The history of life also includes "inventions" in biological counterparts to fluid dynamics, material science, electrochemistry, mechanical engineering, "computer science", acoustics, quantum optics and nanotechnology.

1916 **Jan Czochralski** (1885–1953, Poland) developed a method for growing single crystal metal needles. In 1952, scientists at Bell Laboratories depended on Czochralski process to develop the first *crystalline silicon photovoltaic cell*.

1931 **Thomas J. Rhamstine** (1893–1975, USA) was first to use photovoltaic cell in *photography*, with the aim of measuring the luminosity of the object to be photographed and adapting the time of exposure and the aperture of the lens to the sensitivity of the film.

1933–1952 **Clarence M. Zenner** (1907–1993, USA) explained electrical breakdown in insulators in terms of the quantum-mechanical *tunneling effect*. Invented the *Zenner diode* voltage regulator to protect dc output from both rapid variations in supply input voltage and variation in load resistance. To avoid breakdown damage, a rectifying diode is connected with the load resistance. In the Zenner breakdown voltage regime, small changes in diode voltage are accompanied by large changes in diode current, producing voltages that compensate for changes in the voltage input and load resistance.

After the invention of the transistor, rectifying *p*-*n* junction diodes were used as Zenner diodes. Here a small increase in the reverse voltage in the breakdown range causes a substantial increase in the reverse current. Consequently, the voltage across the load resistance remains practically constant. Zenner's *avalanche breakdown mechanism* is the basis of *avalanche diodes* used for *light amplification* devices.

1938 **Chester Carlson** (USA) invented *electrophotography* or *xerography*, a method of photocopying utilizing the internal photoeffect in semiconductors.

A thin film of *high resistivity metal oxide* (usually ZnO) is deposited on a sheet of paper. Before the photographic process, the film is negatively charged by a gas discharge. When the image to be photographed is optically projected onto such paper, the surface charges from the *illuminated parts* leaks through the film much more readily than from the non-illuminated parts, and accordingly, an electric image of the object remains on paper after the exposition. To *develop* the electrical image, the paper is sprayed by a weak spray of special dry paint, or "toner". The particles of the toner are deposited on the negatively charged parts of the paper, thus *developing the image*. The image is *fixed* by heating the paper to the temperature at which the toner particles melt and adhere firmly to the paper.

The main advantage of electrophotography over normal photography is the exclusion of *chemical* development and fixation processes. This makes it possible to *increase the speed* of photographic processes drastically, reducing the necessary time to about a few seconds. However, electrophotography is as yet inferior to normal photography in accuracy and resolution.

1941 **Russell Ohl** (USA) invented a *silicon solar cell*. Its efficiency is about 1%.

1947–8 Invention of the *transistor* at the Bell Laboratories (USA) by **John Bardeen** (1908–1991), **Walter Houser Brattain** (1902–1987) and **William Bradford Shockley** (1910–1989).

1948–1956 The basic theory of the internal photoelectric effect, photoconductivity, semiconductor-metal junctions and photovoltaic cells, was developed in the framework of *semiconductor physics* by **Nevill Francis Mott** (1905–1996, England) and **Walter Hans Schottky** (1886–1976, Switzerland). In particular, Schottky discovered that aluminum in contact with an n-type material creates a *rectifying contact*, known as the *Schottky barrier diode*. Since in the Al-n diode there are only majority carriers (electrons in the n-region), *switching* is very fast because there is no wait for the recombination of injected minority carriers (holes in the n-region). Such diodes have switching times of the order of 10^{-11} sec. This makes them useful in radioelectronic pulsed circuits, and in computer and automation circuits where there is a need for high operational speeds.

The contact of aluminum with a p-type material creates an anti-barrier metal-semiconductor junction used to provide *ohmic contact* by means of which a semiconductor device is connected into an electric circuit (flow of hole current is easily accomplished by recombination with electrons supplied by the external circuit).

1952 **Gerald Pearson** (USA) invented the *alloy-junction diode*, thereby creating a *p*-*n* junction with controlled characteristics. First to discover the Zenner breakdown in semiconductors.

1952 Bell Lab engineers **G.K. Teal** and **J.B. Little** adopted the **Czochralski** process for producing *highly pure germanium single crystals*.

1954 **Paul Rappaport**, **J.L. Loferski** and **Dietrich A. Jenny** (RCA, USA) reported the PV effect in the element *Cadmium*.

Darryl Chapin, **Carl Fuller** and **Gerald Pearson** (Bell Labs, US) developed the first crystalline silicon photovoltaic cell. They refined the silicon solar cell, raising its efficiency to 6%, and then to 15%. This ushers an age of new solid state technology that pervades our lives today. The foundations have been laid for an industry of high-efficiency solar cells.

1958 The *space race* spurred improvement in solar cell design and efficiency. The U.S. Vanguard space satellite carried a small array of PV cells to power its radio. However, the drive to make space-grade qualified solar cells efficient and lightweight led to high costs, making them uneconomical for terrestrial applications where low price is the main concern.

With electricity, natural gas and oil being so cheap, U.S. government hesitated to promote the development of cheaper and more efficient cells; only few sensed the need for alternative energy sources.

1958–1974 The American space program created and sustained a solar cell industry; solar cells have powered every U.S. satellite from the first Vanguard to Skylab.

1959 *Explorer 6* was launched with a PV array of 9600 cells, each only of 1 cm $\times$ 2 cm.

1960 Hoffman Electronics achieved 14% efficiency in PV cells.

1962 Development of the *semiconductor laser*. It operates much the same way as the LED, except that the transitions are stimulated instead of spontaneous; *p*-*n* boundary layers between highly doped *p*- and *n*-regions (e.g. GaAs) are used. If a voltage of a few volts is applied for short periods in such a way that the *n*-type region's conduction electrons are lifted in energy and flow into the conduction band of the p-type region, its occupation by electrons can become higher than that of the p-type valence band (with a corresponding inversion occurring in the n-type region due to hole injection from the p-type side).

This process is called *electric pumping*[728]. Beyond a critical current density of this electron flow from the n-type region to the p-type region, induced transitions from the conduction band to the valence band of the p-type region are possible with emission of recombination radiation, since the electrons from the conduction band recombine with the positive holes of the valence band. Such an *injection laser* may consist of a tiny GaAs cube with a planar *pn* junction; Two parallel end faces of this cube carry electrodes for applying the pumping voltage, whereas two perpendicular end faces are polished so that they partly reflect, partly transmit the emitted radiation.

The photons of the recombination radiation are then partly reflected from these end faces back into the crystal where they induce further transitions until a narrow bandwidth, highly collinear intense light beam finally leaves the LASER. The efficiency of this transformation of electric energy into light is extremely high. Theoretically, it might approach 100% if incidental losses are neglected.

Semiconductor laser have evolved (1962–2004) into highly complex marvels of material science and opto-electronic engineering, involving engineering alloy crystal lattices, quantum effects, built-in optical cavities and optical feedback, thermo-electric cooling, advanced electrooptic modulation techniques, and molecular deposition manufacturing technologies.

Infra-red laser chips — with optical fibers running through them — are commonly used in the optical communication industry.

1963 Japan installed a 242 W PV array on a lighthouse.

1964 The *Nimbus* spacecraft was launched with a 470 W PV array.

[728] Other pumping mechanisms used in lasers are *chemical* and *optical* pumping.

1965 Invention of the *light-emitting diode* (LED), the inverse of the solar cell: electrical energy is fed into it to produce light energy. It is essentially a *pn*-junction semiconductor with a large *forward bias*, producing a large excess concentration of electrons that move to the p side and holes that moved to the n side of the junction. There they undergo radiative recombination and light is emitted. Since $E = h\nu$, we can obtain different frequencies of light by varying the energy difference through which the electron falls. We can vary the energy difference by using materials with different (even engineered) energy gaps, or cause the transition to be made to defect states within the forbidden energy gap.

Using different dopants and alloys, we can then obtain different light frequencies. LEDs are commonly used as displays for digital watches and calculators and in scanners; at higher luminosities they are used as everyday efficient light sources. The emitted radiation may be either invisible (infrared) or in the visible spectrum. Visible solid state lamps are used for long life indicator service. Infrared diodes have outputs carefully matched to silicon photoreceivers. They are used in conjunction with the receivers, for counting, sensing, and positioning applications. LEDs generally operate in the range of 1 to 3 volts at currents of 10 to 100 milliamperes. Their light output is not coherent as that of semiconductor lasers, yet it is nonetheless relatively monochromatic, collimated and bright.

1966 The Orbiting Astronomical Observatory was launched with a 1-kW PV array.

1968 The OVI-13 satellite was launched with two CdS panels.

1969–1990 *Carged-coupled device* (CCD) was first demonstrated at Bell Labs (1969), a *solid-state chip* which transforms light into electricity. Arrays of CCD's are used to capture images in video and digital cameras.

1975–1999 Rising energy costs, sparked by a worldwide oil crisis, renewed interest in making PV technology more affordable. Since 1975 the U.S. federal government, industry, and research organizations have invested billions of dollars in research, development, and production.

1979 NASA completed a 3.5 kW PV system in Arizona — the world's first village PV system.

1980 A 105.6 kW PV system established in Utah.

1982 A 1-MW plant was established in California.

1983 Worldwide PV production sales exceed 250 million dollars.

1995 Price of photovoltaics dropped from 200 dollars/Watt during the space program to 10 dollars/Watt or less.

1999 Commercial PV systems can convert from 7% to 17% of sunlight into electricity. They are highly reliable and last 20 years or more. The cost of PV-generated electricity has dropped 15–20 fold; PV modules cost about 6 dollars per Watt and produce electricity for as little as 25–50 cents per kWh.

The Plateau Problem — soap films and minimal surfaces

The theory of minimal surfaces *was initiated by* ***Lagrange*** *as an application of his studies in the calculus of variations (1760–1761).* ***Monge***, ***Meusnier***, ***Legendre***, ***Bonnet***, ***Riemann*** *and* ***Lie*** *contributed to the theory in the framework of differential geometry. It was Meusnier who discovered in* 1776 *the second* elementary *minimal surface, the right helicoid (the first one, the catenoid, which is the only curved minimal surface of revolution, was discovered by Euler in 1744).* ***Karl Weierstrass*** *(1866)* and ***H.A. Schwarz*** *developed the relationship between the theory of complex analytic functions and the real minimal surfaces.*

In the theory of capillarity the importance of minimal surfaces of least potential surface energy was demonstrated by the experiments of ***Plateau*** *(1873), who dipped a wire in the form of a closed space curve into a soap* *solution. Owing to the action of surface tension, a film of liquid is in stable equilibrium only if its area is a minimum. Plateau raised the mathematical question: can every closed curve in space be spanned by at least one minimal surface? This mathematical question became known as the Plateau problem. Many famous mathematicians of the* 19^{th} *and* 20^{th} *centuries*[729] *were intrigued by this problem, but its solution appeared to be difficult.*

Although the soap film shape is the solution to the corresponding physical problem, pure mathematicians do not admit empirical evidence in lieu of proof of mathematical existence. For a long time, all efforts to prove even the existence of such a minimal surface for every preassigned boundary curve, were unsuccessful. It was only in 1930–1931 *that the existence of the solution for the general case was proved.*

In recent years the problem of minimal surfaces has been studied when not only one but any number of contours is prescribed, and when, in addition, the topological structure of the surface is more complicated. For example, the surface might be one sided (non-oriented) or of genus different from zero. These more general problems produce an amazing variety of geometrical phenomena that can be exhibited by soap film experiments.

Consider for example soap bubbles; we know that out of all solids of a given volume, the sphere has the smallest surface area. Physically, the stable equilibrium of the bubble indicates a state of minimal potential energy (Bernoulli's law of virtual work). However, a sphere is a figure of constant mean curvature, i.e. not a minimal surface in the sense of the Plateau problem. (Inside the bubble the pressure is higher than outside it and the pressure difference is related to the surface tension T *and mean curvature* H *via the Laplace equation* $p = TH$*.) Another example is a cylindrical soap bubble between two coaxial rings. Beyond a certain critical separation of the rings, the cylindrical film becomes unstable and will decompose into two separate spherical bubbles of different sizes.*

This phenomenon was discovered by Plateau. He also found that there are exactly six different kinds of surfaces of constant mean curvature which are also surfaces of revolution: the plane and the catenoid (mean curvature zero), the sphere, the cylinder, the unduloid and the noboid (mean curvature

---

[729] In the period 1975–1990, the number of published pages devoted to minimum surface type problems reached many thousands. One thus sees that the appeal of this problem to mathematicians has not diminished through the ages.

A relativistic Minkowski-space version of the problem turned out to be of some relevance to *String theories*; there, the surface represents the *world sheet* of an oscillating, fundamental string of typically Planck-scale sizes — the sheet being the 4-D locus of the *worldlines* of all points along the string.

nonzero). [Imagine the curve formed by one of the foci of the ellipse that rolls on a straight line. When this curve is rotated it generates the unduloid. The same setup with an hyperbola forms the noboid.]

The area of a surface $z = z(x, y)$ *over a region* D *of* $\mathbb{R}^2$ *spanned by a given contour, is determined by the double integral* $\iint_D \frac{dxdy}{\cos(\boldsymbol{n}, e_z)}$ *where* $\boldsymbol{n}$ *is the unit normal to the surface and* $\boldsymbol{e}_z$ *a unit vector in the direction of the* z *axis. Since* $\cos(\boldsymbol{n}, \boldsymbol{e}_z) = (1 + z_x^2 + z_y^2)^{-1/2}$, $z_x = \frac{\partial z}{\partial x}$, $z_y = \frac{\partial z}{\partial y}$, *the area functional is*

$$J[z] = \iint_D \sqrt{1 + z_x^2 + z_y^2}\, dx\, dy.$$

The Euler equation for the extremalization of a functional of a function of two independent variables, $J(z) = \iint_D F(z, z; z_x, z_y)\, dx\, dy$, *is*

$$\frac{\partial F}{\partial z} - \frac{\partial}{\partial x}\left(\frac{\partial F}{\partial z_x}\right) - \frac{\partial}{\partial y}\left(\frac{\partial F}{\partial z_y}\right) = 0.$$

For the case under discussion we want to find the surface of least area spanned by a given contour. Putting $F = (1 + z_x^2 + z_y^2)^{1/2}$ *in Euler's equation, we obtain the second-order* PDE,

$$Q = z_{xx}(1 + z_y^2) - 2z_{xy}z_xz_y + z_{yy}(1 + z_x^2) = 0.$$

This equation has a simple geometrical meaning since

$$H = \frac{1}{2}(\kappa_1 + \kappa_2) = \frac{Q}{F}$$

is the mean curvature *of the surface. This implies that the mean curvature of the required surface equals zero. Surfaces with zero mean curvature are called* minimal surfaces*. The* PDE $Q = 0$ *was discovered by* **Lagrange** *but* **Euler** *showed by a different method that every minimal surface, not part of a plane, must be saddle-shaped and that its mean curvature must be zero at every point.*

The mean curvature of a surface at a point is defined as follows: consider a normal vector to the surface at the point and a plane containing this normal. As this plane rotates *about the normal, the curvature,* κ*, of the curve defined by its intersection with the surface, varies. Half the sum of its principal values:* κ_1 *(minimum),* κ_2 *(maximum) is the mean curvature at the point. In general, the planes containing these extremal curvatures will be perpendicular to each other. The Gaussian curvature* $\kappa = \kappa_1\kappa_2$ *is obviously negative for a minimal surface.*

The nonlinear differential equation $Q = 0$, although it has been pursued with remarkable success, has proven to be both cumbersome and essentially inadequate. Surfaces are excluded if they cannot be globally represented by a function $z(x, y)$, while the geometrical minimum problem, formulated for arbitrary surfaces, in no way permits such a restriction. Thus it is advantageous to represent the minimal surface parametrically by a vector $\boldsymbol{r}(u, v)$ with components (x_1, x_2, x_3) which are themselves functions of the parameters u, v.

The area is expressed by the functional

$$A(\boldsymbol{r}) = \int\!\!\int_D w\, du\, dv$$

where

$$w = \sqrt{EG - F^2}, \quad E = \frac{\partial \boldsymbol{r}}{\partial u} \cdot \frac{\partial \boldsymbol{r}}{\partial u} = \sum_{k=1}^{3} \left(\frac{\partial x_k}{\partial u}\right)^2,$$

$$G = \frac{\partial \boldsymbol{r}}{\partial v} \cdot \frac{\partial \boldsymbol{r}}{\partial v} = \sum_{k=1}^{3} \left(\frac{\partial x_k}{\partial v}\right)^2, \quad F = \frac{\partial \boldsymbol{r}}{\partial u} \cdot \frac{\partial \boldsymbol{r}}{\partial v} = \sum_{k=1}^{3} \frac{\partial x_k}{\partial u} \cdot \frac{\partial x_k}{\partial v}$$

and D is the domain in the plane bounded by (u, v)-plane image of the closed Jordan curve γ that spans the minimal surface.

Euler's conditions for the functional w are a system *of differential equations*

$$\frac{\partial}{\partial u}\frac{\partial w}{\partial \alpha_k} + \frac{\partial}{\partial v}\frac{\partial w}{\partial \beta_k} = 0,$$

where $\alpha_k = \frac{\partial x_k}{\partial u}$, $\beta_k = \frac{\partial x_k}{\partial v}$, $k = 1, 2, 3$. These equations express again the fact that the mean curvature of the surface $\boldsymbol{r}(u, v)$ is zero.

Although the mathematical problem of proving the existence of a surface $\boldsymbol{r}(u, v)$ that solves the preceding differential equations and is bounded by a prescribed curve γ, has long defied mathematical analysis, the soap film experiments of Plateau have exhibited surfaces of stable equilibrium*, which corresponds to a* relative minimum area*.*

However, the general *Plateau problem can accommodate contours bounding* unstable *minimal surfaces, whose areas do not furnish relative minima.*

During the 19th century the Plateau problem was solved for many specific contours. Progress was made on the basis of one idea: taking advantage of the freedom of choice of the parameters u and v, one can simplify the nonlinear differential equations by introducing isometric parameters *u, v such that $F = 0$, $E = G = w$. The differential equation immediately becomes*

$\nabla^2 \boldsymbol{r} = 0$ *or* $\nabla^2 x_k = 0$ *and the corresponding surfaces are called Harmonic surfaces.*

Harmonic functions $x_k(u, v)$ *may be considered as real parts of analytic functions* $f(w) = x_k + i\widetilde{x}_k$ *of the complex variable* $w = u + iv$, *where* $\widetilde{x}_k$ *is the conjugate harmonic to* x_k. *It then follows from the Cauchy-Riemann relations that*

$$\phi(w) = \left(\frac{df_1}{dw}\right)^2 + \left(\frac{df_2}{dw}\right)^2 + \left(\frac{df_3}{dw}\right)^2$$
$$= \sum_{k=1}^{3} \left(\frac{\partial x_k}{\partial u} - i\frac{\partial x_k}{\partial v}\right)^2 = (E - G) - 2iF = 0.$$

This is known as the characteristic equation *of the minimal surface.*

As domain D for the variables u, v or for $w = u + iv$ *we may choose the disc* $u^2 + v^2 \leq 1$. *Plateau's problem is to solve the equation* $\nabla^2 \boldsymbol{r} = 0$ *for D under the additional conditions that* $\phi(w) = 0$ *and that* $\boldsymbol{r}$ *maps the boundary* $u^2 + v^2 = 1$ *onto the prescribed contour* γ. *After this simplification, the nonlinear character of the problem remains only in the boundary condition and in the condition* $\phi(w) = 0$.

A natural question that may be asked about a given contour is how many minimal surfaces can it bound? *It has long been known that planar curves bound only one minimal surface, a planar one. A second result was found (1932) by* ***Tibor Radó***[730] *(1895–1965, Hungary) who showed that if a contour has a simple projection onto a convex curve in a plane, then it can bound only one disc-type minimal surface. It was then shown that if a given contour has a* total curvature *of less than* 4π *(a circle of radius* 1 *has a total curvature of* 2π*), then there can be only one disc-type minimal surface bounded by that contour. If however, the total curvature of a curve is even slightly larger than* 4π, *then the curve can bound* infinitely many *disc-type minimal surfaces. An algebraic formula relating the minimal surfaces that span a fixed contour was derived by* ***Marston Morse*** *(1892–1977, USA) in 1936.*

---

[730] The disc version of the Plateau problem was solved simultaneously by **Jesse Douglas** (1897–1965, USA) and **Tibor Radó** in 1930–1931.

1931 CE **Georges de Rham** (1903–1990, Switzerland). Mathematician. A leading topologist of the 20th century. Known especially for his "*de Rham Theorem*".

de Rham was born in Roche, Canton Vaud, Switzerland. He was educated at the Universities of Lausanne (1921–1925) and Paris (Ph.D. 1921) and held positions at the Universities of Göttingen (1930–1931), Lausanne (1932–1971) and Geneva (1936–1973).

1931 CE, May 01 *Empire State Building* officially opened at 350 5th Avenue in New York City. The building has 102 stories and is 381 meters high. It was the world's tallest building until 1972.

It cost about 41 million dollars and houses about 10,000 tenants. The building's steel structure creaks slightly when heavy winds cause it to sway and during winds of 160 km/hour, it yields a maximal sway of 3.7 cm from center.

1931 CE, May **Auguste Piccard** (1884–1962, France). Physicist. Ascended in his airtight *gondola* [which he attached to a huge hydrogen-filled balloon] to a height of 15,880 meters, the first venture into the *stratosphere*. In 1932 he ascended 16,800 meters and gathered information on cosmic rays and radioactivity.

1931 CE, June The *Yellow River* (Huang-ho) in Honan Province, China, overflowed, causing the worst flood in recorded history: over two million people perished out of a total of 180 million affected by the flooding.

1931 CE, June **Wiley Post** and **Harold Gatty**. Americans; *circled the globe* by airplane in 8 days, 15 hours elapsed time. In 1933 Wiley Post, alone, circled the globe in 7 days, 18 hours.

1931–1933 CE **Karl Guthe Jansky** (1905–1950, U.S.A.). Radio engineer. Discovered the cosmic radio waves — a radio emission from the Milky Way.

Jansky was the first person to detect radio waves from outside the solar system. His discovery led to the development of *radio astronomy*[731] (a branch

[731] The first radio telescope was built in 1937 by **Grote Reber** (1911–2002, U.S.A. and Tasmania). This lone amateur was the only radio astronomer until 1946, when wartime research provided a separate stimulus. A great opportunity was lost during these years, for since then radio communications have grown so rapidly that the longer wavelengths are all but closed to radio astronomy by overwhelming man-made radio interference.

of astronomy that studies radio waves from stars and other celestial objects). In 1931 he was carrying out for Bell Laboratories a study of the noise level to be expected when a sensitive short-wave radio is used with a directional aerial system in long-distance communication. He wanted to track down the source of inexplicable noises that were interfering with radio transmission to ships at sea and across the Atlantic. He was expecting crackling noises from thunderstorms but he heard only steady hissing sound, quite different in character from the crackles of thunderstorms.

He then found that the noise level never decreased below a certain level and that the greatest signal always occurred when the aerial pointed in a certain direction in space, fixed relative to the stars and not relative to the earth or even the sun. After extensive study, Jansky determined that the noise came from the neighborhood of constellation Sagittarius, near the center of the Milky Way galaxy. Thus, as often happens in science, Jansky discovered something completely unexpected.

Had 1932 been a year of high sunspot activity, Jansky would undoubtedly have found the radiation from the sun for which Edison had looked in vain. As it was, the sun was quiescent, and instead the radio waves coming from our galaxy were discovered.

Most technicians probably would not have spent much time fretting over a peculiar hissing. It was so faint it hardly seemed of any consequence. But Jansky would not let the puzzle rest. A frail, dedicated young man who suffered from a chronic kidney disease, he examined every conceivable cause for the 'flaws' in the antenna: disturbances by nearby power lines, electrical storms or stray signals from radio transmitters in the vicinity. Nothing seemed to explain the noise.

It was not until the 1950s' that the Russian physicist and Nobel Laureate (2003) **V.L. Ginzburg**, worked out the theory of *synchrotron radiation*, which explains the observed radio spectrum. Synchrotron radiation results from electrons moving at speeds close to the speed of light in magnetic fields.

Reber was born in Chicago. He received the B.Sc degree from the Illinois Institute of Technology, Chicago (1933). In 1962 he received an honorary D.Sc. degree from the Ohio State University, Columbus. In 1963 he received an Eliot Cresson gold medal from Franklin Institute of Philadelphia, Pennsylvania.

In the 1950s, Reber sought a field that seemed neglected by most other researchers and turned his attention to cosmic radio waves at very low frequencies (1–2 MHz, or wavelength 150–300 meters). Waves of these frequencies cannot penetrate the Earth's ionosphere except in certain parts of the Earth at times of low solar activity. One such place is Tasmania, where Reber lived for many years. He died in Tasmania on December 20, 2002.

Our galaxy is full of high speed charged particles, including electrons, known as "cosmic rays". We now believe that these particles were blasted into interstellar space as a result of supernova explosions. This is the origin of most of the radio radiation from the Milky Way that Jansky and Reber measured.

Jansky was born in Norman, Oklahoma and graduated from the University of Wisconsin.

Chemical Bonds[732] *— from Kekulé to Pauling (1858–1939)*

Comparatively few substances (among them the noble gases and mercury vapor) are composed of discrete atoms. More commonly, atoms combine into larger aggregates: molecules (Cl_2, H_2O, CO_2, O_2, N_2, H_2, C_8H_{18}); *ionic solids* [Na^+Cl^-, $Ca^{++}(F^-)_2$]; *metallic solids* (Na, Cu, Fe); *and covalent crystals* (*giant molecules such as diamond or quartz*).

The fundamental problem of chemistry is — which kind of forces cause the binding of atoms, either like or unlike, in a molecule. One has to explain, for example, why is there H_2 *and no* H_3, *CO and* CO_2 *but no* CO_3, H_2SO_4 *and no HSO, etc. Any attempt to interpret the course of a chemical reaction, such as the decomposition of nitrogen dioxide,* $2NO_2 \rightarrow 2NO+O_2$, *must start with the intimate details of molecular structure. These include not only (in this example) the strength of the* $N—O$ *and* $O—O$ *bonds, but also the sizes and shapes of the molecules.*

To date, molecular geometry (bond lengths, bond angles), has been determined for thousands of molecules via a variety of techniques, including microwave spectroscopy and electron and X-ray diffraction[733]. *In principle, if*

[732] To dig deeper, see:

- Pauling, L., *General Chemistry*, Dover, 1988, 959 pp.

[733] The gas-phase electron diffraction was developed in Germany in 1930 by **G. Mark** and **R. Wierl.** They built the first electron diffraction unit and studied the structure of several dozen simple molecules. Further work carried out in the 1930's and 1940's revealed important patterns of molecular geometry.

we know the structure of a molecule, all other properties, such as its melting point, its boiling point, its viscosity as a liquid and as a gas, its hardness and malleability as a solid, its solubility in other substances, and its color, should be predictable.

Consequently, the physical and chemical properties of matter are related to the molecular structure of its component parts and can best be understood in terms of one of the most powerful and pervasive theories of science — the theory of the chemical bond, which finalized the development of the electronic theory of valence.

The theory of valence originated in the middle of the 19^{th} *century. With the rapid development of organic chemistry, there arose the need for a unifying structural theory of organic compounds. It was provided by* ***A.S. Couper*** *and* ***F.A. Kekulé*** *(1858). Working independently, they both concluded that carbon has a common valence of four, and that carbon atoms could link to form chains. This theory culminated more than half a century of spectacular advances in analytical and synthetical chemistry and was inextricably linked to the simultaneous development of a rational scale of atomic weights. The theoretical explanation of the periodic table was the first major achievement of atomic physics for chemistry (1869). The valence theory was subsequently given a 3-dimensional form by* ***J.H. van't Hoff*** *and* ***J.A. Le Bell*** *who showed independently (1874), that the 4-valence bonds of the carbon atom are directed toward the corners of a regular tetrahedron; it deserves to rank as one of the outstanding intellectual achievements of the* 19^{th} *century.*

Soon after the discovery of the electron by ***J.J. Thomson*** *(1897), efforts were made to develop a more detailed structural theory of valence; the general ideas of electron transfer and electron sharing were developed at this time, but detailed electronic structures could not be assigned with confidence because of the lack of knowledge of the number of electrons in an atom and lack of information about atomic structures in general.*

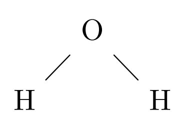
The determination of the atomic numbers of the element by ***H.G.J. Moseley*** *(1913) and the development of an early quantum theory of the atom by* ***N. Bohr*** *(1913), provided the basis for further progress. A most important contribution was made by* ***G.N. Lewis*** *(1916), who pointed out the significance of completed shells of 2 and 8 electrons. Lewis and* ***Irving Langmuir*** *(1919) identified the covalent bond with a pair of electrons shared by two atoms and jointly occupying an outer-shell orbital belonging to each atom.*

After the discovery of the theory of quantum mechanics (1925–1926), when ***E. Schrödinger*** *and* ***W. Heisenberg*** *were formulating the modern theory of the hydrogen atom, and* ***W. Pauli*** *was discovering his exclusion principle — a detailed quantitative theory of the covalent bond was developed. The* physical explanation of chemical bonds in homopolar molecules, achieved by the methods of quantum mechanics in 1927, completed the successful attempts at understanding the basic features of chemistry from the property of atoms and the matter-waves of electrons.

The chemical bond is the manifestation of the electrostatic interaction between charged units such as atoms and molecules; together with quantum effects. There is a binding force between atoms; consequently, there are polyatomic molecules in nature. Similarly, there is a binding force between molecules; consequently, there are inter-molecular forces and bonds, and aggregated states of matter. Were it not for chemical bonds, all matter would be gaseous and chemically inert, and compounds (let alone life) would not exist.

Clearly, the chemical bond must be something more specific than a simple attraction between atoms, or we would have to refer to all water in a glass as a single molecule, or to a table top as a single molecule. This specific property is really only one of degree, but generally if the attraction between two atoms is such that an energy of at least 10 kcal/mole at room temperature is required to break it, a chemical bond exists and that energy is called bond energy or dissociation energy.

The idea of a chemical bond is an important and logical hypothesis that is overwhelmingly supported by experimental evidence. The assumption that a molecule of many atoms is a structure connected by bonds, each joining two atoms, is an oversimplification, although it is usually justified. For example, consider the water molecule, H_2O. The chemist designates its structure by



where there is a single chemical bond between the oxygen atom and each of the hydrogen atoms. Yet there is no bond between the two hydrogen atoms.

In principle, the Schrödinger equation and the postulates of quantum mechanics are all that is required to calculate all properties of any molecule. In practice, however, the exact solution of the Schrödinger equation for complicated molecules has not been achieved; analytical and numerical approximations, coupled with experiments, are required to determine the structure and behavior of molecules. Although approximate methods of solution lead us to important conclusions, the theoretical predictions seldom have a precision as good as 10 percent. The difficulty is not in the theory; rather, it is a mathematical problem. Even for the hydrogen molecule, the difficulty of solving the fundamental equations of the theory is formidable, and tedious calculations *are required. For other molecules, the mathematical difficulties preclude an exact solution even with the aid of high-speed electronic computers.*

The major conclusions of quantum mechanical analysis are generally in agreement with the following experimental observations:

I. *Except in special cases, electrons constituting a bond are* localized *to the region of the bond and the two atoms it connects. Shifting of electrons between bonds can be important but is generally a second-order effect. The poor electrical conductivity of nonmetallic crystals such as diamond is an experimental demonstration of this fact. It is this* localization of electrons *that enables us to think of a chemical bond as something real.*

II. *Electrons in bonds are described by* molecular orbitals. *These orbitals are one-electron wave-functions that are approximated by* weighted sums of atomic orbitals *centered at the (two or more) atoms of interest. Such molecular orbitals are extremely useful in developing a descriptive picture of the nature of molecules. These sums, or* linear *combinations of atomic orbitals are merely approximations, not exact representations.*

Chemical bonds may be divided into two groups:

A. Intramolecular Bonds

From one point of view a molecule is a stable arrangement of a group of nuclei and electrons. The exact arrangement is determined by electromagnetic forces and the laws of quantum mechanics (Heisenberg's uncertainty principle, Pauli exclusion principle). This concept of a molecule is a natural extension of the concept of an atom.

Another view regards a molecule as a stable structure formed by the association of two or more atoms. In this view the atoms retain their identity. In general, the structure and properties of molecules are best described as a combination of both views.

When a molecule is formed from two atoms, the inner-shell electrons of each atom remain tightly bound to its nucleus and are barely disturbed at all. The outermost loosely bound electrons, however, are strongly disturbed *and are influenced by all the particles (ions + electrons) of the system. Their wave functions are significantly modified when the atoms are brought together. Indeed, it is this very interaction that leads to binding, i.e., to a* lower total *energy, when the nuclei or ions are close together. This bond, or interatomic force, is of electromagnetic (mainly electrostatic) origin.*

There are two principal types of intra-molecular binding, the ionic bond *and the* covalent bond*.*

I. IONIC BOND *is caused by the* Coulomb electrostatic attraction *between positively and negatively charged ions, and molecules thus bound can form ionic crystal lattice. Each ion in the crystalline compound has as its nearest neighbors, ions of the opposite sign; ions of the same sign are more distant from each other. The crystal is held together by the* relatively strong *electric attractions between the ions, the* electrovalent bond*. The cations and anions exist as discrete, not paired, units. The strength of the bond accounts for the high melting point, transparency, nonvolatility, hardness, brittleness and generally high stability of these substances.*

A typical example is common salt, $Na^{+}Cl^{-}$*. The sodium atom has lost its outer-shell electron (or valence electron) to the chlorine atom*[734]*. Since the sodium atom has now* 11 *protons and* 10 *electrons it became electropositive, while the chlorine atom now has* 17 *protons and* 18 *electrons, which makes it electronegative. Moreover, the electronic configuration of the* Na^{+} *ion is the same as that of an atom of neon, the noble gas preceding sodium; while the electronic configuration of the* Cl^{-} *ion is the same as that of an atom of argon, the noble gas following chlorine. In many such ionic compounds the atoms have the* stable electronic configuration *of noble gas atoms. Other examples are:* KBr, CaF_2, $AgCl$, $Ba(NO_3)_2$, $CaCO_3$*.*

Each ionic lattice *is characterized by two fundamental entities: plan of the elementary cell and the packing of the ions. Thus, in the NaCl crystal lattice, we have a* 3*-dimensional checker-board arrangement in which each sodium ion has* 6 *equivalent chlorine ions as nearest neighbors while each chlorine ion similarly has* 6 *equivalent sodium ions as nearest neighbors. The edge of the elementary cell, according to X-ray diffraction measurements, is* 5.64 Å*. It was also possible to determine that the chlorine ion is approximately* twice as large *as the sodium ion.*

Each ion in the lattice has ions of opposite charge as nearer neighbors and ions of like charge as more distant neighbors. The resultant effect is a net attractive electrostatic configuration*, with* inter-ionic forces *generally far stronger than the Van der Waals forces between neutral molecules containing comparable number of electrons. Consequently, ionic crystals, like covalent*

---

734 More accurately, the electron is *shared* but spends more time in the chlorine component of the superposition of single-atom orbitals.

crystals, are far more stable physically than molecular crystals having molecular weights of similar magnitude. Computations show that about 90 *percent of the total dissociation energy of NaCl (183 kcal/mole) is attributed solely to electrostatic potential energy of Coulomb forces between ions; the balance is attributed to Van der Waals interaction.*

II. Covalent bond *exists between two atoms that* share *an electron-pair, jointly occupying an outer-shell orbital belonging to both of them. The atoms in these molecules are held tightly together in a bond that is nearly universally present in substances. It is conveniently represented by a connective line or* valency bond *drawn between the two atoms. This device was introduced as early as* 1864 *by the Scottish chemist* ***Alexander Crum Brown*** *(1838–1922) long before* ***G.N. Lewis*** *interpreted each line as representing a shared pair of electrons (1919).*

The simplest example of a covalent molecule is the hydrogen molecule, in which the two electrons are held jointly *by the two nuclei, and enable a firm attachment between them. This strong bond holds the nuclei at an average distance of* 0.74 *Å apart (they oscillate with an amplitude of a few hundredths of an Ångström at room temperature). A large energy of* 103.4 *kcal/mol is required to break the bond.*

In general, stable molecules (or complex ions) having covalent bonds have structures such that each atom achieves a noble-gas electronic configuration or some other stable configuration, the shared electrons being counted for each of the bonded atoms. The exact solution of the SE, even for a molecule as simple as H_2*, is not feasible and several approximate methods are used instead.* The valence bond method *regards the molecule as made up of atoms, slightly distorted to produce a bond. It is consistent with the traditional chemical concept of* localized bonds *between atoms, a point of view supported by the additivity of bond lengths and bond moments.*

Another approximation, the molecular orbital method*, considers the molecule as a collection of nuclei and electrons, the individuality of the atoms having largely disappeared. The bonding electrons belong to the molecule as a whole and need not be regarded as localized between pairs of nuclei. The interpretation of molecular spectra, for example, does not require any assumptions about localized bonds. This scheme is backed up mathematically by the* Born-Oppenheimer approximation *(1927).*

A covalent bond serves as a basis to a covalent lattice *in which a network of covalent bonds extends in fixed patterns throughout a crystal to form* a single giant molecule*, such as* diamond*: the unit cell shows a cubic symmetry, each atom having* 4 *equivalent nearest neighbors, located at positions outlining* *the corners of a regular tetrahedron about it. Since the carbon atom has just 4 electrons and 4 vacancies in its valence shell, it seems clear that in diamond the atoms are bonded to each other by covalent chemical bonds. Since the diamond crystal shows exceptional physical stability and is one of the hardest solids known, it is logical to regard the entire crystal as a single, gigantic molecule. Silicon and germanium crystallize in the same manner. Other examples are SiC (carborundum), SiO_2 (quartz), BN (borazon).*

As distinguished from the ionic bond, the covalent bond is often directional. *The directional property is not present in the H_2 molecule since the probability density of the valence electron in each separated H atom is spherically symmetrical, so that the only defined direction in the H_2 molecule is the one connecting the two nuclei, and the covalent bond acts along that direction, whatever it may be. In a more typical case the probability of a valence electron* has its own directional dependence *and certain preferred directions for forming covalent bonds. The directional properties of covalent bonds are manifested in the structural properties of covalently bonded molecules, and so form the basis of organic chemistry.*

The bond energies *for single covalent bonds range (at 25° C) from about 30 to 135 kcal per mole [e.g., C—H (99); N—H (93); H—H (104); H—F (135); C—O (84); C—C (83)]. Double and triple bonds (with each* bonding electron pair *represented by a line) may be higher [e.g., C=C (147); C=O (174); C ≡ C (194); N ≡ N (226)].*

Metallic solids exhibit a binding that can be thought of as a limiting case of covalent bonding in which electrons are shared by all *ions in the crystal.*

III. METALLIC BOND *exist between positive metal ions and mobile valence electrons.*

Although copper and argon atoms crystallize in precisely the same geometric pattern — a close-packed cubic structure — their physical properties are entirely different. A typical metal, copper is opaque with a highly reflecting surface. It is an excellent conductor of both heat and electricity. Its melting point is rather high at 1083° C and the liquid boils at 2582° C. Argon crystals are transparent, resembling Dry Ice in appearance. They are poor conductors of heat and electricity. The crystals melt far below room temperature at −189.3° C, and the liquid boils at −185.9° C. The nature of the forces in the two systems must therefore be totally different.

Consider the metals silver and copper: these have one *valence electron per atom which is responsible for the bonds to* all *neighbors in the lattice. Now, most metals crystallize with an atomic arrangement in which each atom has surrounded itself with the maximum number of atoms that is geometrically* *possible (cubic closest-packed structure, hexagonal closest-packed structure, body-centered cubic structure, etc.). Thus, for a silver atom which is symmetrically surrounded by 12 nearest neighbors, only $\frac{1}{6}$ of one electron is responsible for the bond between two neighboring atoms, in contrast to the 2 full electron charges between each two carbon atoms in diamond.*

Quantum-mechanically, the wave-function describing the behavior of the valence electrons is approximated by a linear combination of the wave functions describing the 12 possible bonds to the 12 partners. This is as if one *"real" electron-pair rotates and successively form the individual bonds. What counts in the final analysis is only the* average electron density *between the atoms to be bound, due to the overlap of atomic orbitals. Therefore, the valence electrons occupy a partially filled bond of delocalized molecular orbitals with closely spaced energies. The relatively high concentration of shared valence electrons in the regions between neighboring nuclei is associated with a lowered electrostatic potential energy through screening of nuclear charges.*

The overall effect is not unlike a covalent bond, except that there are vacant molecular orbitals *at energies slightly above the highest occupied ones. The bonding electrons are therefore* comparatively mobile: *little energy is required for them to transfer from one atom to another throughout the crystal.*

The physical picture of metallic binding is thus a negatively charged free-electron gas permeating a structure of positive ion cores. Their mobility accounts for the high electric and heat conductivities of the metals. The metallic bond per pair of nearest neighbor atoms is not as strong as ionic or covalent bonds. Nevertheless, ordinary metals are quite strong because of the large number of nearest neighbors.

B. Intermolecular Bonds

Molecular solids consist of molecules which are so stable that they retain much of their individuality when brought in close proximity. The electrons in the molecule are all paired so that atoms in different *molecules cannot form covalent bonds with one another.*

One kind of intermolecular binding force is the weak Van der Waals attraction *that is present between such molecules in the gaseous, liquid and solid phases. This attraction is the result of the mutual* interaction of the electrons and nuclei *of the molecules; it has its origin in the electrostatic attraction of the nuclei of one molecule for the electrons of the other.*

At small distances (about 4 Å *for argon, for example) this force of attraction is completely compensated (balanced) by a force of repulsion of electrons by electrons and nuclei by nuclei due to interpenetration of the outer electron shells of the molecules.*

It is these intermolecular Van der Waals forces that enable substances such as the noble gases, the halogens, etc., to condense to liquids and to freeze into solids at sufficiently low temperature. The physical mechanism involved in the Van der Waals attraction is an interaction between fluctuating electric dipoles. Because of the fluctuating quantum mechanical behavior of the electrons in a molecule[735]*, all molecules have a fluctuating electric dipole moment, even though for many of them symmetry considerations require that it fluctuates about an average value of zero. At a time when a molecule has a certain instantaneous electric dipole moment, the external electric field that it produces will induce in the charge distribution of a nearby molecule a dipole moment such that the resulting force between the inducing and the induced electric dipole is always attractive.*

The binding energies are of the order of 10^{-2} *eV and the force, known as London force (1930) generally varies approximately as the inverse seventh power of the intermolecular separation at large distances. In the solid, successive molecules have electric dipole moments which alternate in orientation so as to produce nearest-neighbor attractions between them. Many organic compounds, inert gases, and ordinary molecular gases such as oxygen, nitrogen, and hydrogen form molecular solids in the solid state.*

The Van der Waals bond is the weakest form of binding, but it occurs with all atoms. Only in the inert gas crystals (which solidify at temperatures of only a few degrees above absolute zero) is it the predominant form of binding. Inert gas atoms are closed shell, neutral atoms with strongly held valence electrons. With no valence electrons about, their closed shells rule out the other types of binding.

---

[735] The *Heisenberg uncertainty principle* does not allow the centroid of the negative charge distribution (the center of the electron cloud) to be at the same place as the center of the positive charge distribution (the nucleus) all the time. Therefore, at some instant of time, the plus and minus charge centers of atom 1 will be separated by some distance. This separation gives atom 1 an electric dipole moment and sets up at atom 2 an electric dipole *field* centered at atom 1 which is proportional to r^{-3} (r is the separation of the centers of the atoms). This field *induces* an average dipole moment $\sim r^{-3}$ in atom 2. Therefore the electric binding energy due to this mechanism is proportional to r^{-6}, and the force to r^{-7}.

Because the binding is weak, solidification takes place only at very low temperatures, where the disturbing effects of thermal agitation are very small. The weak binding makes molecular solids easy to deform and compress, and the absence of free electrons makes them very poor conductors of heat and electricity. Intermolecular bonds of the Van der Waals type occur among:

I. NON-POLAR MOLECULES *with the appropriate molecular composition and symmetry such as Cl_2, have the center of the positive charge halfway between the nuclei, which is also the center of the negative charge. Yet, a second order Van der Waals attraction is formed between the non-polar covalent molecules. Other examples are CH_4, CF_4, CCl_4, CI_4, I_2, Br_2, H_2, CO_2, C_6H_6, where the vector sum of all bond moments in the molecule average to zero either due to linearity or spatial symmetry.*

II. POLAR MOLECULES *with non-zero vector sum of all dipole moments in the molecule. Such is the HCl molecule, in which the electron pairs are not shared equally in the covalent bond. Consequently, the centers of positive and negative charge do not coincide. Between such molecules we may have either a dipole-dipole interaction (which is either attractive or repulsive, depending on the orientation of the two dipoles) or dipole-induced dipole interaction, through which a molecule with a permanent dipole moment is able to induce a dipole moment in neighboring molecule, which always results in an attractive force between them. Other examples are: N_2O_5, P_4O_{10}, HNO_3.*

III. HYDROGEN BOND: *The covalently bonded hydrogen is unique among other atoms in chemical combination, because it has no inner shell of non-bonding electrons partially screening the nucleus. Particularly when it is bonded to one of the highly electronegative atoms (such as fluorine, oxygen or nitrogen), the pair of shared electrons is closer to the other nucleus, causing the whole molecule to become polarized.*

Consider, e.g., the water molecule[736] $H\text{—}\ddot{\underset{..}{O}}\text{—}H$; *due to the covalent bond between oxygen and hydrogen, an oxygen atom will form a 2-electron shared*

---

[736] For many purposes it is convenient to represent the outer-shell electronic configuration succinctly by means of electron-dot formulas: The chemical symbol for the element is written with as many dots around it as corresponds to the *number of valence electrons present in the outer shell*, e.g.:

1. Neutral *hydrogen* has a positive proton in the nucleus and one valence electron in its outer shell; its symbol will be $H\cdot$

2. Neutral *oxygen* has 8 protons and 8 neutrons in its nucleus, two *paired* electrons (opposite spins ⇅) in its inner shell, and 6 electrons in its outer shell (2*s* and 2*p* subshells), of which 4 are paired (⇅, ⇅) and 2 are unpaired. Its symbol

pool with each hydrogen atom. But the oxygen atom, having the stronger hold on valence electrons, will hold them more firmly, so to speak, in its own outermost shell. These electrons will occupy the electron shells of the hydrogen atom to a correspondingly lesser degree.

Since the oxygen atom has more than an equal share of the pooled (bonding pair) electrons, it has more than an equal share of the negative charge of those electrons. There will be therefore a fractional negative charge on the oxygen atom. The hydrogen atom, deprived of its fair share, will have a small balancing positive charge.

Two such molecules can thus attract each other, mainly by an electrostatic interaction between a proton belonging to one and the unshared pair of electron belonging to the other; for example, two molecules $H\!-\!\ddot{\underset{\cdot\cdot}{F}}:$ *will join into a dimer* H_2F_2 *by the hydrogen bond* $H\!-\!\ddot{\underset{\cdot\cdot}{F}}: - - - H - \ddot{\underset{\cdot\cdot}{F}}:$ *, indicated by a dashed line. Likewise, the molecule of ammonia*

$$\begin{array}{c} H\!-\!\ddot{N}\!-\!H \\ | \\ H \end{array}$$

is capable of joining another ammonia molecule through a hydrogen bond.

Most common hydrogen bonds are of medium energies between 3 and 7 kcal/mole (a few tents of eV per bond), which is about one tenth as strong as a typical covalent bond. This fact is of crucial importance to the chemistry of

is $:\dot{\underset{\cdot\cdot}{O}}\cdot$

3. Neutral *fluorine* has 9 protons in its nucleus, two *paired* electrons in its inner shell, and 7 electrons in its outer shell, 6 of which are paired. Its symbol is $:\ddot{\underset{\cdot\cdot}{F}}\cdot$

4. Neutral *nitrogen* has 7 protons in its nucleus, two *paired* electrons in its inner shell, and 5 electrons in its outer shell, 2 of which are paired. It symbol is $:\dot{\underset{\cdot}{N}}\cdot$

5. Neutral *carbon* has 6 protons in its nucleus, two *paired* electrons in its inner shell, and 4 electrons in its outer shell, 2 of which are paired. Its symbol is $\ddot{\underset{\cdot}{C}}\cdot$

6. Neutral *neon* has 10 protons in its nucleus, two *paired* electrons in its inner shell, and 8 electrons in its outer shell, all paired. Its symbol is $:\ddot{\underset{\cdot\cdot}{Ne}}:$

life[737] *because it allows for weak, but highly specific, intermolecular interactions that can be altered without affecting the covalently bonded structures of the molecules in question.*

The fact that ammonia, water, and hydrogen fluoride are all capable of hydrogen bonding to themselves *has varied consequences and of great importance, especially for water. For example, the melting and boiling points of these compounds are abnormally high relative to other hydrogen compounds in the same groups. Without it water would be a gas at room temperature.*

Most substances diminish in volume and hence increase in density, with decrease in temperature. Water has the very unusual property of having a temperature at which its density is maximum. This temperature is $4°C$. *With further cooling below this temperature the volume of a sample of water* increases *somewhat. A related phenomenon is the increase in volume which water undergoes on freezing. Without this anomaly, life in lakes and rivers would not be possible during severe winter conditions, since they would freeze (throughout — not just a surface layer, as actually occurs). All these unusual properties of water are due to the* hydrogen bond *for the following reason: each molecule has two attached hydrogen atoms and two unshared electron pairs and hence can form* 4 *hydrogen bonds with its neighbors.*

Indeed, X-ray diffraction studies of ice *show that each oxygen atom is surrounded by* 4 *other oxygen atoms located about it at the corners of a* regular tetrahedron. *The hydrogen atoms presumably lie on the lines between the centers of the oxygen atoms. This structure, in which each molecule is surrounded by only* 4 *immediate neighbors, is a very open structure, and accordingly ice is a substance with abnormally low density.*

When ice melts, this tetrahedral structure is partially destroyed and the water molecules are packed more closely together, causing water to have greater density than ice. Many of the hydrogen bonds remain, however, and aggregates of molecules with the open tetrahedral structure persist in water above the freezing point. With increase in temperature, some of these aggregates break up, causing a further increase in density of the liquid; only at $4°C$ *does the normal thermal expansion due to* increase in molecular agitation *overcome this effect, and cause water to begin to show the usual decrease in density with increasing temperature.*

---

[737] The hydrogen bonds in DNA can be "unzippered" open for replication of gene structures, then closed again until needed. The hydrogen bond is also important in certain ferroelectric and polymerization processes.

A great many salts are soluble in water, whereas they are insoluble in most other common solvents[738]*. The high solubility of salts in water is the result of two closely related properties of water:*

(1) *Water has an extremely high dielectric constant (80). This arises not only from the polarity of the individual molecules, but also from the correlated mutual orientations of the molecules. So the force of attraction between oppositely charged ions in water, as given by Coulomb's law is only* $\frac{1}{80}$ *the force that would exist between them in vacuum (or in air). Thus, a great many salts dissociate into ions upon contact with water.*

(2) *Water molecules have a large dipole moment (1.86 D; 1 D(Debye) = 20.85 e · picometer), which interacts strongly with the ions, especially the cations, to form hydrated ions. This process is accompanied by release of thermal energy. Typical hydrated ions are* $[Be \cdot (H_2O)_4]^{2+}$, $[Mg \cdot (H_2O)_6]^{2+}$, $[Al(H_2O)_6]^{3+}$ *in which the relatively negative end of the water molecule (the oxygen) interacts with the positive central ion.*

This striking power of water to dissolve ionic substances is partly due to its power to form hydrogen bonds[739]*.*

A few other liquids are ionizing solvents like water, resulting in salt solutions that conduct electricity because of the mobile ions in the solution. Some such liquids are hydrogen cyanide (HCN), hydrogen peroxide, liquid ammonia (NH_3) *and liquid hydrogen fluoride (HF). They all have high dielectric constants and large dipole moments, and are therefore called polar solvents. Hydrogen bonding is the factor primarily responsible for solubility of organic compounds in water.*

---

738 If water were like most other liquids, the salt-like minerals would be practically insoluble in it and it would be far above its boiling point at the mean temperatures of the earth's surface. Therefore, life as we know it is completely dependent on the peculiar physical properties of water.

739 In some cases, however, some hydration actually has the opposite effect, increasing the stability of ionic solids or even allowing them to crystallize. Such hydrated crystals spontaneously pulverize into powder at low enough ambient humidity levels.

The Mystery of Aqua Regia

The ancient metallurgists — as well as brewers, dyers, and potters – accumulated much empirical knowledge that is now incorporated into the science of chemistry. Thus, the resistance of gold to corrosion by atmospheric oxygen, water, and acids has long been known. Indeed, Electrum, a natural mixture of gold and silver, was used for the early coins minted in Lydia in the eighth century BCE. Copper was added to coins by the Roman emperors to conserve the more precious metals.[740]

Aqueous acids "dissolve" most of the free metals by oxidation. Though none of the common laboratory acids are individually able to dissolve gold, a combination of 4 *parts of* HCl *to* 1 *part of* HNO_3 *does it. This fact was known already to medieval alchemists and the early chemists [e.g.* ***Lully*** *(1305),* ***Libau*** *(1611),* ***Van Helmont*** *(1648)]. The mixture is known as aqua regia, since gold was considered the "king of metals".* ***Gay-Lussac*** *(1844) tried to explain the phenomenon through the atomic theory known in his time. It was not until the theory of oxidation-reduction reactions through electron transfer became well-understood [****G.N. Lewis*** *(1916);* ***I. Langmuir*** *(1919);* ***G.A. Perkins*** *(1921);* ***W. Pauli*** *(1925);* ***L. Pauling*** *(1931)] that chemists finally resolved the aqua regia phenomenon.*

[740] Gold coins have long since been withdrawn from circulation in the United States, and the silver coins are being replaced by sandwich alloys of nickel and copper.

Table 5.7: PROPERTIES OF THE COINAGE METALS

	Cu	**Ag**	**Au**
Electron configuration	$[Ar]3d^{10}4s^1$	$[Kr]4d^{10}5s^1$	$[Xe]4f^{14}5d^{10}6s^1$
Atomic radius, 10^{-12} m	128	144	144
First ionization energy, kJ/mol	745	731	890
Electrode potential, V			
$M^+(aq) + e^- \to M(s)$	+0.520	+0.800	+1.83
$M^{2+}(aq) + 2e^- \to M(s)$	+0.340	+1.39	—
$M^{3+}(aq) + 3e^- \to M(s)$	—	—	+1.52
Oxidation states	+1, +2	+1, +2	+1, +3

The data in Table 5.7 helps us understand why this is so: The metal ions are easy to reduce to free metals, which means that the metals are difficult to oxidize.

In Mendeleev's periodic table, the alkali metals (group 1) and the coinage metals (group 11) appear together as group I. The only similarity between the two subgroups, however, is that both have a single s electron in the valence shells of their atoms. More significant are the differences between the group 1 and group 11 metals. For example, the first ionization energies for the group 11 metals are much larger than for the group 1 metals, and the standard electrode potentials are positive for the group 11 metals and negative for the group 1 metals.

Like the other transition elements that precede them in the periodic table, the group 11 metals are able to use d electrons in chemical bonding. Thus they can exist in different oxidation states, exhibit paramagnetism and color in some of their compounds, and form complex ions. They also possess to a high degree some of the distinctive physical properties of metals — malleability, ductility, and excellent electrical and thermal conductivities.

Copper, silver, and gold – the coinage metals – are used in jewelry making and the decorative arts. Gold, for instance, is extraordinarily malleable and can be pounded into thin translucent sheets known as gold leaf. The coinage metals are valued by the electronics industry for their ability to conduct electricity. Silver has the highest electrical conductivity of any pure element, but *both copper and gold are more often used as electrical conductors because copper is inexpensive and gold does not readily corrode. The most important use of gold is as the monetary reserve of nations throughout the world.*

The group 11 metals do not react with $HCl(aq)$, but both Cu and Ag react with concentrated $H_2SO_4(aq)$ or $HNO_3(aq)$. The metals are oxidized to Cu^{2+} and Ag^+, respectively, and the reduction products are $SO_2(g)$ in H_2SO_4 and either $NO(g)$ or $NO_2(g)$ in $HNO_3(aq)$.

Au does not react with either acid, but it will react with "royal water" – aqua regia. The $HNO_3(aq)$ oxidizes the metal and Cl^- from the $HCl(aq)$ promotes the formation of the stable complex ion $[AuCl_4]^-$

$$Au(s)+4H^+(aq)+NO_3^-(aq)+4Cl^-(aq) \rightarrow [AuCl_4]^-(aq)+2H_2O(l)+NO(g).$$

1931–1946 CE **Robert Jemison Van de Graaff** (1901–1967, U.S.A.). Physicist. Invented the electrostatic generator named after him, designed to accelerate particles in the realm of '*low energy*' nuclear physics (below about 10 MeV).

Van de Graaff produced the first generator of this kind at the Massachusetts Institute of Technology (MIT). In the generator, a continuous belt composed of an insulating material moves past a source of negative electricity. This source sprays electrons on the belt. The belt then goes into a hollow metal dome were a fine metallic brush moves the electrons onto the dome surface. When the charge at the top of the dome is high enough, electrically charged particles are hurled at targets at the bottom of the generator. The great merit of the Van de Graaff generator lies in its extremely steady potential when it is suitably stabilized.

Van de Graaff was born in Tuscaloosa, Alabama. He graduated from the University of Alabama in 1922 and did postgraduate work at the Sorbonne in Paris and Oxford University in England. He joined M.I.T. in 1931. In 1946 he helped found the High Voltage Engineering Corporation, where developments led to the production of the "*tandem*" machine — which is effectively two accelerators in series. Here, *negative ions* are first accelerated to the high-voltage terminal, then stripped of their electrons and accelerated a second time to the target.

Worldview XLIV: Paul Valéry[741]

* * *

"One has to be a Newton to note that the moon is falling when everyone sees that it does not fall."

* * *

"The science of mathematics is to a large extent, only a science of pure repetitive patterns. It grasps the mechanism of patterns and summarize it."

* * *

"All our inventions tend either to save our energies, or to save repetition"

* * *

"Everything that requires no effort is a waste of time"

* * *

"History will justify anything. It teaches precisely nothing, for it contains everything and furnishes examples of everything."

* * *

"History is the science of things that do not repeat themselves."

---

741 **Paul Valéry** (1871–1945, France). Thinker, poet and essayist. Born in France of an Italian mother and a Corsican father. A rationalist who was deeply versed in 19^{th} century scientific ideas. He wrote on mathematics and physics from a viewpoint of a philosopher-poet.

* * *

"The past is an entirely mental thing. It is nothing but images and beliefs."

* * *

"In 1887, the air was strictly reserved for the birds. Electricity has not yet lost its wires. Solid bodies were still fairly solid. Opaque bodies were sill quiet opaque. Newton and Galileo reigned in peace. Physics was happy and its references absolute. Time flowed by in quiet days; all hours were equal in the sight of the universe. Space enjoyed being infinite, homogeneous, and perfectly indifferent to what went on in its august bosom. Matter felt that it had good and just laws... Could the greatest scholar, the profoundest philosopher of 1887 even have dreamed of what we know and see, after a mere fifty-five years?"

* * *

"Never has humanity combined so much power with so much disorder, so much anxiety with so much playthings, so much knowledge with so much uncertainty."

* * *

"Hitherto, all politics gambled on the isolation of events. *History was made up of events that could be localized. Any disturbance had at one point on the globe as it were, a boundless medium in which to reverberate; its effects were nil at a sufficient distance; everything went in Tokyo, as though Berlin were at infinity. It was therefore possible (it was even reasonable) to predict, to calculate, to act. There was room in the world for one or several great policies well planned and carried out. That time is coming to an end – the age of the finite world has began"*

(1931)

* * *

"One of man's most extraordinary inventions is the invention of the past *and the* future: *by expanding the moment, by using imagination to generalize the*

present, man creates time; *and in doing so he not only sets up perspectives before and after his intervals of reaction but, what is more, he lives but very little in the moment itself ... he continually feels the need of what does not exist."*

(1932)

* * *

"Nature is indifferent to individuals. If man prolongs or betters his life he is acting against nature"

(1932).

* * *

*"*Living *is an essentially monotonous practice, based on the regular recurrence of a few reflexes ...* Knowledge, *on the other hand, tends to absorb the particular and singular mundane into the general law".*

(1932)

* * *

"Modern life tends to spare us intellectual effort just as it does physical effort; for example, it replaces imagination by images, reasoning by symbols and writings, or by machines ... and often by nothing. It offers us every short cut for arriving at our goal without making the journey. It thus combines to produce a certain diminution of value and effort in the realm of the mind."

Science 'Progress Reports'

Worldviews

Environmental Events that Impacted Civilization

1898–1923 *Bubonic plague* pandemic kills 20 million people in China, India, North Africa and South America

1900 The Galveston (TX, USA) *hurricane* kills 8000 persons

1902 The eruption of the Mt. Pelée *volcano* (Martinique) kills 30,000 people

1906 The San-Francisco *earthquake*

1908 The Messina *earthquake* kills 160,000 people

1908 The Tunguska *bolide explosion*

1912 The 'Titanic' disaster

1917–1920 Worldwide Influenza pandemic kills 80 million people, mostly in Europe and Asia

1921–1930 *Cholera*, *smallpox* and *typhus* pandemic in India kills ca 2 million people

1923 The Tokyo *earthquake*

1931–1950 *Floods* of the Yellow and Yangtze Rivers in China (1928, 1929, 1931, 1936, 1938, 1950) kill 22 million people

1942 *Hurricane* at the Bay of Bengal kills 40,000 people

1970 *Cyclone storm* and *tsunami* kill 500,000 people at the Bay of Bengal

1976 *Earthquake* in Tangshan (China) kills 650,000 people

1983–1985 Famine in Ethiopia kills ca 1 million people

Political and Religious Events that Impacted World Order

1904–1905	Russia and Japan at war
1917	The Bolshevik Revolution
1914–1918	World War I
1936–1939	The Spanish Civil War
1939–1945	World War II and the Holocaust
1947–1949	The rebirth of Israel
1949	Independence of India
1949	Foundation of the Republic of China
1949–1989	The 'Cold War'
1950–1953	The Korean War
1965–1975	The Vietnam War
1991	The Soviet Union officially ceased to exist
2001	The 'Nine-Eleven' event – Muslim terror hits the USA

1931–1949 CE **Lars Onsager**[742] (1903–1976, Norway and U.S.A.). Theoretical physicist. Discovered certain symmetry relations, known as *Onsager reciprocal relations*, which form the basis for the entire discipline of macroscopic irreversible thermodynamics. Onsager relations apply mostly to the *linear*, *near-equilibrium* regime, i.e., as long as the changes (temporal and spatial) of temperature, pressure, chemical potentials, etc. are small on the molecular scale.

The reciprocity relations are rigorous consequences of the *principle of microscopic reversibility*, or alternatively the *time-reversal invariance* property of the irreversible phenomena at the microscopic scale. Indeed, the principle of microscopic reversibility hinges on *time-symmetry* of the mechanical equations of motion (classical or quantum-mechanical) of the individual particles and fields of the system. It implies that fluctuations which take the system away from equilibrium occur at the same rate as those taking it toward equilibrium. However, *microscopic* reversibility in no way contradicts the fact that in a *macroscopic* description physical systems exhibit irreversible behavior (e.g., heat and material diffusion). Irreversible processes result from the statistics of the 2^{nd} law of thermodynamics, and (ultimately) from the nature of the initial state — and have nothing to do with violations of time-reversal invariance.

Consider the following 'thought experiment': a gas, originally occupying a certain volume V_2, is confined to a smaller box V_1 at time $t = 0$. At time $t = t_2$ it is allowed to diffuse to all the available volume V_2. It is clear that the time-asymmetry crept in through the fact that we *forced* the gas to occupy the smaller box at time $t = 0$, but *allowed* the gas to relax back to occupy the full volume at later times. Had we waited for the equilibrium gas configuration to *spontaneously* contract to the box and expand back again, there would have been complete temporal symmetry, but the expected wait time would exceed the age of the universe by many orders of magnitude.

In other words, the time asymmetry stems from the peculiar fact that we are able to impose special initial conditions on the gas, but do not know how

---

[742] For further reading, see:

- Reif, F., *Fundamentals of Statistical and Thermal Physics*, McGraw-Hill, 1965, 651 pp.
- Rumer, Yu.B. and M.Sh. Ryvkin, *Thermodynamics, Statistical Physics, and Kinetics*, Mir Publisher: Moscow, 1980, 600 pp.

- Rocard, Y., *Thermodynamics*, Pitman, 1961, 681 pp.

to arrange (in advance) that at some *future* time the gas will be confined to the box! Another way of saying it: all that asymmetry means is that the *conditional probability*, given a gas volume V_1 at $t = 0$, to achieve a volume V_2 at $t = t_2 > 0$, is *not* a symmetric function of V_1, V_2. This in itself *does not* contradict time-symmetry and the ensuing Onsager symmetry relation, *because* that symmetry only says that the *joint probability* of $V(0) = V_1$ and $V(t_2) = V_2$ *is indeed* symmetric in V_1 and V_2. Thus the real mystery is that we are able to impose macroscopic initial (but not final) conditions on a system.

The simplest example of Onsager's reciprocity is this: a system accommodates two simultaneous processes: a mass flow driven by a concentration gradient force and a heat flow driven by a temperature gradient. This mixed regime will then exhibit '*cross influences*' in the form of a mass flow induced by the temperature gradient and a heat flow induced by the concentration gradient, in such a way that the coupling coefficients of these cross influences are equal.

A molecule that moves by Brownian motion from position A to position B in the direction of a concentration gradient, has as much probability of moving from B to A against the concentration gradient, although the overall macroscopic state for all molecules of the species in question spontaneously evolves irreversibly in the direction of increasing global entropy (disorder). In this case, therefore, *diffusion* occurs (a tendency for concentration to become more uniform, and thus for their gradients to decrease).

Likewise, the random (thermal) component of molecular kinetic energy tends, macroscopically, to spread more equally over the available volume. The cross-influence coupling coefficients quantify how these two tendencies interact.

The importance of the Onsager relations lies in their generality. It is immaterial, for instance, whether the irreversible processes take place in a gaseous, liquid or solid medium. *The reciprocity expressions are valid independently of any model-dependent microscopic assumptions*. Their validity showed, for the first time, that nonequilibrium thermodynamics leads, as does equilibrium thermodynamics, to general results independent of any molecular model.

The discovery of the reciprocity relations can be considered to have been a turning point in the history of thermodynamics, as it marked a crucial point in the shift of interest away from equilibrium toward nonequilibrium. Classical thermodynamics alone does not make it possible to establish such relations, since it either ignores the irreversible changes that the system undergoes, or analyzes them indirectly (via changes of the state variables from an *initial* to a *final* equilibrium state). Whenever we have a precise molecular model which permits to set up a theory, then we have an exact expression for the coupling coefficients such that the *symmetry* implied by Onsager's relations holds.

Even before the development of the thermodynamics of irreversible processes, a few linear phenomenological laws had been known for a long time:

Fourier (1822) discovered the simple linear law relating the thermal flux to the temperature gradient: $\boldsymbol{J}_q = -\lambda \,\mathrm{grad}\, T$ where λ is the coefficient of *thermal conductivity* in solids.

Fick (1856) established that the diffusive flux of matter is proportional to the concentration gradient which generates the flux, $\boldsymbol{J}_d = -D \,\mathrm{grad}\, c$, where c is the solute concentration (number of moles) per unit volume and D represents the *diffusion coefficient* of the dilute mixture.

In a *thermodiffusion cell*, a nonreacting dye (solute) of (possibly inhomogeneous) concentration c is dissolved in a tube containing water (solvent). The tube is sealed and then subjected to a temperature gradients at its ends. The temperature gradient generates a concentration flow, and vice versa; thus, interference effects between the diffusion of matter and heat flow take place. The system, therefore, operates under the combined influence of Fourier and Fick laws and the cross-influences:

$$\boldsymbol{J}_d = -D \,\mathrm{grad}\, c - D^T \,\mathrm{grad}\, T, \qquad \boldsymbol{J}_q = -\lambda^D \,\mathrm{grad}\, c - \lambda \,\mathrm{grad}\, T.$$

The two new *phenomenological coefficients* are:

$$\lambda^D = \frac{L_{qd}}{T}\left(\frac{\partial \mu}{\partial c}\right)_T \quad (\textbf{Dufour} \text{ coefficient}),$$

$$D^T = \frac{L_{qd}}{T^2} + \frac{L_{dd}}{T}\left[\left(\frac{\partial \mu}{\partial T}\right)_c - \frac{\mu}{T}\right] \quad (\textbf{Soret} \text{ coefficient}).$$

where $\mu = \mu(c, T)$ is the *chemical* potential[743] of the solute. Setting also

$$D = \frac{L_{dd}}{T}\left(\frac{\partial \mu}{\partial c}\right)_T, \qquad \lambda = \frac{L_{qq}}{T^2} + \frac{L_{qd}}{T}\left[\left(\frac{\partial \mu}{\partial T}\right)_c - \frac{\mu}{T}\right],$$

$$\boldsymbol{X}_d = -\,\mathrm{grad}\left(\frac{\mu}{T}\right), \qquad \boldsymbol{X}_q = \mathrm{grad}\left(\frac{1}{T}\right),$$

[743] According to equilibrium thermodynamics, it is μ, rather than the concentration c, which tends to equalize between different samples in diffusional contact. If the solution may be approximated as an ideal gas, $\mu \approx k\,T \ln\left(\frac{c}{c_0}\right)$, with k Boltzmann's constant and c_0 an undetermined constant.

the flux equations assume their Onsager form $(d \equiv 1,\ q \equiv 2)$:

$$\boldsymbol{J}_1 = L_{11}\boldsymbol{X}_1 + L_{12}\boldsymbol{X}_2, \qquad \boldsymbol{J}_2 = L_{21}\boldsymbol{X}_1 + L_{22}\boldsymbol{X}_2.$$

The *Onsager reciprocity relation* $L_{12} = L_{21}$ relates the coefficient which gives the heat flux caused by a concentration gradient, to the coefficient yielding the mass flux caused by a temperature gradient. This, as well as the numerous other reciprocity relations when other gradients and flows interact, follows from the fact that the *microscopic* dynamics are time-reversal invariants discussed above.

In certain situations — such as external *magnetic fields*, *Coriolis forces* or certain types of *weak nuclear interactions* — microscopic reversibility *breaks down*, and then the Onsager reciprocity relations may be invalid or require modifications.

In general, if a system is subject to different flows and gradient "forces", every flow J_i is dependent to some degree on all other forces, X_j, and conversely, each force is dependent upon all flows appearing in the system:

$$J_i = J_i(X_1, \ldots, X_n) \quad \textit{and} \quad X_i = X_i(J_1, \ldots, J_n).$$

Here n is the total number of forces (or fluxes). In general, the explicit functional relationships between these quantities are not known. If the system is in equilibrium, all forces and consequently all flows vanish. Therefore, it is reasonable to assume that if we introduce weak forces (i.e. small gradients) into the system, the ensuing flows will be proportional to the forces. Also, the properties of the new nonequilibrium system are not drastically different from those of the equilibrium state. The new system remains in the neighborhood of the equilibrium state. As forces are weak in this regime, we may expand J_i in a Taylor series around the equilibrium state, and consider only first-order corrections:

$$J_i = (J_i)_{eq} + \sum_k \left(\frac{\partial J_i}{\partial X_k}\right)_{eq} X_k + \cdots.$$

By definition all fluxes $(J_i)_{eq}$ vanish at equilibrium, and therefore

$$J_i = \sum_k L_{ik} X_k.$$

Onsager, in a general proof, assuming microscopic reversibility, established that the coefficients L_{ik} of the phenomenological equations are symmetrical, provided $\boldsymbol{X}_i = \boldsymbol{\nabla}\left(\frac{\partial s}{\partial e_i}\right)$, with s the local entropy per unit volume, and e_i the local density of the extensive thermodynamic quantity, the flow (current density) of which is J_i.[744] In that case, the symmetry (reciprocity) relations read $L_{ik} = L_{ki}$, or alternatively:

$$\left(\frac{\partial J_i}{\partial X_k}\right) = \left(\frac{\partial J_k}{\partial X_i}\right).$$

It means that the increase in the flux J_i caused by a unit increase in the force X_k (while the remaining forces are held fixed) is equal to the increase of the flux J_k due to unit increase in the force X_i. For non-isotropic media, each index i or k includes both a flow/force type index and a spatial index.

Long before 1931, the symmetry relations were suggested by experiments on the conduction of heat in *anisotropic crystals*. **Charles Soret** (1854–1904, France) noticed in 1893 that the conductivity exhibits a much greater symmetry than exists in the crystal itself.

Indeed, the tensor relation (a generalization of Fourier's law)

$$J_i = \sum_{k=1}^{3} L_{ik} \frac{\partial T}{\partial x_k} \quad (i, k = 1, 2, 3)$$

with i, k *spatial* indices and $L_{ik} = L_{ki}$, expresses the fact that in a general anisotropic crystal, the *static equilibrium properties* (elastic constants, refractive index, etc.) do not have the symmetry of its dynamic irreversible diffusive properties. An entirely analogous situation is exhibited by the electric conductivity of single crystals (**H.B.G. Casimir**, 1945).

The Onsager relations can be applied also to *thermoelectric phenomena*, including the *Seeback effect* (1822), the *Peltier effect* (1834), and the *Thomson* (*Lord Kelvin*) *effect*.

Since their formulation, Onsager's reciprocal relations have been tested for a wide range of flows and forces, and their validity seems to be universal — to such an extent that they are sometimes labeled as the fourth law of thermodynamics.

They apply to a gamut of systems, involving chemical reactions, heat conduction, viscous flow, electrical conduction, polarized matter, and nonlinear dissipative systems which may be seen as prototypes for biological cells and membranes. Although the validity range of Onsager's relations is still a matter of debate, his theory is a good approximation in the linear response region.

---

[744] For *chemical reactions* the situation is slightly different: e_i is the density of a particular reagent of the reaction, $\boldsymbol{X}_i$ the reaction-causing variation δS per $\delta e_i = 1$, and J_i the reaction-caused piece of $\dot{e}_i$.

Onsager's other major contribution to theoretical physics was his solution (1942–1949) of the two-dimensional *Ising problem*[745], which was the first exact

[745] In some metals, e.g., Fe and Ni, a finite fraction of the spins of the atoms becomes spontaneously polarized in the same direction, giving rise to a *macroscopic* magnetic field. This happens, however, only when the temperature is lower than a characteristic temperature known as the *Curie temperature*. The transition from the non-ferromagnetic state to the ferromagnetic state is a *phase transition*. The *Ising model* is a crude toy model in which each *domain* in a ferromagnetic substance is replaced by a single microscopic magnet, of fixed magnetic moment, which can point in either of two opposite directions. Its main virtue lies in the fact that a two dimensional Ising model yields to an exact treatment in *statistical mechanics*. The three-dimensional problem is already so difficult that it has so far defied an exact solution.
Consider a solid consisting of N identical atoms in a regular lattice. Each atom has a net electronic spin $\boldsymbol{S}$ and associated magnetic moment $\boldsymbol{m}$ related to its spin by $\boldsymbol{m} = g\mu_0\boldsymbol{S}$, where μ_0 is the *Bohr magneton* and the g (the *gyromagnetic ratio*) is of order unity. If no external magnetic field is present there are two possible interactions between atoms:

(1) a *magnetic* dipole-dipole interaction, which is far two small to account for ordinary ferromagnetism.

(2) an *electrostatic* interaction between the valence-electrons and cations of neighboring atoms, including *exchange interactions* between electrons of neighboring atoms which are a quantum-mechanical consequence of the Pauli exclusion principle. Since the exchange interaction between two atoms depends on the degree to which their electrons can overlap as to occupy approximately the same region in space, this interaction is negligible except when the atoms are sufficiently close to each other unlike the ordinary (non-exchange) electrostatic inter-atomic interactions, *the exchange forces mimic inter-atomic dipole-dipole magnetic forces*, except they are several orders of magnitude stronger. Thus each atom will interact "pseudo-magnetically" only with its nearest neighbor atoms. A two-atom exchange interaction Hamiltonian is written in the form $H_{jk} = -2J(\boldsymbol{S}_j \cdot \boldsymbol{S}_k)$, where J is a parameter (depending on the separation between the atoms) which measures the strength of the exchange interaction.

To simplify the problem, the *Ising model* leaves the essential physical situation intact by adopting the approximation $H_{jk} = -2JS_{jz}S_{kz}$, where the x and y terms of the scalar product have been neglected. The total Hamiltonian representing the interaction energy between the atoms can be written in form $H' = \frac{1}{2}\sum_{j=1}^{N}\sum_{k\neq j} H_{jk}$ where J is the exchange constant for neighboring atoms and the index k refers to atoms in the *nearest neighbor shell* surrounding the j-th atom.

solution of a nontrivial problem in the statistical mechanics of the equilibrium between different phases of matter.

Onsager was born in Oslo, Norway, and was trained as a chemical engineer. His work on electrolyte solutions (with **P. Debye** in Zürich) and his interest in chemical reactions in solutions led him to ponder general issues in irreversible thermodynamics. In 1928 he moved to the United States, where he spent the rest of his career, mostly at Yale (1934–1972, professor from 1945). He was awarded the Nobel Prize for chemistry in 1968.

1931–1951 **Linus Carl Pauling** (1901–1994, U.S.A.). Distinguished chemist. Applied quantum mechanics to the study of molecular structures and *chemical bonding*, and showed (1931) how quantum mechanics could yield results of broad chemical significance that went well beyond earlier theories of valency. His book *The Nature of the Chemical Bond* (1939) is one of the turning points in modern chemistry. He received the Nobel prize for chemistry in 1954.

Pauling utilized X-ray diffraction, electron diffraction, magnetic effects and the heat involved in forming chemical compounds for the calculation of interatomic distances and angles between chemical bonds, and related intermolecular geometry to molecular characteristics and to interactions between molecules.

He introduced the concepts of *hybrid electron orbitals*, *covalent bonds* (atoms sharing electrons) and *resonance hybrids* (1931–1934) vital for the understanding of the directional character of chemical bonding and the well-defined shapes of bonded atomic aggregates. He thus proposed (1931) that the phenomenon of *resonance* causes the stability of the *benzene ring*. In 1934 Pauling began to apply his knowledge of molecular structure to the complex molecules of living tissues, particularly in connection with proteins, and became interested in proteins involved in *immunological reactions*.

He recognized the importance of *hydrogen bonding* in protein structure and the interaction between macromolecules. He suggested (1946) that *enzymes* work by lowering the energy-barrier of a reaction through binding to a transitional state as the atoms in a compound move from position to position about the central core. This mechanism was later established for many enzymes.

From the observed shapes of amino acids and small peptide molecules, Pauling and **Robert Corey** (1951) formulated a set of structural conditions that any model of a *polypeptide chain* must satisfy. This led to the α-helix structure of proteins.

Pauling was born in Portland, Oregon. He took his Ph.D. at the California Institute of Technology (Caltech), Pasadena, in physical chemistry

(1925). He later worked under **Sommerfeld** in Münich, **Bohr** in Copenhagen, **Schrödinger** in Zürich and **Bragg** in London. He returned to Caltech in 1927 and became a full professor there in 1931. He left Caltech in 1963 to devote himself to the study of problems of war and peace.

1931–1953 CE The advent of *industrial fiberglass*: Fiberglass is glass[746] in the form of fine fibers (threads). The fibers may be many times finer than human hair, and may look and feel like silk. The flexible glass fibers are stronger than steel and will not burn, stretch, rot, or fade. The ancient Egyptians used *coarse* glass fibers for decorative purposes.

For a long time fiberglass was thought of as a curiosity without much of a future. However, in experiments conducted from 1931 to 1939 by the American firm Owens Illinois Glass Company, fiberglass material began to be used on a large scale for its heat-insulation properties. It was first used to make the entire bodywork of cars by the American firm Chevrolet (1953). The construction of fiberglass *streamlining* quickly won over the pleasure boats industry.

1931–1953 CE **Henry John Kaiser** (1882–1967, USA). Prominent industrialist, engineering administrator and innovator, master of creative entrepreneurial improvisations, builder and founder of giant businesses in cement, aluminum, magnesium, steel, tourism and health care. Known as the father of modern shipbuilding.

His many projects put thousands to work during the Depression in the 1930's and his massive shipbuilding during WWII (The *Liberty Ship Project*[747]) was a decisive factor in winning the war.

Kaiser was born in Sprout Brook, N.Y. He left school at 13 to go to work. Later, he went to the Pacific Coast, where he became a road builder.

---

[746] *Glass* is a complex network of silicon and oxygen atoms. Because of its *irregular* arrangements of atoms, glass is not a bona fide crystalline solid. It is often regarded as a supercooled liquid and has no definite melting point as crystalline solids do but softens over a wide range of temperatures. Even at ordinary temperature it will *flow* appreciably over long periods of time.

[747] He ignored the usual methods of building from keel up, and used assembly-line methods. His ships were built in separate sections and welded together in a few days. During WWII, Kaiser yards constructed more than 1500 cargo ships: The first 'Liberty Ship' took 196 days to deliver. Kaiser cut the time to 27 days and by 1943 he was turning one out every 10.3 hours! The concept he developed for mass production of commercial and military ships are still used today. The USNS tanker *Henry J. Kaiser*, built in 1986 (205 m long, 30 m wide; deadweight tonnage 27,561 long tons), carried 180,000 barrels of JP-5 fuel.

As one of the executants of the early New Deal, especially the TVA, he had been outstanding not merely for thinking big but for producing an endless succession of ingenious small ideas too — putting wooden tires on wheelbarrows and having them drawn by tractors, replacing petrol engines in tractors and earth-shovels with diesels, and so on.

His major building and construction enterprises were:

- Organized the combine that built the Hoover Dam[748] (1931).
- Built the piers for the Oakland – San Francisco Bay Bridge.
- Erected the Permamente cement plant, then the world's biggest, in six months; produced the cement for the Shasta Dam (1935).
- Built the West's first steel plant, at Fontana, California, and when the government demanded 50,000 aircraft, he constructed *Kaiser Aluminum*, then *Kaiser Magnesium* in California. (It was a tragedy for the South that it had no capitalist leader comparable to Kaiser: that is why its own thrust into the modern world was delayed by nearly two decades.)
- Constructed one of the first commercially practicable *geodetic domes*.
- With Joseph W. Frazer founded the Kaiser-Frazer Corporation to build automobiles (1946).
- Advanced *medicine* with the development of hospitals, medical centers, clinics, and medical schools. Founded the largest American Health Maintenance Organization (now known as *Kaiser Permamente*). As founder of a medical care program, he worked with partnerships of physicians and established nursing schools and contributed to medical education.
- Built civic centers, roads, tunnels, housing industries.
- Spent much of his later years developing the urban landscape of Oáhu.

[748] It was the biggest dam in the world, followed by three other linked dams: Parker, Bonneville, and Grand Coulee. In building Grand Coulee, he had devised a special trestle, costing $1.4 million, to pour 36 million tons of concrete. Its cheap power made possible the vast manufacturing industries which flourished in CA during WWII, and transformed the entire West Coast, enriching it still further. Kaiser became chairman of the building consortium (1933). Federal money paid for most of it.

Since the 1930's Kaiser, more than any other man, was building the economic infrastructure of the modern Western USA, making the West the principal supplier of mass-produced weaponry and advanced technology. Some of his quotations reflect his personality, motives and achievements:

I always have to dream up there against the stars. If I don't dream I will make it, I won't even get close.

* * *

I make progress by having people around me who are smarter than I am and listening to them. And I assume that everyone is smarter about something than I am.

* * *

Live daringly, boldly, fearlessly. Taste the relish to be found in competition — in having put forth the best within you.

* * *

Problems are only opportunities in work clothes.

* * *

When your work speaks for itself, don't interrupt.

* * *

1931–1968 CE **Sewall Wright** (1889–1988, USA). Geneticist and statistician. One of the founders of the mathematical theory of *population genetics*. Helped modernize Darwin's theory of evolution, using statistics to model the behavior of population of genes; showed that within small isolated populations, certain genetic features may be lost randomly if the few individuals possessing the genes happen not to pass the genes on to the next generation, This is known as the *Sewall Wright genetic drift effect* (1945) that allows evolution to occur without the influence and involvement of natural selection (*Wright's formula*).

Wright was born in Melrose MA. He took his doctorate at Harvard, worked at the US Department of Agriculture (1915–1925), where he conducted experimental work in animal genetics, then became a professor at the universities of Chicago (1926–1954) and Wisconsin (1955–1960).

Wright introduced stochastic processes to models of population structure and evolution. He showed that when populations were small, *chance* could play an important role in changing the frequency of genes in populations, which is the essence of the evolutionary process. The phenomenon is known as *genetic drift*. The extent, however, to which drift contributes to long-term evolution depends upon whether *alternative genes* affect reproduction and survival and are thus subject to *natural selection*, or whether they are *neutral*. There is still substantial controversy on this point; while some genes are clearly adaptive, many others appear to behave as though they were neutral.

The population structure of *man*, throughout most of human history, has been ideally suited for drift effect with small population size and geographical isolation, but it still remains problematic how important drift has been in human evolution.

Wright's major book is *Evolution and the Genetics of Populations* (1968).

1931–1968 CE **Karol Borsuk** (1905–1982, Poland). Mathematician. Introduced fruitful new ideas in *metric differential geometry* (1931) and the notion of *cohomotopy groups* into topology (1936). He created the concept of a divisor of a map (1936) and initiated *shape theory* (1968). Shape theory grew at the same time as *infinite-dimensional topology* and the interaction between the two fields was of great mutual benefit.

Borsuk was born in Warsaw and was educated at the University of Warsaw (Ph.D. 1930). He held positions at the Universities of Warsaw (1931–1978), Princeton (1946–47), Berkeley (1959–60), Madison (1963–64).

Where did all the water come from? (1931–1951)

"And Steam would go up from the Earth and water the whole face of the ground".

Genesis **2**, 6

"All the rivers run into the sea; yet the sea is not full".

Ecclesiastes **1**, 7

One of the first methods used to determine the age of the ocean was to divide the total salt content of the world ocean by the annual increment of salt discharged into the sea by rivers. This procedure was suggested by **Edmund Halley** *in* 1715 *but not implemented until* 1899 *when* **John Joly** *(1857–1933, Ireland) made the first estimate using data on the abundance of sea salt obtained by the Challenger expedition.*

The result of several such computations of the salt age is somewhat less than 100 *million years. This period of existence is clearly too brief, because marine organisms, as well as present-day species, have been found in early Cambrian rocks of an age of the order of* 500 *million years. The source of the discrepancy stems from a recycling mechanism through which part of the salt leaves the ocean's surface, only to return via the rivers of the world. It is generally assumed that the oceans are at least as old as marine fossils.*

Closely associated with the age of the world ocean is the question of the origin of such a vast quantity of water (about 1 *billion* km^3*) and of the salt (about 3%) that it contains. Early speculations were concerned with a deluge. When* **James Hutton** *(1785) and* **John Playfair**[749] *(1802) proposed the uniformitarian doctrine, such ideas as the cataclysmic appearance of the land and the sea were in general currency, partly due to the lingering influence of religious dogma.*

There are only two possible sources for the water. Either it is the residue of a vast, dense primordial atmosphere and is almost as old as the earth, or

[749] Scottish mathematician and geologist (1748–1819).

else there was little or no ocean when the earth formed and it has since leaked out from the interior. But it can be shown that at present temperatures the atmosphere, fully saturated, can hold no more than some $13,000$ km^3 of water at any one time.

As water vapor over a molten earth (at perhaps $1200\,^\circ C$), only 16% of the present ocean volume would have remained in gaseous equilibrium. Moreover, if the earth had been much hotter during its early history than it is at present, the velocity of escape[750] of both molecular and dissociated water would have been exceeded and the earth would have lost any volatiles originally accumulated. The depletion of noble gases[751] suggests that the surface of the earth must have been very much hotter than it is today. Thus, the

---

750 The earth's retention of volatile components such as air and water depends on its temperature. Because of their thermal motions, gases are continuously diffusing outward, but this tendency is counteracted by the gravitational attraction of the earth. In order to escape from the earth, a molecule, like a spaceship, must have a velocity that is greater than the escape velocity from earth, namely $11.2\ \frac{\text{km}}{\text{sec}}$. The average kinetic energy of a gas molecule is given by $\frac{1}{2}m\overline{v}^2 = \frac{3kT}{2}$ (T is the absolute temperature). Therefore $\overline{v} = \sqrt{\frac{3kT}{m}}$. Consequently, the lighter the molecule, or the higher the temperature, the more likely it is that gas can escape from the earth's surface. Under present conditions, hydrogen and helium are rapidly lost from the atmosphere while the heavier gases such as oxygen and nitrogen are retained.

751 A clue to the early thermal history of the earth is offered by the relative abundance of the noble gases on earth and in stars. These gases, unlike water, do not combine chemically, and so have always been in a gaseous state. We must compare the abundances of these permanent volatiles with those of elements that are chemically bound in the solid matter of the earth, such as silicon, the major metallic element in rocks.

Since the earth originally accumulated from stellar material, the original ratio of the noble gases to silicon was probably similar to the ratio that is currently observed in stars. If the material of the primitive earth was then heated, there would be a loss of the volatile components resulting in a decrease in the ratio of noble gases to silicon. The depletion of noble gases will be greatest for those elements of low atomic weight, helium and neon, and less for those of increasing atomic weight.

The data on the abundance of noble gases suggest that all the water in the ocean and the gases of the atmosphere must once have been held within the solid earth: The mantle of the earth has a volume of 10^{27}cm^3. Assuming a density of 4, this amounts to a mass of 4×10^{27} g, while the water of the ocean has a mass of 1.4×10^{24} g. Thus the mantle must have lost 0.035 percent of its weight in the form of water, on the average. We must compare this figure with *atmosphere and the ocean cannot be a remnant of the primordial earth; these gases must originally have been chemically combined within the solid earth; they could have accumulated on the surface only since the earth cooled to near its present temperature, perhaps by being released slowly within the earth and at temperatures lower than that of molten rock.*

In 1931, ***R.W. Goranson***[752] *found that water dissolve readily in molten silicate, basaltic and granitic rock. These are large constituents of volcanic lava. Molten rock can contain approximately* 5 *percent of its weight as dissolved water under temperatures and hydrostatic pressures approaching those supposed to exist in volcanic pipes and intrusive magmas within the crust of the earth.*

In 1951, ***W.W. Rubey***[753] *showed that the geological record was incompatible with a primordial origin for the water, and that volatile substances, including water, pour out of volcanoes in amounts much greater than are necessary to form the ocean. Although it was later found that most of the water emerging from volcanoes was recycled rain, Rubey's theory remained valid; geological time has been so long that only a miniscule amount of juvenile water from each volcanic eruption would be sufficient to have produced the ocean.*

It thus seems that the water on the surface of the earth flowed out of the interior along with volcanic rocks, but when and at what rate?

The simpler possibilities are that the flow was constant during geological time, or faster than average to begin with, or faster than average recently. All

---

the average water content of the mantle. Although the mantle is not accessible for sampling, *meteorites* offer us samples of mantle-like material.

Meteorites are fragments of a planet-like object in the solar system that broke up. Pieces of this material are frequently captured by the earth's gravitational field. Some meteorites consists mainly of iron with a high nickel content and are believed to resemble the material of the core of the earth. Others, the stony meteorites, contain silicates and are believed to resemble the mantle. By examining the water content of the stony meteorites, we can therefore obtain an estimate of the water content of the mantle.

The average water content is about 0.5 percent or 10 times as much as the loss from the mantle that is required to account for the present ocean. Thus the mantle could be an adequate source for the water in the ocean.

752 Goranson, R.W., The solubility of water in granitic magmas, *Am. J. Sci.* **22**, 481–502, 1931.

753 Rubey, W.W., Geologic history of sea water, *Bull. Geol. Soc. Am.* **62**, 1111–1147, 1951.

possibilities have been proposed. Rubey assumed a constant flow, essentially on the philosophical grounds that it is the simplest possibility.

In conclusion, the Goranson-Rubey scenario is this: as the rock solidified, the water were expelled as steam. The quantity of steam from the volcanoes of a cooling earth can account for the volume of water in our oceans. Chemical similarities between volcanic steam and ocean water indicate that this steam, rising from a cooling earth, was very likely the source of our oceans and the atmosphere.

Once water was present at the surface, weathering *of crystalline rocks could commence. As a result, crystalline rocks were transformed to sediments and the salts of seawater. The dynamics of the lithosphere then led to the formation of continental crust so that, as the volume of water at the surface increased, the difference in elevation between the floor of the ocean and the surface of the continents also increased.*

Originally, the atmosphere was devoid of oxygen, and the ultraviolet irradiation of the sea surface led to the synthesis of complex organic molecules. Life evolved from, and was originally nourished by, the organic matter produced by solar radiation near the surface of the sea. The evolution of the first marine plants led to the biological emission of free oxygen and the gradual oxidation of the surface environment. Eventually this led to the present oxygen-containing atmosphere. Thus life processes have transformed the surface environment of our planet.

1932 CE *A Wonder Year* for elementary particles:

- **James Chadwick** discovered the *neutron*
- **Carl David Anderson** discovered the *positron*
- **Harold Clayton Urey** discovered the *deuterium*
- New particle accelerator technology
- New nuclear physics

1932 CE **James Chadwick** (1891–1974, England). Physicist. Discovered the neutron and determined its mass. In 1932 Chadwick observed that beryllium, when exposed to bombardment by alpha particles, released an unknown radiation that in turn ejected protons from the nuclei of various substances. Chadwick interpreted this radiation as being composed of particles of mass approximately equal to that of the proton, but without electrical charge — neutrons.

This discovery provided a new tool for inducing atomic disintegration, since neutrons, being electrically uncharged, could penetrate undeflected into the atomic nucleus.

Chadwick was born in Manchester and was educated at the Universities of Manchester, Cambridge and Berlin. From 1923 he worked with **Ernst Rutherford** in the Cavendish Laboratory, Cambridge, where they studied the transmutation of elements by bombarding them with alpha particles and investigated the nature of the atomic nucleus, identifying the proton, the nucleus of the hydrogen atom, as a constituent of the nuclei of other atoms. He won the Nobel prize for physics in 1935.

1932 CE **August Dvorak** (1894–1975, USA). Inventor and scholar. Designed a scientific, ergonomically designed typewriter keyboard that is twice as fast, makes half the errors and enables the typists to move their fingers 20 times less for as with the QWERTY keyboard. Yet *his revolutionary invention was never adopted*! The reason: the commitment to QWERTY of tens of millions of typists, teachers, sales people, office managers, and manufactures.

Dvorak (born in Glenco, MN) was a professor of education at the University of Washington in Seattle and a distant relative of the Czech composer Antonin Dvořak. Around 1914, Augustin's brother-in-law, William Dealy, attended some industrial efficiency seminars and watched slow-motion films of typists, and reported what he saw to Dvorak. The brothers in law then devoted *two decades* to enormously detailed studies of typing, typists errors, hand physiology and function, and the relative frequencies of letters, pairs of letters, and words in English. Finally they assembled all they had and in 1932 designed a new keyboard.

August died a bitter man: "I'm tired of trying to do something worthwhile for the human race", he complained. "They simply don't want to change."

The ‘QWERTY’ Syndrome — or: A Comedy of Errors

All human societies have many apparently arbitrary *practices that persist for centuries or even millennia — writing systems, counting systems, sets of number signs, calendars, to name just a few examples. At one time there existed alternatives to the system that was eventually adopted. Were some of these alternatives better than others? Did we in fact end up committed to the best ones? Are our alphabets, decimal counting, Arabic numerals, and Gregorian calendar really superior to Chinese logograms, Babylonian base-*60 *counting, Roman numerals, and the Mayan calendar?*

The origins of many other commitments are now lost in remote history. How did China become committed to its hard-to-memorize writing system? Chinese children can master pinyin *(a Roman alphabet adapted to Chinese) in one-tenth of the time required to learn the traditional writing system.*

Why do Americans cling to the awkward English measuring system of pounds, inches, and gallons? How did we become committed to decimal counting and a 24-hour clock? These questions are tantalizing but perhaps academic, because there is no prospect of our abolishing the 60 *minute hour or reverting to base-*60 *counting, even if such changes did prove advantageous.*

In modern times, commitments have shaped the history of technology and culture, often selecting which innovations become entrenched and which are rejected. In the 19th century United States, for example, those who profited from canals, barges, stagecoaches, and the pony express resisted the construction of railroads; In England, electric *street-lighting spread slowly, partly because of opposition from local governments with heavy investment in* gas *lighting. Even today, commitments influence railroad gauges and television technology, and whether we mark our rulers with centimeters or inches and drive on the right or on the left.*

The transistor was invented and patented in the United States in the 1940s, but Japan today dominate the world market for transistorized consumer electronic products. The reason: the company that became Sony bought transistor licensing rights from Western Electric at a time when the American consumer electronics industry was committed to churning out vacuum tube *models and reluctant to compete with its own products.*

There is, however, one example which serves to demonstrate this absurdity of conventions and commitments better than others because it is a comedy of errors that keeps going on to the very present day — the curse of QWERTY. It *started in 1874 when **Christopher Sholes** designed the typewriter keyboard to took like*

Q W E R T Y U I O P
A S D F G H J K L ← *'home row'*
Z X C V B N M

To overcome the problem of invisible jamming, Sholes applied antiengineering *principles with the goal of slowing down the typist and thus preventing the second bar from jamming the falling first bar. The idea of eight-finger touch-typing was still unknown. Typists rummaged around with one of two fingers while looking at the keyboard, and Sholes was ecstatic if the resulting typing rate reached* 20 *or* 30 *words per minute, the rate of writing by hand. To this end he scattered the most common letters or letter combinations in English texts as widely as possible over the keyboard.*

Why did QWERTY prevail even after improvements in typewriter technology (reducing the jamming problem) and the demand for fast typing had removed the original motivation for it? The reason was that its early head start and success created a commercial dominance and hence a commitment of its manufacturers (Remington) to the original layout.

When typing, one rests his finger on the 'home-row'. The more typing one can do without having to move the fingers from the home row, the faster one is able to type, the fewer errors one will make and the less one strains his fingers. Motion-picture studies prove that typing is fastest on the home row and slowest on the bottom row.

When Augustin Dvorak started his detailed studies of typing (1914) he immediately noticed the following shortcomings of QWERTY:

- *Not more than 100 English words can be typed without leaving the home row because QWERTY perversely puts the most common English letters on the other rows: The home row nine letters include two of the least used (*`J` *and* `K`*) but none of the three most frequently used (*`E`*,* `T` *and* `O`*) and only one of the five vowels (*`A`*), even though* 40 *percent of all letters in a typical English text are vowels. Thus, when typing the* *words pumpkin or minimum, ones fingers must not only reach from the home row to the top or bottom but must at times hurdle completely over the home row, moving directly from top to bottom and back again! These awkward hurdles and reaches slow one down and introduce typing errors and finger strain.*

- *In typing, whenever the left and right hands type alternative letters, one hand can be getting into position for the next letter while the other is typing the previous one. One can thereby fall into a steady rhythm and type quickly. A good positioning of letters in the keyboard should therefore strive to avoid typing strings of consecutive letters by the same hand. The longer the string, the slower the typing and the more frequent the errors. QWERTY typing tends to degenerate into long one-handed strings of letters, especially strings for the weaker left hand.*

  More than 3000 *English words utilize QWERTY's left hand alone (e.g. exaggerated, greatest; million, monopoly). The underlying reason for this shortcoming is that most English syllables contain both vowels and consonants, but QWERTY assigns some vowels (*`A` *and* `E`*) as well as some common consonants (*`R`, `S`, *and* `D`*) to the left hand, and others (*`I`, `O`, *and* `U` *plus* `H`, `L`, *and* `N`*) to the right hand. Hence for about half of all digraphs (two consecutive letters) in a typical English text, QWERTY allocates both letters to the same hand.*

- *Most people are right-handed with a weaker left hand. Yet QWERTY allocates to the weaker hand the most common English letter (*`E`*), the second common (*`T`*), and the* 4*th most common (*`A`*), thus making the left hand perform more than half of all typing strokes (*56 *percent).*

- *On each hand the* 5*th finger (pinkie) is the weakest, and finger-strength increases from the* 5*th to the* 2*nd (index). Yet QWERTY makes almost as much use of our weakest finger (left* 5*th) as of our* 2*nd stronger (right* 3*rd).*

- *When one must type two successive strokes with the same hand, it's fastest to do so with two remote fingers, next fastest with two adjacent fingers, slower with the same finger on the same row, and slowest of all with the same finger on different rows. Yet with the QWERTY keyboard,* 20 *percent of all English digraphs are typed by adjacent fingers, and more than* 4 *percent by the same finger.*

The results of these shortcomings is that typing on a QWERTY keyboard is unnecessarily tiring, slow, inaccurate, hard to learn and hard to remember. The infinitely superior Dvorak keyboard, the end result of twenty years of an arduous study, proposed the plan

P Y F G C R L
A O E U I D H T N S ← *'home row'*
Q J K X B M W V Z

with the following merits and advantages over QWERTY:

- *Devotes the home row 9 out of 12 most common English letters — including all 5 vowels and the 3 most common consonants (`T`, `H`, `N`), while the 6 rarest letters (`V`, `K`, `J`, `X`, `Q`, `Z`) are relegated to the bottom row. As a result, 70 percent of tying strokes remain on the home row, only 22 percent are on the upper row, and a mere 8 percent are on the hated bottom row; thousands of words can be typed with the home row alone; reaches are 5 times less frequent than in QWERTY typing, and hurdles hardly ever happen.*

- *The Dvorak keyboard forces one to alternate hands. It does so by placing all vowels plus `Y` in the left hand, but the 13 most common consonants in the right. As a result, not a single word or even a single syllable can be typed with the right hand alone, and only a few words can be typed with the left hand alone.*

- *56 percent of all strokes are given to the right hand. Only 2 percent of all English digraphs are typed by adjacent fingers and only 1 percent by the same finger.*

In a normal workday a good typist's fingers cover up to 30 km on a QWERTY keyboard, but only 1.5 km on a Dvorak keyboard! and all this with twice the speed and half the errors that QWERTY typists make.

Whatever the original reasons for adopting QWERTY, we now seem firmly committed to it. The typewriter, and its successor the computer are among the most widely used office machines in the world, and keyboard-related repetitive-strain injuries are among the most common industrial accidents. But if we were to overcome the fear of long-held commitments, millions of people would be able to type with increasing speed, greatly lowered finger fatigue, greater accuracy, and reduced sense of frustration — altogether ending a bad marriage that has long outlived its original justification.

1932–1935 CE **Gerhard Domagk** (1895–1964, Germany). Chemist, pathologist and physician. Discovered the first of the *sulfanilamide* drugs (*Prontosil*). In 1935 he used it successfully on his youngest daughter to prevent her death from a streptococcal infection, the first use on a human being.

Following **Ehrlich**'s spectacular success with Salvarsan (1910), researchers began to test virtually every substance that might be effective against infectious diseases. Although there were some successes — antimalarial drugs and those that fought protozoal infections such as amoebic dysentry — everything else proved either as destructive to the patient as to the bacteria, or unable to kill the germs once they had started to multiply. Scientists began to despair of finding any more 'magic bullets'.

However, in 1931, the American Bacteriologists **René Jules Dubos** (1901–1982) and **Oswald Theodore Avery** (1877–1955), of the Rockefeller institute, announced that they had discovered an *enzyme* derived from a soil bacteria that could break down the capsule that protected one particular type of pneumococcus. Although this proved too toxic for human use, the discovery gave new life to the search for anti-bacterial drugs.

In 1927, Domagk was appointed research director of the German chemical company, I.G. Farbenindustrie. Its main products were azo dyes used for color textiles, and Domagk decided to find out whether they had any adverse effect on streptococci. In 1932, he found that one azo compound — Prontosil red — cured mice injected with a lethal doze of hemolytic streptococci.

Domagk won the Nobel prize for physiology or medicine in 1939, but was prevented by the Nazis from accepting[754, 755].

---

[754] **Carl von Ossietzky** (1889–1938, Germany). German journalist and pacifist, won the Nobel prize for peace (1935). He fought for Germany in WWI. In his capacity as a staff member of *Berliner Volks-Zeitung* and later (1928) as the editor of *Weltbühne*, he wrote vigorously in defense of pacifism, denouncing Nazi rearming. Consequently he was imprisoned in a concentration camp on charge of being an enemy of the state (1933–1936). He contracted tuberculosis in prison and was in a sanitarium when the Nobel prize was announced. The German government considered the award as a "challenge and an insult" and prohibited Germans thenceforth from accepting such awards.

[755] Domagk did not publish his findings until February 1935, and scientists were surprised that even then, his report failed to mention sulphanilamide, the component of Prontosil responsible for its bacteriostatic action. It is believed that Domagk and his associates knew that sulphanilamide was unpatentable because it had already been synthesized by a Viennese student, **Paul Gelmo**, who had published his findings in his doctoral dissertation (1908).

It is surmised that Domagk spent the years between 1932 and 1935 in a vain

Sulfanilamide possesses a rather simple chemical structure, and this, together with the later proof that it owed its action to a similarity to and competition with an essential bacterial metabolite, was an immense stimulus to pharmaceutical industrial research (sulphanilamide did not kill bacteria like an antibiotic, but prevented them from multiplying).

1932 CE **Harold Clayton Urey** (1893–1981, U.S.A.). Chemist. Discovered *deuterium* (heavy hydrogen). Awarded the Nobel Prize in chemistry (1934).

1932–1933 CE **Marian Rejewski**[756] (1906–1980, Poland). Cryptoanalyst and mathematician. A key figure in breaking the code of the German *Enigma* machine, by taking advantage of *repetition* in the Enigma encryption (a message key was enciphered *twice* at the beginning of every message). Applying certain theorems from the theory of permutations, he was able to separate the effect of *plugboard settings*[757] from those of the *scrambler settings*, thus reducing the total number of possible keys from 10^{16} to $105,456$. This eventually enabled the Polish team to find the day key in about two hours.

Rejewski studied mathematics at the University of Poznan. He was recruited into the *Biuro Szyfrów* (Polish Cipher Office) in 1929.

The Poles successfully used Rejewski's technique for several years. When Herman Göring visited Warsaw (1934), he was totally unaware of the fact that his communications were being intercepted and deciphered. As he and the other German dignitaries laid a wreath at the Tomb of the Unknown Soldier next to the offices of the Biuro Szyfrów, Rejewski could stare down at them from his window, content in the knowledge that he could read their most secret communications.

---

attempt to find a drug similar to but better than sulphanilamide and one that could be patented. In the meantime, thousands of patients had suffered, and some had died — all for the sake of profits. The integrity of Domagk was therefore called into question. He was, however, awarded the Nobel prize (1939) despite the rumors about possible suppression of research results.

[756] For further reading, see:

- Singh, S., *The Code Book*, Anchor Books, 1999, 411 pp.

[757] *Plugboard settings*, i.e. number of ways of *swapping*, say, 6 pairs of 26 letters in $100,391,791,500$. But on its own, the plugboard would provide a trivial cipher, because it would do nothing more than act as a monoalphabetic substitution cipher, having no effect on the *frequency* of letters. The *scramblers* contribute a smaller number of keys, but their setup is continually changing, which means that the resulting ciphertext cannot be broken by *frequency analysis*.

Rejewski received little monetary compensation for his efforts, not much in the way of promotion, and only a minor Polish decoration. He merited, however, the highest accolade of all the Allied Nations. Perhaps his satisfaction came from a job well done.

1932–1936 CE **Carl David Anderson** (b. 1905, U.S.A.). Physicist. Discovered the *positron* (anti-electron), the first known particle of anti-matter (1932), as predicted by **P.A.M. Dirac** in 1928.

In 1936 he participated in the discovery of the *mu-meson* in cosmic rays at Pikes Peak, Colorado (an elementary fermionic particle about 207 times as massive as the electron; at first erroneously thought to be the carrier of the strong nuclear force) predicted by **H. Yukawa** (1935).

Carl Anderson was born in New York city and received his doctorate at the California Institute of Technology, Pasadena (1930), where he spent his entire career. In 1930 he began research on gamma rays and cosmic rays, utilizing the magnetic cloud chamber. In 1932 Anderson discovered the positron in the course of cosmic-ray studies, and one year later succeeded in producing positrons by gamma irradiation. He shared the Nobel prize for physics in 1936.

1932–1937 CE **Hans Adolf Krebs** (1900–1981, England). Distinguished biochemist. A pioneer of the field of *bioenergetics*: studied energy transformations of intermediate metabolic processes in living matter.

Discovered (1932) the cycle of reactions whereby urea is formed from ammonia and carbon dioxide in the livers of ureotelic organisms (*urea cycle*). This was the first biosynthetic pathway and metabolic cycle to be discovered[758]. Formulated (1936–1937) the citric acid cycle (known as the *Krebs cycle*), the final common pathway for the oxidation of all foodstuff.

Krebs' cycle is one of the most important metabolic pathways and energy producer in living organisms. It consists of a cyclic series of stepwise oxidation

---

[758] The over-all reaction is: $2NH_3+CO_2 \rightarrow NH_2CONH_2+H_2O$; but ammonia is highly toxic and there is no ammonia to speak of anywhere in the body at anytime. It was not until the 1950's, however, that the *details* of the conversion were worked out; the nitrogen-containing groups are added in the form of *amines* obtained from amino acids. In going from *ornithine* to *citrulline*, *glutamic acid* (one of the commonest amino acids) donates both the amino group and the equivalent carbon dioxide. In doing so it must make use of a *high-energy phosphate bond* obtained from ATP. In going from citrulline to arginine, another amino acid, *aspartic acid*, donates an amine group, again at the expense of ATP. Thus, the production of urea is an energy-consuming reaction. Each turn of the urea cycle consumes two molecules of ATP.

reactions that occur in mitochondria and represents the final phase in the oxidation of nutrients to CO_2 and H_2O, with the release of large amounts of energy.

All the major nutrients of cells, notably carbohydrates, fats, and proteins ultimately pass through the Krebs' cycle.

Awarded (with **Fritz Lipmann**) the Nobel prize for physiology or medicine (1953).

Krebs was born in Hildsheim, Germany to Jewish parents. Following the Nazi rise to power (1933), he was dismissed from his post at Freiburg University and moved to England, where he became a naturalized citizen (1939). He later became professor of biochemistry at Sheffield (1945–1954) and Oxford (1954–1967).

1932–1939 CE **Eduard Cech** (1893–1960, Czechoslovakia). Mathematician. A foremost contributor to modern topology. Introduced (1932) the topic which today is called *Cech homology theory*[759].

Cech was born in Stracov, Bohemia (now Czech Republic). He studied at the Charles University of Prague (1912–1920) and Turin (1921–1922) and continued to work with **Fubini** in Turin (1922–1923). He then became a professor at the University of Brno (1928–1945) and Prague (1945–1959).

---

759 *Homology theory*: If a closed curve C is the boundary of a region on a surface, C is homologous to zero, which is symbolized by $C \sim 0$. If motion on C are orientable (clockwise and anticlockwise), then $-C$ has a meaning. Since one can go round and round a closed curve, $\pm nC$ also have a meaning (cycles).

Cycles may be added and subtracted. Thus $C \pm C'$ have meaning too.

If one selects a convention concerning the bounded region (e.g. having the area to the *left* of the bounding curves), then $C - C'$ bounds an annulus such that $C - C' \sim 0$. In this case C is said to be homologous to C', i.e. from the point of view of homology, C and C' are equivalent. If all cycles homologous to a particular one are considered equivalent, then they can be classified as a single type.

Thus homology is an *equivalence relation* for the classification of cycles, just as *homeomorphism* is an equivalence relation for spaces. The number of types of cycles, that is, the number of *homology classes*, on a manifold, is an *invariant* of the manifold and the cycle types on a manifold form a *commutative* (abelian) group w.r.t. the operation of addition. This is known as the *Betti group*.

The concept of cycles and their homologies can be extended to n-dimensional manifolds. On higher dimensional manifolds one has not only closed curves but also closed surfaces, etc.

1932–1944 CE **Alexander Yakovlevich Khinchin**[760] (1894–1959, USSR). An outstanding mathematician. Established the general theory of stationary random processes, their spectral representations and correlation functions (*Wiener-Khinchin theorem*).

Studied the convergence of discrete Markov chains to continuous diffusion. With Kolmogorov he founded the Moscow School of Probability Theory.

Khinchin was born in Kondrovo, Russia, to Jewish parents. He graduated from Moscow University in 1916, and from 1927 onwards served as a professor of mathematics there. In 1944 he became an Academician of the Soviet Academy of Sciences.

1932–1947 CE **Edwin Herbert Land** (1909–1991, U.S.A.). Inventor and physicist. Invented the *polaroid* material (1932) and the polaroid Land camera that takes and prints a finished picture in seconds (1947). Both inventions resulted in numerous commercial, military and scientific applications.

The polaroid polarizes light through *selective absorption* by aligned submicroscopic crystals of iodoquinine-sulfate that are embedded in a sheet of plastic. The molecules *absorb* light whose electric-field-vector is parallel to their length, while they *transmit* light whose electric-field-vector is perpendicular to their length. In 1963 Land began to use polaroid material in sunglasses and other optical devices such as infrared filters, lightweight range finders, night adaptation goggles and many others. In 1947, he invented a one-step process for developing and printing photographs that produced a revolution in photography unparalleled since the advent of the roll-film.

Land was born to a Jewish family in Bridgeport, CT. He attended Harvard University, but never graduated. He nevertheless issued more than 500 patents for his innovations in light and plastics, and won honorary degrees and awards from numerous scientific institutions and organizations.

1932–1949 CE **Karl Theodor Jaspers** (1883–1969, Germany and Switzerland). Philosopher and psychiatrist. His central idea is that Pure Being (existence) inevitably escapes our efforts at apprehension; Existence eludes the conceptual intellect and all attempts at inclusive intellectual systematization must fail; man constantly tries to transcend his limitations through science, religion and philosophy, but he experiences failure or "shipwreck".

Jaspers believed that man learns most about himself in "limit situations" such as death, guilt, suffering, conflict and failure. He held that *philosophy* is

---

[760] For further reading, see:

- Khinchin, A., *A course of Mathematical Analysis*, Hindustan Publishing Corp.: Delhi, 1960, 668 pp.

not a set of doctrines, but an *activity* trough which each individual can become aware of the nature of his own existence: He was not primarily interested in the philosophers' conclusions, because he held that in philosophy all context and *all conclusions are unimportant.*

Jaspers urged the study of other philosophers as a way to disturb and stimulate us so profoundly that we would be compelled to engage in the activity of philosophizing.

Jasper's major work, *Philosophy* (1932), gives his view of the history of philosophy and introduces his major themes. He identified philosophy with philosophical thinking itself, not with any particular set of conclusions. His philosophy is an effort to explore and *describe the margins and limits of experience.*

Jasper was born in Oldenburg, Lower Saxony. He began his intellectual career as a medical student and went on to carry out research in a psychiatric clinic (1916–1920). He then became a professor of philosophy at Heidelberg (1920–1937). Dismissed by the Nazis and barred from teaching for having a Jewish wife (1938–1945). In 1948 he accepted a professorship in philosophy in Basel, Switzerland.

1932–1956 CE **Lev Davidovich Landau** (1908–1968, Russia). Among the top-level physicists of the 20^{th} century. A master of the modern theoretical physics techniques of his time. A major contributor to theories of superfluidity[761], superconductivity and phase-transitions. Created the quantum Fermi-liquid theory (1956). Landau was awarded the 1962 Nobel prize for his work on the superfluid properties of Helium II. Landau left his mark

[761] Superfluidity of Helium 4 – the so-called Helium II phase was discovered by **P.L. Kapitsa** in 1938. It is the property of flow without viscosity in narrow capillaries or gaps. It was long thereafter believed that only one isotope of Helium, He^4, is a superfluid. But in 1972 it was discovered [**D.M. Lee** et all] that liquid He^3 also becomes a superfluid, at much lower temperatures (2 millikelvin, as opposed to 2.2 °K for He 4, at 1 atm pressure). Helium was the last of the elements to be liquefied, and is the most remarkable of all liquids. At temperatures other than absolute zero, Helium II behaves as if it were a mixture of two different liquids. One of these is a superfluid, and moves with zero viscosity along a solid surface. The other is a normal viscous fluid. No friction occurs between these two parts of the liquid in their relative motion.

He 4 atoms each contain 2 electrons and 4 nucleons and therefore an even number of fermions, and are thus *bosons*, and their Bose-Einstein condensation is manifested as superfluidity. He 3 atoms are *fermions* which can pair up, with each pair being a boson, at low enough temperatures; Superfluid He 3 is thus a condensate of He 3-atom pairs.

on a wide range of fields including low temperature, atomic, nuclear, plasma, high energy and cosmic-ray physics. His contributions are partly reflected in such terms as *Landau diamagnetism*[762], *Landau levels*, *Landau damping*, *Landau energy-spectrum*, *Landau cuts*, *Landau-Ginsburg potential, Landau-Pomeranchuk-Migdal effect*.

Landau suggested (1932), for the first time, the possibility of cold dense stars, composed principally of neutrons. He later suggested (1938) that every star has a neutron core. He gave a value for the limiting mass, above which an ordinary star becomes a neutron star.

However, Landau maintained that some stabilizing effect prevents the great mass of neutrons in the core to collapse indefinitely, and therefore he did *not* accept the concept of a 'black hole'. In his astrophysical work Landau used Newtonian gravitational theory.

Landau was born in Baku, Azerbaijan, to Jewish parents. His father was an engineer who worked in the Baku oil industry, and his mother a doctor who had at one time done physiological research. Landau was graduated at 13 from the Gymnasium and, because he was too young for the university, attended the Baku Economical Technical School. He matriculated in 1922 at Baku University, after studying physics and chemistry, and transferred in 1924 to the Leningrad State University, which at that time was the center of Soviet physics. Graduating in 1927, he continued research at the Leningrad Physico-Technical Institute.

At that time there were practically no outstanding senior theoretical physicists in the Soviet Union, and, since the younger men had to teach themselves and each other, it was important for them to go abroad and be in touch with the western theoretical physics schools that were flourishing in such centers as Copenhagen and Münich.

In 1929 Landau visited Göttingen and Leipzig and then stayed at Copenhagen's Institute for Theoretical Physics, where he came under the influence of **Niels Bohr**. After his stay in Copenhagen he visited Cambridge and Zürich, before returning to the Soviet Union. Apart from short visits to Copenhagen in 1933 and 1934, Landau spent the remainder of his life in his own country.

In 1932 Landau went to Kharkov to become the head of the Theoretical Division of the Ukrainian Physico-Technical Institute, a position he combined in 1935 with that of head of the Department of General Physics at the Kharkov

[762] In addition to the spin paramagnetism, there is an *orbital diamagnetism* of free electrons. This effect, unlike the paramagnetic spin susceptibility, is inversely proportional to the effective electron mass, in simple cases. [It is especially strong for Bismuth, where the electrons have abnormally low effective mass.]

A.M. Gorky State University. In Kharkov Landau began to build a Soviet school of theoretical physics, so that the city soon became the center of theoretical physics in the U.S.S.R. It was also in Kharkov that, with his friend and former student **E.M. Lifshitz**, he started to write the well-known *Course of Theoretical Physics*, a set of nine volumes that together span the whole of the subject. His great interest in the teaching of physics is also shown in his plans for a "*Course of General Physics*" and even a series entitled "*Physics for Everybody*".

Landau required that his students master all necessary mathematical techniques before coming to him. After that he expected them to master the so-called theoretical minimum, which included a basic knowledge of all the domains of theoretical physics. Only the ablest of the students were able to pass this minimum. In this way his students became proper physicists, rather than narrow specialists.

In 1937 **Pyotr Leonidovich Kapitsa** (1894–1984, England and U.S.S.R.), a low-temperature experimentalist, persuaded Landau to move to Moscow and to head the Theory Division of the S.I. Vavilov Institute of Physical Problems, which had been created by the U.S.S.R. Academy of Sciences.

Landau's attitude to physics and physicists was critical; he did not suffer fools gladly. While always willing to help anybody, he hated pomposity. People either adored him or were his bitter enemies. He was imprisoned during the Stalin era (1938) and only a personal intervention by Kapitsa freed him.

In 1937 Landau married K.T. Drobanzeva, and in 1946 they had a son, Igor, who became an experimental physicist.

On Jan. 7, 1962, Landau was involved in a car accident. He was unconscious for six weeks and was several times declared clinically dead, but he somehow revived. Distinguished specialists from several countries helped to save his life. After Landau had regained consciousness his faculties slowly returned to him, but he was no longer able to perform creative work. His physical condition never returned to normal, and he died six years later.

The Landau School (1932–1962)

Landau envisioned theoretical physics as one indivisible science with its own logic based on certain general principles. Later he converted this vision into a course on theoretical physics he developed with Evgeni M. Lifshitz at the Institute of Physical Problems at Kharkov University. The plan of the course became the "theoretical minimum" for the students; it also involved a number of mathematical problems which Landau regarded as indispensable knowledge for every theorist. By imparting this philosophy to his students, he set the tone of 20th century Soviet theoretical physics.

Virtually all his students and associates were tested on the theoretical minimum: The first exam Landau gave anyone eager to become his student was in mathematics: the exam required the applicant to be able to calculate any indefinite integral *that could be expressed in terms of elementary functions, to be able to solve any ordinary* differential equation *and to have knowledge of* vector analysis, tensor algebra *and the principles of functions of* complex variable.

Landau believed that tensor analysis and group theory should be studied together with the fields of theoretical physics in which they find application. Only after passing this exam could the applicant move successively on to study the seven sections of the "theoretical minimum". This study demanded basic knowledge of all fields of theoretical physics. Landau thought that all theorists should master this basic knowledge, regardless of their eventual specialty fields.

Of course, not everybody had the ability or the persistence to complete the study of the theoretical minimum. All in all, 43 physicists have passed the exam[763].

Attendance in the 'Landau seminar' was compulsory of all Landau's students. There, articles from authoritative scientific journals were surveyed.

---

[763] In a recent article (Amer. Math. Soc. Transl. (2), **212**, 2004), **S.P. Novikov** (Field Medalist, 1970) reviewed the declining state of higher education in Russia and the West. He stated

"I can clearly see that contemporary education cannot produce a theoretical physicist capable of passing Landau's theoretical minimum.

...The purely democratic evolution of education, when people freely choose courses, works poorly in these sciences... physics and mathematics education is not a democratic structure in nature; it is not like a free economy... Thus we are entering the 21st century in a state of profound crisis."

Landau himself marked the articles he thought of particular interest, which ranged over all fields, from solid-state physics to GTR. *Presenting a report at the seminar was very time consuming and required an extensive background. One was to summarize the contents of the chosen paper based on a complete understanding of the subject. This is where the training ensured by the 'theoretical minimum' manifested itself. Landau was grounded in all fields of theoretical physics, and he required the same of his students and colleagues.*

After the presentation Landau would give an evaluation of the results obtained in the review article. If the results were outstanding, they were inscribed into the "Golden Book". If in the course of the discussion there arose problems requiring further investigation, these were introduced into the "Book of Problems".

Some articles Landau denounced as "pathological", which implied that principles of scientific analysis were violated, either in the solution of the problem or in its formulation. Landau himself did not read scientific journals, and thus the seminar was converted into a "creative laboratory", where Landau's students, while feeding him scientific data, were taught his deep critical analysis and understanding of physics.

Each physicist who passed the theoretical minimum acquired both rights and duties. He acquired the right to be backed by Landau, but at the same time, he made a commitment to give reports at the seminars. If a speaker failed to give intelligible answers to the questions pertaining to the reviewed material or could not clearly expound his thoughts, his situation was not enviable. Sometimes the unlucky fellow's name was excluded from the list of speakers, and he was deprived of the right to review articles from scientific journals (this happened rather seldom). In Landau's circle this measure was regarded as capital punishment: Landau despised such a theorist and immediately denied him backing.

Not all seminars were devoted to reviewing articles. Landau's students and physicists from other institutes and cities also made reports on original work. As a rule Landau would acquaint himself with original papers before the seminar; if he found a paper interesting, it would be presented. Landau personally spoke on all his own works at the seminar.

It was difficult, but a great honor, to deliver a talk at the seminar. The speaker was subjected to severe interrogation. The audience had the right to interrupt. The presentation was more a dialogue between the speaker and the audience (led by Landau) than a report. Often if the course of the dialogue, errors, gaps of logic, discrepancies and points of disagreement on basic assertions of the paper were brought to light. Landau was a man of great critical intellect: His criticism always helped find the truth.

If an author was a success at the seminar, he could be sure that his work was not logically inconsistent and that he had new results. This is why theorists were anxious to report their work at Landau's seminar: They knew they would always get an impartial, unprejudiced assessment of their work, and that from the highest possible authority.

Critical analysis of research is important in any field of science, and particularly so in theoretical physics. Investigation in theoretical physics is a chain of logical constructions that can sometimes be ruptured. In beginning his work an author may make assumptions whose validity is not always confirmed at the end; often these assumptions are not explicit. At Landau's seminar it would sometimes happen that after exhausting all his arguments, an author would unsuccessfully resort to his trump card: showing that his results coincided with the observed experimental data. This argument invariable provoked only laughter in the audience, since no coincidence of theory with experiment can justify logical gaps in the theorist's work.

Landau's working day always started with a visit to the experimental laboratories on the ground floor of the Institute for Physical Problems. There he rushed through the laboratories, found out the latest news and lingered on in case anyone wanted his immediate theoretical assistance. Landau believed the problems experimenters were currently solving had priority over the problems of theorists. He was always willing to cut short any activity whenever an experimenter asked him for a calculation however minor. His cooperation with experimenters gave rise to many of Landau's outstanding works. Indeed, his magnum opus — the formulation of the theory of superfluidity — was the fruit of his close cooperation with the experimenter Kapitsa.

For the sake of "economy of thought" Landau would often employ fundamental general principles, rejecting anything that could not be confined within these principles. But any new nontrivial result plunged him into deep thought. In such a case, Landau would apply his methods to the problem, either confirming or rejecting the result. It was in just this fashion that Landau became interested in the kinetic equation for elementary excitations in a quantum liquid; soon he found its exact solution.

Landau never did for his pupils what he believed they should do themselves. Sometimes, after many unsuccessful attempts to solve a problem, a student would ask Landau for help and hear the reply: "This is your problem. Why should I do it for you?" After Landau's flat refusal it become clear that no outside help would arrive; if the student was lucky, enlightenment would dawn and the problem would soon be solved. Neither did Landau formulate problems for his students, or supply thesis topics to his postgraduates: They were responsible for these tasks themselves. He thus trained them to be independent, educating them as future leaders of science.

Clear-cut logic and simplicity were characteristic of Landau's work. He thoroughly thought over his lectures and articles. He did not write his articles himself: His associates — most often Lifshitz — were entrusted with this respected task.

In mathematics, Landau always set greater store by methods that enable one to solve concrete physical problems than he did by existence theorems. He had however underestimated abstract mathematics which was not yet widely adopted in physics.

He used to say in jest: "We know that the mathematics of the 21^{th} *century is nothing but theoretical physics". Yet, by the 1970's, a growing list of modern mathematical disciplines such as topology, algebraic geometry, algebraic topology and differential geometry – have joined group theory and* 19^{th}*-century applied mathematics at the forefront of modern physics.*

Superconductivity[764]

Lev Landau *and* ***Vitaly L. Ginzburg***[765] *cast the phenomenology of superconductivity in the language of quantum mechanics (1950); they introduced a macroscopic wave-function* (ψ) *whose square modulus represents the Cooper-pair density* (n)*:* $|\psi|^2 = n$. *This wave-function satisfies a Schrödinger-like equation called the Ginzburg-Landau equation, which may be written in one dimension as* $\frac{d^2\psi}{dx^2} = \frac{2m^*a}{\hbar^2}\psi$, *where* m^* *is the effective mass of a Cooper-pair and* a *is a temperature-dependent real parameter. The solution is in the form* $\psi = Ce^{-x/\xi}$, *where* C *is a constant and* $\xi = \frac{\hbar}{\sqrt{2m^*a}}$ *is a coherence length.*

A microscopic theory of superconductivity was developed (1957) by ***John Bardeen***, ***Leon Cooper*** *and* ***Robert Schrieffer***, *known as the BCS theory. It provided a major conceptual breakthrough in the quantitative understanding of the mechanism of superconductivity. The central ingredient of the BCS theory is that electrons form Cooper pairs. By interaction with the ionic lattice, the conduction electrons develop a weak attraction for each other, mediated by quanta of lattice vibrations (phonons). This may be thought of in the following way: One electron passes through the lattice and the positive ions are attached to it, causing a distortion in their nominal positions. The second electron of the Cooper pair is then attracted by the clustered ions. The*

[765] **Vitaly L. Ginzburg** (b. 1916) was awarded the Nobel Prize in physics (2003) with **A.A. Abrikosov** (b. 1928) and **A.J. Leggett** (b. 1930) for their pioneering contributions to the theory of superconductors and superfluids.

Cooper pairs (each of which consists of electrons of anti-aligned momenta vectors and spin states) behave like bosons and form a condensate *analogously to photons in a laser beam. The distance over which the electron pair is correlated is several thousand Å, much greater than the typical distance between neighboring conduction electrons.*

The attraction between the electrons is extremely weak. In spite of the weakness of the interaction, the superconductivity phase transition occurs because the electrons close to the Fermi energy *have a net attraction preventing them from being scattered by lattice defects or thermal phonons.*

At temperatures just above the critical temperature *(T_c) the material is in the normal (non-superconducting) phase. At temperatures just below T_c, however, a small energy gap develops where there are no electronic states. The energy gap is caused by the binding energy due to the formation of the Cooper pair.*

In this superconducting phase, *whenever an electron hits a defect or phonon, it is unlikely that its Cooper-pair partner – typically many lattice-spacings away – would simultaneously encounter an identical obstruction; so the attraction between these two electrons suffices to keep the pair from being slowed down.*

If external influences (e.g. electromagnetic fields) induce a current *within the superconductor, the momenta of a Cooper-pair's electrons no longer cancel, but the energy gap still protects pairs from dissociation; the currents then fail to dissipate and become* permanent *(provided a flow-circuit is available within the superconductor).*

The formation of the condensed Cooper pairs is hindered by the thermal excitation of the electrons above the critical temperature, or by too-high current densities and/or external magnetic fields even when $T < T_c$. As the temperature is lowered beneath T_c, the number of electrons that can cross the gap is significantly reduced, a greater number of Cooper pairs are formed, and the energy gap becomes larger. At a temperature of zero Kelvin, all the states below the gap are filled, and the total energy is lower than in the normal state.

1932–1951 CE **Allan Balcom Du Mont** (1901–1965, USA). Engineer, inventor and pioneer in the practical development of television. Invented the first commercial television oscilloscope by perfecting the cathode-ray tube, devised the first TV guidance system for missiles, and invented the "tuning eye".

Du Mont was born in Brooklyn, NY and obtained a B.Sc. in electrical engineering from Rensselaer Polytechnic Institute (1924). He founded the Du Mont Laboratories (1931) in his garage with $1000 — half of it borrowed. By 1939 he became the first television millionaire and by 1951 his company was doing a gross business of about $75 million a year. Regular television broadcasts were initiated on April 30, 1939.

1932–1959 CE **Francis Thomas Bacon** (1904–1992, England). Engineer and inventor. Direct descendant of **Francis Bacon** (1561–1626). Developed the first practical hydrogen-oxygen *fuel cell*, which convert air and fuel into electricity through electrochemical processes.

Although **William Grove** discovered the principle of fuel cells in 1842, they were considered a scientific curiosity until the early 1940's, when Bacon proposed their use in submarines.

Bacon was born in Billericay Essex, UK. He graduated from Eton College and from Trinity College, Cambridge.

Bacon began experimenting with alkali electrolytes in the late 1930s, settling on potassium hydroxide (KOH) instead of using the acid electrolytes known since Grove's early discoveries. KOH performed as well as acid electrolytes and was not as corrosive to the electrodes. Bacon's cell also used porous "gas-diffusion electrodes" rather than solid electrodes as Grove had done. Gas-diffusion electrodes increased the surface area in which the reaction between the electrode, the electrolyte and the fuel occurs.

Also, Bacon used pressurized gases to keep the electrolyte from "flooding" the tiny pores in the electrodes. Over the course of the following twenty years, Bacon made enough progress with the alkali cell to present large scale demonstrations.

He continued his research with the Anti-submarine Experimental Establishment, then returned to Cambridge (1946), where he demonstrated a successful six-kilowatt fuel cell (1959). The first practical application of this high-efficiency, pollution-free technology was in the *Apollo space vehicles* of the United States, which used the alkaline fuel cells to provide in-flight power, heat, and clean drinking water, the latter a by-product of the electrochemical reaction.

Bacon sought new applications for fuel cells as a principal consultant to National Research Development Corp. (1956–62), Energy Conservation Ltd. (1962–71), and the U.K. Atomic Energy Authority (1971–73).

By the end of the century, the technology was being developed internationally. He was made an Officer of the Order of the British Empire (1967), elected a fellow of the Royal Society (1973), and awarded the first Grove Medal (1991).

Electrochemical Technologies — Origin, Legacy and Perspectives

A. Introduction

Aristotle postulated that all matter is comprised of four basic elements: earth, water, air, and fire. The idea dominated science until the late 18th century, when revolutionaries from rival nations transformed chemistry from a jumble of medieval alchemy into a true science. The pace of discovery accelerated rapidly as chemists on the frontiers of knowledge established the theories and methodologies of modern science. Electrochemical systems have played a determinant role in the history of mankind. They are an intrinsic part of our evolution on this Planet.

The whole of electrical technologies is based on magnetic and electrical phenomena and no history of the subject can ignore the origins of these two groups, remote and sometimes uncertain as these origins may be. For many centuries man has observed magnetic effects in natural minerals found in the ground and electrical effects in lightning, the aurora borealis, St. Elmo's fire, the electric eel and the attraction of light objects by natural resins when rubbed.

Some of these observations have been put to practical use from the very earliest recorded times — the lodestone for navigation, the electric eel for medicinal purposes — so that, if electrical engineering is the practical application of electrical and magnetic science, there is a sense in which it has not only its roots in the remote past but actually existed as a human activity even in those far-off days. The two sides, magnetism and electricity, however, remained quite apart until the beginning of the nineteenth century, when the discovery of the close relationship between them brought the two streams of thought together and opened the way to the establishment of their *interrelationship. The great surge forward in understanding the foundations of electromagnetism made modern electrical engineering possible.*

Electrochemistry plays a dominant role in a vast number of research and applied areas. This is basically a consequence of a unique combination of different features of electrochemical reactions.

Today, electrochemical processes comprise a substantial part of chemical industry and consume about seven percent of the industrial electricity use. They are of increasing importance w.r.t. environmental protection, safety and energy technology.

Electrochemical reactions are known for a wide range of materials such as metals, semiconductors, polymers, and biological systems. Electrochemistry currently plays a large role in a number of rather diverse areas such as preparative chemistry, analytical chemistry, energy storage, energy conversion, biochemistry, solid state chemistry, materials science, and microelectronics.

At the beginning of the twentieth century, electrochemistry was mainly dominated by studies of the transport of charged species and thermodynamic considerations.

Kinetic aspects of electrochemistry have become more important in electrochemical research since the middle of the twentieth century with an increased understanding of the chemical and electronic structure of the solid/solution interface. These studies have been accelerated by the application of numerous in-situ and ex-situ spectroscopic techniques, which have been combined with electrochemical experiments over the last thirty years. Recently,the introduction of in-situ scanning probe techniques has allowed us to follow electrochemical reactions on an atomic or molecular scale.

Based on theoretical and experimental results and methods gathered by electrochemists for many decades, electrochemistry is now used in many fundamental fields, such as the study of new organic and inorganic compounds biological systems. In more applied arenas, it is used to shape materials from the macroscopic to the microscopic scale, to accurately analyze for chemical impurities, to understand and prevent the corrosion of materials at low and extremely high temperatures, to probe the functioning of living cells, and to directly convert chemical energy into electricity.

Electrical energy does not exist naturally in any convenient form and it must be converted from some other energy form when needed. Chemical energy is the most practical source and is generally used in one of two ways. Fuel can be burnt in a heat engine, such as a petrol or diesel engine, or a gas turbine, which then drives an electrical generator. This process is inherently inefficient. Alternatively, the fuel may be consumed in an electrolytic reaction in a battery or fuel cell.

For low power (less than 50 W) and short duration missions, batteries are the logical choice. Engine generators and fuel cells are the preferred choices for applications demanding greater than 500 W. The following list highlights the salient points of each technology:

Diesel (or gasoline) generators produce electricity in a multi-step process. The energy in the fuel is first converted into rotary mechanical energy in the engine. Then, the rotary mechanical energy is converted to DC or AC electrical energy by a generator.

As this is a multi-step energy conversion process, involving a heat engine with moving parts and, thus, frictional losses, it is an intrinsically inefficient method for producing electricity. Diesel generators typically have lower efficiencies, in the range of 20% to 30%. Gasoline generators usually exhibit lower efficiencies, in the 10% to 15% range.

Diesel and gasoline generators are also characterized by a high operating temperature, noise, air pollution, and their requirement for regular maintenance. On the other hand, diesel and gasoline generators are inexpensive and readily available. They are also easily, even continuously, refuelable. The energy available from the generator is limited only by its supply of fuel.

A battery is an electrochemical energy conversion device. It converts the energy in the fuel (active material of the electrodes) directly into DC electricity. There is no combustion, no multi-step energy conversion, and no frictional loss. The battery is intrinsically efficient, silent and non-polluting. In most embodiments, the battery is also a low temperature device that produces power immediately upon demand.

However, batteries suffer from the limitation that all the available fuel is contained within the battery case. When a non-rechargeable (primary) battery has consumed its fuel, it is discarded and, with it, the energy conversion device and the "fuel tank". In a rechargeable (secondary) battery, one can reuse the energy conversion device and the "fuel tank", but one must wait for several hours for the recharging process to be completed. One cannot operate a battery continuously as one can operate the diesel generator.

The fuel cell is a device that converts fuel and an oxidant directly into electricity by an electrochemical process. The fuel is not burned to produce heat and the efficiency of energy conversion is not limited by the Carnot Cycle limits placed upon heat engines. The fuel cell, like a battery, has no moving parts in the energy conversion device, and thus suffers no frictional losses.

Realistic energy efficiencies in excess of 50% can be achieved with fuel cell systems in generator set applications. Fuel cells combine the advantages of both diesel generators and batteries, while eliminating the major drawbacks of both. A fuel cell is essentially the electrochemical energy conversion device *for the battery, engineered in such away that it is continuously refuelable, like the diesel generator.*

A fuel cell is intrinsically energy efficient, non-polluting, silent, and reliable. In some embodiments, it is a low temperature device that provides power instantly upon demand, and exhibits a long operating life with minimal maintenance.

B. Timeline History of Electrochemistry

1766 **Henry Cavendish** (1731–1810, England) studied the properties and the processes of preparation of hydrogen (without knowing its elemental character) in great detail and gave it the name "inflammable air".

1781 **Joseph Priestley** (1733–1804, England) produced water by igniting hydrogen in oxygen.

1783 **Henry Cavendish** observed combustion of hydrogen to produce water. Lavoisier repeated the experiments conducted by Cavendish and realized that this was a new gas. He gave it the name 'hydrogen' from the Greek Words for 'water former'.

1791 **Luigi Galvani** (1737–1798, Italy). Discovered that an animal muscular tissue could be induced to twitch if two different metals (later called 'electrodes') were brought into contact with it. His experiments eventually laid the foundations for the principle of *storage batteries*.

1800 **Alessandro Volta** (1745–1827, Italy). Discovered the principle of *electrolysis*: the production of a chemical reaction by passing an electric circuit through an *electrolyte* (a liquid that conducts electricity as a result of the presence of positive or negative ions, such as solutions of ionic salts).

Invented the first battery (the *voltaic pile*). He described two arrangements that produced an electric current: one was a pile of silver and zinc discs separated by cardboard moistened with brine, and the other — a series of glasses of salty or alkaline water in which bimetallic curved electrodes were dipped; it enabled electric currents to be produced, and was the first method of artificially producing a reasonable and controllable electric current.

1800 **William Nicholson** (1753–1815, England). Broke water into its components hydrogen and oxygen through *electrolysis.*

1800–1803 **Johann Wilhelm Ritter** (1776–1810, Germany). Invented *electroplating*[766] when he passed current through a copper-sulfate solution (1800). Discovered that water consists of two parts of hydrogen and one part of oxygen. Invented the *accumulator* or *rechargeable* battery.

1802 **William Cruickshank** (England) designed the first electric battery capable of mass-production.

1807 **Humphry Davy** (1778–1829, England). Isolated potassium and sodium through electrolysis. He thus established the use of electrochemistry for isolating highly active elements which had proved unresponsive to traditional chemical techniques.

1815–1828 **William Hyde Wollaston** (1766–1828, England) made (1815) improvements to the voltaic pile. Further improvements were made by **Robert Hare** (1781–1858, USA) during 1820–1831, and in 1829 by **Antoine-César Becquerel** (1788–1878, France).

1832 **Michael Faraday** (1791–1867, England) developed the *quantitative theory* of electrochemistry. His basic laws are:

- The amount of a substance deposited on each electrode of an electrolytic cell is directly proportional to the quantity of electricity passed through the cell.
- The quantities of different elements deposited by a given amount of electricity are in the ratio of their chemical equivalent weights.

1836 **John Daniell** (1790–1845, England). Improved the *voltaic cell*, replacing it with the *Daniell cell* which more reliably produced a steady current.

[766] The origins of electroplating go back to the *alchemists* of the 16th century: an iron rod decomposed when soaked in blue-vitriol ($CuSO_4 \cdot 5H_2O$). The *Parthians* (250–224 BCE) may have used an electric battery to supply electricity for a silver-plating process. This artifact was discovered in 1957 in the Baghdad museum. Some Biblical scholars have speculated that the *Ark of the Covenant* (I Sam *4*, II Sam *6*), was indeed a powerful high-voltage battery or a charged capacitor.

1837 **Moritz Hermann Jacobi** (1801–1874, Germany and Russia). Improved the process of *electroplating*; the object, a conductor of electricity, was placed (as a cathode) in a bath in which the electrolyte was the salt of a metal to be deposited. His first undertaking was *silverplating*.

1839 **William Robert Grove** (1811–1856, England). Constructed the first *fuel-cell* through the reverse process of electrolysis; he placed test tubes of hydrogen and oxygen gases over two respective platinum stripes in a vessel containing a dilute sulfuric acid with a connecting wire.

In such a device, the reactions producing the electric current are obtained from substances contained *outside* and not inside the casing. The chemical energy of a fuel is converted directly into electric energy, i.e. the energy released in the *oxidation* of a conventional fuel is made *directly* available in the form of an electric current. It thus avoids the wasteful detour of conventional, thermal power stations.

1841 **Robert Wilhelm Bunsen** (1811–1899, Germany). Replaced the expensive platinum electrode used in Grove's battery with a *carbon* electrode.

1859 **Gaston Planté** (1834–1889, France). Invented the first practical *accumulator* or *rechargeable battery*.

1868 **Georges Leclanché** (1839–1882, France). Devised the *dry-cell* with zinc alloy and manganese dioxide electrodes in an ammonium chloride electrolyte. This is the type of battery used in flashlights, radiosets etc. This cell was later improved (1888) by **Carl Gassner**.

1870 **Jules Verne** predicted the use of hydrogen fuel in his science-fiction book *Mysterious Island*. Verne describes a process whereby "*...water will one day be employed as fuel, that hydrogen and oxygen which constitute it, used singly or together, will furnish an inexhaustible source of heat and light, of an intensity of which coal is not capable... Water will be the coal of our future.*"

1875–1879 **Friedrich Kohlrausch** (1840–1910, Germany) found that Ohm's Law also applies to dissolved electrolytes. Discovered the law of the independent migration of ions, i.e.: each type of migrating ion has a specific resistance no matter what its original molecular combination may have been, and therefore a solution's electrical resistance is due only to the migrating ions of a given substance.

1877–1896 **Svante August Arrhenius** (1859–1927, Sweden), **Friedrich Ostwald** (1853–1932, Germany) and **Jacobus Van't Hoff** (1852–1911, Holland) expounded the theory of electrolytic dissociation and conduction of dilute solutions of electrolytes in the framework of general chemical kinetics.

1888–1906 **Hermann Nernst** (1864–1941, Germany). Elucidated the theory of voltaic cells by assuming an *electrolytic pressure of dissociation* (1889) which forces ions from electrodes into solution and which is opposed to the *osmotic pressure* of the dissolved ions.

He applied the *principles of thermodynamics* to the chemical reactions proceeding in a battery and showed how the characteristics of the current produced, could be used to calculate the *free energy change* in a chemical reaction producing the current. The *Nernst Equation* relates the cell's voltage to its chemical properties (1906). Nernst also invented the Nickel-Cadmium battery (1899) and worked out the thermodynamics of the 'dry cell' (1891).

1906 **Joseph John Thomson** (1856–1940, England) discovered that a hydrogen atom has a single electron.

1923 **Johannes Nicolaus Brönsted** (1879–1947, Denmark) developed the donor-acceptor theory of acids and bases.

1923 **John B.S. Haldane** (1892–1964, England) presented a paper to Cambridge University in which he proposed to meet the increasing demand for energy by using wind energy to electrolyze water into hydrogen and oxygen. The gases, first liquefied, can be stored until needed. They can then be recombined in combustion motors or 'oxidation cells'.

1929 **Rudolf Erren** (Germany) advanced the concept of injecting hydrogen into the air-fuel mixture of combustion engines, serving to heighten the output of the combustion process. He converted buses, vans, rail cars, and even *submarines* to be powered by hydrogen or any combination of hydrogen-fuel mixtures.

1930 **James J. Drumm** (1897–1974, Ireland) invented the *zinc-nickel alkaline battery*. The cell is an alkaline cell and the only metals which enter into its construction are stainless steel and pure nickel. Its mechanical strength is therefore quite satisfactory. The positive-plate system consists of the hydroxides of nickel mixed with nickel flakes. This electrode was first developed by **Edison** (1905).

The negative plate is a grid of nickel gauze and the electrolyte is a solution of zinc oxide in potassium hydroxide (potassium zincate). During charge, zinc is plated on to the nickel grid, and during discharge this zinc dissolves readily in the potassium hydroxide.

1931 **Hermann Honnef** (Germany) designed huge wind-power generators which could theoretically produce up to 100 megawatts of power, stored as hydrogen.

1932–1959 **Francis Thomas Bacon** (1904–1992, England). Invented the first successful *fuel-cell*. He improved on the expensive platinum catalysts employed by **Ludwig Mond** (1839–1909) and **Charles Langer** (1889) with a hydrogen-oxygen cell using less corrosive alkaline electrolytes and inexpensive nickel electrodes (1932). In 1959, Bacon and his coworkers were able to demonstrate a practical 5-kilowatt system capable of powering a welding machine.

1932 **Harold Clayton Urey** (1891–1981) discovered deuterium (heavy hydrogen).

1934 **Marcus Laurence Elwin Oliphant** (1901–2000) discovered tritium.

1938 **Igor I. Sikorski** (1889–1972, USA) suggested the use of liquid hydrogen as an aircraft fuel.

1943 **Samuel Ruben** (1900–1988, USA) invented the *Mercury-oxide cell* [*Anode*: Zn; *Cathode*: HgO; *Electrolyte*: KOH or NaOH aqueous solution]. It revolutionized battery technology by packing more capacity in less space and by being durable enough for the harsh climates of wartime theaters like North Africa and the South Pacific — places where ordinary zinc-carbon batteries (used in flashlights, mine detectors, and walkie-talkies) could not hold up. Ruben joined efforts with the P.R. Mallory company to manufacture millions of mercury cells for the WWII war effort. Both Ruben and Mallory then created the *Duracell* company.

1948–1955 **R.O. King** (Canada) and his associates at the University of Toronto showed that combustion engines can be converted to run on hydrogen, simply and cheaply.

1950's The U.S. Air Force was using hydrogen fuel in experimental, high-altitude, long-range reconnaissance aircraft.

1956–1965 **Rudolph Arthur Marcus** (USA). Established the modern theory of chemical kinetics, including theories of *electron transfer reactions*, unimolecular reactions, *electrode reactions*, semiclassical theory of collisions and bound states, intermolecular dynamics, solvent dynamics, and chemical reaction coordinates.

Application of his theories include such phenomena as photosynthesis, electrically conducting polymers, *chemiluminescence*[767] and corrosion. Awarded the Nobel Prize for Chemistry (1992).

1957 **Carl Walton Lillehei** (USA), a cardiovascular surgeon, developed the long-life miniature mercury battery.

1959–1980 **Lew Urry** (USA) and **Karl Kordesch** (USA) independently developed the *alkaline primary battery* which replaced the zinc-carbon flashlight batteries. In 1966, Kordesch developed a 150 kW *Alkaline fuel cell.* In 1970 he built an alkaline fuel cell/battery hybrid electric car based on an A-40 Austin. The fuel cell was installed in the trunk of the car and hydrogen tanks on the roof, leaving room for 4 passengers in the 4-door car.

1960's

- Lockheed (USA) was developing a high altitude supersonic spy plane to run on liquid hydrogen fuel.
- NASA (USA) developed the use of the hydrogen fuel-cell for use in the Apollo missions to the moon. The fuel-cells, utilizing expensive platinum electrodes, provided on-board electrical power, as well as generating drinking water for the crew's consumption.

767 Photon emission of a substance resulting from a chemical reaction (such as slow oxidation of phosphorus). The light emitted by the fire-fly or glow-worm, and luminous combustion, are examples of this common phenomenon.

- **John O'M. Bockris** at General Motors (USA), began advancing the idea of '*hydrogen economy*'. In this ambitious energy project, the cities of the United States could be supplied with *energy derived from the sun*, and the energy could be stored using hydrogen.

1960–1980 **Allen J. Bard** (USA). Fostered the development of electroanalytical methods and instruments that deepened the fundamental understanding of *electron-transfer reactions* and electrogenerated *chemiluminescence*.

1966–72 **Roger Billing** (USA) converted many late automobile models to run on hydrogen, using their internal combustion engines.

1974 **Joseph Lindmayer** (USA) developed a silicon photovoltaic cell for harnessing solar power.

1975 **Alan J. Heeger** (USA), **Hideki Shirakawa** (Japan) and **Alan G. MacDiarmid** (USA) shared the 2000 Chemistry Nobel Prize for the discovery and development of organic conducting polymers ("synthetic metals").

C. Thermochemistry

When a chemical reaction occurs some chemical bonds are broken and others are formed. Thus, the energy associated with chemical bonds and intermolecular attraction (chemical energy) changes, and some of this energy change appears as the intake or release of heat, i.e.: microscopic kinetic energy associated with random molecular motion.

A heat of reaction *is the quantity of heat exchanged between a system and its surrounding when a chemical reaction occurs within the system at constant temperature (e.g.: heat combustion).*

If reaction occurs in an isolated system *(neither matter nor energy are exchanged with its surroundings), the reaction produces a change in the thermal energy of the system, accompanied by a change in temperature. An* *exothermic reaction* produces a temperature increase in an isolated system or, in a nonisolated system, gives off heat to the surrounding (*negative* heat of reaction). The reverse is true for an *endothermic reaction.*

Internal energy, U is the total energy of a system (both kinetic and potential) including:

- Translational, rotational and vibrational energy of molecules.
- Energy stored in chemical bonds and intermolecular interactions.
- Energy associated with the interaction of protons and neutrons in atomic nuclei (unchanged in a chemical reaction).

Heat transfer and *work* are means by which a system exchanges energy with its surrounding, and occur only during a *change* in the system.

The first law of thermodynamics dictates the relationship between heat supplied (q), external work done (W) and changes in internal energy:

$$\Delta U = q + W$$

The convention followed is that energy *entering* the system carries a *positive* sign. Thus, if heat is *absorbed* by the system, $q > 0$. If work is done *on* the system, $W > 0$. Any energy *leaving* the system carries a *negative* sign. Thus, if heat is *given off* by the system, $q < 0$. If work is done *by* the system, $W < 0$.

If, on balance, energy enters the system, $\Delta U > 0$. If more energy leaves the system, $\Delta U < 0$.

The *state* of a system is indicated by a complete set of *state variables*, such as its *temperature* (T), *pressure* (P) and the types and amounts of substances present.

One useful state variable is the *enthalpy* $H = U + PV$ $(V =$ volume). If a process is carried out at a constant temperature and pressure, $\Delta H = \Delta U + P\Delta V$. For example, the equation for the combustion of sucrose is

$$C_{12}H_{22}O_{11}\ (\textit{solid}) + 12O_2\ (\textit{gas}) \rightarrow 12CO_2\ (\textit{gas}) + 11H_2O\ (\textit{liquid})$$

for which

$$\Delta H = -5.65 \times 10^6\ \textit{Joule/mole} \qquad (\textit{heat is produced}).$$

This reaction is *exothermic*. On the other hand, for the reaction

$$N_2\ (\textit{gas}) + O_2\ (\textit{gas}) \rightarrow 2NO\ (\textit{gas})$$

$$\Delta H = +1.8 \times 10^5 \ Joule/mole$$

and heat is absorbed from the surroundings (endothermic).

The exothermic ionic reaction

$$H^+ \ (aq) + OH^- \ (aq) \rightarrow H_2O \ (liquid), \qquad \Delta H = -5.58 \times 10^4 \ J/mole$$

describes the neutralization of a strong acid by a strong base.

It is useful to define the Gibbs free energy $G = H - TS$, *where* S *is the entropy function. For a process occurring at constant* T, *the free energy change is* $\Delta G = \Delta H - T\,dS$.

We might think that the quantity of energy available to do work in the surroundings as a result of an exothermic chemical process as $-(\Delta H)$. *This would be the same as the quantity of heat that an exothermic reaction releases to the surroundings (including any volume-changing mechanical work, if* P *is held fixed). However, that quantity of heat must be adjusted for the heat requirement in reversibly producing the accompanying entropy change in the system* ($q_{\text{rev}} = T\Delta S$).

If an exothermic reaction is accompanied by an increase in entropy, the amount of energy available to do work in the surroundings is greater than $-\Delta H$. *If entropy decreases in the exothermic reaction, the amount of energy available to do work is less than* $-\Delta H$. *But in either case, this amount of energy is equal to* $-\Delta G$. *Thus, the amount of work that we are free to extract from a chemical process is* $-\Delta G$, *so the Gibbs function* G *is called the free energy function.*

Notice also that this interpretation of free energy allows for the possibility of work being done in an endothermic process if $T\Delta S$ *exceeds* ΔH[768]. *We will see next how the free energy change accompanying a reaction can be converted to electrical work. In any case we must not think of free energy as being "free" energy. Costs are always involved in tapping an energy source.*

Because we cannot establish absolute values for G *or* H *we must refer these state variables to a certain standard cell, with standard potential difference* ΔE° *(for an electrochemical process) and with corresponding* ΔH° *and* ΔG° *(for any chemical reaction or process).*

Now, we know that the entropy change for an isothermal expansion of one mole of an ideal gas is simply $\Delta S = R \ln \frac{V_f}{V_i}$ *(R the gas constant), where* V_f *is its final volume and* V_i *is its initial volume. Since for an ideal gas*

[768] A reaction for which $\Delta G < 0$ is called *exergonic*, whereas, if $\Delta G > 0$, it is referred to as *endergonic*.

$\Delta H = \Delta H^\circ$ and $\Delta S = \Delta S^\circ - R \ln Q$, where Q is the reaction quotient[769]*, we obtain $T\Delta S = T\Delta S^\circ - RT \ln Q$ and thus*

$$\Delta G = \Delta H^\circ - T\Delta S^\circ + RT \ln Q = \Delta G^\circ + RT \ln Q.$$

Hence the Nernst Equation (1889):

$$\Delta G = \Delta G^\circ + RT \ln Q.$$

Fossil Fuels

Energy-source materials, called fuels, liberate heat through the process of combustion. The bulk of Carnot cycle needs are met by petroleum, natural gas and coal, so-called fossil fuels. These fuels are derived from remains of plant and animal life from millions of years ago.

The original source of the energy locked into these fuels is solar energy; in the process of photosynthesis, CO_2 and H_2O, in the presence of enzymes, the pigment chlorophyll, and sunlight, are converted into carbohydrates which are compounds with formulas $C_m(H_2O)_n$, where m and n are integers [e.g. in sugar glucose $m = n = 6$, that is, $C_6(H_2O)_6 = C_6H_{12}O_6$. Its formation through photosynthesis is an endothermic process, represented as

$$6CO_2\ (gas) + 6H_2O\ (liquid) \xrightarrow[\text{sunlight}]{\text{chlorophyll}} C_6H_{12}O_6\ (solid) + 6O_2\ (gas),$$

$$\Delta H = +2.8 \times 10^6 \text{ Joules/mole of } C_6H_{12}O_6.$$

When this reaction is reversed (combustion of glucose), heat is produced in an exothermic process.

The complex carbohydrate cellulose, with molecular masses ranging up to 500,000 amu, is the principal structural material of plants. When plant life decomposes in the presence of bacteria and out of contact with air, O and H atoms are removed and the approximate carbon content of the residue increases in the progression (percentage by mass)

$$\text{peat} \to \text{lignite } (32\%\ C) \to \text{sub-bituminous coal } (40\%\ C) \to \text{bituminous coal } (60\%\ C) \to \text{anthracite coal } (80\%\ C)$$

[769] Q is defined as the product of $n_i^{a_i}$ for all *reagents* and *products* with n_i the molar concentrations, and a_i = number of molecules of species i in the balanced reaction ($a_i > 0$ for products, $a_i < 0$ for reagents).

For this process to proceed all the way to anthracite coal may take about 300 *million years. Coal, then, is a combustible organic rock consisting of carbon, hydrogen, and oxygen, together with small quantities of nitrogen, sulfur, and mineral matter (ash). (One proposed formula for a "molecule" of bituminous coal is* $C_{153}H_{115}N_3O_{13}S_2$*.)*

Petroleum and natural gas have formed in a somewhat different way. The remains of plants and animals living in ancient seas fell to the ocean floor, where they were decomposed by bacteria and covered with sand and mud. Over time, the sand and mud were stacked in layers and converted to sandstone by their own weight. The high pressures and temperatures resulting from this overlying sandstone rock formation transformed the original organic matter into petroleum and natural gas. The ages of these deposits range from about 250 *million to* 500 *million years.*

A typical natural gas consists of about 85% *methane* (CH_4), 10% *ethane* (C_2H_6), 3% *propane* (C_3H_8), *and small quantities of other combustible and noncombustible gases. A typical petroleum consists of several hundred different hydrocarbons that range in complexity from* C_1 *molecules* (CH_4) *to* C_{40} *or higher* (*such as* $C_{40}H_{82}$).

One way to compare different fuels is through their heats of combustion: In general, the higher the magnitude of the heat of combustion, the better the fuel. Table 5.8 lists approximate heats of combustion for the fossil fuels. These data show that biomass (living matter or materials derived from it — wood, alcohols, municipal waste) is a viable fuel, but that fossil fuels yield more energy per unit mass.

Table 5.8: APPROXIMATE HEAT OF COMBUSTION OF SOME FUELS

FUEL	HEAT OF COMBUSTION, KJ/GRAM
Municipal waste	−12.7
Cellulose	−17.5
Pinewood	−21.2
Methanol	−22.7
Peat	−20.8
Bituminous coal	−28.3
Iso-Octane	−47.8
Natural gas	−49.5

Methanol (methyl alcohol), CH_3OH, *can be obtained from coal by the reaction*

$$CO\ (gas) + 2H_2\ (gas) \rightarrow CH_3OH\ (liquid).$$

It can also be produced by thermal decomposition (pyrolysis) of wood, manure, sewage, or municipal waste. The heat of combustion of methanol is only about one-half that of a typical gasoline on a mass basis, but methanol has a high octane number — 106 — compared with 100 for the gasoline hydrocarbon iso-octane and about 92 for premium gasoline. Methanol has been tested and used as a fuel in internal combustion engines and is cleaner burning than gasoline. Methanol can also be used for space heating, electric power generation, fuel cells, and as a reactant to make a variety of other organic compounds.

Ethanol (ethyl alcohol), C_2H_5OH, *is produced mostly from ethylene,* C_2H_4, *which in turn is derived from petroleum.*

Ethanol production by fermentation is probably most advanced in Brazil, where sugarcane and cassava (manioc) are the plant matter (biomass) used. In the United States, ethanol fuel is used chiefly as a 90% gasoline–10% ethanol mixture called gasohol. Ethanol admixture is also used to raise the octane number of gasoline.

Another fuel with great potential is hydrogen. Its most attractive features are the following:

- *On a per gram basis, its heat of combustion is more than twice that of methane and about three times that of gasoline.*
- *The product of its combustion is* H_2O, *not* CO *and* CO_2 *as with gasoline.*

Currently, the bulk of hydrogen used commercially is made from petroleum and natural gas. (Alternative methods of producing hydrogen, and the prospects of developing an economy based on hydrogen are current subjects of research and development.)

Combustion reactions are only one means of extracting useful energy from materials. An alternative, for example, is to carry out reactions that yield the same products as combustion reactions in electrochemical cells called fuel cells. The energy is released as electricity rather than as heat. Solar energy can be used directly, without recourse to photosynthesis. Nuclear processes can be used in place of chemical reactions.

Alternative energy sources, including those intended for automobiles, are likely to become increasingly important in the twenty-first century.

D. Electrochemistry[770]

"A conventional gasoline-powered automobile is only about 25% efficient in converting chemical energy into kinetic energy (energy of motion). An electric-powered auto is about three times as efficient. Unfortunately, when automotive technology was first being developed, devices for converting chemical energy to electrical energy did not perform at their intrinsic efficiencies. This fact, together with the availability of high-quality gasoline at a low cost, resulted in the preeminence of the internal combustion automobile. Now, with concern about long-term energy supplies and environmental pollution, there is a renewed interest in electric-powered buses and automobiles."

"Chemical reactions can be used to produce electricity and electricity can conversely be used to drive chemical reactions. The practical applications of electrochemistry are countless, ranging from batteries and fuel cells as electric power sources, to the manufacture of key chemicals, the refining of metals, and the methods of controlling corrosion. Also important, however, are the theoretical implications. Because electricity involves flow of electric charge, a study of the relationship between chemistry and electricity gives us additional insight into reactions in which electrons are transferred in oxidation-reduction reactions.*"*

A basic concept of electrochemistry is that of oxidation number. *It is a number related to the number of electrons that an atom loses or gains, or otherwise appear to use in joining with other atoms in compounds. The following (somewhat arbitrary) conventions or rules are assigned:*

- *In its compounds,* hydrogen *has an oxidation state (O.S.) of* $\boxed{+1}$, *except in metal hydride compounds, where it has O.S. of* $\boxed{-1}$.
- *In its compounds,* oxygen *has an O.S. of* $\boxed{-2}$.
- *The O.S. of an individual atom in a* free element *(uncombined with other elements) is zero,* $\boxed{0}$.
- *The total oxidation states of all atoms in* neutral species *(isolated atoms, molecules) is zero; In* ions*, the O.S. number is equal to the charge of the ion.*

[770] Section D includes quotations and Figures (5.5, 5.6, 5.7, 5.8, 5.9) from ch.21 of: Petrucci, R.H., W.S. Hardwood and F.G. Herring, *General Chemistry*, Prentice-Hall, 2002, 1160 pp.

A reagent which gains oxygen (O) atoms is said to undergo oxidation. A reagent which loses oxygen (O) atoms is said to undergo reduction. An oxidation and a reduction must always occur together and such a reaction is called an oxidation-reduction or redox reaction.

In a broader sense: oxidation is a process in which the O.S. of some element increases and in which electrons appear on the r.h.s. of a half-equation. Accordingly, reduction is a process in which the oxidation number of some element decreases and in which electrons appear on the l.h.s. of a half-equation. For example,

$$\mathrm{Zn}\ (solid) + \mathrm{Cu}^{2+}\ (aq) \to \mathrm{Zn}^{2+}\ (aq) + \mathrm{Cu}\ (solid)$$

is rewritten as two half-equations that hold simultaneously:

$$\begin{array}{lrl} \textit{oxidation} & \mathrm{Zn}\ (s) & \to \mathrm{Zn}^{2+} + 2e^- \\ \textit{reduction} & \mathrm{Cu}^{2+}\ (aq) + 2e^- & \to \mathrm{Cu}\ (s) \end{array}$$

Explanation:

> *In the first half-reaction,* Zn *is oxidized — its oxidation state increases from* 0 *to* +2. *This change corresponds to a loss of two electrons by each zinc atom.*
>
> *In the second half-reaction,* Cu^{2+} *is reduced — its oxidation state decreases from* +2 *to* 0. *This change corresponds to the gain of two electrons by each* Cu^{2+} *ion.*

Consider a strip of metal (called an electrode) immersed in a solution containing ions of the same metal. This combination is known as a half-cell. Two kinds of interactions are possible between metal atoms in the electrode and metal ions in solution (assuming the metal does not interact with the water solvent):

1. *A metal cation* M^{n+} *from the solution may collide with the electrode, gain n electrons from it, and be converted to a metal atom* M. *The ion is reduced.*
2. *A metal atom* M *on the surface may lose n electrons to the electrode and enter the solution as the ion* M^{n+}. *The metal atom is oxidized.*

An equilibrium is quickly established between the metal and the solution, which we can represent as

$$M(s) \underset{reduction}{\overset{oxidation}{\rightleftarrows}} M^{n+}(aq) + ne^-$$

However, any changes produced at the electrode or in the solution as a consequence of this equilibrium are not easily measured. Instead, our measurements must be based on a combination of two different half-cells. *Specifically, we must measure the tendency for electrons to flow from the electrode of one half-cell to the electrode of the other. Electrodes are classified according to whether oxidation or reduction takes place there. If oxidation takes place, the electrode is called the anode. If reduction takes place, the electrode is called the cathode.*

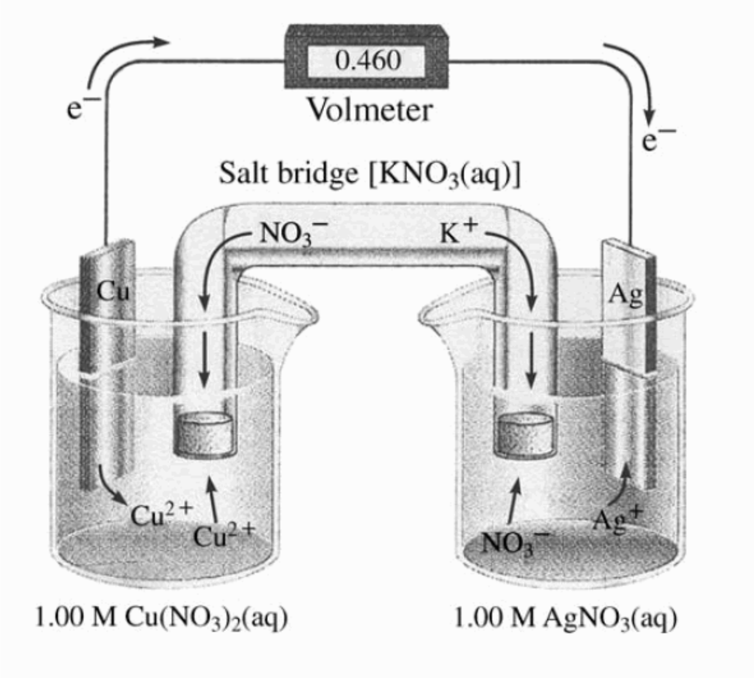

Fig. 5.7: Electrochemical cell

Example (Figure 5.7):

An electrochemical cell consists of two half-cells, one with Cu *electrode in contact with* Cu^{2+} *(aqueous), and the other with* Ag *and* Ag^{+} *(aqueous). The two electrodes are joined by wires and the solutions are joined by a third solution in a U-tube called a salt-bridge. The ends of the salt-bridge are plugged with a porous material that allows ions to migrate but prevents the bulk flow of liquid.*

Now, Cu *atoms on the anode release electrons and enter the* $Cu(NO_3)_2$ *aqueous solution as* Cu^{2+} *ions. These electrons pass through the wires to the* *cathode, where they are gained by the* Ag^+ *ions from the* $AgNO_3$ *solution, producing a deposit of metallic silver. Simultaneously, anions* (NO_3^-) *from the salt-bridge migrate into the copper half-cell and neutralize the positive charge of excess* Cu^{2+} *ions; cations* (K^+) *migrate into the silver half-cell and neutralize the negative charge of the excess* NO_3^- *ions. The overall reaction that occurs as the electrochemical cell* spontaneously *produces electric current is*

oxidation (at anode)	$\mathrm{Cu}\ (solid) \rightarrow \mathrm{Cu}^{2+}(aq) + 2e^-$
reduction (at cathode)	$2\left\{\mathrm{Ag}^+\ (aq) + e^- \rightarrow \mathrm{Ag}\ (solid)\right\}$
Overall	$\mathrm{Cu}\ (solid) + 2\mathrm{Ag}^+\ (aq) \rightarrow \mathrm{Cu}^{2+}\ (aq) + 2\mathrm{Ag}\ (s)$

The reading of the voltmeter $(0.460\ \mathrm{V})$ *is the cell voltage or the potential difference between the two half-cells. The unit of cell voltage Volt* (V) *is an energy per unit charge. Thus, a potential difference of one volt signifies a energy of one Joule for every coulomb of charge passing through an electric circuit. This voltage is the driving force for electrons through the circuit.*

The cell described above which produces electricity as a result of a spontaneous ($\Delta G < 0$, *exergonic) chemical reaction is called voltaic or galvanic cell. An electrochemical cell in which electricity is used to accomplish a non-spontaneous chemical change* ($\Delta G > 0$, *endergonic) is known as electrolytic cell.*

When a reaction occurs in a voltaic cell, the cell does electrical work. It is the work of moving electric charges. The total work (W_{elec}) *done is the product of three terms:* (*a*) E_{cell}*;* (*b*) n, *the number of moles of electrons transferred between the electrodes; and* (*c*) *the electric charge per mole of electrons, called the Faraday constant* (F). *The Faraday constant is equal to* $96,485$ *coulombs per mole of electrons* $(96,485\ \mathrm{C/mol}\ e^-)$. *Because the product* Volt $\times$ Coulomb $=$ Joule, *the unit of* W_{elec} *is joules* (J). *Thus*

$$W_{\mathrm{elec}} = nFE_{\mathrm{cell}}$$

This expression applies only if the cell operates reversibly. The maximal amount of available energy (work) that can be derived from a process is equal to $-\Delta G$, *namely*

$$\Delta G = -nFE_{\mathrm{cell}},$$

where G *is the Gibbs free energy function. It then follows from* $\Delta G^\circ = -nFE^0_{\mathrm{cell}}$*:*

$$E_{\mathrm{cell}} = E^\circ_{\mathrm{cell}} - \frac{RT}{nF}\ln Q,$$

which is the Nernst equation applied to electrochemistry.

Batteries

A battery is a device that stores chemical energy for later release as electricity. Some batteries consist of a single voltaic cell with two electrodes and the appropriate electrolyte(s); an example is a flashlight cell. Other batteries consist of two or more voltaic cells joined in series fashion — plus to minus — to increase the total voltage; an example is an automobile battery. We will consider three types of cells and batteries.

- *Primary batteries (or primary cells). The cell reaction is not reversible. When the reactants have been mostly converted to products, no more electricity is produced and the battery is dead.*
- *Secondary batteries (or secondary cells). The cell reaction can be reversed by passing electricity through the battery (charging). Such a battery can be used through several hundred or more cycles of discharging followed by charging.*
- *Flow batteries and fuel cells. Materials (reactants, products, and electrolytes) pass through the battery, which is simply a converter of chemical energy to electric energy.*

Batteries are vitally important to modern society: In developed nations, annual production has been estimated at over 10 *batteries per person per year.*

The most common form of voltaic cell is the Leclanché cell, invented by the French chemist ***Georges Leclanché*** *(1839–1882) in 1868. Popularly called a dry cell (because no free liquid is present) or flashlight battery, the Leclanché cell is diagrammed in Figure 5.8. In this cell, oxidation occurs at a zinc anode and reduction at an inert carbon (graphite) cathode. The electrolyte is a moist paste of* MnO_2, $ZnCl_2$, NH_4Cl, *and carbon black (soot). The maximum cell voltage is* 1.55 *V. The anode (oxidation) half-reaction is simple:*

$$\textit{Oxidation}: \qquad Zn\ (s) \rightarrow Zn^{2+}\ (aq) + 2e^-$$

The reduction is more complex. Essentially, it involves the reduction of MnO_2 *to compounds having* Mn *in a* $(+3)$ *oxidation state, for example,*

$$\textit{Reduction}: \qquad 2MnO_2\ (s) + H_2O\ (l) + 2e^- \rightarrow Mn_2O_3\ (s) + 2OH^-\ (aq)$$

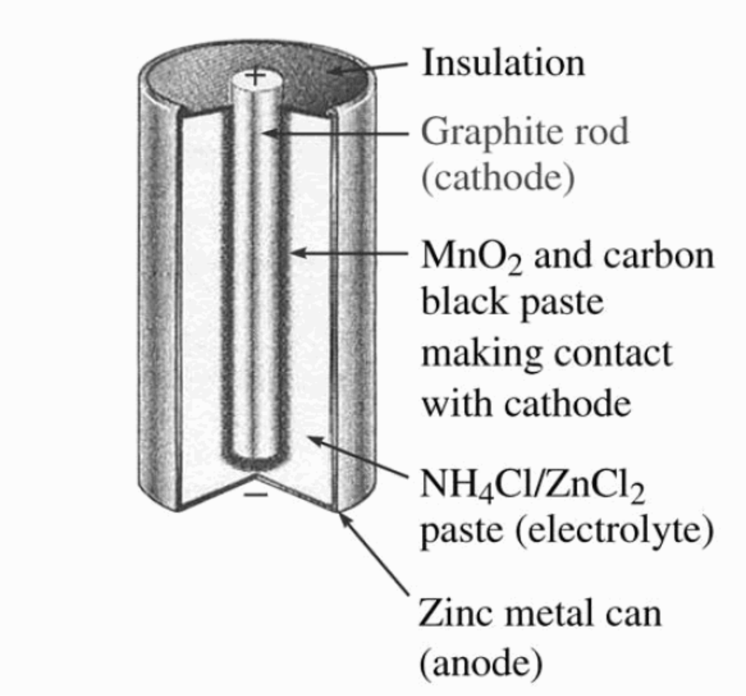

Fig. 5.8: Leclanché (dry) cell

An acid-base reaction occurs between NH_4^+ *(the cation from the salt* NH_4Cl*) and* OH^-.

$$NH_4^+\ (aq) + OH^-\ (aq) \rightarrow NH_3\ (g) + H_2O\ (l)$$

A buildup of NH_3 *(g) cannot be permitted to occur around the cathode because it would disrupt the current by adhering to the cathode. That buildup is prevented by a reaction between* Zn^{2+} *and* NH_3 *(g) to form the complex ion* $[Zn(NH_3)_2]^{2+}$, *which crystallizes as a chloride salt.*

$$Zn^{2+}\ (aq) + 2NH_3\ (g) + 2Cl^-\ (aq) \rightarrow [Zn(NH_3)_2]Cl_2\ (s)$$

The Leclanché cell is a primary cell; it cannot be recharged. This cell is cheap to make, but it has some drawbacks. When current is drawn rapidly from the cell, products such as NH_3 *build up on the electrodes, causing the voltage to drop. Also, because the electrolyte medium is acidic, the zinc metal slowly dissolves.*

A superior form of the Leclanché cell is the alkaline cell, which uses NaOH *or* KOH *in place of* NH_4Cl *as the electrolyte. The reduction half-reaction is the same as that shown above, but the oxidation half-reaction involves the*

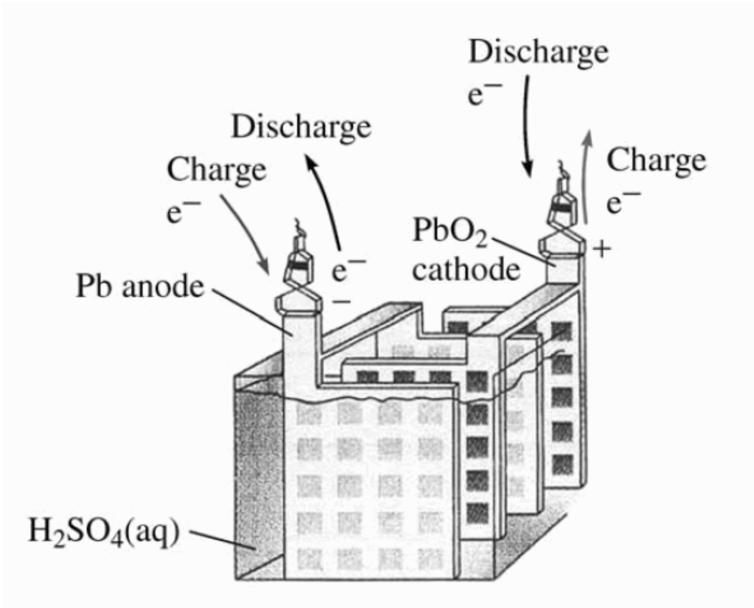

Fig. 5.9: Lead-acid cell

formation of $Zn(OH)_2$ *(s), which we can think of as occurring in two steps.*

$$\begin{array}{rrcl} & \text{Zn (s)} & \rightarrow & \text{Zn}^{2+}\ \text{(aq)} + 2e^- \\ & \text{Zn}^{2+}\ \text{(aq)} + 2\text{OH}^-\ \text{(aq)} & \rightarrow & \text{Zn(OH)}_2\ \text{(s)} \\ \hline \textit{Overall}: & \text{Zn (s)} + 2\text{OH}^-\ \text{(aq)} & \rightarrow & \text{Zn(OH)}_2\ \text{(s)} + 2e^- \end{array}$$

The advantages of the alkaline battery are that zinc does not dissolve as readily in a basic (alkaline) medium as in an acidic medium and the battery does a better job of maintaining its voltage as current is drawn from it.

The most common secondary *battery is the lead-acid battery or* storage battery, *used in automobiles since about 1915 (Figure 5.9). A storage battery is capable of repeated use because it uses chemical reactions that are reversible. That is, the discharged energy can be restored by supplying electric current to recharge the cell.*

The reactants in a lead-acid battery are spongy lead packed into a lead grid at the anode, red-brown lead (IV) oxide packed into a lead grid at the cathode, and dilute sulfuric acid with about 35% H_2SO_4, *by mass. In this strongly acidic medium the ionization of* H_2SO_4 *does not go to completion. Both* HSO_4^- *(aq) and* SO_4^{2-} *(aq) are present, but* HSO_4^- *predominates. The half-reactions and overall reaction are*

$$\begin{aligned} PbO_2\ (s) + 3H^+\ (aq) + HSO_4^-\ (aq) + 2e^- &\rightarrow PbSO_4\ (s) + 2H_2O\ (l) \\ Pb\ (s) + HSO_4^-\ (aq) &\rightarrow PbSO_4\ (s) + H^+\ (aq) + 2e^- \\ \hline PbO_2\ (s) + Pb\ (s) + 2H^+\ (aq) + 2HSO_4^-\ (aq) &\rightarrow 2PbSO_4\ (s) + 2H_2O\ (l) \end{aligned}$$

$$E_{\text{cell}} = E_{\text{PbO}_2/\text{PbSO}_4} - E_{\text{PbSO}_4/\text{Pb}} = 1.74V - (-0.28V) = 2.02V$$

When an automobile engine is started, the battery is at first discharging. Once the car is in motion, an alternator powered by the engine constantly recharges the battery. At times, the plates of the battery become coated with $PbSO_4$ *(s) and the electrolyte becomes sufficiently diluted with water that the battery must be recharged by connecting it to an external electric source. This forces the (non-spontaneous) reverse of the above reaction:*

$$2PbSO_4\ (s) + 2H_2O\ (l) \rightarrow Pb\ (s) + PbO_2\ (s) + 2H^+\ (aq) + 2HSO_4^-\ (aq) \qquad E_{\text{cell}} = -2.02\ V$$

To prevent the anode and cathode from coming into contact with each other and causing a short circuit, sheets of insulating material are used to separate alternating anode and cathode plates. A group of anodes is connected together electrically, as is a group of cathodes. This parallel connection increases the electrode area in contact with the electrolyte solution and thus increases the current-delivering capacity of the cell. Several such cells are then joined in a series fashion, positive to negative, to produce a battery. The typical $12\ V$ *battery consists of six cells, each cell potential of about* $2\ V$*.*

An important modern variant of the dry cell is the miniature button battery *— the* silver-zinc cell *used in watches, hearing aid, cameras, and other portable electronic equipment. In addition it fulfills the requirements of space craft, satellites, missiles, rockets, torpedoes, underwater vehicles, and life-support systems.*

The cell diagram of a silver-zinc cell *(Figure 5.10) is*

$$Zn\ (s),\ ZnO\ (s)\ |\ KOH\ (satd)\ |\ Ag_2O\ (s),\ Ag\ (s)$$

The half-reactions on discharging are

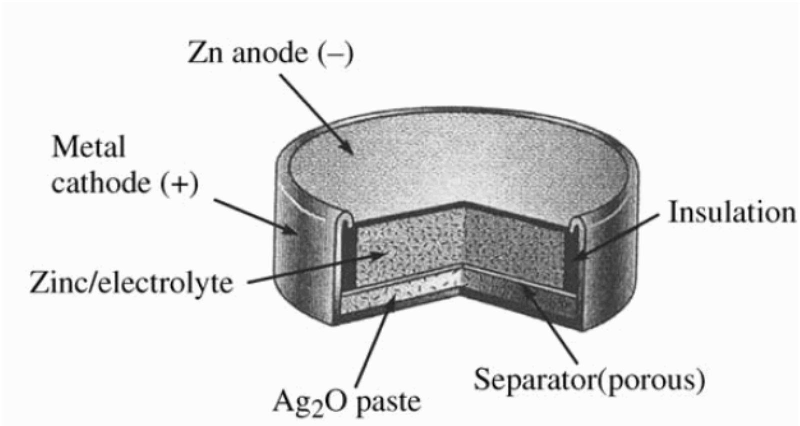

Fig. 5.10: Silver-Zinc cell

$$\begin{array}{ll} \textit{Reduction}: & Ag_2O\ (s) + H_2O\ (l) + 2e^- \rightarrow 2Ag\ (s) + 2OH^-\ (aq) \\ \textit{Oxidation}: & Zn\ (s) + 2OH^-\ (aq) \rightarrow ZnO\ (s) + H_2O\ (l) + 2e^- \\ \hline \textit{Overall}: & Zn\ (s) + Ag_2O\ (s) \rightarrow ZnO\ (s) + 2Ag\ (s) \end{array}$$

Because no solution species is involved in the overall cell reaction, the quantity of electrolyte is very small and the electrodes can be maintained very close together. The cell voltage is 1.8 *V, and its storage capacity is six times greater than that of a lead-acid battery of the same size.*

Rechargeable Batteries

In the field, a battery that suddenly goes dead is unacceptable. Secondary cells can be charged and discharged many times, making it economic to use, but requiring a more costly construction.

The nickel-cadmium cell is commonly used in cordless electric devices, such as electric shavers and handheld calculators. The anode in this battery is cadmium metal, and the cathode is the Ni *(III) compound* NiO(OH) *supported on nickel metal. The half-cell reactions for a nickel–cadmium battery*

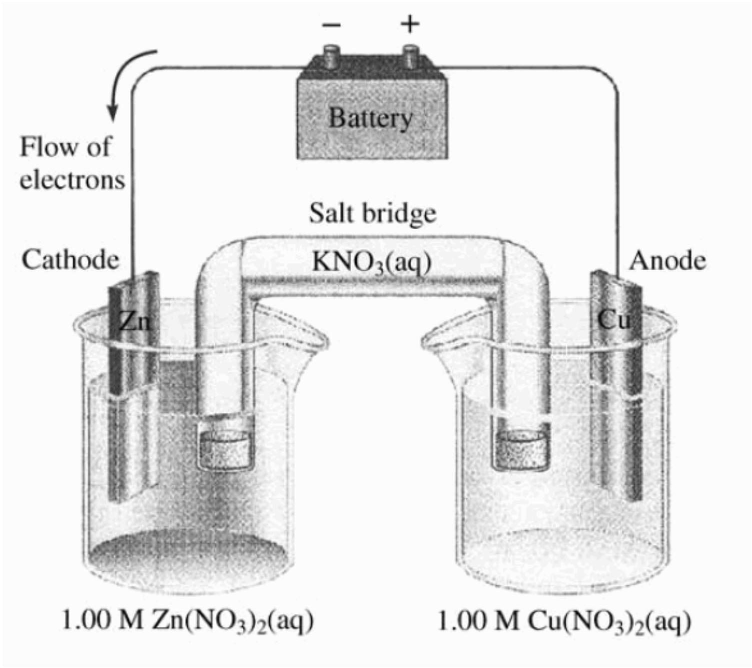

Fig. 5.11: An electrolytic cell

during discharge are

$$\textit{Reduction:}\quad \begin{matrix} 2NiO(OH)\ (s) \\ +\,2H_2O\ (l) + 2e^- \end{matrix} \rightarrow 2Ni(OH)_2\ (s) + 2OH^-\ (aq)$$

$$\textit{Oxidation:}\quad Cd\ (s) + 2OH^-\ (aq) \rightarrow Cd(OH)_2\ (s) + 2e^-$$

$$\textit{Overall:}\quad \begin{matrix} Cd\ (s) + 2NiO(OH)\ (s) \\ +\,2H_2O\ (l) \end{matrix} \rightarrow 2Ni(OH)_2\ (s) + Cd(OH)_2\ (s)$$

This battery gives a fairly constant voltage of 1.4 *V. When recharged by connecting the battery to an external voltage source, the reactions above are reversed. Nickel–cadmium batteries can be recharged many times because the solid products adhere to the surface of the electrodes.*

Note that assigning the terms anode *and* cathode *is not based on the electrode charges; it is based on the half-reactions at the electrode surfaces. Specifically,*

- Oxidation *always occurs at the* anode *of an electrochemical cell. Because of the buildup of electrons freed in the oxidation half-reaction, the anode* *of a voltaic cell is* $(-)$*. Because electrons are withdrawn from it, the anode in an electrolytic cell is* $(+)$*. For either type of cell, the anode is the electrode from which electrons exit the cell.*

- *Reduction always occurs at the cathode of an electrochemical cell. Because of the removal of electrons by the reduction half-reaction, the cathode of a voltaic cell is* $(+)$*. Because of the electrons forced onto it, the cathode of an electrolytic cell is* $(-)$*. For either type of cell, the cathode is the electrode at which electrons enter the cell.*

The following table summarizes the relationship between a voltaic cell and an electrolytic cell. Note that the sign of each electrode in an electrolytic cell is the same as the sign of the battery electrode to which it is attached. (However, in electronics a battery's anode is defined as "+".)

Electrolysis

Until now, we have emphasized voltaic (galvanic) cells, electrochemical cells in which chemical change is used to produce electricity. Another type of electrochemical cell — the electrolytic cell — uses electricity to produce a nonspontaneous reaction. The process in which a nonspontaneous reaction is driven by the application of electric energy is called electrolysis.

When the Zinc-Copper cell functions spontaneously, electrons flow from the zinc to the copper and the overall chemical change in the voltaic cell is (Fig. 5.11)

$$\mathrm{Zn}\ (s) + \mathrm{Cu}^{2+}\ (aq) \rightarrow \mathrm{Zn}^{2+}\ (aq) + \mathrm{Cu}\ (s) \qquad E^\circ_{\mathrm{cell}} = 1.103\ V$$

Now suppose we connect the same cell to an external electric source of voltage greater than $1.103\ V$*. That is, the connection is made so that electrons are forced into the zinc electrode (now the cathode) and removed from the copper electrode (now the anode). The overall reaction in this case is the inverse of the voltaic cell reaction, and* E°_{cell} *is negative.*

$$\begin{array}{ll} \textit{Reduction:} & \mathrm{Zn}^{2+}\ (aq) + 2e^- \rightarrow \mathrm{Zn}\ (s) \\ \textit{Oxidation:} & \mathrm{Cu}\ (s) \rightarrow \mathrm{Cu}^{2+}\ (aq) + 2e^- \\ \hline \textit{Overall:} & \mathrm{Cu}\ (s) + \mathrm{Zn}^{2+}\ (aq) \rightarrow \mathrm{Cu}^{2+}\ (aq) + \mathrm{Zn}\ (s) \end{array}$$

$$E^\circ_{\mathrm{cell}} = E^\circ_{\mathrm{Zn^{2+}/Zn}} - E^\circ_{\mathrm{Cu^{2+}/Cu}} = -0.763\ V - 0.340\ V = -1.103\ V$$

Table 5.9: RELATIONSHIP BETWEEN A VOLTAIC CELL AND AN ELECTROLYTIC CELL[(*)]

	Voltaic Cell			*Electrolytic Cell*	
Oxidation	$A \rightarrow A^+ + e^-$	Anode (negative)	Oxidation	$B \rightarrow B^+ + e^-$	Anode (positive)
Reduction	$B^+ + e^- \rightarrow B$	Cathode (positive)	Reduction	$A^+ + e^- \rightarrow A$	Cathode (negative)
Overall	$A + B^+ \rightarrow A^+ + B$ $\Delta G < O$ Spontaneous redox reaction releases energy		Overall	$A^+ + B \rightarrow A + B^+$ $\Delta G > O$ Nonspontaneous redox reaction absorbs energy to drive it	
	The system (the cell) does work on the surroundings			The surroundings (the source of energy) do work on the system	

(*) Table 5.9 and Figs. 5.5–5.9 were taken from Ch. 21 (pp. 823–856) of '*General Chemistry*' by Petrucci, Harwood and Herring, Prentice Hall, 1997.

Thus, by reversing the direction of the electron flow, we change the voltaic cell into an electrolytic cell.

E. Fuel-Cell Technology

In 1839, the Welsh-born jurist-physicist ***William Robert Grove*** *realized that if electrolysis, using electricity, could split water into hydrogen and oxygen, then the opposite could also be true, i.e.: combining hydrogen and oxygen in a suitable way, would produce electricity. To test his reasoning he indeed built a device that would do just that — the world's first fuel-cell. Grove's work thus advanced the idea of* energy's conservation and reversible conversion.

However, at that time, society was not intrigued with the fuel-cell and had little grasp of its technological potential. In fact, interest in Grove's invention diminished as the dawn of cheap fossil fuels *approached and the soon to be discovered* internal combustion engine *captivated the late 19th century populace; a larger segment of Western Society was enjoying a higher standard of living through the utilization of cheap energy and machines to do work. Against this background, Grove's invention was little more than a curiosity as the internal combustion engine and petroleum enthralled the age.*

Fossil fuels and the internal combustion engine reigned supreme from Grove's day to the present and they probably will into the near term future. However, looming on the horizon is the day when the world will run out of fossil fuels. This event will threaten energy prices and energy security. To avoid the turmoil a smooth transition to a hydrogen-based economy seems necessary.

Let us briefly survey the evolution of the fuel-cell concept since its inception by Grove. Since then, a variety of visionaries have worked to develop the technology to use hydrogen as an energy medium, and thus to create a non-polluting, cold-combustion, hydrogen economy.

First articulated by the French science fiction master Jules Verne, this vision has animated generations of engineers and scientists seeking a source of hard energy that is renewable and non-polluting. Hydrogen, when burned, yields water vapor energy; it is a viable replacement for the coal, petroleum and methane that are causing a dangerous rise in the CO_2 *content of the earth's atmosphere.*

Hydrogen is not a primary source, but rather an 'energy carrier' which must be 'broken' from water using electrolysis or chemical processes and recombined to generate electricity, heat or mechanical energy. Solar, wind or hot nuclear hydrogen fusion are candidates primary energy sources. If primary energy source is clean and cheap enough, a 'hydrogen economy' makes sense, and adapting cars, aircraft, electrical generation and heating becomes a manageable goal of commercial development engineering.

From 1889 until the early 20th century, many people tried to produce fuel cells (FC) that could convert coal or carbon directly to electricity. These attempts failed because not enough was known about metals or electricity. In 1932, ***Francis T. Bacon*** *developed the first successful FC. He used hydrogen, oxygen, an alkaline electrolyte, and nickel electrodes. In 1952, Bacon and a co-worker produced a* $5\ kW$ *fuel cell system.*

The large boost to FC technology came from NASA; In the late 1950's NASA needed a compact way to generate electricity for space missions. Nuclear energy was deemed too dangerous, batteries too heavy, and solar power too cumbersome. The answer was fuel cells.

There are presently five major fuel cell types:

- *alkaline fuel cell (AFC),*
- *molten carbonate fuel cell (MCFC),*
- *phosphoric acid fuel cell (PAFC),*
- *polymer electrolyte fuel cell (PEFC),*
- *solid fuel cell (SOFC).*

Both alkaline and polymer fuel cells have demonstrated their capabilities in the Apollo, Gemini and Space Shuttle manned space vehicle programs. The major efforts are presently focused on developing electric vehicles.

In order to provide an example of the electrochemical process that occurs in a fuel cell we consider the proton exchange membrane fuel cell (PEMFC) which uses one of the simplest reactions of any fuel cell:

The pressurized hydrogen gas molecules H_2 *(assumed to be available) are fed into the anode side of the cell where it encounters a catalyst. The catalyst is usually made of platinum powder very highly coated onto carbon paper or cloth. It is rough and porous so that the maximum surface area of the platinum can be exposed to the hydrogen. The platinum coated side of the catalyst faces the Proton Exchange Membrane (PEM) which plays here* *the role of electrolyte. It is a specially treated material, which looks like kitchen plastic wrap. The membrane blocks electrons and only conducts (lets through) positively charged ions.*

Now, when an H_2 *molecule comes in contact with the platinum of the catalyst, it splits into two* H^+ *ions and two electrons* (e^-)*:*

$$2H_2 \longrightarrow 4H^+ + 4e^-.$$

The electrons are conducted through the anode, where they make their way through an external circuit *doing useful work (such as: lighting a bulb, turning a motor, etc) and return to the* cathode *side of the fuel cell. The hydrogen ions* (H^+) *travel through the electrolyte contained in the fuel cell until they too reach the cathode. Meanwhile, on the cathode side of the fuel cell, oxygen gas* (O_2) *is being forced through the catalyst, where it forms two oxygen ions* (O^-)*. Altogether, on the cathode side*

$$O_2 + 4H^+ + 4e^- \longrightarrow 4H^+ + [2O^{2^-} - 4e^-] + 4e^- \longrightarrow 4H^+ + 2O^{2^-} \longrightarrow 2H_2O$$

The net reaction is therefore

$$2H_2 + O_2 \longrightarrow 2H_2O \qquad \text{(liquid)}$$

The by-products of the electrochemical reaction that occurs in the cell are: electricity, water vapor and heat. Theoretically, the water vapor can be recycled to produce additional hydrogen. The waste heat can be utilized for heating. Since this direct conversion of fuel (hydrogen) into electricity is not limited by the Carnot's law of thermodynamics, fuel cells can achieve substantially higher efficiencies then combustion. Fuel cells achieve efficiencies of 35 *percent to* 90 *percent depending on whether the waste heat is employed. These efficiencies are about* 2 *to* 3 *times higher than that of a combustion engine which converts fuel to heat, then into mechanical energy and finally into electricity.*

Another popular fuel-cell is the direct methanol fuel-cell *(DMFC), in which the working fuel is not* H_2 *but* CH_3OH *(methanol). Here again the* proton exchange membrane *is employed; a thin membrane covered on both sides with a sparse layer of platinum based* catalyst *and sandwiched between two electrodes. The methanol acts as an ideal hydrogen carrier because it readily frees its hydrogen to react in the fuel cell.*

How does the cell work? — A methanol/water solution is introduced to a negatively charged anode electrode that spontaneously reacts by breaking the methanol molecules apart. Once broken up, the carbon atoms combine with the oxygen atoms from methanol and water at the negative electrode to form *carbon-dioxide. At the same time the hydrogen atoms are further divided into protons and electrons.*

Altogether, the oxidation process at the anode yields

$$CH_3OH + H_2O \rightleftharpoons CO_2 + 6H^+ + 6e^- \qquad \textit{Anode}$$

Meanwhile, the hydrogen electrons are forced to flow to the positively charged electrode (cathode), forming an electrical current, while the protons pass through the membrane to the cathode.

The reduction process at the cathode is

$$\frac{3}{2}O_2 + 6H^+ + 6e^- \rightleftharpoons 3H_2O \qquad \textit{Cathode}$$

in which the two parts of the hydrogen atom are reunited and combine with oxygen to produce water. The overall reaction is thus

$$2CH_3OH + 3O_2 \rightarrow 2CO_2 + 4H_2O + \textit{waste heat.}$$

The reaction takes place at temperatures in the range 50°–85° C *with an efficiency of about* 50 *percent.*

It can be seen that the overall cell reaction consumes 4 *moles of methanol* (128 g) *with* 6 *moles of oxygen to produce* 4 *moles of carbon-dioxide gas and* 8 *moles of water* (144 g) *with a transfer of* 24 *moles of electrons* (24 *faradays*). *The potential of a single cell is* 0.6 *volts.*

The theoretical maximum electric energy available in any electrochemical cell is the free energy change for the cell reaction. The maximum thermal energy release when a fuel (at fixed ambient temperature and pressure) is burned is the enthalpy change, ΔH°. *One of the measures used to evaluate a fuel cell is the efficiency value* $\epsilon = \Delta G^\circ / \Delta H^\circ$. *For a hydrogen-oxygen cell* $\epsilon = -474.5$ kJ$/(-571.6$ kJ$) = 0.83$. *When methane (natural gas) is used,* $\Delta H^\circ = -890$ kJ, $\Delta G^\circ = -818$ kJ, $\epsilon = 0.92$.

Air Batteries

In a fuel cell, O_2 *(g) is the oxidizing agent that oxidizes a fuel such as* H_2 *(g) or* CH_4 *(g). Another kind of flow battery is known as an air battery, because it uses* O_2 *(g) from air. The substance that is oxidized in an air battery is typically a metal.*

One heavily studied battery system is the aluminum-air battery. In this battery oxidation occurs at an aluminum anode and reduction at a carbon-air cathode. The electrolyte circulated through the battery is NaOH *(aq). Because it is in the presence of a high concentration of* OH^-*, the* Al^{3+} *ions produced at the anode forms the complex ion* $[Al(OH)_4]^-$*. The half-reactions and the overall cell reaction are*

$$\textit{Reduction:}\quad 3\{O_2\ (g) + 2H_2O\ (l) + 4e^- \rightarrow 4OH^-\ (aq)\}$$

$$\textit{Oxidation:}\quad 4\{Al\ (s) + 4OH^-\ (aq) \rightarrow [Al(OH)_4]^-\ (aq) + 3e^-\}$$

$$\textit{Overall:}\quad \begin{array}{c} 4Al\ (s) + 3O_2\ (g) \\ + 6H_2O\ (l) + 4OH^-\ (\mathrm{aq}) \end{array} \rightarrow 4[Al(OH)_4]^-\ (aq)$$

The battery is kept charged by feeding chunks of Al *and water into it. A typical air battery can power an automobile several hundred miles before refueling is necessary. The electrolyte is circulated outside the battery, where* $Al(OH)_3$ *(s) is precipitated from the* $[Al(OH)_4]^-$ *(aq). This* $Al(OH)_3$ *(s) is collected and can then be converted back to aluminum metal at an aluminum manufacturing facility.*

The reaction in a single fuel cell produces only about 0.7 *Volts. To get the voltage up to a reasonable level, many separate fuel cells must be combined to form a fuel-cell stock.*

PEMFC's operate at a fairly low temperature (about $80°C$*), which means they warm up quickly and do not require expensive containment structures. Constants improvements in the engineering and materials used in these cells have increased the* power density *to a level where a device about the size of a small piece of luggage can power a car.*

Since most households appliances operate on high-voltage AC power, a final major compound of a fuel cell requires a converter from low-voltage DC power into high-voltage AC power.

Certain fuel cells are renewable*, that is, can accomplish the electrochemistry associated with both the production of electricity from fuel and oxidant* and *the production of fuel and oxidant from water when supplied with electricity, i.e. accomplishing* both *electrolysis and reverse electrolysis in the* same *cell. This allows one to consider the completely renewable production of electricity by using a renewable energy supply (e.g. solar, wind) to produce from water hydrogen and oxygen which can subsequently be used to produce electricity through the* same *fuel cell from the fuel and oxidant previously produced.*

A fuel-cell never 'runs down': it continues to produce electricity as long as fuel is present. When a battery 'runs down', it has to undergo a lengthy recharge time to replace the spent electricity. Depending on where the recharging current originates, pollution, costs and efficiency problems are then transferred from the batteries location to the central generating point.

When most people think of oil, they think of gasoline and other fuels. But in fact, oil and its hydrocarbon products are intertwined with many things we take for granted today. Plastics, chemicals, fertilizers and many other common products are based on oil and its by-products. When utilizing a finite, rapidly dwindling resource the question becomes: how can that resource best be utilized?

The answer that comes to mind is: use it for the things where there is no other substitute. In terms of chemicals, fertilizers and others there is no substitute for oil as a raw material. Regarding energy, however, there are alternatives. These alternatives include renewables, with hydrogen as the energy carrier and storing medium, and domestically produced hydrogen from natural gas or off-peak electricity. The largest hurdle for the hydrogen economy to overcome is a lack of infrastructure. This problem is by no means insurmountable with the proper investment by industry and government.

The United States is extremely dependent on other, politically unstable and unfriendly, countries for its supply of oil. According to the US Department of Energy (DOE) reports, the United States imports more than 50% *of its oil supply and this figure is expected to increase to* 65% *by 2020. The global demand for oil is increasing at* 2% *per year.*

The fuel flexibility inherent in fuel cells and the ability to produce hydrogen domestically would result in a decline in the dependence on foreign energy sources, greater national energy security, a reduction of the military forces now poised to defend energy interests at a moment's notice in the Persian Gulf and a decrease in foreign trade debt.

Internationally, the demand for energy is expected to increase by 50% *over the next ten years. Fuel cells and distributed generation will allow developing nations to undergo the "cellular phenomenon" when structuring their utility grids. In many developing countries, phone lines are almost non-existent. Instead, cell towers have been erected and people communicate via cell phone. This allows phone system operators to avoid the staggering cost of running a phone line to every residence and building.*

Fuel cells could have the same effect by allowing developing countries the opportunity to install smaller community and industrialized based energy generation sites. This avoids many of the costs associated with establishing a large utility distribution and grid system (distributing hydrogen via pipeline *has been estimated to be around $\frac{1}{4}$ as expensive as transmitting an equal amount of energy in the form of electricity over transmission lines) in addition to elimination of the pollution associated with fossil fuel energy plants.*

In conclusion, fuel cells and a potential hydrogen economy are riding some powerful historical trends. Throughout history, mankind's energy use has moved towards a higher hydrogen ratio in chemical composition of fuel and a reduction in the other components. Starting with wood, then to coal, oil and natural gas, society's shift in type of fuel is simply a movement along a hydrocarbon chain.

As the form of the fuel changed, more of the carbon, from which a significant percentage of the pollution associated with fossil fuels originates, was eliminated. Hydrogen fuel cells complete the process of eliminating the dirty carbon and finish the task of employing pure, clean hydrogen. Aside from historical forces, fuel cells and hydrogen are riding the momentum created by an increased environmental awareness, the inevitable eventual extinction of our fossil fuel reserves, and sound economic policy.

The forthcoming 'Hydrogen Economy' will eventually transform everyday life; the future will bring:

- *Reduced anthropogenic air pollution from fossil fuel combustion.*
- *Cell phones and laptops whose battery life is measured in days instead of hours.*
- *Vehicles operating silently and emitting harmless water vapor.*
- *Individual homes generating their own electricity and heat independent from the utility grid.*
- *Hydrogen power for sensitive electronic equipment, computer centers, cellular towers, mining equipment, banks, schools, hospitals, jails, sophisticated manufacturing, entertainment complexes, communication centers, navigation equipment, airports, road signs, defense installations, hotels, urban transit systems, heavy trucks, personal vehicles and remote sites requiring power.*

F. Hydrogen Power — From Science-Fiction to Science

Hydrogen is the lightest and most abundant element in the universe as well as the ultimate source of virtually all energy-release processes known to man, both in the solar system and beyond. Deep within the sun and stars, nuclear fusion converts hydrogen into helium[771]*. The energy that is released when four hydrogen nuclei become a helium atom is the energy which lights main-sequence stars and fuels all life. Evidence of the incredible amount of energy contained within a hydrogen atom is the thermonuclear or hydrogen bomb, which exploits nuclear fusion to release its destructive power.*

In our natural environment, hydrogen exists primarily in chemical combination with other elements. In order for hydrogen to be useful as a chemical fuel, it must exist as H_2 *or "free hydrogen".* H_2 *must therefore be produced, unlike fossil fuels such as natural gas, coal and oil which can be directly mined or extracted. In this sense, hydrogen is a secondary source of energy, analogous to electricity.*

The energy used to produce H_2 *is stored, after some losses, within the* H_2 *molecule. This energy can then be kept in storage, used on-site, or transported to a remote location for energy conversion. The fact that hydrogen must be produced is a major consideration when examining its effectiveness as an energy carrier, and is the biggest stumbling-block to widespread use in commercial applications.*

Free hydrogen exists at normal atmospheric conditions as an odorless, colorless gas. It is stable and will co-exist harmlessly with free oxygen (O_2) *until an input of energy drives the exothermic (heat-releasing) reaction which forms water. This reaction from a higher energy state to a lower one generates a positive output of energy.*

For over a century it has been predicted that a system will be developed in which hydrogen, extracted from pure water using energy derived from the

[771] Once the amount of hydrogen in a star's core become depleted enough, nuclear fusion of hydrogen into helium can no longer sustain pressure required to oppose gravitational collapse, and the latter forces other fusion processes; these produce nuclei of all elements and isotopes (beryllium, carbon, oxygen, nitrogen, etc) not initially produced in the Big Bang explosion. Latter-generations stars, such as our sun, are assembled via gravitational collapse of interstellar gas and dust enriched with elements produced in earlier stars. In some stars (but not our sun) the nuclear conversion of hydrogen to helium is mostly *indirect*, catalyzed by a series of intermediate processes involving carbon and other elements present within the stellar core.

sun, will be used as a fuel or as an "energy-carrier", and will serve to provide all of society's power requirements. The beauty of the system being that solar energy and water, the sources, are practically limitless and that the resulting energy conversion is relatively pollution-free with the only waste product being again pure water. A seemingly perfect cycle, beginning and ending with energy and water.

Since the early 19th century, scientists have recognized hydrogen as a potential fuel. Current uses of hydrogen are in industrial processes, rocket fuel, and spacecraft propulsion. With further research and development, this fuel could also serve as an alternative source of energy for heating and lighting homes, generating electricity, and fueling motor vehicles. When produced from renewable resources and technologies, such as hydro, solar, and wind energy, hydrogen becomes a renewable fuel.

Unlike most other fuels, hydrogen cannot be produced directly by digging a mine or drilling a well. It must be extracted chemically from hydrogen-rich materials such as natural gas, water, coal, or plant matter. Accounting for the energy required for the extraction process is critical in evaluating any hydrogen use option. Production techniques now used include steam reforming of natural gas, cleanup of industrial by-product gases, and electrolysis of water. A number of other technologies are being studied, including several that produce hydrogen from water or biomass using solar or other renewable energy.

Hydrogen is the most abundant of all the elements in the universe, and makes up more than three-quarters of the mass of the universe. Based on the "Big Bang" theory of cosmology, it is believed that most of the heavier elements were built up from hydrogen and helium inside stars, and that this process is still ongoing. Hydrogen is found in our sun and other stars and plays an important role in the reactions that account for their energy.

Hydrogen ranks ninth of all the elements in order of abundance on Earth, and makes up about 0.76% of the weight of the Earth's crust. The most important naturally occurring compound of hydrogen is water, which is the principal source of the element. In the quest for new and improved energy sources and uses, interest has been aroused in employing hydrogen as an energy currency.

It has been suggested that solar, wind, hydro, nuclear, or even coal conversion could be used to produce hydrogen. The hydrogen would be stored as a compressed gas or liquid and subsequently utilized in a fuel cell, or combusted to return the stored energy when needed. This is the basis for the hydrogen economy, or hydrogen energy research carried out throughout the *world. This research recognizes that fossil fuels will not last forever, and that the hydrogen cycle is simple and non-polluting.*

There are four processes which must be considered when developing a hydrogen-fuel system. These processes are:

- *Production*
- *Storage*
- *Transportation*
- *Energy conversion*

There are many alternatives from which to choose when developing a hydrogen system. The factors based on which each alternative is evaluated, involve efficiency, economic feasibility, and environmental impacts. How these factors are weighted against each other is open for debate. Currently the prevailing trend is to consider cost-effectiveness above all else. Recent trends in legislature and public concern are shifting emphasis towards renewability and pollution-free considerations as a priorities for development of hydrogen technology.

Hydrogen is a secondary source of energy, not a primary source like oil or natural gas. Therefore, in order to be utilized hydrogen must first be produced. There are many ways in which this can be done. Methods of production include chemical, electrochemical, photochemical, biological, and thermochemical processes.

The simplest method to produce hydrogen is to dissolve metals in acid. For example, when zinc (Zn) *is placed in a solution of hydrochloric acid, it reacts to produce zinc chloride and hydrogen:*

$$\mathrm{Zn} + 2\mathrm{HCl} \quad \rightarrow \quad \mathrm{ZnCl_2} + \mathrm{H_2}$$

This reaction can be reproduced simply in the laboratory, although the amount of hydrogen produced is minimal. Still, this method was used to a large extent during World War II when scrap aluminum was dissolved in sodium hydroxide in order to generate hydrogen. The hydrogen was then used to inflate unmanned balloons for weather observation and raising radio antennas.

This method is relatively expensive, and is not considered suitable for mass production (today, research is being done with scrap iron to produce hydrogen, for use in transportation as a method of producing hydrogen onboard vehicles). Small amounts of hydrogen can, however, be economically *produced via this method to provide the needs of a small hydrogen-fuel system.*

The cheapest, and by far the most widely used method for producing hydrogen is steam reformation. Steam, and a carbon-based feedstock (usually methane or natural gas), are combined under high temperature and pressure to produce carbon dioxide and hydrogen. It is estimated that 95% of the hydrogen produced in the US is created by the steam methane reformation method. Most of this hydrogen is used in industrial applications. Although hydrogen can be produced in this manner for about $0.65 per kilogram, the environmental consequences of the use of hydrocarbons are still a concern.

The production of carbon dioxide, a "greenhouse gas", as well as nitrogen oxides (NOx) contribute to the pollution of the earth's atmosphere. Also, the use of limited resources can only drive their costs up as the supplies of fossil fuel sources decrease. A newly developing renewable option is the use of biomass, or recycled carbonaceous material, as the feedstock in the steam reformation process. The air pollution problems still exist, but it will be an intelligent use of a waste product.

Another method for producing hydrogen is electrolysis. Electrolysis involves the application of a small voltage (approx. 2 V DC) to pure water. The electrical energy decomposes the water molecule into its constituent elements, hydrogen and oxygen. This technique has the advantage of producing hydrogen directly from water, with none of the environmental drawbacks which accompany processes using fossil-fuels. Still, the relatively low-efficiency (currently 60–65% with a theoretical maximum of 85%) of the process, and the high cost of electricity make this an expensive option. The cost of producing hydrogen via electrolysis is about $3.00 per kg.

The method of electrolysis is the most attractive for those interested in a completely clean, renewable process using solar energy to produce the electricity. Photovoltaic cells, hydropower, and wind turbines are currently being used to generate the electricity required to electrolyze water for hydrogen production.

Other renewable options include geothermal, tidal, wave action, and thermal gradients in the ocean. Although most of these processes do not produce sufficient amounts of energy to provide hydrogen on a large scale, on-site electricity production coupled with a small on-site electrolyzer can produce enough energy to provide for the energy needs of a household, along with fuel for the family automobiles. This allows hydrogen to be produced easily without having to wait for an infrastructure to develop.

Other attempts at water-splitting have involved super-heating water to temperatures high enough to liberate the hydrogen from the water molecule *(thermochemical). The temperatures required are in the range of* 5000°–6000° F. *Adding chemicals such as sulfuric acid can lower the required temperature but the bottom line is that the only feasible way of generating the heat required is by way of a nuclear reaction. Nuclear power generation, needless to say, has severe environmental and safety implications. There is still research being done on thermochemical production of hydrogen which doesn't require nuclear power plants.*

An example would be solar power plants in which the sun's infra-red radiation focused into a tiny point where the heat accumulates, much like a magnifying glass. Yet there are still environmental concerns due to the chemicals involved, and the nitrogen oxides which are formed from a heat reaction in air (which has a high concentration of nitrogen).

Photoprocesses involve the use of light energy for the production of hydrogen. These methods in one way or another, attempt to mimic the natural phenomena of photosynthesis. In plants, chlorophyll captures light energy and uses it to produce complex sugar-phosphate compounds. The most astonishing fact is that this chemical reaction, basically

$$CO_2 + H_2O + \textit{light energy} \quad \rightarrow \quad \textit{sugars} + O_2$$

occurs at room temperature! Much research has been done to reproduce this feat. Photobiological techniques which coax photosynthetic plants, algae, and bacteria into respiring hydrogen, photochemical techniques which synthetically duplicate the photosynthetic process, and photo electrochemical techniques which use layers of semiconductors separated by water are all being studied today. These are promising technologies, although still in the experimental stage. If efficiency improves, then photoprocesses may play a part in the future of hydrogen.

Storage and Transportation

Hydrogen is typically stored as a liquid, or gas. There are advantages and disadvantages to each of these storage options, the choice depending upon the ultimate use.

Hydrogen becomes a liquid at temperatures below −252.9°C. *Liquification of hydrogen is very energy-intensive, with one third of the energy content of the hydrogen used in the liquification process. This is offset by a reduction of volume requirements for hydrogen storage, with much less storage space required for a liquid than a gas. Less volume needed for storage, makes liquid* *hydrogen the preferred form of hydrogen used in the Aerospace industry with NASA being one of the largest consumers of liquid hydrogen in the world.*

Once in liquid form, hydrogen can be transported in pressurized tanks by truck, barge, or rail. Due to the very low boiling temperature of hydrogen, losses due to boil-off can be considerable. Insulation of the tanks is of utmost importance to reduce these losses. If insulated properly, hydrogen can be stored for as much as five years without significant losses.

Hydrogen can also be stored as a pressurized gas. It can then be transported via pipelines, using existing natural gas distribution lines. A concern would be possible embrittlement of the lines due to absorption by the metal fittings. Storage of hydrogen as a gas is the most economical method, but due to the necessity for larger tanks, weight and space requirements can be a problem. It is estimated that the mass of a pressure tank is 100 times the mass of the hydrogen stored within it. Higher pressure means less volume required, but the walls then need to be reinforced to withstand the greater pressure. Although hydrogen is extremely light, the containers necessary to store gaseous hydrogen can be heavy and bulky.

Another method of storing gaseous hydrogen involves metal hydrides. Certain metals such as magnesium, titanium, or iron, have an affinity for hydrogen. Under certain conditions, these metals will adsorb gaseous hydrogen, and store it within its molecular structure. When the hydride is heated, the hydrogen is released. Although energy is required to store and to release the hydrogen, this option has proved attractive for use as a storage medium onboard automobiles. The main reason is that it is much less energy-intensive than the liquification process, although heat energy is required to release the hydrogen. Also, safety and space concerns are reduced when metal hydride storage is used in automobiles.

There are a variety of other methods being developed for hydrogen storage. These include carbon adsorption, glass microspheres, onboard partial oxidation reactors, and recyclable liquid carriers. Some of these options appear promising, but they will still take some time to develop.

Power Conversion

There are two ways of using hydrogen to generate power. One is simple combustion. The use of hydrogen in internal combustion engines has been extensive. The other is the conversion of hydrogen into electricity in a fuel cell, which is essentially electrolysis in reverse. Both of these have their advantages and disadvantages.

Internal combustion engines can be easily converted to run on hydrogen, or a hydrogen-fuel mixture. The noxious emissions are greatly reduced, with water being the only by-product if pure hydrogen and oxygen are used. Nitrogen oxides are still formed from the high heat of combustion, and are still a source of air pollution.

Over the past two decades, most research has gone into the development of the fuel cell. The operation of a fuel cell involves the combination of hydrogen (anode) and oxygen (cathode) in the presence of an electrolyte. Output voltages range from 0.7 *to* 1.12V*. The type of fuel cell varies depending on the electrolyte used. Fuel cell types include the Phosphoric acid fuel cell, the alkaline fuel cell, and the solid oxide fuel cell.*

The most common type, the alkaline fuel cell, is still used by NASA on board spacecrafts. Another type of electrolyte being developed is the proton-exchange membrane which uses a solid polymer to facilitate the reverse electrolysis process. This solid polymer, which is much like plastic kitchen wrap, conducts protons, and is very conducive to the purpose of an electrolyte. Although membrane costs are high, this type of fuel cell appears very promising, and is currently being used in advanced research.

The use of hydrogen is at an all-time high. It is possible to convert any car sitting in the driveway to run on hydrogen. It is being proven every day that hydrogen can be used as a replacement not only for gasoline, but natural gas in heaters and stoves in the home. Hydrogen could some day replace high-voltage electrical power lines as the primary energy-carrier via high-voltage power lines, being transported in pipelines and converted to electricity on-site.

Production of hydrogen is also becoming easy to do for any one with access to about 2 V *of DC electricity. Many homesteads generate enough electricity using windmills and solar panels to supply the household's needs and even sell back some power to the regional utility company. A small electrolyzer added to this system could easily produce enough hydrogen to fuel a vehicle. It is clearly possible that anyone with a little ingenuity and skill can convert the household to use hydrogen, convert the car to run on hydrogen, and generate the electricity for hydrogen production using only solar energy, all for about the cost of a mid-sized American sedan.*

Any in-depth study of hydrogen reveals the vast array of possible system configurations for hydrogen power. The bottom line is that any system which utilizes hydrogen in any capacity is going to be better off for it. Harmful emissions are reduced, efficiency is increased and water(the original source), is reproduced. On a larger scale, it would seem possible that use of hydrogen alone or in conjunction with other fuels would be a major step in the right direction, and bring us a little closer to a more harmonious cycle of energy use.

G. Harnessing Solar Energy

The sun is an average main-sequence star with a mass equal to nearly one-third of a million earths. It is made up of almost 80% *hydrogen by mass and is entirely gaseous and plasma-phase, although the gas near its center is under such tremendous pressure that it behaves like a fluid. Because of this gaseous state, the sun rotates unevenly. Its equatorial section turns on its axis once every 25 days while the higher latitudes on the sun take over* 27 *days to rotate. The sun derives its energy from the fusion reaction of two hydrogen nuclei joining together to make one helium nucleus. This is basically the same nuclear reaction as that enabling the hydrogen bomb (although the latter makes use of several hydrogen isotopes).*

The fusion reaction began a few billion years ago as a result of the high temperatures in the sun's core, caused by the gravitational contraction of the huge mass of gas and dust (mostly hydrogen) from which the sun formed. The production of heat from the sun is quite small per unit of volume, because like all large bodies, its surface is relatively small compared to its volume. Also, the sun has had billions of years to heat up.

The sun's relatively small core is very hot (approximately $14,000,000°C$*) and it is in the core that the fusion reaction occurs. Even though the sun's energy output is small compared to its huge size, it turns out energy on an enormous scale by earth's standards, some* 5 *million megatons of energy per second. There is estimated to be enough hydrogen in the sun convertible to helium to allow the sun to shine at its present rate for 5 billion years to come.*

Man sees only the glowing surface (photosphere) of the sun, which emits an approximate blackbody radiation spectrum at $5,800\,°C$*. During solar eclipses when the main disc of the sun is blotted out, one can also see the solar atmosphere or corona. The corona is made up of ionized hydrogen, a hydrogen atom with its one electron knocked off. However, the corona also contains all of the elements common on earth. The corona is much more diffuse than the rest of the sun and much hotter that the surface —* $2,000,000°C$ *just above the sun's surface.*

This corona is thought to extend in diffuse form to the outer limits of the solar system. Even during quiet periods of the sun, there are coronal streamers of very hot gas out to ten solar diameters. The sun's diameter is $1,400,000$ *km. The surface of the sun is covered with bright granules, but the most noticeable features are the sun spots, darker and cooler regions* ($4,500\,°C$)*. Sun spots have tremendous local magnetic fields* ($3,000$ *to* $4,000$ *Gauss compared with about one Gauss for the rest of the sun's surface*).

Sun spots are believed to be places where doughnut-shaped magnetic field knots emerge from the sun's surface, and they usually occur in pairs of opposite magnetic polarity. At the maximum of solar activity in 1947, a sun spot of five billion square miles was seen. The sun alternates from very quiet to very turbulent and active, then back to quiet, over 11-year cycles. At the peak of a cycle, numerous solar flares occur which throw out huge masses of hot gas and energetic particles.

These masses of hot, ionized hydrogen hit the earth's magnetic field, bend it out of shape, disrupt radio communications, cause the aurora borealis, and feed the Van Allen radiation belts. Flares are $1,000$ *to* $100,000$ *times more dense than the surrounding material on the solar surface; the corona around the flares gets four times hotter than normal; and gas thrown out travels at around* $3,600,000$ *kmph.*

The cause of solar flares is not known, but they are generally believed to be related to sunspot magnetic fields. In addition to flares, the sun constantly throws out ionized hydrogen in the solar wind. This material moves at nearly 1.6 *million kmph and contains one to ten particles per cubic centimeter. This is still more diffuse than the "hardest" vacuum yet made on earth.*

The earth lives and feeds on energy from the sun, with little help from its own radioactivity. In addition there is a contribution from its own gravitation and the gravitation of the moon and the sun, (via tides) and a tiny component of cosmic radiation from the rest of the universe. Of these, the flow of radiation from the sun is paramount.

Over the lifetime of the earth this radiation has induced life in the earth's surface and that life has laid down a fossil record of the solar energy it once received hundreds of millions of years ago as chemical energy stored in coal, gas, oil and peat. At the present time, that fossilized solar radiation is our civilization's main source of exploitable energy. These fossil fuels are the life savings of the earth. As it is used, much of the fossil energy, inevitably, is lost as heat. But some is converted into metals, plastics, chemicals, electronic crystals and buildings.

In combination with gravity and the earth's rotation, solar energy drives the hydrological cycle which is responsible for floods, atmospheric circulation, hurricanes, thunderstorms, and other climatic and weather phenomena. Only 13 *percent of the total solar energy available to earth is responsible for evaporating water (mostly in the tropics) needed to drive the hydrological cycle.*

The rate of solar energy incident upon earth just outside the atmosphere is $1.35\frac{\mathrm{kW}}{\mathrm{m}^2}$. *This energy falls upon a circular disc of radius* 6380 *km which has the area of* $1.27 \times 10^{14}\ \mathrm{m}^2$. *Hence the total rate over the daylight hemisphere is* 1.72×10^{11} *megawatt. Of this* 7.5×10^{10} *megawatt is absorbed at the surface, and* 3.7×10^{10} *megawatt is absorbed in the atmosphere.*

Radiation reaching the surface is mostly converted into heat, but a fraction is used by vegetable life on land and sea to photosynthesize carbohydrates out of CO_2 *and water, and a fraction could be used by man to generate electricity in solar cells made out of semiconductors such as silicon or gallium arsenide.*

A realistic covering of 0.1 *percent of the earth with solar cells operating at* 10 *percent efficiency would produce a power of* 7.5×10^6 *megawatt.*

The power 7.5×10^{10} *MW is the average rate of surface ground-level absorption by the earth as a whole, and it corresponds to a continuous surface flux of* $590\ Wm^{-2}$. *A given location on the earth's surface is not exposed to this flux continually because of the earth's rotation and because the incident energy of solar radiation is spread over a hemisphere and not a disc. Rotation alone causes the average flux to be halved since there is exposure to sunlight during, on average, only* 12 *hours of the day.*

Another factor of two is introduced by the curvature of the earth since the area of a hemisphere is twice that of a disc of the same radius. Thus the global average insolation at a point on the earth's surface is $150\ Wm^{-2}$ *(roughly* $300\ Wm^{-2}$ *during the day and zero at night). In Europe the average is about* $120\ Wm^{-2}$, *in the U.S.A. it is* $200\ Wm^{-2}$, *and in the Sahara* $260\ Wm^{-2}$.

We summarize the global solar energy flow:

Solar radiation, incident	1.72×10^{11}	*MW*
absorbed in atmosphere	3.7×10^{10}	*MW*
absorbed at surface	7.5×10^{10}	*MW*
Atmospheric circulation	1×10^{10}	*MW*
Photosynthesis (Land + Ocean)	3×10^{8}	*MW*

The tapping of solar energy

Humans have used sunlight to perform a variety of tasks for centuries, but a serious scientific approach to the subject began in the wake of the industrial revolution in Europe. The Swiss scientist ***Horace de Saussure*** *invented (1767) the world's first solar collector. It was then used by* ***John Herschel*** *to cook food during his expedition to Southern Africa (1830).*

There are a variety of technologies that have been developed to take advantage of solar energy. These include:

- *Photovoltaic (solar cell) systems:*
  Producing electricity directly from sunlight.
- *Concentrating solar systems:*
  Using the sun's heat to produce electricity.
- *Passive solar heating and day lighting:*
  Using solar energy to heat and light buildings.
- *Solar hot water:*
  Heating water with solar energy.
- *Solar heating and cooling*
  Industrial and commercial uses of the sun's heat.

Solar thermal systems concentrate heat and transfer it to a fluid. The heat is then used to warm buildings, heat water, generate electricity, dry crops or destroy dangerous waste. Solar thermal collectors are divided into three categories:

Low-temperature collectors provide low grade heat, less than $43°C$, through either metallic or nonmetallic absorbers for applications such as swimming pool heating and low-grade water and space heating.

Medium-temperature collectors provide medium to high-grade heat (greater than $43°C$, usually $60°C$–$82°C$), either through glazed flat-plate collectors using air or liquid as the heat transfer medium or through concentrator collectors that concentrate the heat to levels greater than "one sun". These include evacuated tube collectors, and are most commonly used for residential hot water heating.

High-temperature collectors are parabolic dish or trough collectors primarily used by independent power producers to generate electricity for the electric grid.

Concentrating Solar Thermal Systems use three different types of concentrators:

Central receiver systems use heliostats (highly reflective mirrors) that track the sun and focus it on a central receiver.

Parabolic dish systems use dish-shaped reflectors to concentrate sunlight on a receiver mounted above the dish at its focal point.

Parabolic trough systems use parabolic reflectors in a trough configuration to focus sunlight on a tube running the length of the trough.

Technology Examples

Pool Heating — These systems can be as simple as water running through a black hose and specially manufactured systems are more efficient modifications on this concept.

Domestic Water Heaters — They come in a variety of styles but all of them collect heat in some liquid, usually water or water mixed with an anti-freeze, that runs through pipes in a box with glass on the front. The box helps keep temperatures inside around the pipes higher, so more heat transfers to the liquid. The hot liquid gives its heat to another loop of pipes through a heat exchanger and this new loop is used for home hot water use or heating the space with a radiator.

Commercial Scale Heaters — These can be designed to heat or cool a large commercial space or to make steam which can turn a turbine to produce electricity.

Photovoltaic systems

Solar electric or photovoltaic systems convert some of the energy in sunlight directly into electricity. Their history dates back to 1839. Photovoltaic (PV) cells are made primarily of silicon, the second most abundant element in the earth's crust, and the same semiconductor material used for computer chips.

When the silicon is combined with one or more other materials, it exhibits unique electrical properties in the presence of sunlight. Electrons are excited by the light and move through the silicon. This is known as the photovoltaic effect and results in direct current (DC) electricity. PV modules have no moving parts, are virtually maintenance-free, and have a working life of 20–30 *years.*

There are three basic categories of photovoltaic systems with several types in each category.

Crystalline Photovoltaic Materials: flat plate collectors are the most developed and prevalent type in use today. These include single crystal silicon and polycrystalline silicon which is either grown or cast from molten silicon and *later sliced into its cell size. They are then assembled onto a flat surface; no lenses are used.*

Thin Film systems are inherently cheaper to produce than crystalline silicon but are not as efficient. They are produced by depositing a thin layer of photovoltaic material to a substrate like glass or metal. This category includes amorphous silicon like the kind found in calculators and watches.*

Concentrators use much less of a specialized photovoltaic material and employ a lens or reflectors to concentrate sunlight on the photovoltaic cell and increase its output. They can be produced more cheaply than either of the other categories due to the reduced amount of expensive PV material required. But they can only use direct sun light, so they must track the sun precisely and do not work when it is cloudy.*

Solar cells (Figure 5.12)

To understand the operation of a PV cell, we need to consider both the nature of the material and the nature of sunlight. Solar cells consist of two types of material, often p-type silicon and n-type silicon. Light of certain wavelengths is able to ionize the atoms in the silicon and the internal field produced by the junction separates some of the positive charges ("holes") from the negative charges (electrons) within the photovoltaic device.

The holes are swept into the positive or p-layer and the electrons are swept into the negative or n-layer. Although these opposite charges are attracted to each other, most of them can only recombine by passing through an external circuit outside the material because of the internal potential energy barrier.

Therefore if a circuit is made, power can be produced from the cells under illumination, since the free electrons have to pass through the load to recombine with the positive holes. The amount of power available from a PV device is determined by:

- *The type and area of the material*
- *The intensity of the sunlight*
- *The wavelengths of the sunlight*

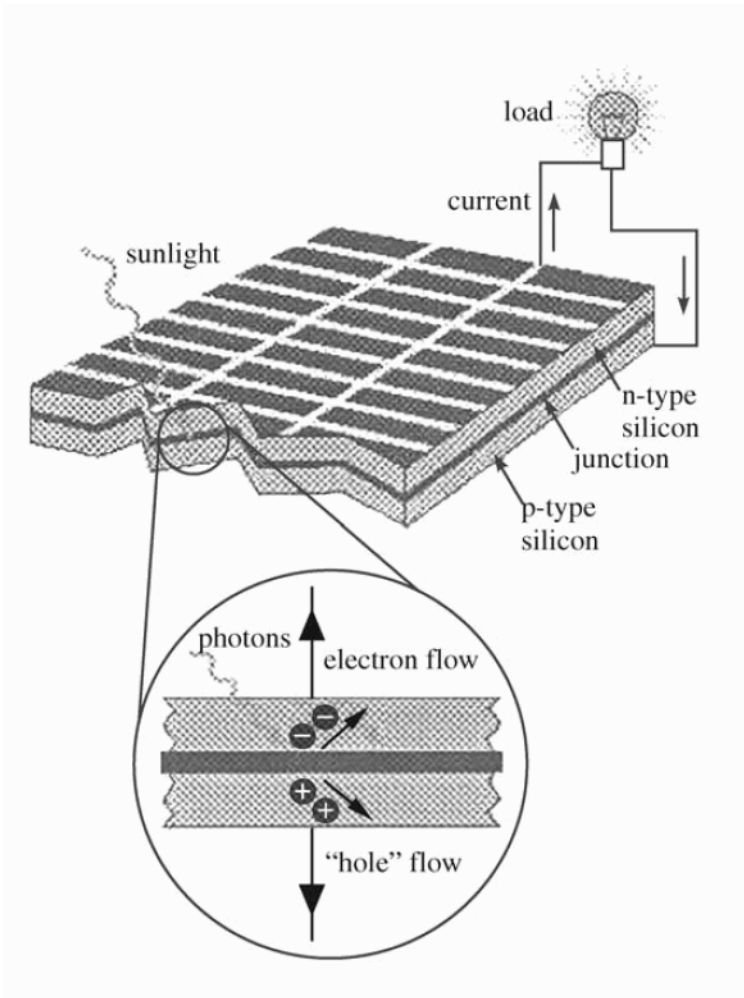

Fig. 5.12: Solar cell

Single crystal silicon solar cells, for example cannot currently convert more than 25% of the solar energy into electricity, because the radiation in the infrared region of the electromagnetic spectrum does not have enough energy to separate the positive and negative charges in the material. Polycrystalline silicon solar cells have an efficiency of less than 20% at this time and amorphous silicon cells, are presently about 10% efficient, due to higher internal energy losses than single crystal silicon.

A typical single crystal silicon PV cell of $100\ cm^2$ *will produce about* 1.5 *watts of power at* 0.5 *volts DC and* 3 *amps under full summer sunlight* ($1000\ Wm^{-2}$). *The power output of the cell is almost directly proportional to the intensity of the sunlight.*

An important feature of PV cells is that the voltage of the cell does not depend on its size, and remains fairly constant with changing light intensity. However, the current in a device is almost directly proportional to light intensity and size. When people want to compare different sized cells, they record the current density, or amps per square centimeter of cell area.

The power output of a solar cell can be increased quite effectively by using a tracking mechanism to keep the PV device directly facing the sun, or by concentrating the sunlight using lenses or mirrors. However, there are limits to this process, due to the complexity of the mechanisms, and the need to cool the cells. The current output is relatively stable at higher temperatures, but the voltage is reduced, leading to a drop in power as the cell temperature is increased.

1933 CE **Fritz Walter Meissner** (1882–1974, Germany). Physicist. Discovered that when a material is cooled into the superconducting phase in the presence of an external magnetic field, the magnetic flux is completely expelled from the interior of the superconductor, provided that the magnetic field is not too strong.

The phenomenon is called the *Meissner effect*. This is analogous to the exclusion of an *electric field* from the interior of an ordinary conductor, where charges in the conductor move and arrange themselves to create a component of electric field inside the conductor that exactly cancels the contribution of the external field. Similarly, an external *magnetic field* does not penetrate a superconductor because eddy currents flow on the surface in such a manner that the net magnetic field inside the superconductor is zero.

1933–1946 CE **Max Delbrück** (1906–1981, Germany and USA). Physicist and biologist. Founded molecular biology. Tested experimentally one of the QED nonlinear processes, known as *Delbrück scattering*[772] (1933). Joined Salvador Luria (1943) to demonstrate that bacteria adopt to new conditions (such as the presence of a virus) by Darwinian mechanisms, just as higher forms do. They concluded that virus resistant mutants preexist in a population, and are not induced by the selective agent (the virus) that is applied to isolate the mutants. Their demonstration of adaptation established bacteria as suitable objects for the study of genetic mechanisms, so that principles applicable to *all* life could be discovered.

Delbrück and Luria believed that they could better understand genetic mechanisms by studying one of nature's simplest creatures: the *bacteriophage* (or simply, *phage*). The phage is a virus that infects bacteria. Viruses reproduce in a living cell by using the cell's apparatus for reproduction of their DNA or RNA. By definition, viruses contain either DNA (*deoxyribonucleic* acid: a large, string-like molecule found in living cells that carries genetic information), which acts to redirect the bacterium's own biosynthetic systems to make more virus phage, or RNA (*ribonucleic* acid: single- or double-stranded molecules).

The final event in the infection process is usually a breakdown of the bacterial wall (called *lysis*), which frees the newly reproduced phage particles. Some phage are tadpole shaped, with a head containing DNA within a wall of protein. The phage's hollow tail, also made of protein, can attach to bacteria and facilitate the transfer of DNA into them. Because of their simplicity,

---

[772] A *photon* is scattered by the electric Coulomb field of the nucleus [in contradistinction to the *Compton scattering* (1922) through which an electron (or a proton, or a whole nucleus) absorbs and reemits a photon]. The Delbrück scattering process is a succession of two *virtual* (where energy and/or momentum are not conserved over short distances or small time intervals) quantum processes:

(1) pair-creation in the nuclear Coulombic field $(\gamma \rightarrow e^+ + e^-)$;

(2) The inverse process $(e^+ + e^- \rightarrow \gamma)$ in the Coulombic field.

Note that the first process cannot occur as a *real* process (energy and momentum conserved), even in the presence of the nuclear Coulombic field, unless the photon energy is at least $2m_ec^2 \simeq 1.02$ MeV, but as a *virtual* process — there is no energy threshold and it can occur at any energy of the photon. [In general a stable particle cannot emit another particle, nor split into several particles – nor can the reverse process occur – without either external influences or one of the particles involved being virtual.]

phages seemed ideal for studying how genetic material reproduces, mutates, and expresses genetic information.

Delbrück was born in Berlin and did his Ph.D. in quantum mechanics under Max Born at Göttingen (1930). He then went to Copenhagen (1931) to work with Niels Bohr, who became his mentor. He returned to Berlin (1932) to work with **Lise Meitner**. He left for the US (1937) on a Rockefeller Fellowship to CalTech, and shortly after he left, Meitner discovered nuclear fission. In the US Delbrück's interests shifted to biology[773]. Following Bohr's line of thinking he thought perhaps new laws of physics may come out of study of biological systems.

At Pasadena he met Emery Ellis, who introduced him to bacteriophage. The phage appealed to Delbrück's physics-talented mind — he likened it to the hydrogen atom of biology, the simplest genetic system known.

Delbrück then took a faculty position at Vanderbilt University (1940–1947). In 1941 he met **Salvador Luria** and they began to collaborate on phage experiments. With **Alfred Hershey**, they discovered (1946) recombinations of viral DNA and received the Nobel Prize for medicine and physiology (1969). Delbrück moved back to CalTech and remained there (1947–1977).

1933–1956 CE **Alfred Tarski** (1902–1983, Poland and USA). Logician and mathematician. Made important contributions to mathematical logic, set theory, measure theory, model theory and general algebra.

Tarski was born in Warsaw and educated there. Excluded, as a Jew, from a faculty university post, Tarski taught concurrently in a high school and at Warsaw University until 1939. Fortunate to escape the holocaust, he came to the US (1939) and joined the faculty of the University of California at Berkeley (1942–1960).

A most notable achievement was his monograph (1933) "*The concept of truth in formalized languages*". This has been the starting point for all logically serious discussions of the subject, ever since. In it Tarski rehabilitates the classical correspondence theory of truth in contemporary logical guise. His later work has served to legitimize semantic discourse about the relations

---

773 During 1932–1944 influential views of life have come from physicists rather than biologists: **Niels Bohr**, in his essay "*Light and Life*" (1932), urged applying the "complementarity" principle from quantum mechanics to biology. **Erwin Schrödinger** in "*What is Life*" (1944) identified the crucial question of how the cell is governed by a 'code-script' inscribed in the genes. The latter book inspired **Francis Crick** and **James Watson**'s investigation of the molecular structure of DNA.

between language and the world. Tarski had much influence on contemporary philosophers of science, especially Popper.

1933–1966 CE **Sergei Pavlovich Korolev** (1906–1966, The Soviet Union). Aerospace engineer. Founder of the Soviet space program. Responsible for the development of the world's first ICBM and artificial earth satellite (SPUTNIK 1). A brilliant engineer and superb organizer, who possessed the political cunning necessary to get his work done and protect his staff from a government so paranoid, he was forced to work in anonymity (known only as the 'Chief Designer') and kept under tight security almost until his death.

Korolev would go in the annals of aerospace technology to make these space records:

- First man-made orbiting satellite (Oct 04, 1957)[774].
- First man to orbit the earth.
- First craft to orbit the moon and photograph its back side.
- First craft to impact Venus.

Korolev was born in Zhitomir, Ukraine and became interested in aviation since early age. He was educated at the Kiev Polytechnic Institute (1924–1926) and the Moscow Bauman High Technical School (1926–1929), at that time the best engineering college in Russia. In 1982, Korolev was appointed chief of Jet Propulsion Research Group, one of the earliest state-sponsored centers for rocket development in the USSR. In 1933, Korolev led the development of cruise missiles and of a manned rocket-powered glider.

His work at that time culminated in designing Russia's first rocket propelled aircraft.

Thus, he was involved in pre-World War II studies of rocketry in the USSR.

On June 27, 1938, at the height of Stalin's purges, Korolev was arrested and sent to the GULAG camps in Siberia. In March 1940, Korolev was returned to Moscow and Imprisoned in the infamous Butyrskaya prison. On July 10 the same year, a special commission chaired by Lavrenti Beria, chief of Stalin's secret police, sentenced Korolev to eight years in labor camps on phony allegations of sabotage. "Fortunately" for Korolev, in September 1940,

---

[774] During the Cold War, Americans were amazed that a culture, supposedly technologically inferior to the West, could excel where they lagged behind. Only after the fall of the Soviet Union could the identity and biography of Korolev be divulged.

he was transferred to "sharashka" – an aviation design bureau in prison. Officially called KB-29, Korolev's sharashka was led by **Andrei Tupolev**, also a GULAG prisoner.

On July 27, 1944, the authorities "paroled" Korolev and on Sept. 8, 1945, Korolev traveled to Germany for evaluation and restoration of V-2 ballistic missiles. In August 1946, while still in Germany, Korolev was appointed chief of a department in the newly created NII-88 in Podlipki, northeast of Moscow. This organization was made responsible for the development and industrial production of missile technology based on German hardware.

In the following years, Korolev led the development of several generations of ballistic missiles, launch vehicles, military and communications satellites, interplanetary probes and manned spacecraft. He died at the height of his career as a result of a botched surgical operation on January 14, 1966.

Due to secret nature of the Soviet space industry, Korolev's contribution to the space program was only recognized by the authorities after his death. For several more decades, Korolev's personality remained a subject of distortions by the official Soviet press. Only in 1994, Yaroslav Golovanov, a Russian journalist and historian, published the first uncensored biography of Sergei Korolev.

His incredible energy, intelligence, belief in the prospects of rocket technology, managerial abilities and almost mythical skills in decision-making made him the head of the first Soviet rocket development center, known today as RKK Energia. He deserves the most credits for turning rocket weapons into an instrument of space exploration and making Russia the world's first space-faring nation.

1933 CE, Jan. 30 Adolf Hitler was appointed chancellor by German President Paul von Hindenburg. Brought into office by a right-wing coalition, he rapidly disposed of his partners and liquidated all opposition to become (1934) dictator (*Führer*) of Germany. With enthusiastic support from a majority of the German people he used the power of the state to gradually strip Germany's Jewish citizens of their livelihood, freedoms and human rights; restored the country to a dominant position in Europe, repudiating the Versailles Treaty (1935), reoccupying the Rhineland (1936), forming the Rome-Berlin axis (1936), intervening in the Spanish civil war (1936–38), invading and annexing Austria[775] (1938), occupying Czechoslovakia (1938), making a pact with the USSR and invading Poland (1939).

[775] The *Anschluss* of March 11, 1938 — when the nation that produced Bach annexed the nation that produced Mozart.

1933, March 02 CE **O**ne of the most energetic earthquakes of the 20^{th} century hit Japan. Its epicenter was at 39.25 °N, 144.5 °E and its submarine fault unleashed a giant tsunami with a visual run-up of 23 m, killing some 3000 people in Sanriku, Honshu. The generating fault extended over an area of 370 km × 100 km accompanied by a displacement of 7.4 m. The energy release of this seismic event was equivalent to 150 Megatons of TNT having a seismic moment of 10^{29} dyn-sec.

1933–1985 CE **Hans Jonas** (1903–1993, Germany and USA). Philosopher. One of the most original and prominent thinkers of his generation. Contributed to the philosophy of biology, anthropology, theology and problems of ethics in a technological age.

Jonas' life spanned 90 years of the 20^{th} century, and like few other Western intellectuals he was able to see the deep and dramatic changes that have taken place in the entire so-called civilized world. His most significant works are: *The Gnostic Religion* (1934, 1958, 2001); *The Imperative of Responsibility* (1979); *The Phenomenon of Life* (1966); *Morality and Mortality* (1979); *On Technology, Medicine and Ethics* (1985).

Jonas was born to Jewish parents in Münchengladbach, Germany. He studied in Freiburg (1921), Berlin (1921–1923) and *Marburg* (1924–1928) under **Husserl**, **Heidegger** and **R. Bultmann** and received his Ph.D. in philosophy (1928). After Hitler had come to power, he first emigrated (1933) to England, then to the Hebrew University in Jerusalem (1934–1940) and finally to Canada (1949). There he taught for six years at McGill and Carleton Universities, before settling down permanently in New York, teaching at the philosophy department of the New School for Social Research.

The range of his topics was extremely wide — from early gnosticism to the philosophy of biology, from ethics to social philosophy, from cosmology to Jewish theology.

Shaped by his exile from Nazi Germany, the murder of his mother in the Auschwitz extermination camp, his participation as a soldier in WWII (the Jewish Brigade of the British Army) during 1940–1945 and the Israeli War of Independence (1948–1949) — he set himself the task of uncovering the intellectual origins of the crisis of Western civilization and proposing a new, positive orientation for humanity.

Jonas' work will become increasingly significant in the years ahead as we face the problems produced by current developments in technology such as biological engineering. Such issues were of particular interest to him, and he was unique among his philosophical contemporaries in devoting attention to them. His eloquent writings on these themes bring wisdom and common sense anchored in Jonas' own historical and biographical experience of the fragility of human life and the common good.

Worldview XLV: Hans Jonas

* * *

"Modern technology, informed by an ever deeper penetration of nature and propelled by the forces of market and politics, has enhanced human power beyond anything known or even dreamt of before. It is a power over matter, over life on earth, and over man himself; and it keeps growing at an accelerated pace. Modern technology is marked by a radical departure from everything previously known. It has disturbed the balance between humanity and nature in ways that are long-range, cumulative, irreversible, and planetary in scale. It has permanently altered the biosphere of the earth, it has challenged our definitions of "life" and "death". It has created a freedom without values.

Traditional ethics presumed that the effects of our actions are limited. All this has changed with modern technology. In its view, nature is a machine, not an end in itself. We may matter to ourselves, but there is no larger system of values to which we belong. In the end humans become the objects of their own fabrications, to be shaped according to the design of biotechnology.

As we are deprived of any consistent image of humanity, we are unable to answer the fundamental ethical question: Why should we care about the distant future of mankind on this planet?"

* * *

"Care of the future of mankind, is the overruling duty of collective human action in the age of technical civilization that has become 'almighty', if not in its productive then at least in its destructive potential. This care must obviously include care for the future of all nature on this planet as a necessary condition of man's own survival. We line in an apocalyptic situation, that is,

under the threat of a universal catastrophe if we let things take their present course. The danger derives from the excessive dimensions of the scientific-technological-industrial civilization.

The danger of disaster through scientific technology arises not so much from any shortcoming of its performance as from the magnitude of its success."

* * *

"The altered nature of human action calls for a change in ethics as well. All previous ethical concepts had as their content the relationship between human beings only. The good or bad of human actions was decided within the short-term context of the here and now or the immediate foreseeable future.

All this has decisively changed: modern technology has introduced actions of such novel scale, objects, and consequences that the framework of former ethics can no longer contain them.

A new dimension of responsibility, never dreamt before, is forced upon ethics. No previous ethics had to consider the global condition of human life and the far-off future, even existence, of the race. Those are now an issue and demand, in brief, a new conception of duties and rights, for which previous ethics and metaphysics provide not even the principles, let alone a ready doctrine.

In order to fulfill this new imperative of responsibility, a scientific futurology is required. An imaginative heuristic of fear must tell us what is possibly at stake and what we must beware of. The prophecy of doom must take priority over the prophecy of bliss. As mankind has no right to suicide, the existence of man must never be put at stake: mankind's existence becomes the First Commandment of a new ethical order."

* * *

The Imperative of Responsibility (1979)

1933–1996 CE **Paul Erdös**[776] (1913–1996; Hungary, USA and Israel). Legendary mathematician. Contributed to: *Analysis* (including Ergodic Theory), *Combinatorics* (including Graph Theory, Combinatorial Algebra, Combinatorial Geometry and Theoretical Computer Science), Number Theory, Probability Theory, and Set Theory.

He founded the field of *discrete mathematics*, which is the foundation of computer science. One of the most prolific mathematicians in history, publishing more than 1600 papers in which he collaborated with 507 people[777]

Erdös was regarded by fellow mathematicians as the most brilliant, if eccentric, mind in the field, being a *problem solver* rather than a builder of theories.

---

[776] For further reading, see:

- Hoffmann, P., *The Man Who Loved Only Numbers*, Fourth Estate: London, 1999, 302 pp.

[777] Around 1965, Casper Goffman concocted the idea of an '*Erdös number*': If you had written a joint paper with Erdös, your Erdös number was 1. If you had written a joint paper with someone with Erdös number 1, your Erdös number was 2, and so on. There is now an *Erdös Number Project* home page on the web where one can see the results:

Erdös number 0	—	1 person
Erdös number 1	—	507 people
Erdös number 2	—	5713 people
Erdös number 3	—	26422 people
Erdös number 4	—	62136 people
Erdös number 5	—	66157 people
Erdös number 6	—	32280 people
Erdös number 7	—	10431 people
Erdös number 8	—	3214 people
Erdös number 9	—	953 people
Erdös number 10	—	262 people
Erdös number 11	—	94 people
Erdös number 12	—	23 people
Erdös number 13	—	4 people
Erdös number 14	—	7 people
Erdös number 15	—	1 person
Erdös number 16	—	0 people

Thus the median Erdös number is 5; the mean is 4.69, and the standard deviation is 1.27.

For more than 50 years, Erdös wandered the globe visiting mathematicians, attending meetings, teaching and lecturing. He had become the center of an enormous web of collaboration.

Erdös was the *supreme problem poser and problem solver of modern times.* His interests were mainly in number theory and combinatorics, though they ranged into topology and other areas of mathematics. He was fascinated by relationships among numbers, and numbers served as the raw material for many of his conjectures, questions, and proofs.

Paul Erdös was born in Budapest to Jewish parents, the original family name being Engländer. Despite the restrictions on Jews entering universities in Hungary, Erdös, as a winner of a national examination (1929), was allowed to enter in 1930.

In 1933 he gave a *simple* proof to *Bertrand's conjecture*[778] (1845) [proved by Tchebyshev, 1850]: for every positive integer n, there is a prime between n and $2n$.

He was awarded a doctorate in mathematics in 1934. He then held appointments at the universities of Manchester (1935–1938), Princeton (1939), Madison (1940–1943), Purdue (1943–1948), Notre Dame (1952–1954) and Jerusalem (1954–1964).

In 1949 he gave a proof (with Atle Selberg[779]) of the *Prime Number Theorem* (= the number of primes less than or equal to the real positive number x is asymptotically equal to $\frac{x}{\log x}$) that avoided using complex analysis.

Stooped and slight, often wearing socks and sandals, Erdös stripped himself of all the quotidian burdens of daily life: finding a place to live, driving a car, paying income taxes, buying groceries, writing checks.

Concentrating fully on mathematics, Erdös traveled from meeting to meeting, carrying a half-empty suitcase and staying with mathematicians wherever

---

778 News about his success was passed around Hungarian mathematicians, accompanied by the rhyme:

> "*Chebyshev said it, and I say it again;*
> *There is always a prime between n and $2n$*"

779 Selberg and Erdös agreed to publish their work in back-to-back papers in the same journal, explaining the work each had done and sharing the credit. But at the last minute Selberg raced ahead with his proof and published first. The following year Selberg won the Fields Medal for his work. Erdös was philosophical about the episode.

he went. His colleagues took care of him, lending him money, feeding him, buying him clothes and even doing his taxes. In return, he showered them with ideas and challenges — with problems to be solved and brilliant ways of attacking them.

He wrote no best-selling books, and showed a stoic disregard for worldly success and personal comfort, living out of a suitcase for much of his adult life. The money he made from prizes he gave away to fellow mathematicians whom he considered to be needier than himself. "*Property is a nuisance*," was his succinct evaluation. The winners would often frame his checks without cashing them. (Solving a $1000 problem would make you internationally famous.)

During the Cold War, Erdös was persecuted by the US immigration and the FBI because of his travels to mathematical conferences behind the Iron Curtain and his correspondence with Chinese mathematicians.

Erdös won many prizes, including the $ 50,000 Wolf Prize of in 1983.

Paul Erdös – The man who loved only numbers

* * *

"My mother said; 'Even you, Paul, can be in only one place at one time.'
Maybe soon I will be relieved of this disadvantage.
Maybe, once I've left, I'll be able to be in many places at the same time.
Maybe then I'll be able to collaborate with Archimedes and Euclid."

* * *

"I am 2 billion years old because when I was in high-school I was taught that the earth was $2\frac{1}{2}$ *billion years old, but now we know that it is* $4\frac{1}{2}$ *billion years old."*

* * *

*On one occasion, **Erdös** met a mathematician and asked him where he was from. "Vancouver," the mathematician replied. "Oh, then you must know my good friend Elliot Mendelson," Erdös said.*

The reply was: "I AM your good friend Elliot Mendelson."

* * *

A salesman was knocking on Erdös' door. Paul, busy with the solution of a mathematical problem, called from his table: "Please come some other time, and at somebody else's door."

* * *

He observed one day that the audiences at his talks had been getting larger and larger, to the point where they filled halls so big that his old and feeble voice could not be heard. Erdös speculated as to the cause of this.

"I think," he said, "it must be that everyone wants to be able to say 'I remember Erdös; why, I even attended his last lecture!' "

* * *

This is my vision of the 'perfect death': It would occur after a lecture, when I have just finished presenting a proof and a cantankerous member of the audience would have raised a hand to ask: "What about the general case?" I would then reply: "I think I'll leave that to the next generation," and fall over dead.

* * *

"Mathematical truths are discovered, not invented."

Mathematicians on Paul Erdös

* * *

"A mathematical genius of the first order, Paul Erdös was totally obsessed with his subject — he thought and wrote mathematics for nineteen hours a day until the day he died. He traveled constantly, living out of a plastic bag, and had no interest in food, sex, companionship, art — all that is usually indispensable to a human life."

(Oliver Sacks)

* * *

"One never knew where Erdös was, not even the country. However one could be sure that during the year, Erdös was everywhere. He was the nearest thing to an ergodic particle that a human being could be."

(Richard Bellman)

* * *

"Because he seemed to be in a state of Brownian motion, it was hard to locate him at any given time.
With his death we have lost one of the great mathematicians and free spirits of this century, and it is hard to imagine that we will see anyone like him again. I feel fortunate to have the privilege of knowing him and working with him."

(Melvin Henriksen)

* * *

"In our century, in which mathematics is so strongly dominated by 'theory doctors', he had remained the prince of problem solvers and the absolute monarch of problem posers, the Euler of our time."

(Ernst Straus)

* * *

"Erdös' driving force was his desire to understand and know. You could think of it as his magnificent obsession. It determined everything in his life."

* * *

"He died with his boots on, in hand-to-hand combat with one more problem. It was the way he wanted to go."

(Ronald L. Graham)

* * *

"He was always searching for mathematical truths. He had an ability to inspire. He would take people who already had talent, that already had some success, and just take them to an entirely new level. His world of mathematics became the world we all entered."

(Mark Spencer)

1933–1941 CE **Fritz Zwicky** (1898–1974, U.S.A.). One of the first to suggest the existence of *dark matter* (1933) and *Neutron stars* (with **W. Baade**, in 1934). Made valuable contributions to the theory and understanding of *supernovae*.

Zwicky was born in Varna, Bulgaria. He received his doctorate in physics from the Swiss Federal Institute of Technology in Zürich (1922) and served on the faculty of the California Institute of Technology, Pasadena during 1925–1972. In 1933 he observed a group of galaxies orbiting one another and estimated the gravity needed to keep the cluster from flying apart. From the required gravitational pull and the size of the cluster, Zwicky could further calculate the mass contained within the cluster: about 20 times what could be generated by the visible stars and gas.

For more than forty years, most astronomers tried to ignore the possibility of dark matter. In 1934 he proposed that supernovae are a class of stellar explosions completely different from the ordinary novae, and occurring less often (ca once every 500 years in our galaxy). From 1937 to 1941 he discovered 18 of them (about 12 had been recorded previously in the history of astronomy).

The neutron was discovered via laboratory experiments in 1932. Within two years **F. Zwicky** and **W. Baade** developed a theory according to which stars too massive to become white dwarves will collapse into a highly compact ball of degenerate neutrons, *a neutron star*[780]. The degenerate neutron pressure could support a stellar 'corpse' against further gravitational collapse.

This prophetic proposal was politely ignored by most scientists for many years because a neutron star was considered a weird object — having, as theory showed, nuclear density of order 10^{15} g/cm^3, relatively small size (some 30 km in diameter) and an escape velocity equal to half the speed of light. All these properties seemed so outrageous in 1934 that few astronomers paid any serious attention to this theory, and the proposal was shelved until the discovery of the first pulsar in 1967.

[780] Neutrons, like electrons, obey the Pauli exclusion principle and can become degenerate if crowded into a sufficiently small volume. At white-dwarf densities, the electrons are degenerate, but not the nuclei. Thus, a star could collapse into degenerate neutrons if, once its nuclear fuel has been exhausted, it is too heavy to be stabilized by forming a white dwarf. In that case, the star's self gravity forces all electrons and protons (except in the star's crust) to combine, pairwise, into neutrons, which causes a massive neutrino burst (ca 10^{57} of them) and leaves behind only degenerate neutrons. The neutrons in such a condition cannot decay into protons and electrons for reasons of energetics — although a *free* neutron is unstable. In a sense, a neutron star is *one gigantic atomic nucleus*!

Extreme Earth – Chronology of Events[781]

We address the subject of singular terrestrial events in recorded history and their impact upon civilizations. Natural disasters have been the scourge of mankind since time immemorial. We survey their history throughout the past 6000 years, including such calamities as volcano eruptions, earthquakes, floods, tsunamis, major storms, hurricanes, droughts, pandemics, collision of earth with bolides, climatic changes and ecological collapses. Not only had many of theses singular events changed the course of civilization, but they have at the same time influenced both the advent and advance of science. It is estimated that ca 500 million people were killed since 4000 BCE by all catastrophes combined. This amounts to about 1.5 percent of all people who ever lived since 4000 BCE. The total fatal energy unleashed on the earth's surface against its inhabitants throughout the said time window is estimated at 2×10^7 *MT.*

The following consist of a chronological list of some 150 terrestrial events which had the most significant impact (and consequences) on human civilizations, since 5000 BCE.

---

Prehistory

4895 BCE *Crater Lake (Oregon, U.S.A.; VEI=7=Volcanic Explosion Index).*

4400–4000 BCE *Neoglaciation* and severe *climatic* depressions on a global scale: severe episodes of climatic deterioration manifest through glacial advance, increased rainfall, decline of average temperatures, rise of a sea-level and major flooding.

4350 BCE *Kakai* (Japan) volcano eruption (VEI=7).

3580 BCE *Vesuvius* (Italy) volcano eruption (VEI=6).

Ancient History

ca 3200 BCE

- Millennial-scale warming terminates with flooding in the lower latitudes followed by drought. Survivors organize into centrally directed and hierarchical culture.
- History begins at Sumer with the invention of the art of writing. Emergence of urban irrigation-based cultures centered on city-states.

  Sea-level changes.

  Index of tree-ring narrowness corresponds to temperature changes. Ice-core samples from Greenland (sulfate concentration, oxygen-isotope ratio indicative of ambient temperature).

  Flood-myths of most civilizations and many oceanic islands.

Ca 2920 BCE *Black Peak* (Alaska) volcano eruption (VEI=6).

Ca 2880 BCE *Taupo* (New Zealand) volcano eruption (VEI=6).

Ca 2297 BCE Massive rains burst the Hwang Ho (Yellow River), Wei and Yangtze rivers, flooding almost the entire North China Plain and turning it into a huge inland sea.

Ca 2180–2130 BCE *Sharp climatic changes* cause rise and fall of civilizations and mass-migration in Europe and Asia.
Failure of Nile annual floods; *drought* and *famine* in Egypt cause collapse of central government and an ensuing chaos.

Ca 2040 BCE *Long Island (New Guinea) volcano eruption (VEI=6).*

1855 BCE *St.Helens volcano eruption (VEI=6).*

ca 1800 BCE

- *Seismo-volcanic upheaval in the Dead-Sea region. Biblical allusions.*
- *Ecological collapse of city-state civilization in Southern Mesopotamia due to salination of cultivated soils. Mass-migration. Age of biblical patriarchs.*

1750 BCE *Veniaminof (Alaska) volcano eruption (VEI=6).*

May 1627 BCE *Thera volcanic paroxysm; ca 100,000 people perish. Ash identified as coming from the eruption has been found in coastal cities as far away as Israel and Sardi in Anatolia. Climatic and economic disruption of late Bronze-age Minoan civilization and Egyptian middle kingdom. Subsequent impact on civilizations in the Eastern Mediterranean. Event linked to myth of Atlantis and biblical account of Israel in Egypt.*

ca 1320 BCE *Bolide fireball explosion over Apasa, Asia Minor.*

ca 1250 BCE *Possible visitation of a comet as "pillar of fire"during the exodus of Israelites from Egypt.*

ca 1200–850 BCE *Sharp climatic changes – northward displacement of arid zone at late Bronze-age cause mass southward migration in Europe and the Aegean zone. Indo-European invasion into Greece and Asia Minor by sword-bearing people. Disruption of agriculture in Crete, Greece and Eastern Mediterranean. Homeric wars, Sea-People in Egypt, Cyprus, Israel and Italy. Decline of Mycenaen and Hittite civilizations. Severe droughts in China (ca 1122 BCE, 842–771 BCE).*

ca 950 BCE *Hekla (Iceland) volcano eruption (VEI=6). Radiocarbon evidence.*

767 BCE *First recorded pandemic in Europe and the Mediterranean world.*

600–500 BCE *Cooler weather, increase of rainfall and floodings in Europe and the Middle-East.*

430 BCE *Decline and fall of Athens by the plague.*

217 BCE *Vesuvius (Italy) volcano eruption.*

210 BCE *Raoul (Kermades Is.) volcano eruption (VEI=6).*

44 BCE *Etna volcano eruption.*

50 CE *Ambrym (New Hebrides) volcano eruption (VEI=6-7).*

65 CE *Bonna-Churchill (Alaska) volcano eruption (VEI=6).*

79 CE**, Aug. 24** *Vesuvius (Italy) volcano eruption (VEI=6). Ruin of Pompeii, Herculanum and Stabiae.*

ca 100 CE *Climatic change forces the abandon of the formerly flourishing (since 300 BCE) cities of Palmyra and Petra (now in the deserts of Syria and Jordan respectively). In these cities vine and olive were cultivated without much recourse to artificial irrigation. This implies higher water table than now and a climate that supplied more dependable rain.*

155 CE *Ksudach (Kamchatka) volcano eruption.*

250–594 CE *Decline and fall of Roman Empire aided by severe climatic changes causing droughts, plague and malaria.*
Plague of Justinian (542); millions perish in Africa and Mediterranean area.

260 CE *Ilopango (El Salvador) volcano eruption (VEI=6).*

536 CE *Rabaul (New Britain) volcano eruption (VEI=6). The greatest aerosol-producing eruption in recorded history.*

550–600 CE *Prolonged drought in the Peruvian Andes put an end to the 1000 year old Nazca Indian Culture, who in their great despair drew impressive geoglyphs to implore their gods for rain.*

Middle Ages

600–650 *Dry period in Arabia preceded the great wave of Arab outburst through the advent of Islam.*

626 *Volcano eruption in the Mediterranean region.*

700 *Bonna Churchill (Alaska) volcano eruption (VEI=6).*

934 *Eldgia (Iceland) volcano eruption.*

1000 *Collapse of the Andean Tiahuancco Empire due to a prolonged drought lasting some 80 years.*

1006 *Merapi (Java) volcano eruption destroyed Hindu-Javanese state of Mataram and its unique civilization.*

1022 *Drought in India; population decimated.*

1054 *Baitoushan (China) volcano eruption (VEI=7).*

1064–1072 *7-year failure of Nile flooding; widespread famine.*

1099 *Sea flood in Thanes Estuary and Holland; 100,000 estimated drowned.*

1104 *Hekla (Iceland) volcano eruption (VEI=5).*

1164 *Floods in northwestern Germany; 100,000 estimated perished.*

1200 *Floods in Friesland (Holland); 100,000 estimated drowned.*

1200–1250 *Drought and moist conditions drive Mongols into China, Europe and Middle-East. Decline of Islamic Empire.*

1212 *Floods in North Holland. Enormous loss of life: estimated 306,000 drowned.*

1218–1287 *Catastrophic floods in the Netherlands; 200,000 victims (coasts of Holland sank 2 m since Roman times). Strong tides and storms in the North Sea.*

1258 *A volcano eruption affects global weather.*

1332 *The Yellow River burst and drowned about 7 million people with possibly a further 20 million dying of famine. The Black Death plague appeared in China at the same time.*

1332–1351 *Black-Death Pandemic in India, China and Europe. History's greatest natural disaster; ca 50 million die in Europe and Asia (about 10 % of world's population at that time). Parching drought with consequential famine in Central Asia have caused rodent migration westward. End of feudal system and advent of the Renaissance in Europe.*

1400–1650 *'Little Ace Age' in Europe.*
Floods in Holland (1421); 100,000 perish. Again: 50,000 die in 1530 and 100,000 in 1646.

1452 *Kuwae (New Hebrides) volcano eruption (VEI=6).*

Modern Era

1507–1595 *Smallpox and typhus pandemics in the New World decimated the native population of Inca and Aztec empires; ca 50 million die.*

1556, Jan. 23 *Earthquake in Shensi (China); 830,000 perish.*

1563 *Bubonic Plague in London; 25% of the population perish.*

1570, Nov. 02 *Floods in the Netherlands; 400,000 perish.*

1577 *Apparition of the 'Great Comet' (0.63 au from earth). Turning point in astronomy.*

1580 *Billy Mitchell (Bougainville) volcano eruption (VEI=6).*

1600 *Plague in Russia; ca 250,000 victims.*
Huaynaputina (Peru) volcano eruption (VEI=6).

1630(1656) *Plague in Venice (Naples); ca 250,000 (100,000) die.*

1631 *Vesuvius (Italy) volcano eruption; more than 4000 perish.*

1641, Jan. 04 *Parker (Philippines) volcano eruption (VEI=6).*

1660 *Long Island (New Guinea) volcano eruption (VEI=6).*

1664 *Plague in London; 100,000 die.*

1669 *Etna (Sicily) volcano eruption; 100,000 perish. Destruction of Catania, Sicily.*

1672 *Plague in Naples; 400,000 perish.*

1693 *Earthquakes hit Naples and Catania; 150,000 victims.*

1703, Nov. 26 *Sea-tempest in the British Channel; 8000 perish. Greatest storm in 2000 years in the North Sea. Worst storm in British history.*

1711 *Plague in Germany and Austria; 500,000 die.*

1717 *Floods in Holland; 12,000 people drowned.*

1730, Dec. 30 *Earthquake hit Tokyo (Japan); 140,000 perish.*

1737, Oct. 11 *Cyclone at the mouth of the Ganges River at Calcutta (India); 300,000 die. Avachinsky (Kamchatka) volcano eruption. Great tsunami.*

1755, Nov. 01 *The Lisbon earthquake; 60,000 killed. Advent of modern seismology.*

1766 *Hekla (Iceland) volcano eruption (VEI=4).*

1769–1778 *Drought causes famine in India; ca 6 million perish.*

1780 *Hurricane hits Cuba and Central America; 25,000 perish by floods.*

1783, June 08 *Laki (Iceland) volcano eruption; 10,000 die; ash fall-out destroyed crops and livestocks causing famine and starvation.*

1792 *Unzen (Japan) volcano eruption; tsunami kills 14,300 persons. Plague in Egypt; 800,000 die; pandemic spread to North Africa (1799) and killed 300,000 more.*

1799 *Plague in North Africa; 300,000 die.*

1803, Apr. 26 *Meteor shower over the village of l'Aigle in France finally established extraterrestrial nature of meteors.*

1812–1813 *Dysentery decimates the Napolean army in Russia; ca 400,000 die.*

1815, Apr.10 *Tambora (Sunda Is.) volcano eruption; perhaps the most energetic single geophysical event in the past 5000 years (20,000 MT); 92,000 died from tephra, tsunami and starvation. Epicenter at Sumbawa 8°15'S 118°00'E. 150* km^3 *ash ejected into the atmosphere and affected world climate. Caused extreme cold winters in many parts of the world; 1816 – the year without summer; famine.*

1826–1837 *Cholera pandemic in Asia and Europe; 900,000 perish in 1831 alone.*

1829–1833 *Malaria epidemic kills 150,000 Indians in the Pacific Northwest.*

1835, Feb. 20 *Major earthquake in Chile; witnessed by Darwin.*

1837–1838 *Drought in India; some 800,000 die.*

1840–1894 *Worldwide Cholera pandemic; mainly Eastern Europe and India (due to crop failures); fatalities in the millions.*

1851–1855 *Tuberculosis ravaged England; 250,000 die.*

1857 *Earthquake in Tokyo (Mar.21; 110,000 die) and Napoli (Dec. 16). First attempts to describe source-mechanism; advent of instrumental seismology.*

1864 *Hurricane in the Calcutta harbor.*

1866 *Drought-related famine in Bengal; 1.5 million die.*

1868 *Earthquake shakes Ecuador, Colombia and Peru; 40,000 die.*

1876 *Tsunami at the Bay of Bengal; 215,000 perish in Calcutta; caused by an earthquake in the Andaman Islands.*

1876–1879 *Prolonged drought in India and Northern China; 18 million perish.*

1881, Oct. 08 *Typhoon hits Haiphong (North Vietnam); 300,000 die.*

1883, Aug. 27 *Krakatoa (Sunda Straits) volcanic eruption; E=200 MT; tidal wave kills 36,000 people. First evidence of jet-stream circulation. Explosion heard 5000 km away. Ejecta reached 80 km high, above the ozone layer.*

1887. Sept.–Oct. *Floods of the Yellow River (Hwang Ho, China); 6 million people reported lost; caused by rains. This river killed more people than any other river in the world. Worst flood in recorded history.*

1889–1890 *Influenza pandemic in the world; millions die.*

1891, Oct. 28 *Earthquake in Mino-Owari (Japan); first documentation of surface faulting; 7300 people die.*

1892–1900 *Drought, famine and plague in India and China; ca 8 million perish.*

1897, June 12 *Earthquake in Assam (India); first observations of P, S, R waves on seismograms.*

1900, Sept. 08 *Hurricane at Galveston (Texas, U.S.A.); 8000 killed. Wind speed of 170* $\frac{\text{km}}{\text{sec}}$ *sent 5 m tidal wave through town.*

1902, May 08 *Peleé (Martinique) volcano eruption; 29,000 perish at St.Pierre in 2 minutes by a fire-storm (nueé ardente).*

1902, Oct. 24 *Santa Maria (Guatemala) volcano eruption; ca 1500 perish.*

1906, Apr. 18 *Earthquake of San-Francisco; M=*$7\frac{3}{4}$*; 700 killed; elastic rebound theory.*

1908, June 30 *The 'Tunguska event'; asteroid explosion over Siberia; on 00:14:28 GMT,* $60°55$*'N,* $101°57$*'E a 100 m bolide mimicked a high-altitude nuclear explosion with yield of ca 12 MT. It arrived with a velocity of ca 40* $\frac{\text{km}}{\text{sec}}$*, having an estimated mass of 50,000 ton. The radius of total destruction was 2000* km^2*. The explosion was heard to a distance of 1270 km, seen at distance 500 km; heat was felt 70 km away and matter was burnt in a radius of 15 km. Had it arrived 4 hours* *and 27 minutes later it would hit Petrograd and may have changed the course of history of the* 20^{th} *century. Nuclear explosion may have been triggered by neutron production as the heated object sped through the atmosphere. Frequency of event – ca once every 300 years (over the entire earth's surface).*

1908, Dec. 28 *Earthquake of Messina (Italy); 160,000 killed in Calabria and Sicily.*

1911 *Floods of the Yangtze River (China); 200,000 die.*

1911, June 06 *Katmai (Alaska) volcano eruption (VEI=6).*

1912 *Novarupta (Alaska) volcano eruption (VEI=6).*

1916, Jan. 14 *Sea-floods in Holland; 10,000 die.*

1916–1919 *Influenza pandemic; 80 million die worldwide, dwarfing the toll of combat in WW1 (ca 10 million).*

1920, Dec. 16 *Earthquake in Kansu and Shensi Provinces (China); 100,000 perish.*

1921–1930 *Cholera and smallpox epidemic in India; 1,300,000 victims.*

1923, Sept. 01 *Earthquake in Yokohama and Tokyo; 100,000 killed by shock and fire. Advent of earthquake-engineering.*

1925, Mar. 18 *'Tri-State-Tornado' in U.S.A.; 43 billion $ damage; 700 dead.*

1927, May 22 *Earthquake in Nanshan (Kansu, China); 200,000 victims.*

1928 *Hurricane in Florida; 1800 die.*

1930, Aug. 13 *Bolide explosion over Curucá River (Brasilian Amazon;* $5°S$, $71.5°W$*; 12:04 MT). Yield =1 MT. A miniature 'Tunguska'. Exploded about 9 km above ground. Explosion heard 240 km away and seismic waves were recorded at La Paz, 1322 km away. Fine red ash fell on the forest but nothing else reached ground level.*

1931, June–Aug. *Floods of the Yangtze River due to rain; more than million people drowned, 180 million affected in Hoanan Province (China).*

1932 *Hurricane in Cuba; 2000 perish.*

1933, Mar. 02 *Seismic tsunami off coast Honshu (Japan); waves 23 m high; 3000 perish.*

1933, Mar. 10 *Long-Beach (U.S.A.) earthquake. Systematic study of the effect of earthquakes on buildings begins.*

1935, Sept. 04 *'Labor-day Hurricane' in the Florida keys; 400 die. Winds 320 km per hour. Barometer 669.3 mm.*

1935, Dec. 11, 10:30 am LT *Bolide explosion over British Guiana (now Guyana); another "'mini Tunguska".*

1937 *"Near miss" of asteroid Hermes (distance of 800,000 km from earth).*

1938 *Yellow River flooding; 1 million victims.*

1956, Mar. 30 *Bezymianny (Kamchatka) volcano eruption.*

1960, May 22 *Earthquake in Chile; experimental verification of propagating rupture of faults and the earth's free oscillations.*

1965, Mar. 31 *Bolide explosion over British Colombia. Explosion heard over 140 km. Estimated yield 4 KT.*

1970, May 31 *Earthquake in Peru; 66, 000 killed.*

1970, Nov. 12 *Tropical cyclone in Bay of Bengal (Bangladesh); 500,000 victims.*

1974 *Hurricane in Central America; 5000 perish by floods.*

1975, Mar. 04 *Bolide explosion over Western New Guinea (3°42'S, 133°17'E). Large area of jungle knocked down. Felled trees point away from center.*

1976, July 27 *Earthquake in Tangshan (China); 655,000 victims (M=7.8).*

1978 *Bolide explosion over South Pacific; yield ≃ 100 KT.*

1980 *St. Helens (Washington, U.S.A.) volcano eruption; yield = 5 MT.*
El Cichón (Mexico) volcano eruption; more than 2000 die.

1985 *Ruiz (Colombia) volcano eruption; 25,000 perish.*

1988, Sept. 13 *Hurricane 'Gilbert'; strongest Atlantic cyclone on record.*

1989, Mar. 23 *Asteroid 1989FC with energy of 1000 MT nearly missed the earth (2 moon-distances away).*

1992, Dec. 12 *Tsunami flooded the South Pacific volcanic islands of Flores and Babi; 2000 killed. Waves, 25 m high swept ashore.*

1995 *Bolide explosion over Northeastern Brazil.*

1998 *Great hurricane induced floods in Central America. 20,000 perish in Honduras and Nicaragua. Million homeless and a third of all homes in these countries destroyed.*
Devastating floods in China.

Hazardous events – background and data

The chronology presented in the last section includes a variety of natural disasters caused by the interaction of life-systems on earth with internal and external dynamic environmental systems such as the earth's crust, its oceans and atmosphere and outer space. We divided these events into a number of categories, each of which will be discussed in some detail. Table 5.10 lists the most destructive catastrophes on earth during the second millennium CE, with the corresponding estimates of human death-toll.

Table 5.10: MOST DESTRUCTIVE GEOPHYSICALCATASTROPHES ON EARTH DURING THE 2nd MILLENNIUM CE

Date	*Location*	*Disaster*	*Estimated death-toll*
1139, Oct. 12	*Syria, Aleppo*	*Earthquake*	*230,000*
1228	*Netherland coast*	*Flood*	*100,000*
1290, Sept. 27	*China, Chihili (Hope Province)*	*Earthquake*	*100,000*
1421	*Netherland coast*	*Flood*	*100,000*
1530	*Netherland coast*	*Flood*	*100,000*
1556, Jan. 26	*China, Shansi*	*Earthquake*	*830,000*
1642	*China, Yellow River*	*Flood*	*300,000*
1646	*Netherland coast*	*Flood*	*100,000*
1693, Jan. 11	*Italy, Naples and Catania*	*Earthquake*	*153,000*
1730, Dec. 30	*Japan, Hokkaido*	*Earthquake*	*137,000*
1737, Oct. 11	*India, Calcutta*	*Cyclonic storm*	*300,000*
1815, Apr. 05	*Indonesia, Tambora*	*Volcano eruption*	*92,000*
1857, May 08	*Japan, Tokyo*	*Earthquake*	*107,000*
1876	*Bay of Bengal (Bangladesh)*	*Seismic tsunami*	*215,000*
1882	*India, Bombay*	*Flood*	*100,000*
1887	*China, Yellow River*	*Flood*	*2,000,000*
1908, Dec. 28	*Italy, Messina*	*Earthquake*	*160,000*
1911	*China, Yangtze River*	*Flood*	*200,000*
1920, Dec. 16	*China, Kansu*	*Earthquake*	*200,000*
1923, Sept. 01	*Japan, Kwanto*	*Earthquake*	*143,000*
1927, May 22	*China, Nanshan*	*Earthquake*	*200,000*
1931	*China, Yellow and Yangtze Rivers*	*Flood*	*3,000,000*
1938	*China, Yellow River*	*Flood*	*1,000,000*
1970, Nov. 12	*Bay of Bengal (Bangladesh)*	*Flood*	*500,000*
1976, July 27	*China, Tangshan*	*Earthquake*	*655,000*

EARTHQUAKES

Plate tectonics refers to the movement and deformation of segments of the earth's lithosphere (plates). There are seven major plates: North American, South American, Nazca, Pacific, African, Indian-Australian and Eurasian.

There are three types of plate boundaries on the surface of the earth:

- *Divergent boundaries:* two plates which are moving away from each other, leaving room for material from the mantle to seep into the space and form new sea floor (e.g., *Mid-Atlantic Ridge*, at the rate of ca 1.5 $\frac{cm}{yr}$. Such zones are characterized by active volcanism, shallow-focus earthquakes, tensile (stretching) stresses and high rates of heat flow.
- *Convergent boundaries:* two plates move *toward* each other, causing one plate to submerge beneath the other (e.g., formation of the Himalayas by the underthrusting of the Indian plate relative to the Eurasian plate).
- *Transform boundaries:* two plates slide past each other (e.g., along the San-Andreas fault system in California at the borders of the North American and Pacific plates), with neither creation nor destruction of lithosphere. In general, each plate is bounded by some combination of these three kinds of zones. The global sum of plate creation and consumption is approximately zero: the plates form and disappear in size and shape as they evolve.

Much of the earth's landscape has been shaped by plate tectonics. As oceanic plates have been created and subducted, and the continents have collided and broken apart, mountains have been built, rift valleys formed, ocean ridges and trenches created, and volcanoes constructed.

Plate tectonics is driven by convective cooling of earth's interior: the continental lithosphere is made largely of rocks such as granite that are less dense than the mantle. The continents thus stay afloat and remain at the surface, although they have drifted together and broken apart many times. By 80 million years ago, most of the continents we know today were isolated and had began moving toward their current positions.

The continents move about 5 to 10 cm per year and it takes millions of years to build a mountain range. Around 250 million years ago, when North America collided with Africa, the ensuing large-scale crustal shortening generated the Appalacian Mountains. Erosion has worn them down, but they were once comparable to the present-day Himalayas. The Himalayas, however, were formed only about 35 million years ago, when India plowed into southern

Asia. The large-scale horizontal shortening that resulted, built up the highest mountains on earth.

Plates not only 'collide' with one another, they can also slip *past each other along a* fault *which is a thin boundary layer of crushed rock between the two moving blocks. Here, stresses build up, the rock breaks. This sudden slip shakes the earth, causing an* earthquake*. Thus, for example, the result of the slip of the Pacific plate and the North American plate created the San Andreas fault in California. It slices through California more than 1100 km and its activity accounts for more than 10,000 earthquakes (most of them minor) each year.*

Deep earthquakes *are associated with the subduction of oceanic plates. Some have been detected at depths exceeding 600 km, indicating how far the plates may plunge into the mantle.*

Earthquakes may release enormous amounts of energy that travel along the surface and through the interior to great distances. Much of what we know about the earth's interior, we have learned by studying how these waves travel through the earth.

During earthquake episodes, plate-motions release stored elastic energy in the earth's crust and upper mantle up to depths of 700 km. Most of this energy is expended, however, in the upper 70 km or so.

Table 5.11: 'Killer earthquakes' during the 2^{nd} millennium CE

(A) 1000–1800 CE *(21,000 or more deaths)*

Date	*Location*	M_s	*Comments*	*Approximate death-toll**
1038	*China: Shensi*			*33,000*
1042, Aug. 21	*Syria: Palmyra*	*7.2*	*City ruined; felt in Iran & Egypt*	*50,000*
1042, Nov. 04	*Iran: Tabriz*	*7.6*	*City ruined*	*40,000*
1057	*China: Chihli*			*25,000*
1139, Oct. 12	*Syria*	*7.4*	*Aleppo destroyed*	*230,000*
1157, Aug. 15	*Northern Dead-Sea Rift*	*7.3*	*Destruction in Syria & Lebanon*	*80,000*
1202, May 30	*Northern Israel*	*7.5*	*Macroseismic area engulfs the entire Middle-East; damage in Israel, Lebanon and Syria*	*30,000*
1268	*Turkey: Silicia*			*60,000*
1290, Sept. 27	*China: Hopeh*	*6.7*		*100,000*
1293, May 20	*Japan: Kamakura*			*22,000*
1444	*Turkey*			*30,000*
1455, Dec. 05	*Italy: Naples*	*7.5*		*40,000*

Volcanoes

Volcanism occurs when magma (molten rock) beneath the surface of the earth breaks through the surface. A volcano is thus a hole in the earth's crust which serves as a vent for magma and gases from below the earth's surface. The volcano forms from a buildup of ash and lava around the hole. Energy is released during a volcanic eruption as heat, partly as explosive energy, and partly in earthquakes. One example of volcanic land-form is a stratovolcano (a cone shaped mountain built by alternating layers of lava and volcanic ash.) Volcanic activity reflects ways in which heat is lost from the interior; ocean-ridge volcanism *creates new oceanic lithosphere.* Convergence-zone volcanism *produces stratovolcanoes in plate margins.* Interplate volcanism *produces shield volcanoes and flood basalt provinces in the interior of plates.*

In convergence-zone volcanism, very steep stratovolcanoes are formed when magma rises through the continental crust. The lava usually contains large amounts of gases that are often released explosively, forming ash. Alternating eruptions of lava and ash build a cone-shaped mountain with steep slopes. In interplate volcanism, magma comes from hot spots *in the mantle. The basalt lava has only small amounts of gas and produces little ash. The relatively free-flowing lava spreads widely, building a broad, domed mountain with gentle slopes. Hot spots are also responsible for the* flood basalt *areas on the continents. Magma from hot spots fractured the continental crust and rose through it.*

About 10,000 volcanoes have erupted in the past 10,000 years, and are thus considered potentially active. Current activity is limited to 500–600 volcanoes, distributed nonuniformly on the plates. Most are found on plate boundaries where lithosphere is being created or destroyed. Many are on the margins of the Pacific plate, forming the so-called Ring of Fire. *Interplate volcanoes account for only a small number of the active volcanoes.*

Volcanism has contributed enormous amounts of water, carbon dioxide, and other gases to the atmosphere. Sunlight broke water molecules into its components, hydrogen and oxygen. Photosynthesis by plants removed carbon dioxide and added oxygen to the primitive atmosphere. Volcanism was also an important factor in the growth of continents. The overall beneficial aspects of volcanism can be summarized as follows:

- *Outgassing the earth to produce the atmosphere and hydrosphere.*
- *Renewal of soil.*
- *Production of rich ore deposits by hydro thermal processes.*

- *Enabling the tapping of geothermal energy.*

The potency of volcanoes is graded on a scale known as the Volcanic Explosivity Index (VEI). It is based on a number of parameters that can be observed during an eruption.

There are six distinguished volcano eruptions that merit special mention, because of the role they played in human history: (E = energy in units of one megaton of TNT)

1. *Yellowstone (USA) VEI = 8,* $E = 2 \times 10^6 MT$.
   The eruption cycle is ca 600,000 years. Last eruption occurred 640,000 years ago.

2. *Toba (Sumatra) VEI = 8,* $E = 6 \times 10^6 MT$.
   Last eruption occurred 74,000 years ago. Lake Toba was discovered in 1949. It is surrounded by a vast layer of ignimbrite rocks. Rhyolite ash, similar to that found around Toba, was discovered 3000 km away in India. Oceanographers discovered a vast dusting of Toba ash on the floor of the Eastern Indian Ocean and the Bay of Bengal. It is estimated that the Toba eruption was perhaps the greatest since Yellowstone. The eruption caused a great collapse to occur, forming a caldera filled with water, creating a lake.

3. *Thera (Santorini) VEI = 6-7,* $E = 10^3 MT$.
   This titanic volcanic explosion (May 1627 BCE) contributed to the downfall of the Minoan in the Eastern Mediterranean. Its echoes resound in the literature of the ancient Hebrews and Greeks even 1200 years (50 generations!) after the event.

   This event changed the whole course of civilization in the Eastern Mediterranean. The Achaean civilization of the Greek mainland took over the Minoan culture and power of Crete. Casualties were estimated at 100,000, believed to be caused by a mega-tsunami. It was the greatest volcanic tsunami to have occurred within the last few thousand years. The ash fall-out due to this event may have been the cause of the great total Eastern Mediterranean famine in the days of Jacob and Joseph, described so vividly in the Old Testament Book of Genesis.

4. *Vesuvius VEI = 6, Aug 24, 79 CE.*
   Mount Vesuvius is but 17,000 years old. It has been intimately involved with mankind for at least 3000 years and is surrounded by the largest population – 2 million people – ever to dwell in the immediate vicinity

of an active crater. No other volcano played so definitive role in history, or has so dramatized the perils that are visited by those who choose to live among that flanks of an eruptive peak.

This mountain was so quiescent during ancient history that it was totally ignored by the gods of Greece and Rome and, again, by chroniclers of superstition during the Dark Ages. It did not achieve the full measure of world fame until archaeologists uncovered the lost cities of Pompeii, Herculaneum and Stabai during the 18th *and* 19th *centuries.*

5. *Tambora* $VEI = 7$, $E = 2 \times 10^4 MT$, *April 05, 1815*
   Perhaps the greatest and deadliest eruption in recent times was that of volcano Tambora on Lesser Sunda Is. In parts of Java, the blanket of ash produced a daytime darkness *more profound then the blanket of nights (Exodus* **10**, *23). A total volume of 150 km*^{3} *(*1.7×10^6 *tons) of ash were ejected into the atmosphere and the released energy reached a value of* 8.4×10^{26} *erg. It affected world climate, causing extreme cold winters in many parts of the world for 3 years (1816 — 'the year without a summer').*

6. *Krakatoa* $VEI = 6$, $E = 200MT$.
   In 1883 (Aug. 26 and 27) the volcano island of Krakatoa in the Sunda Straits, was blown to pieces. A volume of 20 km^3 *of material was emitted during a paroxysmal eruption, unleashing an energy of about* 10^{25} *erg. Material was shot 80 km high (above the ozone layer). Its global effects lasted for 4 years.*

   Certain aspects of the destruction mechanisms of volcano eruptions were clarified, on close scrutiny, only in the 20^{th} *century. One of these is the fire-storm known as* Nueé ardente *that caused the death of some 30,000 people on May 08, 1902 at St. Pierre, near Mt. Peleé, Martinique: A hot gas hurricane avalanche swept the city at a speed of 100 km/hr. The hot gas was found to be composed of* CO_2*, glass and dust at ambient temperature of about* $800^\circ C$*.*

Tsunamis

"This is what the Lord says: 'See how the waters are rising in the north; they will become an overflowing torrent. They will overflow the land and everything in it, the towns and those who live in them. The people will cry out; all who dwell in the land will wail at the sound of the hoofs of galloping steeds, at the noise of enemy chariots and the rumble of their wheels. Fathers will not turn to help their children; their hands will hang limp. For the day has come to destroy all the Philistines and to cut off all survivors who could help Tyre and Sidon. The Lord is about to destroy the Philistines, the remnant from the coasts of Caphtor."

Jeremiah **47**, *2–4 (ca 625 BCE)*

"... who calls for the waters of the sea and pours them out over the face of the earth."

Amos **9**, *5–7 (ca 780 BCE)*

It speeds across the sea as fast as a jet airplane. On reaching land, it can suck all the water out of a harbor. Then the creature may grow more than 30 meters tall and flatten whole villages. This sea monster is a tsunami. They are the most destructive waves in the ocean. Tsunamis, often wrongly called tidal waves, are not caused by tides or even by the wind, but by underwater earthquakes, landslides, volcanic eruptions, or worst of all — an asteroid impact in the ocean. These disturbances cause the sea bed to move very quickly, which shifts a large amount of water and disrupts the sea surface. A train of waves is set in motion traveling away from the source of disturbance. The resulting long waves can be devastating to low-lying coastal areas.

About four out five tsunamis happen within the "Ring of Fire", a zone of frequent earthquakes and volcanic eruptions roughly matching the borders of the Pacific Ocean. Along the ring's edges, giant slabs of the earth's crust, called tectonic plates, grind together. Sometimes the plates get stuck, and pressure builds, causing the plates to suddenly come apart and slam into a new position. This jolt causes an earthquake. If an earthquake lifts or drops part of the ocean floor, the water above it starts moving, too, triggering a tsunami.

A tsunami can race across the ocean at 800 km an hour. Oddly, in deep water its waves are only a few feet high, but when the waves approach shore, they increase in energy and height. Often before a tsunami hits, water is sucked from harbors and beaches. People see the bare sea bottom littered with flopping fish and stranded boats. That is because waves are made out of crests, or high points, and troughs, or dips between crests. When a trough hits land first, the water level drops drastically. Usually another wave blasts ashore about 15 minutes later, then another and another, for two hours or more.

The damage caused by a tsunami is due not just by a heavy wall of water hitting things, but much more due to the solid debris carried by up the powerful, churning deep water wave as it hits the continental shelf — the solid debris rams and batters anything in its way.

For example, the tsunami from the 1960 Chile earthquake created a deep water wave of only 20 cm above sea level, but when it hit the shore it had risen to an average height of ten times its ocean size — over 2 meters, and in some places much higher (10 m).

It is not easy to determine the frequency of tsunamis in the world historically. Unusual debris has been found in high places in many parts of the world which could be the result of a tsunami, though it is not easy to determine what happened for sure and when, by the ordinary nature of the material. There has been little effort to date to systematically assess the frequency and nature of tsunamis well before the 20^{th} *century. Recorded history by civilizations along the Atlantic Ocean has not noted major tsunamis. Yet, it has been even* speculated *that the old stories of Atlantis, and even Noah's Arc, may have origins in some prehistoric tsunami which wiped out coastal settlements.*

Searches for tsunamis in the geological record have mostly been started only in the 1990's. Of particular interest are tsunami along the Atlantic coast, where earthquake-induced tsunami are rare, so that any detected tsunami would probably be due to an asteroid. The results of these ongoing efforts will shed some light on the frequency of asteroid hits into the oceans.

A mainstream scientific analysis currently estimates that a tsunami exceeding 100 meters in height along the entire coast probably occurs once every few thousand years, which slightly exceeds written history in most of these ocean coastal regions. Such a 100 meter tsunami would cause unprecedented damage to low lying areas all along the U.S. east coast, and may totally submerge vast areas in Europe such as in Holland and Denmark. A 100 meter tsunami would travel inland about 22 km and a 200 meter tsunami would travel inland about 55 km.

Tsunamis have killed more than 275,000 people since 1870. To save lives, scientists established the Pacific Tsunami Warning System, based in Hawaii, in the U.S.A. Its network of earthquake detectors and tide gauges detects earthquakes that may cause a tsunami.

Table 5.13 lists some of the deadliest tsunamis that plagued the coasts of the world since 1628 BCE.

Extreme Universe

There are about a hundred billion stars in the Milky Way galaxy. One of these stars is the sun, which gives our earth the light and warmth that it needs to sustain life. However, even though the time scales are long by human standards, the galaxy is a dynamic, changing place, with new stars being born and old stars evolving and eventually dying. New stars are born out of collapsing clouds of gas and dust that float between the stars. Initially, these clouds are cold, but as they contract, they heat up. The temperature at the core of such as "protostar" eventually becomes so high that nuclear fusion reactions set in. Hydrogen atoms are fused into helium atoms, releasing energy which makes the newborn star shine. Once born, the life stories of the stars are different depending on how much material they started out with at their births.

Light-weight stars like our sun live a long and sedentary life. After 5 billion years, the Sun still generates light and heat from fusing hydrogen into helium. Later in its life it will become a red giant star, fusing helium into carbon. The higher temperatures in the core will cause the sun to puff up to 100 or more times its current size, engulfing the earth; but that will not happen for another 5 billion years! Finally, the nuclear reactions in the sun will run down and it will become a white dwarf star. Without a power source at its center, the sun will slowly cool and grow dimmer and dimmer. There are many stars like our sun in the galaxy.

Massive stars, such as Wolf-Rayet stars, are rare and differ from our sun in several important ways. These heavy-weight stars live relatively short but very intense lives. They have very strong stellar winds, about 10 billion times stronger than the solar wind. The solar wind can sometimes be noticed on earth when it creates the Northern lights or disrupts radio communications, but it has very little direct effect on the sun's evolution. The winds from massive stars are so substantial that matter from the stars is carried away by the wind; they are evaporating as we watch.

Massive stars burn much hotter than the sun and are strong sources of UV radiation. They are capable of fusing progressively heavier elements, such as carbon, nitrogen, oxygen and so on up to iron after which nuclear fusion becomes endothermic.[782] *If you have ever wondered where all the chemical elements came from, the answer is that nearly all of them were made inside*

[782] The elements heavier than iron are thought to have been created in stellar explosions, via endothermic nuclear reactions.

of massive stars. The very material in our bodies was once inside of massive stars, with the exception of hydrogen. We are all made of stardust!

The strong stellar winds of massive stars carry away so much material that they peel away layer after layer from the star like the different layers of an onion. Different chemical abundances become exposed at the surface of the star, allowing us to study the material that was once inside it. At the ends of their lives, massive stars explode as supernovas.

Thus, when massive stars die, they scatter their ashes back out into the galaxy. This material mixes with gas and dust in interstellar space and provides the building materials out of which new and different stars, the next generation of stars, may form.

During the past 70 years (1933–2003) great advances were made in both physics and technology: the advent of relativistic cosmology, astrophysics and astrochemistry, plasma physics and magnetohydrodynamics, quantum physics, nuclear and elementary particle physics, solid state physics, rocket and satellite technology, communication and guidance technology, nuclear power technology and computer technology – all gave us new tools and capabilities to probe deep space and monitor a host of phenomena and events extending to the edge of the observable universe. Data associated with the birth and death of stars are unfolding daily before the 'eyes' of our telescopes over the entire range of the electromagnetic spectrum[783]*, enabling us to understand and reconstruct the complicated physical process that take place at the core of galaxies, in exploding stars, and in previous cosmological epochs.*

Among the bizarre astronomical objects that were thrusted upon astronomers, astrophysicists and cosmologists in the course of the 20th century are: neutron-stars, pulsars, black holes, white dwarfs, accretion discs, supernovae, hypernovae, quasars *and* gamma-ray bursters. *Let us briefly describe these in chronological order:*

Supernovae

Stars which are five times or more massive than our sun end their lives in a most spectacular way; they go supernova. A supernova explosion will occur *when there is no longer enough fuel for the* fusion *processes in the core of the*

[783] As well as though the new window of *neutrino astronomy* and the imminent one of *gravitational-wave astronomy.*

star to create an outward pressure which balances the inward gravitational *pull of the star's great mass.*

First, the star will swell into a red supergiant, at least on the outside. On the inside, the core yields to gravity and begins shrinking. As it shrinks, it grows hotter and denser. A new series of nuclear reactions begin to occur, temporarily halting the collapse of the core.

When the core contains essentially just iron, it has nothing left to fuse (because of iron's stable nuclear structure, it cannot fuse into heavier elements without a net intake of energy). Fusion in the core ceases. In less than a second*, the star begins the final phase of* gravitational collapse*. The core temperature rises to over 100 billion degrees as the iron atoms are crushed together. The repulsive force between the nuclei overcomes the force of gravity, and the core recoils out from the heart of the star in an explosive* shock wave*. As the shock encounters material in the star's outer layers, the latter is heated, fusing to form new elements and radioactive isotopes. The shock then propels the* matter *out into space. The material that is exploded away from the star is now known as a supernova remnant.*

The hot material, the radioactive isotopes, the free plasma *moving in the strong* magnetic field *of the* neutron star *— all of these produce X-rays and* gamma-rays.

All that remains of the original star is a small, super-dense core composed almost entirely of a degenerate "Fermi sea" of neutrons *–a neutron star; the electrons and protons of the core were squeezed together to form neutrons and* neutrinos*, the latter escaping out to interstellar space at essentially light-speed. Or, if the original star was very massive indeed (say 15 or more times the mass of our sun) even the neutrons cannot survive the core collapse, and a* black hole *forms.*

Another type of supernova involves the sudden explosion of a white dwarf star in a binary star system. A white dwarf is the endpoint for stars of up to about 5 times that of the sun. The remaining white dwarf has a mass of about 1.4 times the mass of the sun, and is about the size of the earth.

A white dwarf star in a binary star system will draw material off its companion star if they are close to each other. This is due to the strong gravitational pull of an object as dense as a white dwarf.

Should the infalling matter from the companion star cause the white dwarf to exceed a mass of 1.4 times that of the sun (a mass called the Chandrasekhar limit *after the scientist who discovered it) the white dwarf will have enough mass to collapse and restart the fusion process. The oxygen and carbon nuclei making up the star begin to fuse uncontrollably, resulting in a thermonuclear* *detonation of the entire star. Nothing is left behind, except a cloud of whatever elements were left over from the white dwarf or forged in the supernova blast. Among the new elements is nickel, which then undergoes fission, liberating huge amounts of energy, including visible light.*

When a star goes supernova, it can be seen across the entire electromagnetic spectrum — including visible light, radio waves, X-rays and gamma-rays.

Supernovae are extremely important for understanding our galaxy. They heat up the interstellar medium. distribute heavy elements throughout the galaxy, and accelerate cosmic rays.[784]

The Crab Nebula in Taurus is the remnant of a supernova whose light reached earth in 1054 CE. The last one observed in our galaxy was seen by Kepler in 1604. They probably occur in the Milky way at a rate of about 1 in 500 years.

In 1987, a supernova explosion just outside our galaxy — ca 10^5 *LY away, in the Large Magellanic Cloud — was observed; besides its electromagnetic radiation, a synchronous burst of neutrinos was observed — the first such neutron star formation signal ever intercepted by man.*

Supernova in other galaxies are routinely observed.

---

[784] Recently, the discovery of a mass-extinction event in the earth's ocean(s) [ca 2 Myr ago] was correlated with unusual iron-isotope abundances. It is thought to have been possibly caused by a supernova in our region of the Galaxy.

One must, therefore, add encounters with nearby supernovae to the list of potential cosmic dangers and catastrophes. However, during the 1 to 2 million years (Myr) that passed since the extinction event in question, the sun has moved thousands of light years (LY) and acquired new stellar neighbors (at our distance from the galaxy center, it takes the sun and nearby star clusters about 200 Myr to circumnavigate the galaxy's axis).

Consequently, astrophysicists now believe that the solar system has been surrounded by a 'protective bubble' of relative vacuum that protects the biosphere (in addition to the protective ozone layer and the earth's magnetic field).

More and more it seems that it is not accurate to say (as people like Carl Sagan have been saying) that we sit in a very typical region of the galaxy. Like much else (the fine-tuned constants of nature, the existence of the moon and key events that led to the evolution of humans) it seems that our galactic environment and history have been unusually friendly and "presaged" our existence, although that probably will not last.

Neutron Star

The central star which is left behind after the supernova explosion is so collapsed that it may become even denser than a White Dwarf. In such a case it is called a neutron star, because the electrons and protons which would normally be present in atoms are squashed together to form neutrons under enormous pressure. The diameter of a neutron star is about 10 km, and its density is that of the nucleus of an atom, around 10^{15} *times higher than the density of ordinary matter. Because of its small size and high density, a neutron star possesses a surface gravitational field of order* 10^{12} *times that of earth.*

Neutron stars may appear in solitary supernova remnants or in x-ray binaries with a normal star. When a neutron star is in an x-ray binary, astronomers are able to measure its mass from the orbital dynamics. From a number of such x-ray binaries, neutron stars have been found to have masses of about 1.4 times the mass of the sun. Astronomers can often use this fact to determine whether an unknown object in an x-ray binary is a neutron star or a black hole, since black holes are more massive than neutron stars.

The energy released through a collapse forming a neutron star of mass M *and final radius* R *is (ignoring GTR corrections)*

$$E \approx \frac{3GM^2}{5R}.$$

With $G = 6.67 \times 10^{-8}$ *cgs,* $M = 1$ *solar mass* $= 2 \times 10^{33}$ *gram and* $R = 5$ *km, we obtain* $E \approx 3 \times 10^{53}$ *erg. About 99% of this energy is emitted as neutrinos in the first few seconds of the collapse, and the observation of the expected fraction of them from the 1987 supernova SN1987A helped confirm the theory of gravitational collapse and pulsar/neutron-star formation. The rest appears as visible and UV light, radio waves, X-rays and gamma rays from a supernova, or is expended in the collapsed star's vicinity (spin kinetic energy, magnetic fields, plasma processes, nebula formation and excitation, etc.).*

Black Holes

It is believed that the mass of a neutron star cannot exceed 2 solar masses.

Astrophysicists have calculated, using GTR, that a neutron star any heavier than this will be crushed into an ever-decreasing volume by its own gravity.

As the star shrinks, the surface gravitational field strength ($g = GM/r^2$) continues to increase and so the escape velocity at its surface ($v = \sqrt{2GM/r}$) gets larger (these formulae ignore GTR effects). Eventually the escape velocity equals the speed of light. This has the intriguing consequence that nothing whatever can escape from the collapsed star by any means. Such a star is therefore totally invisible and is known as a black hole. *It has been suggested that a few binary star systems contain black holes; these particular systems are very powerful X-ray sources.*

Even back in Newton's time, scientists speculated that such objects could exist, even though we now know they are more accurately described using Einstein's General Theory of Relativity. According to GTR, black holes are fascinating objects where space and time become so warped that time practically stops in the vicinity of the "event horizon" of a black hole (as viewed by external observers), and even stranger things happen inside *that horizon.*

There is a great deal of observational evidence for the existence of three types of black holes; those with masses of a typical star, *those* with masses of a typical galaxy, *and those at* centers *of galaxies (of order* 10^6–10^7 *solar masses).*

The first type have measured masses ranging from 4 to 15 suns, and are believed to be formed during supernova explosions. *The after-effects are observed in some* X-ray binaries *known as black hole candidates.*

On the other extreme, galaxy-mass black holes are found in Active Galactic Nuclei *(AGN). These are thought to have the mass of about 10 to 100 billion suns. The mass of one of these* supermassive black holes *has recently been measured using radio astronomy.* X-ray *observations of iron in* accretion discs *may actually be showing the effects of such a massive black hole as well.*

X-ray Binaries

Binary star *systems contain two stars that* orbit *around their common center of* mass. *Many of the stars in our* galaxy *are part of* binary systems.

A special class of binary stars *is that of* X-ray *binaries, so called because they emit X rays.* X-ray *binaries are made up of a normal star and a collapsed star (a* white dwarf, neutron star, or black hole). *These pairs of stars produce* X rays *if the stars are close enough together such that material is pulled off the normal star by the* gravity *of the dense, collapsed star. The X rays are* *emitted from the area around the collapsed star where the material that is falling toward it is heated to very high temperatures (over a million degrees!).*

Pulsars

Pulsars are rotating neutron stars. They were first discovered (1967) as radio sources that blink on and off at a certain constant frequency.

The brightest pulsars are observable at almost every wavelength of light.

Pulsars are spinning neutron stars that have jets of particles moving almost at the speed of light streaming out their two magnetic poles. These jets produce very powerful beacons of EM radiation.

For a similar reason that "true north" and "magnetic north" are different on earth, the magnetic and rotational axes of a pulsar are also misaligned. Therefore, the beam of light from the jet sweeps around as the pulsar rotates, just as the spotlight in a lighthouse does.

Wolf-Rayet stars (WR)

Observed Wolf-Rayet stars form a rare group of $\approx$ 200 *supergiants with spectacular emission line spectra. They have exceptional surface temperatures approaching, in some cases, 100,000K, and about 50 solar masses. Although very brilliant, they are all so remote that a telescope is needed to view them. They suffer from a high mass loss through a turbulent atmosphere and show very strong, broad emission lines of ionized* He *and* O *in addition to nitrogen [WN type] and carbon [WC type] respectively. The Doppler broadening of the lines is only evident at higher resolution.*

These lines rise as bright 'peaks' above the star's background spectral continuum. Some of these stars are binaries and the relative intensity of the emission lines is affected by the continuum contribution of the companion star. A concentration of bright WR stars in Cygnus makes it the best site for Northern Hemisphere observers

Wolf-Rayet stars are linked to hypernovae, which in turn are associated with gamma-ray bursters.

Quasars, Active galaxies and double radio sources

A quasar (or quasistellar object) is an object in the sky that looks like a star but has a huge redshift corresponding (by the Hubble law) to a very great distance from the earth.

To be seen from earth, a quasar must be very luminous – typically about 100 times brighter than an ordinary bright galaxy.

Relatively rapid fluctuations in the brightnesses of quasars indicate that they are unlikely to be much larger in size than the diameter of our solar system.[785]

An active galaxy is an extremely luminous galaxy that has one or more unusual features: an unusually bright, star-like nucleus; strong emission lines in its spectrum; extreme variations in luminosity; or jets or beams of radiation emanating from its core.

Most double radio sources seem to have an active galaxy located between the two radio lobes that distinguish this type of radio source.

The strong energy emission from quasars, active galaxies, and double radio sources may be produced as matter falls toward a supermassive black hole at the center of the object.

Gamma-Ray Burster stars (GRB)

Short-lived bursts of gamma-ray photons are associated with a special type of supernovae — the explosions marking the death of especially massive stars ("Gamma-Ray Bursters", or GRBs).

Lasting anywhere from a few milliseconds to several minutes, gamma-ray bursts shine hundreds of times brighter than a typical supernova making them briefly the brightest source of cosmic gamma-ray photons in the observable

785 This is so because the time patterns of brightness variations at two quasar points, a distance r apart, are unlikely to vary in phase unless they have a common cause. This in turn makes it likely that $r \lesssim ct$, with c the speed of light and t the typical fluctuation timescale.
This line of argument (which is admittedly model dependent) depends on the *local causality* principle of STR.

universe. GRBs are detected roughly once per day from wholly random directions of the sky.

It is highly likely that GRB are not located within our galaxy, but are at cosmological distances.

This makes them extremely interesting, because for them to be seen at such large distances they must correspond to events in which as much as 100 times the energy of a supernova is being liberated in a short period in the form of gamma rays. Furthermore, the mechanism producing the gamma rays must be such as to allow the gamma rays to escape without too much interaction with surrounding matter, because that interaction would convert the gamma rays to radiation of longer wavelength.

Although the exact picture has not been worked out, astronomers think the gamma-ray photons are probably produced inside the star. The explosion originates at the center of these massive stars. While a black hole forms from the collapsing core, this explosion sends a blast wave moving through the star close to the speed of light. The gamma rays are created when the blast wave collides with stellar material still inside the star. These gamma rays burst out from the star's surface just ahead of the blast wave. Behind the gamma rays, the blast wave pushes the stellar material outward.

Erupting through the surface, the blast wave of stellar material sweeps through space at nearly the speed of light, colliding with intervening gas and dust to produce additional emission of photons. These emissions are believed responsible for the "afterglow" of progressively less energetic photons, starting with X-rays and then visible light and radio waves. (Whether additional gamma rays are also produced in this "afterglow" phase is still not settled, although some evidence indicates they are.)

The afterglow phase can last for days or even weeks. Under this model, we detect both the GBR and the afterglow when the earth happens to lie along or very near the axis of the blast. In general, there are many more GRBs than are detected simply because we are not favorably aligned to see them.

Observations have allowed a distance to be estimated to the gamma ray bursters because spectral lines and their Doppler shift have been observed in the transients after the burst. Assuming these transients to be near the center of the gamma ray burst and the Doppler shifts to be Hubble redshifts, these observations have almost conclusively shown that gamma ray bursters are at cosmological distances, rather than in the halo of the Milky Way galaxy.

The enormous amounts of energy implied by such large distances suggest a gravitational source. Two popular candidate mechanisms are the merger of two black holes or the merger of two neutron stars. However, although such events might yield the required energy, it is not clear that they can be made *consistent with all the observations. Thus, the source of gamma ray bursts remains one of the most important mysteries in modern cosmology.*

GRB may be linked to the mass extinction that occurred 444 million years ago at the end of the Ordovician period. Such a cosmic explosion, a few thousand light years away, could have altered the environment and extinguished much of life on earth. In general, a supernova explosion could flood our planet with deadly radiation if it happens within about 100 light years of us. (In absolute power output, supernovae are mere firecrackers in comparison with GRBs).

Water would protect marine organisms from the heat of a GRB, but not from its other effects. Its gamma-rays would convert some nitrogen and oxygen in the atmosphere into nitrogen dioxide, the brownish gas present in urban smog.

Nitrogen dioxide would filter out sunlight, turning the skies dark. The cooling effect could trigger an ice age – there is evidence of widespread glaciation 440 million years ago. Nitrogen oxides also cause acid rain and destroy the ozone layer, exposing earth to more of the sun's harmful ultraviolet rays.

Ultraviolet radiation can penetrate tens of meters of water, so it could harm marine organisms at these depths. Indeed shallow water dwelling species, or those that spend their early lives in shallow water, seem to have suffered more than deep species in the Ordovician extinction.

In short, a nearby GRB might first have showered harmful radiation onto the exposed face of the planet, killing more or less indiscriminately, and may then have exposed the other hemisphere to increased ultraviolet radiation, damaging marine life decreasingly with increasing depth.

Table 5.14: Evolution of a massive star

Stage	Radius (approximation)	Balance against gravitational collapse
Young star	10^6 *km*	*Radiation pressure from proton fusion*
White dwarf	10^4 *km*	*Electron degeneracy pressure (Pauli Exclusion Principle)*
Neutron Star	10 *km*	*Neutron degeneracy pressure (Pauli Exclusion Principle)*
Black hole	1 *km*	*None*

Table 5.15: TIMETABLE OF OBSERVATIONS OF OUTSTANDING ASTROPHYSICAL AND COSMOLOGICAL PHENOMENA

130 BCE ***Hipparchos*** *observed a few WR stars, but parallax was insufficient for useful luminosity calibration. In 1989 CE, a satellite of the European Space Agency, bearing his name, was launched to survey the positions of more than 100,000 stars.*

1867 CE ***C.J.E Wolf*** and ***G.A.P Rayet*** *discovered the first three 'WR stars'.*

1871 CE The Italian astronomer ***Lorenzo Respighi*** *(1824–1889) was first to see the remarkable spectrum of the Southern WR star Gamma Velorum, an interacting binary of magnitude 1.74*[786].

1884 CE The Astronomer-Royal of Scotland, ***Ralph Copeland*** *(1837–1905) led an expedition to Lake Titicaca (Peru, altitude 4000 meters) to record the spectrum of Gama Velorum. In his own words:*

"Its intensely bright line in the blue, and the gorgeous group of three bright lines in the yellow and orange, render its

---

786 Astrophysicists express the brightness of stars in visible light in two related forms.

Apparent visible magnitude, mv, measures the light that actually reaches us on earth. But that is not the true measure of a star or galaxy's brightness because distance makes objects appear dimmer. *So, absolute magnitude – Mv – is used to compare how bright stars would be if they all were 32.6 light years (10 parsecs) away.*

Bright stars are ranked first and are assigned the low numbers, followed by dim stars with higher numbers (6^{th} magnitude is the faintest that the naked eye can detect; reaching $mv = 25$ requires extremely sensitive telescopes and instruments). A few have negative magnitudes given when modern instruments showed them to be brighter than the initial magnitudes given by astronomers just using their unaided vision. A magnitude 1 object is about 2.5 times brighter than the next dimmer magnitude. A 100-fold difference in brightness makes a difference of 5 in magnitude.

At $mv = -1.45$, Sirius A has the greatest apparent magnitude of any star in our sky. At $Mv = +1.41$, it's still in the Top 20 for absolute magnitude. But that parade is led by *Deneb*, a blue supergiant in Cygnus (the Swan) with a whopping $Mv = -7.3$. The closest competitors are *Antares* and *Mimosa* (beta Cruces) at $Mv = -4.7$

spectrum incomparably the most brilliant and striking in the whole heavens. To a great extent it was the extraordinary beauty of this spectrum that led me to devote a considerable part of my time to more or less systematic sweeps of the neighborhood of the Milky Way."

1918 CE ***H.D. Curtis*** *discovered that the spiral nebula Andromeda was far beyond the reaches of our galaxy.*

1924–1928 CE *Observation of light from distant galaxies showed systematic red shifts, indicating that they are receding from us.*

1929 CE ***Edwin Hubble*** *discovered that the universe as a whole is expanding isotropically and homogeneously like a 3D version of a balloon surface.*

1932 CE ***Karl Jansky*** *(1905–1950) accidentally discovered radio waves from the Milky Way.*

1932 CE ***Bengt Edlen*** *correctly identified the observed spectral lines of Wolf and Rayet with laboratory spectra of highly ionized carbon, nitrogen and oxygen. He also explained that the Doppler broadening within strong stellar winds contributes to line width. It was later found that not all of the broadening could be attributed to this effect.*

1933 CE ***F. Zwicky*** *(1898–1974) and* ***W. Baade*** *(1893–1960) predicted the existence of neutron stars. This was verified in 1967 upon the discovery of pulsars.*

1936 CE ***Albert Einstein*** *and* ***Rudolf W. Mandl*** *proposed the theory of gravitational lensing as a testable prediction of GTR.*

F. Zwicky *stated (1937) that galaxies could act as gravitational lenses.*

1943 CE ***Carl Seyfert*** *(1911–1960, USA) identified a small number of galaxies whose nuclei show unusual spectra. Theses features will be later associated with Quasars.*

1960–1963 CE ***Alan Sandage*** *and* ***Maarten Schmidt*** *observed Quasar 3C 48, a qusistellar radio source with X-ray luminosity of* 10^{47} *erg/sec, estimated to be located* 5×10^9 *LY away. It was later suggested (1973) that a quasar is generated by a supermassive black hole at the center of a galaxy.*

1967 CE **Jocelyn Bell** and **Anthony Hewish** *discovered the first pulsar ($CP191$), a radio source in the middle of the Crab Nebula: now believed to be a rotating neutron star with period* 1.337 *sec emitting beams of synchrotron radiation. It is a remnant of the 1054 CE supernova explosion. Its total energy rate in synchrotron radiation is* 3×10^{38} *erg/sec [the sun's total EM emission is* 4×10^{33} *erg/sec].*

1967 CE *Gamma-ray bursts (GRB) discovered serendipitously by U.S. military satellites which were on the lookout for Soviet clandestine nuclear testing in the atmosphere.*

1971 CE *An X-Ray binary source known as Cygnus X-1 is identified as a Black Hole.*

1974–1978 CE **Russel Hulse** and **Joseph Taylor** *discovered the first binary pulsar* $PSR\ 1913 + 16$*: a pulsar orbiting around a companion star. Its behavior is in accordance of Einstein's GTR.*

1979–1983 CE **Dennis Walsh**, **Robert Carswel** *and* **Ray Weymann** *discover a gravitationally lensed Quasar.*

In 1980, an Einstein Ring, a gravitational lens distortion effect, was observed for the first time.

In 1987, **Roger Linds** and **Vahe Petrosian** *discovered an image of a distant unseen galaxy that has been formed by a gravitational lens. By 1993, the existence of compact dark objects in our galaxy, was confirmed via their gravitational lensing of more distant light sources.*

1987 CE *A supernova detected in the Large Magellanic Cloud, a satellite of the Milky Way galaxy. The supernova was the first in almost 400 years that could be seen without the aid of a telescope.*

1990 CE *Hubble Space Telescope launched. The HST has produced images of breathtaking clarity and has allowed astronomers to see light from more distant objects than ever before.*

1991 CE *The Compton Gamma Ray Observatory (GRO), a satellite, is launched by NASA to study the universe. It is more sensitive than earlier gamma ray telescopes. By 1995, the survey recorded about 3000 gamma-ray bursts isotropically distributed, suggesting a cosmological distribution.*

1992 CE ***Felix Miraber*** *and* ***Luis Rodriguez*** *discovered radio sources near our galactic center that resemble quasars. One of these sources, SS 433, shows signs of high-speed relativistic jets.*

1995–1996 CE *Hubble Space Telescope (HST) images of quasar PKS2349 support the hypothesis that quasars occur in the cores of galaxies. The images revealed that the environment surrounding a quasar is far more complex than first suspected. These new observations suggest galactic collisions and mergers between quasars and companion galaxies can reignite the supermassive black holes that drive quasars.*

In 1996 HST recorded a Quasar a billion LY from earth.

1997 CE *Japan's institute of Space and Astronautical Sciences linked a satellite in space with earth-based radio antennae to create an effective telescope larger than earth, called the Very Long Base Interferometry Space Observatory (VLBI). This telescope's resolving power is equivalent to reading a newspaper headline in Tokyo from Los Angeles.*

1997 CE, Feb 28 *Beppo SAX, equipped with both gamma-ray and X-ray detectors, spotted an X-ray afterglow signature associated with the gamma-ray burst of event GRB 970228.*[787]

---

[787] Not until astronomers were able to make afterglow observations could they develop a working hypothesis on what caused gamma-ray bursts. And while the *Compton Gamma Ray Observatory's* Burst And Transient Source Experiment (BATSE) detector catalogued 2,704 GRBs during the observatory's nine year lifetime (1991 -2000), it was not equipped to make afterglow observations. Furthermore, it had not been possible to get either a ground or space-based telescope look up quickly enough to a spot where a GRB had been detected.

As a result, the first afterglow observation did not come until the Beppo SAX *satellite*. Beppo SAX, an Italian satellite, was equipped with both a *gamma ray* and an *X-ray* detector. It spotted the X-ray afterglow signature associated with the gamma-ray burst on February 28, 1997.

Today a worldwide network called the Gamma-ray Burst Coordinates Network (GCN) coordinates space-based observations and ground-based follow-through observations of GRB afterglow. NASA satellites include the High Energy Transient Explorer (HETE) operated by the Massachusetts Institute of Technology, and the Rossi X-ray Timing Explorer (RXTE). The European Space Agency operates *Integral*, a new gamma-ray mission launched in 2002. And there is the Interplanetary Gamma-Ray Burst Timing Network (IPN), which consists of a group of space probes with gamma-ray detectors at different locations in the

1999 CE, Jun 27 *'Blast from the past': one of the most powerful cosmic explosion ever recorded, bathed the earth in gamma rays. This gamma-rays burst called GRB 990123 – was so intense that its visible light could have been seen through common binoculars*[788]*. The duration of the event was about 110 seconds. The redshift measurement implied that it took the signal about 10 billion years to reach the earth.*

For the first time, scientists have witnessed a burster's visible light emitted at the same time as a gamma-ray burst.

2003 CE, Mar 29 *NASA's High energy Transient Explorer (HETE-II) detected a very bright gamma-ray burst (designated GRB 030329) is a sky region within the constellation Leo.*

Following identification of the "optical afterglow" by a 40-inch optical telescope of the Siding Spring Observatory (Australia), the redshift of the burst was determined as 0.1685 *by means of a high-dispersion spectrum analyzer of the UVES spectrograph of the 8.2 m telescope at Parnal Observatory (Chile). The corresponding distance is 2650 MLY.*

The optical spectrum was nearly identical to that of a supernova*, and* X-ray *observations also showed a signature associated with oxygen heated to high temperature. Such a pattern occurs when the supernova blast wave excites oxygen atoms in the vicinity of the star.*

*All this evidence pointed to a connection between the GRB and a "*hypernova*" explosion of a very massive, highly evolved star.*

This is caused by a very heavy star — presumably 25 times heavier than the sun.

These observations therefore indicate a common physical source of hypernova explosion *and the associated emission of strong gamma radiation.*

Solar System.

By timing the arrival of gamma-ray photons at each satellite, the location of the burst can be "triangulated". The *GCN sends out automatic notices* by email to astronomers worldwide; enabling both professional and amateur astronomers to make follow-up afterglow observations.

788 The peak gamma-ray *power* was estimated at that of 10^{16} suns, namely 10^{50} erg/sec. This is 100 times more energetic than a supernova explosion and is comparable to burning up the entire mass-energy of the sun in a few hours.

Glossary of Cataclysmic events

Huge explosions and other sorts of cataclysmic events are a natural part of the life-cycle of stars. Stars formed in swirling clouds of gas move along the H-R diagram, incorporating such occurrences into their evolution and forming in the process the elements needed to form new stars. The main 'cast of characters' and the fundamental concepts in this drama are the subjects of this small dictionary:

parsec — *The distance you would have to be from the solar system for the angular separation between the earth and the sun to be one arcsecond. That distance is*

$$206,265\ AU = 3.1 \times 10^{13}\ km = 3.26\ light\ years.$$

Magnitude — *A system for classification of stars according to apparent brightness. The human eye can detect stars with magnitudes up to 6 (the faintest). The Hubble space telescope is capable of imaging a magnitude 30 star, which has been compared to detecting a firefly at distance equal to the diameter of the earth (ca 12,800 km).*

Spectral classification — *A system for classifying stars according to their surface temperatures.*

Red dwarfs — *The most common stars, accounting for about 80 percent of the star population in the universe.*

Binaries — *Two-star systems, in which the stars orbit one another. The way the companion stars move can tell astronomers much about the individual stars, including their masses. Visual binaries can be resolved from earth. Spectroscopic binaries are too distant to be seen as distant points of light, but their relative motions can be studied with a spectroscope. In this case, a binary system is manifested via Doppler shifting of spectral lines as the stars receded and advanced along the line of sight. Eclipsing binaries: periodic, sharp changes in light intensity due to one star eclipsing the other. This yields information about orbital motion, masses and radii.*

Core hydrogen burning	*The principal fusion reaction process of a star. The hydrogen of the star's core is fused into helium (sometimes in nuclear reaction cycles catalyzed by carbon, nitrogen and oxygen nuclei), producing enormous amounts of energy in the process.*
Red giant	*The last stage in the evolution of stars about as massive as the sun. Its relatively low surface temperature produces its red color.*
White dwarf	*The remnant core of a red giant after it has lost its outer layers as a planetary nebula. Since fusion has now halted, the carbon-oxygen core is supported against further collapse only by the degeneracy pressure supplied by densely-packed electrons.* *Their small size makes them relatively faint objects despite their high surface temperatures.*
Core-collapse supernova	*The extraordinarily energetic explosion that results when the core of a high-mass star collapses under its own gravity.*
Neutron star	*Superdense compact remnant of a massive star, one possible survivor of a supernova explosion. It is supported by degenerate neutron pressure, not fusion. It is a star with the density of an atomic nucleus.*
Pulsar	*A rapidly rotating neutron star whose magnetic field is oriented such that its synchrotron-radiation "searchlight" sweeps across earth with a regular period. When pulsars were first detected (1967), their signals were so regular that some astronomers suspected they might be a sign of extraterrestrial intelligence. Further observations provided a more mundane explanation.*
Stellar mass black hole	*The end result of the core collapse of a high-mass star. It is an object from which no matter or even light can escape (apart from negligibly feeble Hawking radiation). Although space behaves strangely very close to a black hole, at astronomical distances the black hole's only signature is a normal Newtonian gravitational field, plus an unusually broad EM spectrum emitted by infalling matter in its accretion disc.*

	Only main-sequence stars of at least 20–30 solar masses will ever collapse into a black hole. *The Schwarzschild radius of any given mass is the radius it must be compacted to, to become a black hole (although the precise quantitative measure is tricky, due to the high GTR space curvature near that radius). The event horizon is a surface (spherical for a non-rotating black hole) whose radius is the Schwarzschild radius; the escape velocity equals light speed on that surface. No information of the events occurring within the event horizon can be communicated to the outside.* *A black hole will draw in matter that wanders too near to the event horizon. With such accretion, the star's mass will increase, even as its collapse continues, causing its Schwarzschild radius and event horizon to grow.*
SINGULARITY	*The infinitely dense remnant of a massive core collapse.*
EMISSION NEBULAE	*Glowing clouds of hot, ionized interstellar gas, located near young, massive stars.*
GIANT MOLECULAR CLOUDS	*Huge collections of cold (10 K to 100 K) gas that contains mostly molecular hydrogen. The cores of these clouds are often the sites of the most recent star formation.* *The expanding shock wave of a nearby supernova explosion might be sufficient to cause a cloud to collapse. A ripple in a galaxy (called a density wave) could also be a trigger. A fast-moving massive star, punching through a molecular cloud, could also cause part of it to collapse.*
BROWN DWARF	*A failed star, i.e. a star in which the hydro-thermodynamical forces reached equilibrium with its self-gravity before the core temperature rose sufficiently to trigger nuclear fusion.*
VARIABLE STAR	*A star that periodically changes its brightness.*
LOCAL GROUP	*A galaxy cluster; a gravitationally bound group of galaxies which includes the Milky Way, Andromeda, and other galaxies.*

SUPERCLUSTER — *A group of galaxy clusters. The Local Supercluster contains some* 10^{15} *solar masses.*

QUASAR — *Bright, distant, tiny objects, which produce luminosity of 100 to 1000 galaxies within the size of a solar system. The first quasars were detected at radio frequencies, though most quasars do not emit large amounts of radio energy. Quasars are among the most luminous objects in the universe, having luminosities in the range* $10^{45} - 10^{49}$ *erg/sec. These numbers average out to the equivalent of 1000 Milky Way Galaxies. (The sun has a luminosity of* 4×10^{33} *erg/sec). Quasar's brightness fluctuations are explained by fluctuations in the accretion-disc – the swirling disc of gas spiraling toward the black hole.*

ACTIVE GALAXIES — *Galaxies that have more luminous centers than normal galaxies.*

SEYFERT GALAXIES — *A subset of spiral galaxies characterized by a bright central region containing strong broad emission lines. Some show violent activities in their cores.*

RADIO GALAXIES — *A class of active elliptical galaxies characterized by strong radio emission, and in some cases, narrow jets and wispy lobes of emission located hundreds of thousands of light years from the nucleus. When radio-emitting blobs are moving at high-velocity toward us, there is an apparent superluminal motion (faster than the velocity of light due to a well-understood STR kinematical effect).*

SYNCHROTRON RADIATION — *Arises when charged particles are accelerated by strong magnetic fields. The emission from radio galaxies is mostly synchrotron.*

Science Progress Report No. 15
The Bookburners

"Where they burn books, they end up burning people".
Heinrich Heine[789], 1848 (1797–1856)

411 BCE Public burning of the books of Protagoras in Athens, Greece.

213 BCE Science books and savants were burned in China.

48 BCE The Romans burn part of the Alexandria library.

53 CE The apostle Paul burns books of pagan lore in Ephesus.

70 CE The Romans burn the library of the Temple in Jerusalem.

273 CE The Romans damage the Alexandria library.

295 The Roman emperor Diocletian ordered the burning of all books on the working of gold, silver and copper.

325 Constantine had the Arian writings burnt.

373 Roman emperor Valens ordered the burning of non-Christian books.

391 Emperor Theodosius I ordered the burning of the remnants of Alexandria library. Bishop Theophilus carries out the order.

431 Theodosius II burned the books of the Nestorians.

440 Valentinian III burned the books of the Manichaeans.

646 The Arabs (under caliph Omar) burn to ashes the remnant of the Alexandria library.

1109 Crusaders burn over 100,000 Muslim books in Tripoli.

---

789 Indeed, the Nazi burned his books too. Since it was impossible to remove his *Lorelei* — so great was its popularity — Heine's name was obliterated and replaced by the words "*Author Unknown*".

1204 Mass-burning of classical books by Crusaders in Constantinople.

1242, Jun 17 Public burning of the Talmud and other Hebrew books in Paris under the order of pope Gregory IX.

1244, Mar 09 Pope Innocent IV orders that the Talmud be burned.

1415 The Inquisition burned **Jan Hus** in Constance.

1481, Feb 06 First Auto-da-fe of the Spanish Inquisition.

1484 Grand Inquisitor, Tomas de Torquemada, burned Marranos and their books in Toledo.

1507 Grand Inquisitor, Cardinal Ximenes, burned 24,000 Jewish books in Granada.

1509, Aug 19 Maximillian I ordered the burning of Jewish books.

1528 The first auto-da-fe in America, held in Mexico City when Jews and their books are burned on the stake. Additional Jews are burned in the New World on 28/29 Feb 1574.

1553 Burning of the Talmud in Italy.

1559 Pope Paul IV burns 12,000 Jewish books in Cremona, Italy.

1562 The Bishop of Yucatan burned to ashes almost the entire native literature of the Maya culture.

1600 The Inquisition burned **Giordano Bruno** in Rome.

1601, Jan 14 The Church burned Jewish books in Rome.

1635, Aug 11 Auto-da-fe in Lima, Peru for Marranos who escaped the Spanish Inquisition.

1649 One hundred and nine Jews and their books burned in Mexico City.

1682 Three Jews were publicly burned in Berlin as a result of a blood libel.

1731, May 28 Pope Clement XII orders the confiscation and burning of all Hebrew books in Papal States.

1757, Nov 13 The Bishop of Kamenets-Podolski burned all copies of the Talmud in his diocese.

1796, Oct 17 Tzar Paul I ordered censorship of Jewish books in Russia.

1836 Tzar Nikolai I decreed the burning of Jewish books. Most Jewish printing presses were closed.

1933, May 10 Nazis burn books of **Albert Einstein**, **Sigmund Freud** and other Jewish scientists in Germany. Later (1940–1945), the Germans perpetrated an industrial genocide through which they gassed[790] and burned 6,000,000 Jews in special ovens in Poland [German scientists developed an efficient *mass-murder technology*].

1966–7 Mao Tse-tung's 'Cultural Revolution': 'Red Guards' march across China burning books, libraries, museums, laboratories, art galleries and university campuses. A cultural heritage of 6000 years is destroyed. About 500,000 intellectuals are murdered in the biggest witch-hunt in history.

1975–6 Khmer-Rouge communists under Paul Pot burn books and exterminate 1,200,000 intellectuals in Cambodia.

---

[790] *Hydrocyanic acid* (HCN) was discovered in 1782 by **Carl Wilhelm Scheele** (1742–1786, Sweden).

Salute to books — mankind's noblest creation

What is a book? Part matter and part spirit; part thing and part thought — however you look at it, it defies definition. Its outward form, essentially unchanged in nearly 2000 years, is a design as functional as, say, the pencil or the glove: you can't improve on it. Yet, by its nature the book is loftier than the common objects of this world. It is a vehicle of learning and enlightenment, an open sesame to countless joys and sorrows. At a touch, our book springs open, and we slip into a silent world — to visit foreign shores, to discover hidden treasure, to soar among the stars.

Sometime ago, by a unanimous decision of its 128 member nations, the United Nations Educational, Scientific and Cultural Organization (UNESCO) designated 1972 as the first International Book Year. The fact that the ensuing salutes were world-wide was only too appropriate, for the book is the end product of a unique conjunction of endeavors, made independently in far-flung corners of the globe. It is as if all mankind had conspired to create it.

The Chinese gave us paper. Phoenicia brought forth our alphabet. To Rome we owe the format of the book; to Germany, the art of printing from movable type. Britain and the United States perfected book production. Today, 15,000 finished books roll off high-speed presses in just one hour, and we find it hard to visualize the bookless world of our forebears, hard to imagine the enormous effort that lies behind the saga of the book.

In the beginning, there was only the spoken word. Then, to entrust his thoughts to a more lasting medium than mere memory, man took to drawing pictures representing things. Perhaps the oldest picture-script originated some 6000 years ago in Mesopotamia. Its images — bird, ox, ear of barley — were scratched into soft clay tablets, which were then baked hard for preservation.

But such writing was a cumbersome affair, mainly used for priestly documents and public records. What "literature" there was — such as heroic poems — depended almost totally on word-of-mouth transmission. The quick Mediterranean mind, awakening to a new culture, demanded a better way of harnessing the spoken language. Shortly before the 9th century BCE, the Phoenicians — swift seafarers, sharp traders and good record-keepers — began breaking spoken sounds into their basic elements, and shuffling the resulting "letters" to form words.

When wandering among the ruins of the Phoenician port of Byblos — one may still see the rudimentary inscription, hewn into the rock wall of a royal *grave shaft, which stands as the world's oldest known alphabetic writing. Soon the alphabet was seized upon by the Greeks, who gave letters more convenient shapes and added the still-missing vowels.*

No sooner had man taught himself to spell than a new problem raised its head. What to write on? Leather, tree bark, leaves and wax tablets had all proved unsatisfactory. In Egypt, for some 2500 years before Year One, texts had been inscribed on brittle sheets made from the pith of a Nile Delta water plant, papyrus.

The use of this material gradually spread through the Mediterranean world. Usually, several papyrus sheets were glued together to form a scroll that could accommodate a lengthy text. (One 40 m scroll containing the picture-script account of the deeds of Pharaoh Ramses III is still extant.) But what a clumsy thing to read! The scroll, wrapped around a wooden stick, had to be held in the right hand, while the left slowly unwound it to reveal the next column of writing. Nevertheless, the royal library at Alexandria — destroyed in the 4th century CE – is believed to have had no fewer than 700,000 scrolls.

Relatively fragile, papyrus invited rivalry. In wealthy Pergamum, on the coast of Asia Minor, scribes wrote on specially prepared sheep, goat or calf skins. This fine, pellucid stationery, tougher than papyrus and foldable, came to be known as parchment. Shortly after Year One, an unknown Roman scribe with a sense of compactness took a stack of thin parchment sheets, folded them and fastened them together at the spine. Thus, the book was born.

Likely as not, its earliest promoters were Rome's Christians. To them, it was essential to preserve the Scriptures in the most lasting medium — and parchment didn't wilt when handled. Moreover, when one wanted to hunt up a reference, chapter and verse, a book was a lot handlier than a scroll.

So it came about that, all through Europe's Dark Ages, an army of devoted monks, ensconced behind monastery walls, hand-copied the torn and shredded writings of the past on sturdy parchment sheets. Without their toil, the literary glories of ancient Greece and Rome, along with vital texts that shaped the Christian faith, might have been lost forever. It frequently took years to finish copying a thick tome, and many a sore-eyed monk, before putting away his goose quill, penned a sigh of relief on the final page: "Thank God I have finished!"

Meanwhile, in distant China, tradition has it that a gentleman named Ts'ai Lun, vexed at the wasteful use of costly silk as a writing material, reported to Emperor Ho-ti that a far cheaper substance could be made by pounding rags, tree bark and old fishing nets into a pulp, skimming thin layers off the top, and drying them.

Thus, in the year 105 CE, paper enters our story — to remain for six centuries, a closely guarded secret of the East. It wasn't until some Chinese papermakers were captured by marauding Arabs that the pliant blossom-white enduring marvel took the world by storm.

The Occident saw the next major breakthrough. In 1439, a stubbornly determined German craftsman, Johann Gutenberg, began experimenting with a substitute for hand-writing. If he could cast the letters of the alphabet in reusable metal type, then arrange them, in a mirror pattern, into words, lines and columns on an even-surfaced plate, an imprint taken from this plate would make one page. In place of one painstakingly handwritten book, he would be able to run off on his "press" as many imprinted books — exact copies of each other — as he wished.

Laboriously, Gutenberg put together his first page plates, each one composed of more than 3700 signs and letters. With the help of a hand-worked wooden press that he had adapted from the wine press of his native Rhineland (and which remained unchanged for the next 350 years), he started printing in a rented workshop in Mainz.

It took three years to turn out some 190 copies of the Gutenberg Bible of 1455. (Today 47 copies still survive, 14 of which are in the United States. One of the finest, worth an estimated $3 million to $10 million, is on display in the Library of Congress.)

Before the printed book, memory *ruled daily life; The memory of individuals and of communities carried knowledge through time. For millennia, personal memory reigned over entertainment, information, perpetuation and perfection of crafts, the practice of commerce and the conduct of professions. Memory was a faculty which everyone had to cultivate. Thus, the epics of the* Iliad *and the* Odyssey *were perpetuated by word of mouth. Laws were preserved by memory before they were preserved in documents. Rituals and liturgy, too, were preserved by memory, of which priests were the special custodians. By the time the printing press appeared, the arts of memory had been elaborate into countless systems.*

After Gutenberg, realms of everyday life, once valued and served by memory, would be governed by the printed page. Since then, the technology of memory retrieval, played a much smaller role in the higher realms of religion, thought, and knowledge. Spectacular feats of memory became mere stunts. The printed book, however, had its own drawbacks: it made it less necessary to shape ideas and things into vivid images and then store them in memory-places.

In the centuries after printing, interest has shifted from the technology of memory to its pathology. By the late 20th century, interest in memory was *being displaced by the interest in amnesia, hysteria, hypnosis and psychoanalysis. Pedagogic interest in the arts of memory came to be displaced by interest in the arts of learning, which were increasingly described as a social process.*

With Gutenberg's remarkable invention, book prices dropped 80 percent overnight, and learning to read became worthwhile. A mere half-century after Gutenberg's exploit, every major European country except Russia was printing its own books. It was as if floodgates had been opened. Some 520,000 titles were published in the 16th century, 1.25 million in the 17th, two million in the 18th and eight million in the 19th. Today, more than 500,000 titles come off the presses in a single year, adding up to an estimated seven billion *individual books.*

These eye-popping figures notwithstanding, there are those today who predict the disappearance of the reading habit. Canadian professor and commentator Marshall McLuhan, for one, has argued that mass media — films, radio, television — involve us more completely, and hence impart their message more directly, than the familiar lineup of black letters on the printed page[791]*.*

Be this as it may, the book has shown considerable fighting spirit in the face of the new threats. Book-club business has erupted into a stampede, and paperbacks are bought off store shelves as fast as they are put there. Indeed, exposure to the electronic media seems to have created a new desire to "curl up with a good book." And, as we turn its pages at our convenience, going back in leisurely fashion over a passage we've especially enjoyed, or skipping a little here, a little there, we are "involved" more intimately and completely than we could be with any other medium yet invented.

Man's thoughts and dreams, his knowledge and his aspirations, are stored in books — wealth to be tapped by all who so desire. From the first wobbly picture-script to quicker-than-the-eye offset presses, the book has come a long, arduous way, propelled by the genius and persistence of many individuals and nations, Indeed, all humanity has reason to be proud of the book, for it shows us at our very best. Long live the book!

[791] Indeed, the increasing role played by the *digital media* and the *internet* in the domains of contemporary communication, education, business and entertainment seem to fulfill the prophecies of McLuhan.

1934 CE First Hetch-Hetchy water delivered to the city of San-Francisco. A major engineering feat brought water (and electric power) along 240 km from the Tuolumne River in east-central California to the city of San-Francisco. The project called for a construction of a dam, built of concrete (277 m long and 131 m high) with a reservoir capacity of 444 million cubic meters of water. It is known as the *O'Shaughnessy Dam* after **Michael Maurice O'Shaughnessy** (1864–1934), the SF city engineer who directed the original construction. 444 miles of pipeline were laid to bring water from Sierra to SF reservoirs and 40 km of tunnel through Coast Range was built (longest in the world at that time). Cost (to 1934) was about $100 million and 89 men were killed in construction accidents.

San-Francisco (SF) water supplies became inadequate as the city grew. First water was shipped across the Bay or piped from local springs. By 1890 SF started to look for water sources in the Sierra. The Hetch-Hetchy Valley in Yosemite National Park was picked as the best site for the Dam, but early SF applications were turned down because site is in a national park. Civic organizations and the SF Examiner (W.R. Hearst) supported the dam while **John Muir** and the Sierra Club led the opposition. Gradually the dam supporters gained more influence in the US Congress and in the cabinet and in 1913 the project was passed by Congress. The O'Shaughnessy Dam was finished in 1923.

1934 CE **William Beebe** (1877–1962, USA) and **Otis Barton** (USA) set a depth record by diving to 1001 m below the ocean's surface in a tethered sphere called a *bathysphere*.

1934 CE **Wallace Hume Carothers** (1896–1937, U.S.A.). Chemist. Synthesized *nylon*, a synthetic fiber stronger and more durable than silk. Depressed by the untimely death of his twin sister, he committed suicide 3 years after his great invention.

1934–1937 CE **Pavel Alexeevich Cherenkov** (1904–1990, Russia). Physicist. Discovered (*experimentally*) the '*Cherenkov effect*'[792] at the Lebedev Institute, Moscow. It may have been the last important basic phenomenon

[792] The velocity of light in a medium c' is expressed by the formula $c' = \frac{c}{n}$, where n is the refraction index of the medium. Since $n > 1$, a high-energy particle can move in the medium with velocity v such that it exceeds the speed of light there, namely $c > v > c' = \frac{c}{n}$. This particle, if it carries a charge, will radiate light even if it travels with a fixed velocity.

The wave front of the Cherenkov radiation is the envelope of spherical waves emitted by the particle, and has the *shape of a cone* with its vertex at the in classical electrodynamics that remained to be discovered. When a charged particle travels close to the speed of light through a transparent liquid or solid, it emits light. This phenomenon occurs when the velocity of the particle is *greater* than that of light in the dense medium (but still less than c, light's speed in vacuum).

Cherenkov was born near Voronezh, Russia and graduated from the University there in 1928. In 1930, after teaching in a high school, Cherenkov moved to Leningrad and entered the Institute of Physics and Mathematics of the Academy of Sciences of the U.S.S.R. as a postgraduate student. In 1932 he started his research under Sergei I. Vavilov on luminescence activated by gamma rays in different liquids. When the Cherenkov effect was discovered, the majority of Cherenkov's colleagues did not show particular interest in his results.

Nobody recollected the calculation by **Arnold Sommerfeld** (1905) of the energy losses of an electron whose velocity exceeds the velocity of light, or the incredible intuition of **Oliver Heaviside**, who actually predicted the Cherenkov effect in 1888! Even as distinguished a physicist as **Leonid Isaakovich Mandelstam** (1879–1944) did not show much interest in Cherenkov's results, being quite sure that an electron moving with constant velocity could not emit radiation. Only Cherenkov's discovery of the asymmetry of the radiation pattern made (partly by chance) in 1936 after several

---

particle. The situation is similar to that of water waves in the wake of a ship or the shock waves generated in air by missiles or aeroplanes which exceed the speed of sound.

The Cherenkov light is emitted forward such that the angle between the shock-wave and the particle's line of motion is given by $\cos\theta = \frac{c}{nv}$. [In lucite $n = 1.5$, the lowest electron energy for Cherenkov emission is 0.17 MeV and the lowest proton energy is 320 MeV.] This simple formula is used to derive the particle's velocity, which is equivalent to the measurement of its energy.

A Cherenkov counter is a particle detector that employs the Cherenkov radiation emitted in a thin conical layer at an angle θ to the direction of motion. The counter usually consists of a lucite block shaped in such a way that the generated light is sent forward and converges on to the cathode of a *photomultiplier tube*. Since no light at all is produced for $\frac{v}{c} < \frac{1}{n}$, these counters have a built-in threshold discrimination, i.e. they are completely insensitive to low velocity background radiation.

The Cherenkov technique is now an important tool for distinguishing particles of different masses in accelerator experiments; the momentum of the particle is measured by magnetic deflection and its velocity by using the angle or intensity of the Cherenkov light.

years of intense experimenting, assured him and his fellow researchers of the reality of the phenomenon and gave them the key to understanding it. But the acceptance of the effect did not come easy. In the middle of 1937, the editor of *Nature* declined to publish Cherenkov's paper. Later in 1937 *Physical Review* published the paper, and soon the phenomenon was confirmed and accepted.

He shared the Nobel prize for physics in 1958 with **Ilya M. Frank** (1908–1990) and **Igor Y. Tamm** (1895–1971) who worked out the theory of the effect in 1937.

The Russians used the Cherenkov effect in making a *cosmic-ray counter*, which their satellite *Sputnik 3* carried around the earth. Today, Cherenkov detectors are routinely used in the study of high energy particle collisions at accelerator laboratories.

1934–1953 CE **Igor Yevgenyevich Tamm** (1895–1971, Russia). Outstanding theoretical physicist. Made significant research in the fields of crystal optics, quantum theory of diffused light in solids, theory of cosmic rays and control of thermonuclear reactions. Developed (with **I.M. Frank**) the theoretical interpretation of the radiation of electrons moving through matter faster than the speed of light in that matter (the *Cherenkov effect*). Worked with his student **Andrei D. Sakharov** on the Soviet nuclear weapons program.

Tamm was born in Vladivostok to Jewish parents. He graduated from Moscow State University (1918), awarded the degree of Doctor of Physico-Mathematical Sciences (1925); Professor (1930); Academician (1933). Appointed (1934) head of the theoretical division of the Lebedev Institute of Physics of the USSR Academy of Sciences.

A decisive influence on his scientific activity was exercised by **L. Mandelstam** (1879–1944), under whose guidance he worked for a number of years, and with whom he was closely associated since 1920.

Tamm was also a member of the American Academy of Arts and Sciences.

1934–1974 CE **Ilya Mikhailovich Frank** (1908–1990, Russia). Distinguished physicist. Made significant research on photoluminescence, photochemistry, gamma rays and neutron physics. Winner of the Nobel Prize for physics (1958) jointly with **Igor Yevgenyevich Tamm** for the interpretation of the Cherenkov effect, leading to the development of the Cherenkov detector.

Frank was born in St. Petersburg (Leningrad) to Jewish parents. He graduated from the Moscow State University (1930) and joined (1934) the

Lebedev Institute of physics; D.Sc (1935); Professor (1944); Academician (1946). He married Ella Abramovna Beilikhis (1937).

1934–1944 CE **Geoffrey Ingram Taylor** (1886–1975, England). Physicist and hydrodynamicist. Introduced statistical mechanics into the analysis of *turbulence and diffusion* of vortex motion (1935–1938), thus initiating the *statistical study of turbulence*. His work was continued by A. Kolmogorov (1941) and W. Heisenberg (1947).

Taylor contributed to the *Manhattan Project* (1944) by solving a problem associated with the hydrodynamics of nuclear explosions. The problem was to calculate the interaction of several shock waves as they evolve through time: the so-called *Rayleigh-Taylor instability*, formed at the boundary between two materials, causes the two materials to mix in way that is extremely difficult to predict. This in turn made it difficult to predict the *yield* of the atomic bomb[793].

Taylor was born in London. Graduated from Trinity College, Cambridge (1908). Except during the world wars, when he provided assistance to the government, he was based at Cambridge throughout his career.

---

793 G.I. Taylor was able to deduce the yield of the first nuclear explosion from a series of photographs of the expanding fireball in *Life* magazine. He realized that he was seeing a strong shock expanding into an undisturbed medium. The pictures gave him the *radius as a function of time*, $r(t)$. All that could be important in determining $r(t)$ was:

- E, the initial energy release.
- ρ, the density of the undisturbed medium (air).

The radius, with the dimension of length, depends on E, ρ and t, and he constructed the distance out of these quantities. Now, E and ρ had to come in the form E/ρ to cancel the mass. But E/ρ has the dimension $(\text{length})^5/(\text{time})^2$, so the only possible combination was $r(t) \propto \left(\frac{E}{\rho}t^2\right)^{1/5}$. A log–log plot of r versus t (measured from the pictures) gave a slope of $\frac{2}{5}$, which checked with the theory, and E/ρ could be obtained in any chosen unit system from extrapolation to the value of $\log r$ when $\log t = 0$. Since ρ was known, E was determined to within a factor of order one. For the practitioner of the art of *dimensional analysis*, the nation's deepest secret had been published in *Life* magazine. However, the energy release of the first nuclear device was not obvious to every reader of *Life* magazine, not even to those who were aware of the technique of dimensional analysis. The key success is to identify the essential features of the problem, which can be hard to do until you have been shown how.

Taylor proposed (1934) the idea of *dislocation* in crystals (a form of atomic misarrangement which enables the crystal to deform at a stress less than that of a perfect crystal). His many original investigations on the *mechanics of fluids and solids* were applied to meteorology, oceanography, aerodynamics and the study of Jupiter's Great Red Spot.

1934–1947 CE **Marcus Laurence Elwin Oliphant** (1901–2000, England). Nuclear physicist. Discovered *tritium*[794] (1934), the radioactive isotope of hydrogen, by bombarding heavy water with deuterons. Built a 60 inch cyclotron particle accelerator (1937) and proposed the idea of *proton synchrotron* already in 1943.

Oliphant was born near Adelaide, Australia. Received his Ph.D. from the University of Cambridge, England (1929). He then worked under Rutherford

---

[794] The *deuteron* is a bound state of one neutron and one proton with total spin $s = 1$. The binding energy of the deuteron is 2.22 MeV. The atom made up of a bound state of a deuteron and an electron is called *deuterium* (^{2}H, or D). Deuterium exists on earth with natural abundance of about 1.5×10^{-4} times that of hydrogen. The deuterons that are found on earth (inside deuterium atoms) were mostly made in nuclear reactions in the early universe during the first 3 minutes following the Big Bang.

The rest-masses of the proton (m_p), the neutron (m_n) and deuteron (m_d) are related by $m_p + m_n - m_d = \frac{2.22}{c^2}$ MeV $= 3.95 \times 10^{-27}$ g $\cong 2 \times 10^{-3} m_p$. The *heavy water* molecule, D_2O, has deuterium instead of hydrogen.

Tritium (^{3}H) is an atom with a nucleus (*triton*) comprising a bound state of two neutrons and a proton with an orbiting electron.

If two light nuclei are combined into a heavier nucleus (*fusion*), the sum of the masses of the lighter nuclei is greater than the mass of the heavier nucleus. Therefore energy is released when the heavier nucleus is formed. In the fusion of deuterium and tritium

$$^2\mathrm{H} + {}^3\mathrm{H} \quad \rightarrow \quad {}^4\mathrm{He} + n + 17.6 \text{ MeV};$$

This is a very important *thermonuclear reaction*. The Oliphant reaction is:

$$^2\mathrm{H} + {}^2\mathrm{H} \quad \rightarrow \quad {}^3\mathrm{H} + {}^1\mathrm{H}$$

and was effected by bombarding deuterated compounds with low-energy deuteron beams. The half-life of the triton is 12.3 y; the first lower bound was measured by **E.M. McMillan** (1936), and the first reasonably accurate actual value was measured by **A. Novick** (1947).

in the Cavendish Laboratory and became a professor at Birmingham University (1937). He worked on the Manhattan Project at Los Alamos (1943–1945). After the war he was a professor at Canberra University (1950–1961) and served as Governor of South Australia (1971–1976).

1934–1941 CE **Rudolf Schoenheimer** (1898–1941, USA). Biochemist and physician. With his associates at Columbia University developed (from 1934) a technique of "tagging" molecules with radioactive isotopes to trace paths of organic substances through plants and animals, thus revolutionizing metabolic studies. Also studied relation of cholesterol to atherosclerosis.

Schoenheimer was born in Berlin to a Jewish family of physicians. He studied medicine at the University of Berlin, where he received his M.D. degree (1922). He then became interested in Biochemistry and taught at Freiburg (1926–1933). There he encountered the idea of using isotopes through Georg de Hevesy (1885–1966) who had applied radioactive isotopes as tracers in botanical studies (1923) to observe the distribution of lead in bean plants. But at that time few elements were available that could be used as isotopes in biological research.

In 1933 he was forced to leave Germany and went to the United States, joining the biochemistry department of Columbia University medical school. Harold Urey's discovery of deuterium (the isotope of hydrogen) at Columbia University (1932) provided Schoenheimer an ideal opportunity to label organic compounds without changing their chemical properties. Soon afterwards (1935), an isotope of nitrogen, ^{15}N, became available.

With David Rittenberg (1906–1970), a physical chemist, he developed the whole field in which stable isotopes were used as labels for the investigation of many important reactions in intermediary metabolism. Schoenheimer's pioneer work and ideas left a profound impact on biochemistry, biology and medicine.

In spite of his family assimilationist background Schoenheimer reacted vigorously to the growing antisemitism in Germany by a proud identification with his Jewish heritage. After WWI, in which he participated as a soldier he became firmly convinced of the need to establish a Jewish homeland in Israel and visited there in 1926. He intended to go there after WWII and help build up science at the Hebrew University in Jerusalem.

1934–1955 CE **Edmund Germer** (1901–1987, Germany and USA). Physicist, engineer and inventor. Invented and developed the *fluorescent lamp*

(1935) and the *high-pressure mercury-vapor lamp*[795] (1934).

Germer was born in Berlin and studied at the University of Berlin during the 1920's, earning a doctorate in light technology. His continued goal was to invent a better light source with higher lumen output and lower energy consumption compared to the incandescent lamp. After WWII he emigrated to the United States.

The *fluorescent lamp* is a low pressure gas discharge source. It consists of a tube that is coated on the inside with a fluorescent material (powder) and filled with *mercury vapor*. An electric discharge in the vapor produces *ultraviolet light*[796], which in turn causes the coating to fluoresce. By adjusting the coating, fluorescent lamps can be produced to give light with wavelengths that are closer to natural sunlight than can be achieved with the incandescent bulb.

The lamps were introduced commercially in 1938.

1934–1957 CE **Karl (Raimund) Popper** (1902–1994, England). Philosopher of natural and social science. In his key work '*The Logic of Discovery*'

---

[795] The first practical mercury-vapor lamp was the Cooper-Hewitt lamp developed by Peter Cooper Hewitt in 1901. This was a tubular source about 4 feet long which produced light that was distinctly bluish green in color. The first high pressure mercury lamps similar to the ones used today, were introduced in 1934 in the 400 watt size. Today available, mercury lamps range in size from 40 watts to 1000 watts. Mercury lamps produce approximately 55–60 lumens per watt.

Operation: the arc tube of the mercury lamp has argon gas and a little pearl of mercury as filling ingredients. Its electrodes are made of tungsten and carry an emitter paste, e.g. a barium-yttrium compound, that reduces the ignition voltage required to start the lamp. Within three to five minutes after ignition, the mercury is completely vaporized and the characteristic blue-green spectrum of the mercury discharge is emitted. It contains strong ultraviolet radiation at wavelengths of 254 nm and 365 nm. Radiation in the red region of the spectrum is virtually negligible. A mercury lamp's color temperature ranges between 4000 K and 4500 K. Applying phosphor coatings to the outer bulb increases the light output by 10 to 15 percent.

[796] Thermal electrons, emitted by the filament of the negative electrode, are accelerated back and forth by an alternating voltage. Some of them collide with the mercury vapor, releasing energy in the form of ultraviolet light. The ultraviolet light causes the phosphorous coating to glow. Typically, a fluorescent lamp must efficiently generate 253.7 millimicron ultraviolet radiation to excite the phosphorous coating inside the tubular glass bulb. Modern fluorescent lamps have an efficiency of about 65–80 lumen per watt.

(1934) he criticized Francis Bacon's inductive method of scientific reasoning. He asserted that a statement is not necessarily scientific just because it can be confirmed by experience; it is essential for such a statement to be capable of being disproved by some possible event which, where it to occur, would exemplify a possibility that the statement itself excludes. This means that scientific theories can never be verified, only falsified, and that falsification is the true aim of scientific endeavor. In other words: falsification rather than verification is the true characteristic of science. It is this feature of *falsifiability*, Popper claimed, that separates science from metaphysics.

Popper asserted that science advances by way of deductive hypotheses created by man's imagination and the eventual test of its particular predictions through experiments and observations. According to this method, a scientist seeks to discover an observed exception to his postulated rule. The absence of contradictory evidence thereby allows tentative acceptance of his theory. According to Popper, such pseudo-sciences[797] as astrology, metaphysics, Marxist

[797] Theorists who insist that they *must* be right, that no experiment or data could disprove the logic and grandeur of their hypothesis are *pseudoscientists*. One of these was Immanuel Velikovsky, who developed a complex hypothesis that the earth had undergone near-collisions with the planets Mars and Venus, that these encounters could explain many of the narratives of the Bible and in other ancient documents, and that our view of the solar system must be largely revised to take account of his *worlds in collision*, planets wandering from what we take to be stable orbits.

Velikovsky was not a scientist, for the simple reason that he was "always right". Indeed, his world view did not allow for the possibility of error on his part: He could not, and did not, state the facts that would disprove his hypothesis if discovered. He stood *outside science*, never being able to present his theories in a way that allowed reasonable people to test them, and refusing to accept the critical ability of science to refute some theories at the expense of others.

By constructing an environment — the world of science — in which theories survive because they fit into the existing framework more successfully than competing theories, scientists have created the potential for anyone within their purview to make important advances in our collective knowledge.

Individuals make the theories; the social structure of science does the testing. He who does not accept this principle, does not belong to the scientific community. This does not mean that his ideas must be wrong, only that he and his ideas, will not be taken seriously. No one guarantees that anybody's ideas will always receive serious considerations in any case, but there certainly is no hope if one does not "think like a scientist".

history, Freudian psychoanalysis and creationism are not empirical sciences, because of their failure to adhere to the principle of falsifiability[798].

Velikovsky, besides being a pseudoscientist, was also dead wrong already in 1950, when he first published his theory; his scheme called for planets to have wandered tens of millions of kilometers from their present orbits within the past few thousand years, and for Mars and Venus to have been expelled from Jupiter shortly before that. But by 1950 we already knew that astronomical records from Mesopotamia showed that Venus must have had its present orbit, or one close to it, before its alleged collision with earth, and our knowledge of planets composition and motion dynamics, ruled out the careening motions that Velikovsky demanded.

798 The importance of falsification was already made clear by the French biologist **Claude Bernard** (1865). In real life, scientists often do *not* conform to this formula for doing science and have rather an unstated set of criteria for choosing one theory rather than another — and these encapsulate some of the main aims of science: accordingly, for a subject to qualify as science it needs at least to satisfy a number of criteria:

- deal satisfactorily with the phenomena it tries to explain;
- its ideas should be self-consistent;
- have as broad a scope as possible and so encompass a wide range of phenomena, i.e., capable of being linked with other branches of science;
- it should be quantitative and its ideas expressible by mathematics;
- predict new relationships and offer scope for further development;
- be as simple as possible, with a minimum number of hypotheses (Ockham Razor).

There are a number of excellent examples to show that neglect of falsifiability was beneficial to science:

(I) Copernicus' theory about the movement of planets had difficulties with the phases of Venus, and these difficulties were resolved only with Galileo's telescope, more than fifty years later. Galileo considered it praiseworthy in Copernicus that he had not permitted one unexplained puzzle to worry him.

(II) Around 1910 there arose a famous disagreement between Robert A. Millikan in Chicago, and F. Ehrenhaft in Vienna: the latter had reported finding charges of only a fraction of that expected to be carried by the electron. Millikan indeed rejected data that did not fit his basic assumption, but justified it on the basis of his experimental skills, and we know that he was right.

Thus falsification may fail as a criteria because experiments are sometimes wrong. In this connection, one must keep in mind the remark of Francis Crick, In his philosophical and autobiographical work, Popper credits himself for having invented the idea that we acquire knowledge by trial and error, yet the relation between philosophy and psychology in Popper's work is always fraught with tension. The earliest traces to Popper's '*searchlight theory*' of mind and knowledge are to be found in his unpublished dissertation *Zur Methodenfrage der Denkpsychologie* (1928).

According to Michel ter Hark[799] (2004), scrutiny of this manuscript reveals the formative influence of **Otto Selz**[800] (1913). Indeed he claims that Popper borrowed his crucially important 'Searchlight theory' from Selz, and demonstrates that Popper's philosophy of science, with its emphasis on the method of trial and error, is largely based on the psychology of Otto Selz, whose theory of problem solving and scientific discovery laid the foundation for much of contemporary cognitive psychology. By arguing that Popper's famous defense of the method of falsification as well as his elaboration of an evolutionary theory of knowledge are equally indebted to German psychology, Michel ter Hark challenges the received view of the development of Popper's philosophy.

Popper was born in Vienna to converted Jewish parents. After studying mathematics, physics and psychology at the University of Vienna, he taught philosophy at Canterbury University College, New Zealand (1937–1945). He was a professor of logic and scientific method during 1949–1969.

"*A theory that fits all the facts is bound to be wrong as some of the facts will be wrong*". In addition, falsification can itself be false; there is no guarantee that the experimental falsification will not itself turn out to be flawed; for example, the initial experiments carried to test the Weinberg-Salam theory (on the unification of electromagnetism and weak nuclear forces) showed that the theory was wrong. Only later experiments showed that the initial experiments were themselves wrong and the theory was confirmed.

Falsifiability is therefore a necessary but not a sufficient criterion. It is just one aspect of science.

Modern and Modernistic Philosophy (1750–1930)

In the medieval world, original meaning was processed by authority *(e.g. the Catholic Church) and the individual was dominated by* tradition*. The collapse of this worldview was caused by a variety of different factors:*

- *The perceived corruption of the* Catholic Church *hierarchy.*
- *The rise of market economy following the increase of wealth and power of a new '*merchant*' class.*
- *The new* astronomical *discoveries of Copernicus and Galileo.*
- *The new* geographical *discoveries of the Spanish, Portuguese, Dutch and British voyagers.*

All these played their part in undermining the religious and metaphysical foundations of Christian Europe. With the scientific revolution, Europeans lost faith in religion and found new hope in science *and* humanism*. Both of these seemed to offer more rational ways of achieving salvation. The new world was to be governed by the truths of science, based on careful examination, manipulation and observation of nature within a mathematical epistemological framework.*

There was to be no place for philosophy *in this new world of scientific modernity. From now on,* analysis*,* method *and* technique *would be the new gods, and the wonder and curiosity of the philosophers was to be replaced with a new kind of question. The question "*What is it?*" was now subordinated to the more technical question: "*How does it work?*". So philosophy became concerned with providing the metaphysical and epistemological supports for the new secular order of modern technocracy.*

The intellectual opposition to the medieval worldview began in the 15th century, during the Renaissance*, with the Humanist ideas of* ***Desiderius Erasmus*** *(1466–1536),* ***Niccolo Machiavelli*** *(1469–1527), and* ***Michel de Montaigne*** *(1533–1592). Each of these thinkers accepted the idea of* ***Protagoras*** *(c. 491–421 BCE) that our own human world is the only world in existence, and that we can make of this world what we will.*

At the start of the 16th century, the growing problems facing the Catholic Church were further compounded by ***Martin Luther*** *(1483–1546), who was about to begin a personal crusade to reform Christianity. Luther added to* this a new sense of individualism when he claimed that Christian belief was a matter of personal faith rather than objective truth.

The "modern" era was boosted by the European Enlightenment and the advent of the Industrial Revolution in England anchored in the development of the steam-driven motor at ca 1750. Although historians have traced elements of enlightenment back to the Renaissance, one can argue that Enlightenment thinking begins with the 18^{th} century.

The basic ideas of the Enlightenment are roughly the same as the basic ideas of humanism. Its main premises are:

- Man's self is knowable, rational, autonomous and universal. This self knows itself and the world through reason, or rationality, posited as the highest form of mental functioning, and the only objective form.
- The mode of knowledge produced by the objective rational self is science, which can provide universal truths about the world, regardless of the individual status of the knower. The knowledge provided by science is truth, and is eternal. The knowledge produced by science will always lead toward progress and perfection. All human institutions and practices can be analyzed by science and improved. Science thus stands as the paradigm for any and all socially useful forms of knowledge. Science is neutral and objective; scientists (those who produce scientific knowledge through their unbiased rational capacities) must be free to follow the laws of reason, and not be motivated by other concerns (such as money or power).
- Reason is the ultimate judge of what is true, and therefore of what is right and what is good (what is legal and what is ethical). Freedom consists of obedience to the laws that conform to the knowledge discovered by reason. In a world governed by reason, the true will always be the same as the good and the right (and the beautiful); there can be no conflict between what is true and what is right.
- Language, or the mode of expression used in producing and disseminating knowledge, must be rational also. To be rational, language must be transparent; it must function only to represent the real (perceivable) world which the rational mind observes. There must be a firm and objective connection between the objects of perception and the words used to name them.

These tenets served to justify and explain virtually all social structures and institutions, including democracy, law, science, ethics, and aesthetics. Moreover, the ensuing powerful and successful approach to nature and culture has *come to dominate the modern university and our social, economic, moral, and cognitive structures. Human reason, as exemplified in the deductive thought of mathematics and physics, would come to replace the superstitious world-views of religion and other forms of irrationality. Reason, science, technology, and bureaucratic management would improve our knowledge, wealth, and well-being through the rational control of nature and society.*

The most important philosopher to emerge from the 18th century philosophical movement known as the Enlightenment was ***Immanuel Kant*** *(Table 5.16). His philosophy tries to combine* scientific rationalism *(i.e. the prerequisite that science be built upon rational principles with the notion that the mind is* actively involved *in the objects it experiences. That is, it organizes experience into definite patterns, creating its own world through the powers of autonomous rational judgment.*

In the wake of Kant's philosophy came the romantics, who viewed both mind and nature as unified and saw art and aesthetic interpretation as the source of all true knowledge. For the romantics, such as ***Friedrich von Schelling*** *(Table 5.16) and the poet* ***Friedrich Schiller*** *(1759–1805) the genuine bringer of knowledge was the artistic genius rather the experimental scientist.*

*By the beginning of the 19th century, various philosophers made new attempts to combine Rationalism and Romanticism into a new '*higher order*' philosophy. The most famous attempt to achieve this new synthesis between seemingly competing philosophies can be seen in the works of the German philosopher* ***Georg Wilhelm Friedrich Hegel*** *(Table 5.16). Hegel accepted Kant's idealism and viewed reality as the product of the activity of a rational mind. however, for Hegel mind was a kind of* universal spirit *('geist') that moved through time and space. Reason was viewed as the underlying principle that governed the movement of this spirit through history. According to Hegel,* history *is a social process driven by contradictions between competing systems of ideas.* Historical changes *produce new forms of knowledge via a process of* thesis*,* antithesis*, and, finally, a new* synthesis*.*

Table 5.16: Leading Western Philosophers and Thinkers[801] 1637–1992

Philosopher	Nationality	Life-span	Publication of Major Work	Philosophy System
Thomas Hobbes	British	1588–1679	1651	Early Rationalism
Rene Descartes	French	1596–1650	1637	Rationalism
Blaise Pascal	French	1623–1662		
Baruch Spinoza	Jewish	1632–1677	1677	Rationalism
John Locke	British	1632–1704	1690	Empiricism
Isaac Newton	British	1642–1727		of physics
Gottfried Leibniz	German	1646–1716	1687	Rationalism
George Berkeley	British	1658–1753	1710	Empirical Idealism
Giambattista Vico	Italian	1668–1744		of historicism
Baron de Montesquieu	French	1689–1755		
Voltaire	French	1694–1778	1764	Empiricism
David Hume	British	1711–1776	1748	Empirical Skepticism
Jean J. Rouseau	French	1712–1778	1762	Naturalism
Adam Smith	American	1723–1790		of Political Economy

801 This Table includes not only *traditional philosophers* but also *thinkers* in the fields of sociology, political science, economics, history, mathematics, logic, physics, anthropology, linguistics and biology, as well as a few novelists and poets who impacted Western society via their deep insight into the human condition.

Table 5.16: (Cont.)

Philosopher	Nationality	Life-span	Publication of Major Work	Philosophy System
Immanuel Kant	German	1724–1804	1781	Idealism
Edmund Burke	British	1729–1804	1757	
Jeremy Bentham	British	1748–1832	1789	Utilitarianism
Johann Wolfgang von Goethe	German	1749–1832		poet-novelist
Friedrich Schiller	German	1759–1805		poet
Johann G. Fichte	German	1762–1814	1792	Idealism
Georg W.F. Hegel	German	1770–1831	1807	Idealism
Friedrich Hölderlin	German	1770–1843		poet
Friedrich W.J. von Schelling	German	1775–1854	1809	Idealism
Heinrich von Kleist	German	1777–1811		novelist
Bernard Bolzano		1781–1848		of mathematics
Arthur Schopenhauer	German	1788–1860	1836	Idealism
Thomas Carlyle	British	1795–1881		of history
Auguste Comte	French	1798–1857	1842	Classical Positivism

Alfred J. Ayer	British	1910–1989		of Logical Positivism

Modernity is fundamentally about order, *creating order out of chaos, and about the pursuit of ever increasing levels of order. The more ordered a society is, the better it will function. This inherent quest for order led to search for* fundamental base-superstructures *in mathematical, physical, social and biological systems. Indeed,* **Charles Darwin** *theory of evolution (1859) presented a base-superstructure through which all 'higher' form of life are necessarily based, in causative formation, on 'lower' forms of life, which are all structured by hidden laws that are not self-evident.*

Karl Marx *(1867) introduces a base-superstructure in his discussion of the fundamental economic laws of a society and the consequent social institutions and philosophies built upon that materialistic foundation.*

Sigmund Freud *(1904) also used a base-superstructure metaphor in his explication of the foundational structures of the human psyche from which the limits and possibilities of human life ensue.*

Thus, just as science was able to prove much in nature that was counterintuitive, like the earth moving around the sun, the new social sciences of economics, psychology, anthropology, *and* sociology *would unveil the true nature of individual beliefs and social structures as causationally derived from some foundational base.*

The modernists were and are mostly hostile to religion, *because it represents a form of immovable unreason and dangerous irrationality. They envision a world freed of religious superstition. This vision profoundly influenced the culture of modern science and the secular university.*

What began with **Darwin**, ***Marx*** *and* **Freud**, *continued in the* 20^{th} *century intellectual history, as new disciplines and sub-disciplinary schools asserted their own foundational causative categories from which all else ensues.*

In conclusion, modernity *is equated with the enlightenment-humanist rejection of tradition and authority in favor of reason and natural science. This was founded upon the assumption of the autonomous individual as the sole source of meaning and truth – the Cartesian 'cogito'. Progress and novelty are valued in a 'real' world that evolves towards a state of increased objectivity. According to Sociologists, this new secular order began with the rise of a* market economy *and the growth of a* centralized bureaucratic state. *Both of these institutions had no need for philosophical wisdom as such. Instead, the burgeoning state and market required accurate information and faster means of communication and energy transport.*

Friedrich Nietzsche *was the first great philosopher after the revolution in Western thought brought about by the work of* **Charles Darwin** *(1859), who claimed that humans, rather than being created in God's image, were the evolutionary cousins of monkeys and apes. For Nietzsche this was devastating* *news and his whole philosophy can be seen as an attempt to answer this one question: How do we live in a world without something (a God) that guarantees that life has meaning?*

Nietzsche was one of the chief prophets of the modern age. He accurately predicted that life in the 20^{th} century would be a Perilous time; in a world without God, people would follow anyone or anything that offered them some sense of personal worth in a universe increasingly perceived to be devoid of significance. Nietzsche warned of the dangers that lay in the future, but he harbored little faith in the moral abilities of the majority of ordinary people. Unlike Marx he denied that any hope for a better future lay with the proletariat. For Nietzsche, the 20^{th} century would be the age of the false prophet who offers salvation but merely manipulates people to their doom. In the light of the atrocities committed by Hitler and Stalin, this is a truly remarkable prediction. Nietzsche's death in 1900 marked the end of philosophical romanticism.

***Sigmund Freud** (1856–1939) accepted the romantic critiques of modern society, but he believed that had found a scientific way of dealing with them. What we need, he thought, was a* new science of the mind *(psychoanalysis) that was more sensitive to hidden, irrational depths of the psyche. He believed that the rationalists and empiricist had only offered models of the* conscious mind *(ego) and had ignored the existence of the* unconscious mind *(id). Freud saw the rational part of the psyche as a thin veneer covering an older and much more unpredictable irrational part. For Freud, the unconscious represents the 'animal' within us: the part of us that is impulsive, instinctive, and demands immediate gratification. According to Freud, the mind is in conflict with itself and that all we can hope for is to accept the "demon within us" and bring it under rational forms of control.*

In his philosophical work: "Civilization and its Discontents" (1930) he argues that our most basic desires can never be satisfied and that the Marxist idea of an ideal communist society is nothing more than a silly wish; There is no easy way to live with our unconscious desires and that every man must find out for himself in what particular fashion he can be saved. Thus, in the end, psychoanalysis became an odd kind of moral philosophy.

Freud's ideas represent a technocratic answer to the problem raised by the 19^{th} century. During part of the 20^{th} century, this was the trend of much of intellectual thinking, and many philosophers believed that science could meet all the difficulties of modern life that the romantics had identified.

An important development in philosophy was stimulated by questions about the foundations of mathematics: *the system of logic laid down by Aristotle remained unaltered in its essentials until the 19^{th} century. By that time* *logic had come to be thought of as consisting of laws that govern thought. The works of* ***Boole*** *(1847),* ***A. de Morgan*** *(1847),* ***Cantor*** *(1872),* ***C.S. Peirce*** *(1878) and* ***Peano*** *(1886) heralded the merger of logic and mathematics at the fringes. Since the time of* ***Kant****, who had considered logic as complete, great changes had occurred in the study of logical theory. In particular, new forms of treating logical arguments by means of mathematical formulae had been developed. The first systematic account of this new way of dealing with logic in due to* ***Frege*** *(1892).*

Many of Frege's ideas were first transmitted by other people, including Peano. As a founder of symbolic logic*, Peano created his own logic notation (as did Frege) and established the basic elements of geometric calculus. Peano also invented his own international auxiliary language 'Iterlingua', which was a fusion of vocabulary from Latin, French, German and English.*

The axioms of Peano, for all their economy, were nevertheless unsatisfactory from a logical point of view, for it seemed somewhat arbitrary that it should be these rather than some other statements that were the basis of mathematical science. Frege then set to exhibit the axioms of Peano as a logical consequence of his symbolic system.

Frege is also one of the founders of linguistic philosophy *(*philosophy of language[802]*) which is the attempt to uncover the logical structure of* all *human languages. The fundamental recognition here is that logical relationships are independent of human thought, ergo: logical prepositions are* objective *truths, the existence of which has nothing to do with any feature of human thinking. Once all meaningful human languages could be reduced to logical formulas (i.e. abstract symbolic expression that look something like algebra), human language could be systematized, opening the way for the modern science of languages (linguistics).*

When this insight was applied to general philosophy it had momentous consequences. Since Descartes, Western philosophy grappled with the question: "What can I know?". Theory of knowledge (epistemology) had been at the center; and this was taken to mean that what went on in people's minds was the main subject of investigation. But Frege's insight had the consequence of de-psychologizing philosophy. If what is the case, and what followed from

[802] *Philosophy of language* is the study of philosophical questions about language, especially about *meaning and truth* (of words, phrases and sentences) in general. Grammar, books and dictionaries only *codify* how we use language, but meaning and truth of linguistic statements shape an entire view of the universe and our place in it. Thus, in arriving at our present philosophical outlook, questions about meaning play a centrally important role.

What, are both independent of the human mind, then our attempts to understand the world cannot legitimately center on epistemology.

The clear implication is that philosophy ought to be logic-based, not epistemology-based[803]*. Indeed, Frege's work precipitated changes in that direction which continued unabated in many of the main areas of philosophy throughout the 20th century.*

The work of Frege was completely ignored for twenty years and in his own country he long remained an obscure professor of mathematics. However, his new philosophy of language would influence ***Bertrand Russell*** *(1913) and* ***Ludwig Wittgenstein*** *(1921).*

Modernistic Philosophy

Modernism started as a movement in visual arts, music, architecture, literature and drama at the turn of the 20th century. It rejected the Victorian standards of how art should be made, consumed and what it should mean. Figures like ***Picasso****,* ***Proust****,* ***Kafka****,* ***Rilke*** *and* ***e.e. Cummings*** *are some of the founders of the 20th century modernism. From a literary perspective, the main characteristics of modernism include:*

- *An emphasis on impressionism, subjectivity and on* how *seeing and perception takes place rather than on* what *is perceived. A movement away from the apparent objectivity provided by omniscient third-person narrators, fixed narrative point of view, and clear-cut moral positions.*
- *A blurring of distinction between genres, so that poetry seems more documentary and prose seems more poetic.*
- *An emphasis on fragmented forms, discontinuous narrative, and random-seeming collages of different materials.*

[803] He helped to change the agenda of modern philosophy from the problem of *knowledge* to the even more fundamental one of *meaning*. Frege stressed that everyday grammatical language is not logical and that logic itself in independent of psychology. Language itself has *two* different functions: First, it consists of '*sense*' or meaning, that which we understand. Second, it '*refers*' to things and concepts. The *sense* of a language is a public phenomenon based on convention and can change, but *reference* is to truth or falsehood. Frege went on to found a complex system of logic based on this insight.

- *A tendency toward reflexivity, or self-consciousness, about the production of the work of art, so that each piece calls attention to its own status as a production.*

The modernistic movement fed on socio-economical changes induced by the major advancements made in physics and astronomy, WWI, monopoly capitalism (associated with electric and internal-combustion-motor industries) and the impact of Freud's new psychoanalysis. Its manifestations in philosophy came through the Analytic Philosophy *founded during the period between the two World Wars (1924–1937) in Western Europe.*

The 20th century was the first since the Middle Ages in which all the leading philosophers were academics. Partly as a result of this, there was a growth of concern with analysis. *In logical analysis and linguistic analysis important development occurred. Otherwise the biggest advances were on two fronts: one was a response to 20th century science, which compelled a reappraisal of the nature of human knowledge as such. The other was an attempt to understand the human condition in a universe no longer seen as created by God, or as having any meaning or purpose of its own.*

A revolutionary school of 20th century philosophy, rejecting traditional points of view is that of Analytic Philosophy *pioneered by* ***Russell*** *(1910–1913) and* ***Wittgenstein*** *(1921). Its adherers contend that the entire business of philosophy is that of analysis. As such, philosophy is devoid of content in the sense that* it does not add to the scope of scientific knowledge, *but instead consists of linguistic activity designed to eliminate problems and perplexities arising form intellectual confusion or misunderstanding and thus* to clarify knowledge which we already possess. *It is no longer to be the task of philosophy to search for ultimate or metaphysical truth; the metaphysical quest which originated with* ***Descartes*** *is to be replaced by the radically different task of philosophical analysis undertaken by Analytic Philosophy as a* nonmetaphysical *school of thought. Thus, Analytic Philosophy represents a reaction against the Idealists' synthesis and concepts of Absolute Reality originating with* ***Hegel***.

Analytic Philosophy came close to dominate philosophy in the English-speaking world for most of the 20th century. In the course of this time it took different forms, but common to them all was the close analysis of propositions, *or of the individual terms and concepts they employed, or of their logical implications both internal and external, with a view to bringing everything that was hidden in them to the surface. The overall question always was: "What are we really saying when we say so-and-so?".*

Among the groups that took up Russell's approach and developed it was one that came into existence in Vienna (1924–1936) and became known as *the Vienna Circle. It consisted more of scientists and mathematicians than philosophers, and its chief concern was to establish the philosophical foundations of a scientific worldview. Theirs was a philosophy that became known as Logical Positivism*[804]*. It considered that the true meaning of a statement was uncovered when we asked ourselves: "What would we have to do to establish the truth or falsehood of this statement?". In other words, what observable difference does its truth or falsehood make to the way things actually are? Only statements that are empirically verifiable are empirically meaningful.*

On the contrary – a statement that purports to be about reality but whose truth or falsehood makes no observable difference to anything, has no meaning[805]*. They thus concluded that all philosophy, especially Hegelian idealism, was metaphysical nonsense. They also thought that the "surface grammar" of language had led philosophers into endless, unsolvable pseudo-debates about imaginary entities like the "substances" of Spinoza and Leibniz.*

Logical Positivists thought that there was no such thing as "philosophical knowledge" – that road to real knowledge was only via science. Philosophy could only be an analytic activity which clarifies concepts and cleared up linguistic conclusions.

However, as a theory of meaning, the 'verification principle' of the Logical Positivists collapsed fairly quickly, partly because a lot of modern science is conceptual *and untestable in a simple "look and see" way. Meaning also has to be prior to testing, not a result of it. How can we test something if we don't understand it first?*

With the rise of the Nazis to power in Austria and Germany, the members of the Vienna Circle were scattered, mostly to the United States and Britain, where they exercised a major influence over a whole generation.

In his later works, **Wittgenstein** *set out to resolve the difficulty that the Logical Positivism had with their 'verification principle'. He showed (1951) that the great 20th century search for 'Meaning of Meaning' is futile because it is founded on the misconception that 'Meaning' is something separate from language. Instead, meaning is the result of socially agreed convention produced by 'forms of life' and cannot possibly be established outside a language.*

---

[804] **Otto Selz** (1881–1943); **Moritz Schlick** (1882–1936); **Otto Neurath** (1882–1945); **Rudolf Carnap** (1891–1970); **Ludwig Wittgenstein** (1889–1951); **Alfred Tarski** (1902–1983); **Kurt Gödel** (1906–1978); **Karl Menger** (1902–1985); **Alfred Jules Ayer** (1910–1989); **Karl Popper** (1902–1994).

[805] So, "*God is absolute and eternal*" looks like sense, but is wholly untestable and therefore gibberish. Assertions about God, souls, immorality, moral values, aesthetic values, and universal substances (matter or spirit) cannot be accepted as a valid or invalid, true or false. Science in the only form of knowledge.

To him, philosophy is a critique of language — an activity which seeks the 'logical clarification of thoughts', the elucidation of propositions. Therefore, he argued that the way in which a word is used, *not its meaning as a name for some object, gives language and statements their validity: "Don't ask for the meaning, ask for the use".*

A different solution to the 'verification principle' was suggested by the philosopher of science ***Karl Popper*** *(1902–1994) in his work* Logic der Forschung *(The logic of Scientific Discovery, 1935); According to Popper, knowledge of the natural world never advances by direct confirmation of scientific theories, but only indirectly, through the systematic* falsification *of their alternatives by reference to our experience. He defended a realistic epistemology in his* Objective Knowledge *(1966).*

In the wake of the Einsteinian revolution (1905–1917) that toppled the Newtonian worldview, Popper realized that if the centuries of corroboration received by Newtonian science had not proved it to be true, nothing was ever going to prove the truth of a scientific theory. The so-called scientific laws were not incorrigible truths about the world after all; they were theories, and as such they were products of the human mind. If they worked well in their practical application then that meant they approximate the truth, yet it was always possible even after hundreds of years of pragmatic success, for someone to come along with a better theory that was closer to whatever the truth was. As ***Einstein*** *himself put it: "only daring speculation can lead us further, and not accumulation of facts".*

Popper developed this insight into a full-fledged theory of knowledge. *According to him, physical reality exists independently of the human mind, and is of a radically different order from human experience – and for that very reason can never be directly apprehended.*

It is impossible to prove, finally and forever, the truth of any scientific theory. But a theory can be disproved, *and this means that it can be tested. Thus, although no number of observations, however large, will ever prove the statement "All swans are white", a single observation of a black swan is enough to disprove it. So we can test general statements by searching for contrary instances. This being so, criticism becomes the chief means by which we do in fact make progress.*

A statement that no potential observation would falsify cannot be tested, and therefore cannot count as scientific, because if everything that could possible happen is compatible with its truth, then nothing can be regarded as *evidence for it*[806] *(e.g. the statement "God exists" is not a scientific statement).*

Postmodernism[807]

In the second half of the 20th *century (especially towards the mid 1980's) we witnessed the rise of an eclectic, nihilistic, irrational and* anti-science *movement known as* postmodernism. *It is a cultural formation which accompanies a particular stage of Capitalism, namely, consumer capitalism with its emphasis on marketing, selling and consuming commodities, not on producing them.*

While Modernism upheld the idea that works of science, art and literature can provide unity, coherence, and meaning (which had been lost in modern life), postmodernists claim that since the world is meaningless (to them), we should not pretend that art and science can endow it with meaning.

Until 1945, science could be been as the friend of mankind (with the exception of the 'gas chambers' annihilees, for whom chemistry was certainly not a best friend). Moderns medicine brought about a great increase not only in longevity but in the capacity to enjoy life physically. However, after the

---

806 But as a scientific method, falsificationism has its own problems. If our observations of the world are themselves always "theory-laden", why should one observation immediately invalidate a complex scientific theory? How do we know which to trust? Scientific theories are complex and interdependent, so it is not always easy to falsify them with a single observation. History also reveals that scientists have often been very reluctant to jettison their pet theories because of one contradictory observation. Sometimes they have been quite right to be stubborn – but not always.

At any rate, as Popper himself argued, "Science is perhaps the only human activity in which errors are systematically criticized and in time corrected."

807 Few scholars have attempted to reduce the term 'Postmodernism' to an objective definition for fear that such definition becomes the immediate target for a Postmodern critique. The evasiveness of the leaders of this movement on this subject has been notorious: Pressed for an answer, one of their proponents, **Jacques Derrida**, a leftist avant-garde French theorist, said: "It is impossible to respond; I can only do something which will leave me unsatisfied". He was apparently following the advice of Wittgenstein: "*Of what one cannot speak, one must remain silent.*" .

explosion of the first atomic bomb its evident capacity to destroy humanity turned science into a potential enemy: for some, the prospect of a sudden cataclysmic end to all human life has destroyed the hope, slowly engendered through the 18th and 19th centuries, that science and research would bring a progressive increase in happiness.

Most generally, Postmodernism *is the abandonment of Enlightenment confidence in the achievement of human knowledge through reliance upon reason in pursuit of foundationalism, essentionalism, and realism. In philosophy, antimodernists typically express grave doubt about the possibility of universal objective truth, reject artificially sharp dichotomies, and delight in the inherent irony and particularity of language and life.*

Starting in the 1960's, computer technology emerged as a dominant force in many aspects of social life: The advent of electronic computer technologies began to revolutionize the modes of knowledge *production, distribution and consumption in our society. Social philosophers worried that anything which is not able to be translated into a form recognizable and storable by a computer (digitalizable) – will cease to be knowledge.*

In this paradigm, the opposite of 'knowledge' is not 'ignorance', but rather 'noise'. This attitude led eventually into a science phobia*, with the rise of religious fundamentalism in the Muslim world as one of its consequences.*

The horrors of WWII, coupled to fears of a nuclear annihilation of mankind, led certain philosophers (mostly European academicians) to the viewpoint that culture in modern times no longer provided meaning and purpose to people's lives, and that the most serious offender is empirical science. *This attitude which took shape in the 1970's might have just remained a European academic fad, were it not for other successive developments which gave it real substance:*

(1) The emerging of chaos *and* complexity *and their manifestation in nature.*

(2) The new cosmology, quantum field theories and their aim – the Theory Of Everything.

(3) The new progress in genetics, molecular biology, and neuroscience and their aims – the Human Genome project*, genetic therapy and engineering, etc.*

(4) The popularity of neo-conservatism *and rise of the Respectable Right in the U.S.A. in the 1970's.*

(5) The collapse of the Berlin Wall symbolizing the complete triumph of a free market economy *over a socialist command economy.*

Items (1), (2) and (3) have come under attack by critics from the disciplines of sociology, philosophy and history. In the academic world, most *professors of humanities are known to have little experience in mathematics, theoretical physics and theoretical biology, and hence have no credibility in passing judgment on highly specialized issues associated with physics, quantum theory, cosmology, nonlinear dynamics, complexity, computer science, molecular biology, etc.*[808]

Nevertheless such non-scientist as ***T. Adorno***[809]*;* ***G. Ryle*** *(1900–1976);* ***J. Derrida****;* ***R. Barthes*** *(1915–1980);* ***J. Lacan*** *(1901–1981);* ***F. Lyothard*** *(1924–1996);* ***M. Foucault*** *(1926–1984), and* ***J. Baudrillard****, pompously announced that the scientific method is little short of myth and that scientific knowledge is in fact manufactured. Furthermore, the self-styled Dadaist* ***Paul Feyerabend*** *claimed that science can be said to be in a condition of* anarchy *(sic!)*

No branch of human knowledge escapes from this radical, nihilistic and irrational corrosive outlook, according to which science and logic are accused of being "constructs" – merely interpretations of experience. There is no timeless and universal reality, and no certain knowledge of it either.

It is obvious that the postmodern anti-science movement stands on feet of clay and will eventually take its place in the dustbin of intellectual history.

Neo-Marxism

In the third quarter of the 20th century there arose a new trend in Western philosophy which integrated into a comprehensive framework of social theory and philosophy the following disciplines:

- *German philosophical thought of* ***Kant****,* ***Schelling****,* ***Hegel*** *and* ***Husserl****.*

808 Today, the sheer mass of scientific knowledge is beyond individual comprehension, despite the far higher level of general education. We have to some extent returned to the situations of primitive man who required myths and mysteries as protection against forces which he could not fully understand or control.

809 **Theodor Adorno** (1903–1969, Germany), born Theodor Wisengrund in Frankfurt, was a radical Marxist Jewish intellectual. He set up the *Frankfurt School for social research* (1923). This school tried to blend Marxist philosophy and Freudian philosophy into a critical theory of society. Adorno fully expected a more free and just society to emerge from the economic ruins of 1930's Germany; the rise of Nazism both shocked and horrified him. After the Holocaust his philosophy became very influenced by Judaism.

- *Marxist tradition as well as the critical neo-Marxist theory of the Frankfurt School as expounded by* ***Horkheimer***, ***Adorno*** and ***Marcuse***.
- *The sociological theories of* ***Weber*** and ***Durkheim***.
- *The linguistic philosophy of* ***Wittgenstein*** and ***Searle***.
- *The American pragmatist tradition of* ***Peirce*** and ***Dewey***.

The proponent of this scheme was ***Jürgen Habermas*** *(b. 1929), a social philosopher at the Frankfurt School, who developed the concept and theory of communicative rationality in his magnum opus, The Theory of Communicative Action (1981). It distinguishes itself from the rationalist tradition by locating rationality in structures of interpersonal linguistic communication rather than in the structure of either the cosmos or the knowing subject. He carries forward the tradition of Kant and the Enlightenment and of democratic socialism through his emphasis on the potential for transforming the world and arriving at a more humane, just, and egalitarian society through the realization of the human potential for reason.*

While postmodernists have "deconstructed" such long-treasured notions as "reason" and "justice" [claiming that "reason" is a name the powerful give to their rationales for holding power and "justice" is just an excuse for the majority to impose its morality on the minority], neo-marxists such as Habermas, disagree.

However, in the aftermath of 9/11, Derrida and Habermas *established a political solidarity by issuing together the book "Philosophy in a Time of Terror" — a plan for common European foreign policy.*

Modern Conservatism

Modern conservatism[810] *is a politico–economical philosophy rooted in the economic theories of the libertarians* ***Ludwig von Mises*** *(1881–1973, Austria),* ***Friedrich Hayek*** *(1889–1992, Austria) and* ***Milton Friedman*** *(1912–2006, USA).*

810 To dig deeper, see:

- Kurtz, P.W. (Ed), *American Philosophy in the Twentieth Century*, Macmillan, 1966.
- Brown, S. (Ed.), *Biographical Dictionary of Twentieth–Century philosophers*, Routledge, 878 pp.

It emerged from the rejection of social liberalism and the New Left counterculture of the 1960's, developing in the works and thoughts of the Americans intellectuals ***Leo Strauss*** *(1899–1973),* ***Ayn Rand***[811] *(1905–1982),* ***Barry Goldwater***[812] *(1909–1998) (who fused libertarianism with conservatism in*

---

[811] **Ayn Rand** (1905–1982, USA; born Alisa Rosenbaum) was an American novelist and social philosopher; founder of *objectivism*. Immigrated from Russia (1926).

The social philosophy evolved by Rand, and explicated in her novels and essays, became known as *Objectivism*, which prescribed individualism with secular morality. It is a particularly pure form of small–government (*minarchic*) Libertarianism, which extends beyond economics and the proper functions of democratic governance to encompass all aspects of the Social Contract (as Rousseau called the contract among individuals that defines the State), and even aspects of morality, ethics, aesthetics, epistemology (the theory of knowledge) and metaphysics.

Rand emphasized the sanctity of the inviolate, rational mind of the *individual*; free individuals interact and form voluntary associations, in which they trade their best intellectual and economic achievements to mutual profit and satisfaction. There are also personal relationships of other kinds, of course – friendship, family, love – in which what is being traded is less concrete. But in all cases, *enlightened, rational self–interest* serves as a guide, and no person should be coerced by others (individually or collectively). Unlike most philosophers, Rand was entirely and implacably opposed to *religion* and *altruism*, seeing no redeeming value in them. Altruism is merely a scheme for making individuals into 'sacrificial animals', for various nebulous collective purposes (or to support other individuals who prefer to live off their more capable, motivated or talented fellows by inducing feelings of *guilt*).

[812] Fascist and communist tyranny has been supported all during the past 75 years by the modern left through its intellectuals and their newspapers, journals and periodicals; The *New York Times*, the *Guardian*, *The New Statesman* and the *Daily Mail* supported Stalin and are now calling for appeasement of Islamic fascism. *The Guardian* even supported the Khmer Rouge.

Among the ardent supporters of Lenin, Stalin and the Soviet mass–killings and purges: **Pablo Picasso**, **G.B. Shaw**, **Eric Hobsbaum**, **Pablo Neruda**, **Charles Chaplin**, **J-P Sartre**, **Graham Greene**, **Bertolt Brecht**, and many other leftist philosophers, intellectuals, journalists, writers and artists. **Clement Atlee** praised Stalin's Soviet Union in the 1930's and **Hobsbaum** supported Stalin's invasion of Finland and the soviet crushing of the Hungarian and Czech's Revolutions.

Among the supporters of Hitler were **Martin Heidegger**, **Knut Hamson**, **Salvador Dali**, **Ezra Pound** (actually worked for the fascists in WW2) and **Werner Heisenberg**. In France **J. Derrida** bemoaned the end of Soviet occu-

the 60's and 70's. His most famous quote: "Extremism in the defense of liberty is no vice, and moderation in the pursuit of justice is no virtue."), ***William F. Buckley*** *(1925–2008) and* ***Allan Bloom*** *(1930–1992). The ideas of these thinkers influenced the administrations of President* ***Ronald Reagan*** *and Premier* ***Margaret Thatcher****, representing a re-alignment in Western politico–economical philosophy, and the defection of many liberals to the right–hand side of the political spectrum.*

One accomplishment was to make criticism from the Right acceptable in the intellectual, artistic and journalistic circles, where conservatives had long been regarded with suspicion. In the U.S, neo-conservatism emphasizes foreign policy as paramount responsibility of government, seeing the need for the U.S. acting as the world sole superpower as indispensable to establishing and maintaining global order.

The Modern Left[813]

The historical Left pioneered on social issues of civil liberties such as rights for women, blacks, gays, atheists and other minorities. It opposed religious and sexual censorship, and enabled sexual freedom. All this however is uncontroversial now, since most of the modern right *agrees with this basic agenda.*

---

pation of Eastern Europe, as did many other tenured academics living in comfort in the free West. **Harry Belafonte**, **Jesse Jackson**, **Norman Mailer** and H**arold Pinter** supported Cuban Communist dictatorship. **Nelson Mandela** supported Libya and Cuba. **Desmond Tuto** attacked the democracies of Israel and USA.

[813] To dig deeper, see:

- Johnson, Paul, *Modern Times.*

The main thing that defines the left in the modern world (new left) is its approach to foreign policy, with the economy *and* crime *being the lesser issues that distinguished them.*

*The left in France (**J.P. Sartre**; **M. Foucault**; **Barthes**; **A. Gide**; **J. Derrida**; **M. Merleau**; **G. Genet**; **G. Marcel**) was the cradle of late* 20^{th} *century tyranny:*

- *The Khmer Rouge trace their intellectual origins to France:* ***Khiew Samphan*** *and* ***Pol Pot*** *were both educated in France in the 1940s–1950s.*
- *The Baath Arab Socialist party of Saddam Hussein in Iraq traces it intellectual origins to France.*
- *The Iranian Islamist revolution traces its intellectual origin to human rights intellectuals in France: Ayatolla Khomeini was granted exile in France, where he openly denounced human rights and human freedom, plotted the Islamic takeover of Iran, and from where he returned triumphant in 1979.*
- *Ho Chi Minh learnt his Marxism in Paris, and was a member of the French Communist Party.*

Worldviews XLVI–XLVIII: Poet-Philosophers of the 20th Century: Rilke, Pessoa, Cummings

* * *

“Who twines green leaves, worthless as common clods,
To wreaths of honor that stay always fresh?
Secure Olympus and unites the gods?
The strength of man, in poets become flesh.”
*(**Goethe**, Faust I, 154–157. Translated by Walter Kaufmann. Anchor Books, 1963)*

* * *

***I: Rainer Maria Rilke** (1875–1926). German language’s greatest poet of the 20th century. His poetry is characterized by a dense, lyrical style and startling images that portray the complexities of modern life and their effect on human beings. It emphasizes human longing for completeness and for the absolute in face of deficiency, transience and emptiness due to changing flux of values and standards in an age of disbelief, solitude, and profound anxiety.*

Rilke was born in Prague. His father, Josef Rilke (1838–1906), became a railway official after an unsuccessful military career. His mother, Sophie (“Phia”) Entz (1851–1931) came from a well-to-do Prague manufacturing family (originally Jewish but later converted to Christianity to escape anti-semitism). His maternal grandmother Caroline née Kinzelberger (1828–1927) was also born in Prague[814].

[814] In his book: “*Rilke-Sein Leben, seine Welt, sein Werk*,” W. Leppmann states that Caroline’s grandmother, Theresia Mayerhof, was Jewish, and lived in Prague around 1775. We recall that all Jews were expelled from Prague in 1745 by Empress Maria Theresa, and Anti-Jewish riots broke again in 1848. Some Jews, at that time, converted to Christianity to escape persecution (see “*A History of Habsburg Jews*” by W.O. McCagg Jr.).
Rilke’s biographer, Ralph Freedman (“*Life of a Poet: Rainer Maria Rilke*,” Northwestern University Press, 1996) pointed out that Rilke’s contradictory relation to Jews was nurtured by a deeply prejudiced mother, with her pro-German dogmatism and cloudy religiosity.

Rilke attended a military academy (1886–1891) and studied literature and philosophy in Prague and Munich. He traveled to Italy (1898), Russia (1899, 1900) and Paris (1902–1910). On these trips he met ***Leo Tolstoy*** *and* ***Paul Cezanne****, and worked as a secretary for the sculpture* ***Auguste Rodin****. He married (1901) the sculptress Clara Westhoff (1878–1954) and they had a daughter Ruth (1901–1972). He spent the greater part of WWI in Munich, excluding six months of military service in Vienna.*

To escape the post-war chaos, he settled in Switzerland, where he died in 1926 of leukemia.

Rilke separated from his wife already in 1902, and during 1900–1926 he seeked intimate relations with many available free women. Some became his lovers and other remained just beloved; yet all of them served to stimulate and inspire his poetic creativity in one way or another.

[Lou Andreas-Salomé (1861–1937); Valeri von David-Rohnfeld (1871–1946); Paula Modershon-Becker (1876–1907); Magda von Hattinberg (1883–1959); Sidone Nadherny (1885–1950); Baladine Kossowska (1886–1969); Claire Studer-Goll (1891–1977); Mariana Tsvetaeva (1892–1941); Nimet Eloui Bey (1903–1943); Harriet Cohen (1895–1967); Loulou Albert-Lazard (1891–1969); Nany Wunderly-Volkart (1878–1962); Regina Ullmann (1884–1961); Ellen Delp (1890–1990); Marie Louise Dobrzensky (1889–1970); Helene von Hostitz (1876–1944); Katherina Kippenberg (1876–1947); Manon Solms-Laubach (1882–1975); Eva Solmitz-Cassirer (1884–1974); Yvone von Wattenwyl (1891–1976); Adelmina Romanelli; Mia (Maria) Mattauch; Elia Maria Nevar; Marthe Hennebert (b. 1887); Auguste (Gudi) Nölke; Jenny de Margerie; Jean de Sepibus; Julie von Nordeck; Lily Ziegler; Margot Sizzo-Noris; Key Ellen; Anna de Noailles; Clara Westhoff-Rilke; Maria von Thurn und Taxis.]

* * *

The only journy is the one within.

* * *

Many of the women Rilke loved were Jewish and he was attracted by a Jewish temperament and responded to it not only sexually but also intellectually. It can therefore be rightly assumed that this ambivalence is due to an inner atavistic conflict between two opposing elements of his personality — the Jewish and the German.

If your daily life seems poor, do not blame it; blame yourself that you are not poet enough to call forth its riches.

* * *

This is the miracle that happens everytime to those who really love: the more they give, the more they possess.

* * *

Live your questions now, and perhaps even without knowing it, you will live along some distant day into your answers.

* * *

There is more to marriage then four legs in a bed.

* * *

The future enters into us, in order to transform itself in us, long before it happens.

* * *

God, with me goes your meaning too.

* * *

In nature there are no loosers and winners — just survivors.

* * *

He who does not at some time, with definite determination, consent to the terribleness of life, or even exult in it, never takes possession of the inexpressible fullness of the power of our existence, but walks on the edge and will, sometime when the decision is made, have been neither alive nor dead.

* * *

God, are you the one who is living life?

* * *

The beast is free and has its death always behind it and God before it, and when it walks it goes toward eternity, as springs flow.

* * *

There are no classes in life for beginners; it is always the most difficult that is asked of one right away.

* * *

Works of art are indeed always products of having been in danger, of having gone to the very end in an experience, to where man can go no further.

* * *

It is our fate to be opposite and nothing else, and always opposite.

* * *

There is an ancient hatred between our normal life and the great work.

* * *

Who speaks of victory — enduring is everything.

* * *

This fleeting world keeps calling to us: once for each thing. Just once — no more, just once — and never again.

* * *

In one of my poems that is successful, there is much more reality than in any relationship or affection that I feel; where I create, I am true.... I may ask and seek for no other realizations than those in my work; there my house is, there are the women I need, and the children that will grow up and live a long time.

* * *

Only because we exclude death, when it breaks suddenly into our thoughts, has it become increasingly a stranger, and because we have kept it an alien, it has become an enemy.... It is conceivable that it is infinitely closer to us than life itself....

It has become more and more clear to me over the years that our effort can only be directed toward presuming the unity of life and death.... Death is a friend, our most intimate and only friend, who is never, never confused by our attitudes and vacillations, especially at a time when we most passionately and profoundly embrace earthly existence, activity, nature and love.

Life always says at the same time: Yes and No. He, death is the actual yes-sayer. He only says yes. In the face of eternity.

* * *

II: Fernando Antonio Nogueira Pessoa *(1888–1935, Portugal). The greatest Portuguese poet of the 20th century. Poet-philosopher Pessoa wrote his poetry under his own name and under that of three heteronymous selves whose biographies he invented. These heteronymous represent Pessoa's voyage of discovery of himself in the course of which he realized that extraordinary range of poetic values. Thus, his personality is diffused through the heteronyms. The strength of his overall poetry rests in his ability to convey a sense of loss, of sorrow for what can never be.*

The work which many consider his masterpiece, Livro do Desassossego *(The Book of Disquiet) was not published until 1982, almost 50 years after his death.*

Pessoa brings to mind the great solitaries: ***Kierkegaard***, ***Rousseau***, ***Schopenhauer*** *and* ***Montaigne***.

"Contradiction is the essence of the universe," Pessoa once wrote. He seems to have lived this apothegm. He was indeed a living contradiction. The dramatic coherences were for Pessoa ultimately the means by which he gave vent to the contradiction that was his life.

Pessoa was born in Lisbon, Portugal. He was descended from New Christians, i.e. Jews forcibly converted to Christianity in the 15^{th} century. His father died when he was five, a loss of lasting influence. In 1895 his mother remarried, and the family moved to Durban, South Africa, where his stepfather was Portuguese consul. He matriculated at the University of Cape Town, where he won the Queen Victoria Prize for English Essay. In 1905 he returned alone to Lisbon where he matriculated at the University. In Portugal he continued to read and write in English, which was the language of his youthful erotic verse. In 1918 he published in Lisbon his 35 Sonnets and in 1922 the three parts of his English Poems, all composed many years before. The Times Literary Supplement spoke of the 'ultra-Shakespearian Shakespearianisms' of this Portuguese writer.

The rest of Pessoa's life passed uneventfully in Lisbon. He earned a pittance from a number of commercial firms, composing free-verse or classical odes at the typewriter in the intervals of translating the firm's foreign correspondence. Many of the poems he wrote were published in literary reviews such as Orfeu *and* Portugal Futurista. *He also wrote much prose on questions of aesthetics, and sketches for detective novels. The only book published in his lifetime was* Mensagem, *a collection of poems on patriotic themes, which won only a consolation prize in a national competition.*

* * *

Contradiction is the essence of the universe.

* * *

Love is essential. Sex, mere accident.

* * *

To think about God is to disobey God, because he wanted us not to know.

* * *

I do not have a philosophy; If I speak of nature, it is not because I know what it is, but because I love it.

* * *

Wise is he who enjoys the show offered by the world.

* * *

Success consists in being successful, not in having a potential for success. Any wide piece of ground is the potential site of a palace, but there's no palace till it's built.

* * *

No intelligent idea can gain general acceptance unless some stupidity is mixed in with it.

* * *

Could it think, the heart would stop beating.

* * *

I have no ambitions or wants; to be a poet is not an ambition of mine. It is way of staying alone.

* * *

If, after I die, they should want to write my biography, there is nothing simpler. I have just two dates — of my birth, and of my death; In between the one thing and the other — all the days are mine.

* * *

After I was born, they locked me up inside me. But I left. My soul seeks me, through hills and valley; I hope my soul never finds me.

* * *

The light of the sun is worth more than the thoughts of all the philosophers and all the poets.

* * *

III: Edward Estlin Cummings *(1894–1962, USA). American poet, painter and essayist. His poetry often deals with themes of love and nature, as well as the relationship of the individual to the masses and the world. He wrote, however, in an unusual style, which includes unorthodox usage of both capitalization and punctuation, in which unexpected and seemingly misplaced punctuation sometimes interrupt sentences and even individual words.*

He was born in Cambridge, Massachusetts and raised in a liberal family. After graduating with a M.A. degree from Harvard (1916) he went to France (1917) as a volunteer for the Ambulance Corps in WWI. During 1921–1931 he traveled throughout Europe (including the Soviet Union) and spent several years in Paris.

After his father's tragic death (1926) he began to focus on more important aspects of life in his poetry.

Throughout 1919–1932 Cummings married and divorced three times. In 1952 Harvard University awarded him an honorary appointment as a guest professor.

* * *

It takes two to be serious.

* * *

Life is not a paragraph and death I think is no parenthesis.

* * *

Tomorrow is our permanent address.

* * *

I feel that (false and true are merely to know)
Love only has ever been, is, and will ever be, So.

* * *

Now you are and I am now and we are a mystery that will never happen again, a miracle which has never happened before.

* * *

Time's a strange fellow; more he gives than takes (and he takes all).

* * *

It's you are whatever a moon has always meant and whatever a sun will always sing is you.

* * *

A pretty girl who is naked, is worth a million statues.

* * *

Never mind a world with its villains or heroes (for god likes girls and tomorrow and the earth.

* * *

Life never grows old.

* * *

Life and day are only loaned: whereas night and death are given.

* * *

Greatness is alone.

* * *

I like the thrill of under me you so quite new.

* * *

Whenever men are right they are not young.

* * *

Spring — you and I may not hurry it with a thousand poems my darling, but nobody will stop it with all the policemen in the world.

Science Progress Report No. 16
Pseudoscience, Antiscience, Nonscience, Postmodernism, Scientific Illiteracy and Superstition, or — the absence of evidence is not evidence of absence

Science thrives on errors, cutting them away one by one. False conclusions are drawn all the time, but they are drawn tentatively. Hypotheses are framed so they are capable of being disproved. A succession of alternative hypotheses is confronted by experiment and observation. Science gropes and staggers toward improved understandings and disproof of scientific hypotheses is recognized as central to the scientific enterprise.

Pseudoscience is just the opposite. Hypotheses are often framed precisely so they are invulnerable to any experiment that offers a prospect of disproof, so even in principle they cannot be invalidated. Practitioners are defensive and wary. Skeptical scrutiny is opposed. When the pseudoscientific hypotheses fails to catch fire with scientists, conspiracies to suppress it are imagined and decried.

Perhaps the sharpest distinction between science and pseudoscience is that science has a far keener appreciation of human imperfections and fallibility than does pseudoscience. If we resolutely refuse to acknowledge where we are liable to fall into error, profound mistakes will forever be our companions.

In ancient China and Rome, astrology was the exclusive property of the emperor; any private use of this "potent" art was considered a capital offense.

In Russia, under the Tsars, religious superstition was encouraged, but scientific and skeptical thinking (except for a few tame scientists) was ruthlessly expunged.

Under Communism, both religion and pseudoscience were systematically suppressed, except for the superstition of the state ideological religion — which was advertised as scientific. Critical thinking — except by scientists in hermetically sealed compartments of knowledge — was recognized as dangerous, was not taught in the schools, and was punished where expressed.

When the lid was finally lifted, the subterranean bubblings of pseudoscience and superstition (as well as virulent ethnic hatreds) were exposed to view.

The region is now awash in UFOs, poltergeists, faith healers, quack medicines, magic waters, and old-time superstition. A stunning decline in life *expectancy, increasing infant mortality, rampant epidemic diseases, subminimal medical standards, and ignorance of preventive medicine all work to raise the threshold at which skepticism is triggered in an increasingly desperate population.*

In China, after the death of Mao tse-tung and the gradual emergence of market economy, UFO's, channeling and other examples of Western pseudoscience emerged, along with such ancient Chinese practices as ancestor worship, astrology and fortune telling — a revival of feudal ideology in the Chinese countryside. Individuals with "special powers" gained enormous followings[815]*.*

Asian Rhinos are being driven to extinction because their horns, when pulverized, are said to prevent impotence; the market encompasses all of East Asia.

Perhaps the most successful recent global pseudoscience (by many criteria, already a religion) is the Hindu doctrine of transcendental meditation (TM). This worldwide organization has an estimated valuation of three billion dollars. For fee they promise to be able to walk you through walls, to make you invisible, to enable you to fly. By thinking in unison they have, they say, diminished the crime rate in Washington D.C., and caused the collapse of the Soviet Union, among other secular miracles. No real evidence has been offered for any such claims. Yet, TM sells folk medicine, runs trading companies, medical clinics and "research universities", and has successfully entered politics.

Pseudoscience in America is part of the global trend. Here, psychics ply their wares on extended television commercials, personally endorsed by entertainers. They have their own channel, the "Psychic Friends Network"; a million people a year sign on and use such guidance in their everyday lives.

For CEOs of major corporations, financial analysts, lawyers and bankers — there is a species of astrologer / soothsayer / psychic ready to advise on any matter. Furthermore, TM seem to have attracted a large number of accomplished people, some with advanced degrees in physics or engineering.

The continuum stretching from ill-practiced science, pseudoscience, and superstition, all the way to respectable mystery religions, based on revelation, is indistinct.

---

[815] Some have claimed they can project the "energy field of the universe" out of their bodies to change the molecular structure of a chemical 2000 kilometers away, to communicate with aliens, or cure diseases. An amateur chemist claimed to have synthesized a liquid, small amounts of which, when added to water, could convert it to gasoline. For a time he was funded by the army and the secret police, but when his invention was found to be a scam, he was imprisoned for his unwillingness to reveal his "secret formula" to the government!

Typical offerings of pseudoscience and superstition are:

- *Astrology.*
- *The Bermuda Triangle.*
- *"Big Foot" and the Loch Ness monster.*
- *Ghosts.*
- *"Evil Eye".*
- *Extrasensory perception (telepathy, precognition, telekinesis, "remote viewing" of distant places).*
- *Triskaidekaphobia: a fear of the number* 13 *or the belief that* 13 *is an "unlucky" number. This is the reason why so many no-nonsense office buildings and hotels in America pass directly from the* $12th$ *to the* $14th$ *floors (why take chances?). No contract or treaty signed on the* $13th$ *day which falls on a Friday* (14 *times in* 28 *years).*
- *Crop circles*[816].
- *The conviction that carrying the severed foot of a rabbit around with you brings good luck.*
- *The prophecies of Nostradamus.*
- *The notion that more crimes are committed when the moon is full.*
- *Palmistry.*
- *Numerology.*
- *Polygraphy.*
- *Comets, tea leaves (plus the ancient divinations accomplished by viewing entrails, smoke, shadows, shape of flames and excrement) — as harbingers of future events.*
- *"Photography" of past events (e.g. the crucifixion of Jesus).*
- *"Sensitives" who can blindfolded read books with their fingertips.*
- *Faith healing.*

[816] Scientists dismissed it as fraud on the basis that *real* extraterrestrials would choose to exhibit something much more exciting than mere dull unimaginative circles in wheat.

- *Water "remembering" which molecules used to be dissolved in it.*
- *Ouija boards.*
- *"Prophets", sleeping and awake.*
- *Out-of-body (e.g. near-death) experiences interpreted as real events in the external world.*
- *Telling character from facial features or bumps on the head (phrenology).*
- *3-cycle biorhythms.*
- *Perpetual motion machines.*
- *Professional "psychics" and their inept predictions.*
- *Jehovah's Witnesses' predictions.*
- *Dianetics and Scientology.*
- *Claims of finding the remaining of Noah's Ark*

Indeed, some claims are hard to test, e.g., if expedition fails to find the ghost of the brontosaurus, allegedly crashing through the rain forests of the Congo Republic, that does not mean it does not exist.

Astrology *has been with us for more than 4000 years. The fraction of U.S. school children believing in astrology rose from* 40 *percent to* 59 *between 1974 and 1984. Yet this takes place at an age when astrologers and scientists alike are aware that astrology*

- *accepts the precession of the equinoxes in announcing an "Age of Aquarius" while* rejecting *the precessing of the equinoxes in casting horoscopes;*
- neglects *atmospheric refraction;*
- *lists supposedly significant celestial objects that are mainly limited to naked eye objects known to Ptolemy in the second century, but* ignores *an enormous variety of new astronomical objects discovered since (e.g. near-earth asteroids);*
- Fails *to pass the identical-twin test;*
- inconsistently requires *detailed information on the time as compared to the latitude and longitude of birth;*

- *ignores major differences in horoscopes cast from the same birth information by different astrologers.*

Science carries us toward an understanding of how the world is, rather than how we wish it to be. When we shy away from it, we surrender the ability to take charge of our future. We are disenfranchised.

This plight is perhaps demonstrated most vividly in the case of scientific illiteracy. *It is hard to believe that more than 450 years after Copernicus:*

- *About* half *of American and Chinese adults do not know that the earth revolves around the sun and takes a year to do so.*
- Most *people on earth still think that our planet sits immobile at the center of the universe, and we are profoundly "special".*
- *Bright students at leading American universities did not know that stars rise and set at night, or even that the sun is a star.*
- *In the US more money is spent on quack medicine than on all of medical research.*
- *Only 9 percent of Americans accept the central findings of modern biology that human beings (and all other species) have slowly evolved by natural processes from a succession of simpler organisms with no divine intervention needed along the way.*
- *A* quarter *of Americans believe in reincarnation.*
- *Astrology seems more popular than ever. At least a quarter of all Americans "believe" in astrology. A third think sun-sign astrology*[817] *is "scientific". There are perhaps ten times more astrologers than astronomers in the United States. In France there are more astrologers than Roman Catholic clergy.*

1934–1971 CE **George Wald** (1906–1997, USA). Biochemist. Unraveled the nature of light-sensing molecules found in photoreceptor cells and

[817] The art of stereotyping people according to their time of birth and then using this bit of information to place them in a small number of previously constructed pigeonholes.

discovered that vitamin A is a vital ingredient of the pigments in the retina and, hence, important in maintaining vision.

With **Ragnar Granit** (1900–1991, Sweden) and **Haldan K. Hartline** (1903–1983, USA) awarded the Nobel Prize in Physiology or Medicine (1967) for his work on the *chemistry of vision*.

George Wald was born in New York, of immigrant parents. He received his B.Sc. from the New York University (1927) and his Ph.D. in Zoology at Columbia University (1932). He spent the next two years in Europe, doing postgraduate research under **Otto Warburg** (Berlin), **Paul Karrer** (Zürich) and **Otto Meyerhoff** (Heidelberg). It was there (1934) that Wald first identified vitamin A in the retina.

When Hitler came to power (Jan 1933), Germany was fast becoming a hostile country, especially for Jews, and both Meyerhoff and Wald were Jewish. He left Germany (Summer 1934) and came to Harvard University as a tutor in Biochemistry, remaining there to the end of his career. He became a Professor of Biology in 1948.

With his coworkers at Harvard he pioneered our understanding of the molecules responsible for the first steps in the vision process. Wald's group was the first to elucidate the molecular structure of the rod cell's functional protein *rhodopsin*. Prior to his work, rhodopsin was thought to be a chunk of molecular material. He determined that the protein consists of two molecular parts: a colorless amino acid sequence called *ospin* and a yellow organic chromophore called *retinal*.

When exposed to light, the rhodopsin releases retinal that is converted into vitamin A[818].

By the early 1950s Wald had succeeded in elucidating the chemical reactions involved in the vision process in the rods. In the late 1950s, with **Paul K. Brown**, he identified the pigments in the retina that are sensitive to yellow-green light and red light and in the early 1960s, the pigment sensitive to blue light. Wald and Brown also discovered the role of vitamin A in forming the three color pigments and showed that color blindness is caused simply by the absence of one of them. Wald became professor emeritus at Harvard in 1977.

[818] **S.T. Ball** et all in Liverpool have shown (1946) that retinal is vitamin A aldehyde.

Timeline: the Physiology of vision (up to 1938)

ca 380 BCE **Plato** taught that the eye is the *source* of illumination. i.e.: the viewer's eye sent out emissions to the object, and those emission enabled vision to occur.

ca340 BCE **Aristotle** put forward an alternative theory of human vision: the object being looked at, somehow altered the "medium" between the object itself and the viewer's eye. This alteration of the medium propagates to the eye, allowing the object to be seen.

ca 170 CE **Galen** expounded and developed the *visual ray theory*, using it for detailed description of the anatomy of the eye. This theory was given credibility with **Euclid**'s geometry (ca 280 BCE) and **Ptolemy**'s optics (ca 150 CE). The advantage of this theory was that its geometrical analysis of the visual fields (i.e. a perspective cone with its apex in the eye and its base on the object) provided a solution to the problem of the size and distance of objects in relation to the eye. The principal organ of vision was the crystalline lens.

ca 1000 CE **Alhazen**, through his *experimental* work, related geometrical optics to the anatomy of the eye, but still considered the lens as the sensitive part. Contested Plato's idealism which made the eye a source of illumination, and appeared to have recognized the eye as what we now call *camera obscura*. He seems to have been well acquainted with the projection of images of objects through small apertures, and to have been the first to show that the arrival of the image of an object at the retina, corresponds with the passage of light from an object through an aperture in a darkened box. He also investigated the problem of *image-inversion* and the uprightness of the perceived object, placing binocular vision in the common optic nerve.

ca 1250–1580 CE No major advance beyond **Alhazen** throughout the Middle Ages and the Renaissance: the problems identified by him remained central in the investigations of **Roger Bacon** (1214–1292), **Witelo** (1230–1275) and **Leonardo da Vinci** (1452–1519).

1583 CE The physician **Felix Platter** (1536–1614, Switzerland) first promoted the idea that it was the *retina* and not the lens which was sensitive to light. He argued that the optic nerve ought to be viewed as the primary organ of vision.

1604 CE **Johannes Kepler** offered the first theory of *retinal image* and firmly established the inverted and reversed point-by-point representation of the image on the retina analogous to the *camera obscura*. Kepler argued that the crystalline lens re-focused rays on the retina where vision is made possible.

1619–1625 CE The astronomer **Christopher Scheiner** (1575–1650, Germany) provided an experimental verification to Kepler's theory of retinal image.

1637 CE **René Descartes** (1596–1650) first suggested point-by-point projection of *retina* onto *brain*.

1684 CE First microscopic observation of the retina: **Leeuwenhock** noticed structures now known to be the *rods* and the *cones*.

1704 CE **Isaac Newton** (1642–1727), in his book '*Optiks*', developed a theory of color vision.

1801 CE Based on Newton's work, **Thomas Young** (1773–1829), physicist and physician, proposed the *trichromatic* theory of color vision: nerve fibers in the retina are capable of reacting to each of the three primary colors (red, green, violet). This helped explain color-blindness. Young carried out a number of studies on the eye that resulted in an understanding of how the lens focused images onto the retina. He also showed that *astigmatism* results from an improperly curved cornea.

1826–1856 CE **Johann H. Müller** (1801–1858, Germany) explained (1826) structure and functions of the compound eye of lower animals. He is regarded as the founder of modern physiology. He noted visual purple in *rods* (1851) and proved that *photoreception* occurs in *rods* and *cones*.

1856 CE **H. von Helmholtz** (1821–1894) conjoined the work of Young and **Maxwell** in a comprehensive work on color vision.

1866 CE Biologist **Max Schultze** (1825–1874, Germany) discovered that the *retinal cones* are the color receptors of the eye and the *retinal rods*, while not sensitive to color, are very sensitive to light at low levels (night-vision). He was also one of the first to establish that the cells of all organisms are composed of *protoplasm* and contain a nucleus. His theory of vision was later amplified by the physician **Henri Parinaud** (1844–1905, France) and by the physiologist **Johannes A. von Kries** (1853–1920, Germany), in 1905.

1876 CE The physiologist **Franz Boll** (1849–1879, Germany) discovered the rod visual pigment.

1878 CE The physiologist **Wilhelm Friedrich Kühne** (1837–1900, Germany) isolated the reddish-purple rod pigment, termed *visual purple*, later to be called *rhodopsin*. Kühne showed it to be a protein.

1938 CE The biophysicist **Selig Hecht** (1892–1947, USA) showed that rods respond to single quanta, i.e.: the absorption of a single photon was sufficient to excite a rod. This suggested that large amplification must occur when rhodopsin is excited.

The Photobiochemistry of Vision, or – How do we see?

From time immemorial humans have tried to understand the phenomenon of vision.

Vision is indeed a complicated process that requires numerous components of the human eye and brain to operate in unison, and the accompanying Timeline bears evidence to the lengthy, slow accumulation of scientific lore in this field.

Although the microscope was first used in scientific research in the late 16th and early 17th centuries, both the tools and the techniques of its use *reached a sufficient level of sophistication by the 19^th^ century to make it invaluable in examination of the structures of the eye.*

During 1826–1878, several German physiologists used the microscope to closely examine the retina. Through their observations, they discovered two different cells in the retina: the rod cells *and the* cone cells*, so named because of their shapes as viewed in the microscope.*

Additional research during 1866–1938 showed that the rod and cone cells were responsive to light[819]*.*

During the 1800's, the visual pigments were discovered in the retina. Scientists, working by candlelight, dissected the retinas from frog eyes. When the retinas were exposed to day light they changed color. These scientists had discovered that the retina is photosensitive. They realized that the color they were observing was due to presence of a visual pigment, which was given the name rhodopsin*. Later studies showed that rhodopsin is a protein that is found in the discs of the rod cell membrane.*

Pigments are also found in cone cells. There are three types cone cells, each of which contains a visual pigment. These pigments are called the red, blue or green visual pigment. The cone cells detect the primary colors, and the brain mixes these colors in seemingly infinitely variable proportions so that we can perceiver a wide range of colors.

The original theory of color vision was introduced by **Thomas Young** *around 1790, prior to the discovery of the cone cells in the retina. Young was the first to propose that the human eye sees only the three primary colors, red, blue and yellow and that all of the other visible colors are combinations of these. It is now known that color vision is more complicated than this, but Young's work formed the foundation of color vision theory for the scientists that followed. The photoreceptor proteins of the cone cells have not yet been isolated. This may possibly be due to the difficulty in obtaining them. There are many fewer cone cells than rod cells in the retina. Also many animals do not have cone cells and hence do not see in color.*

During the early part of the 20^th^ century, work continued on the frontier of research aimed at understanding vision. It was also around this time that

819 In the human eye there are many more rod cells in the retina than there are cone cells. The number of rod cells and cone cells in animals is often related to the animal's instincts and habits. For example, birds such as hawks have a significantly higher number of cones than do humans. This let them to see small animals from a long distance away, allowing them to hunt for food. Nocturnal animals, on the other hand, have relatively higher numbers of rod cells to allow them better night vision.

the relationship between vision and proper nutrition began being studied at universities and agricultural schools. It had been shown during World War I that a vitamin A deficiency caused night blindness. The link between vitamin A and night blindness, however, did not become clear until ***George Wald*** *and his coworkers isolated vitamin A from the retina in 1933. Prior to this finding the importance of vitamins was poorly understood. Additionally, the complete role of vitamins in physiological processes was unknown. It is now understood that the human body makes* retinal *from vitamin A through the following process:* Enzyme-catalized oxidation *converts vitamin A (retinol) into* trans-retinal.

Trans-retinal is present in the light-receptor cells of the human eye, but before it can fulfill its biological function, it has to be isomerized by an enzyme, retinal isomerase, *to give cis-retinal. This molecule fits well into the active site of a protein called opsin (approximate molecular weight 38,000). Cis-retinal reacts with one of the amine substituents of opsin to form the* imine rhodopsin, *the light-sensitive chemical unit in the eye.*

When a photon strikes rhodopsin, the cis-retinal part isomerizes extremely rapidly, in only picoseconds (10^{-12} *s), to the trans isomer. This isomerization induces a tremendous geometric change, which appears to severely disrupt the snug fit of the original molecule in the protein cavity. Within nanoseconds* (10^{-9} *s), a series of new intermediates form from this photoproduct, accompanied by conformational changes in the protein structure, followed by eventual hydrolysis of the ill-fitting retinal unit. This sequence initiates a nerve impulse perceived by us as light. The trans-retinal is then reisomerized to the cis form by retinal isomerase and re-forms rhodopsin, ready for another photon. A schematic flow-diagram is shown in Fig. 5.13.*

What is extraordinary about this mechanism is its sensitivity, which allows the eye to register as little as one photon impinging on the retina. Curiously, all known visual systems in nature, even though they might have a completely different evolutionary history, use the retinal system for visual excitation. Evidently, this molecule offers an optimal solution to the problem of enabling organisms to see.

Thus, the photoreceptor neurons in the retina collect the light and send signals to a network of neurons that then generate electrical *impulses that go to the brain. The brain processes those impulses and yields information about what we are seeing. i.e., it decodes the retina images into information that we known as* vision.

Scientists continue to study the role and mechanisms of photoreceptors in vision both to better understand the mechanism of human vision and to try to understand and remedy eye disease and blindness. Additionally, studies on

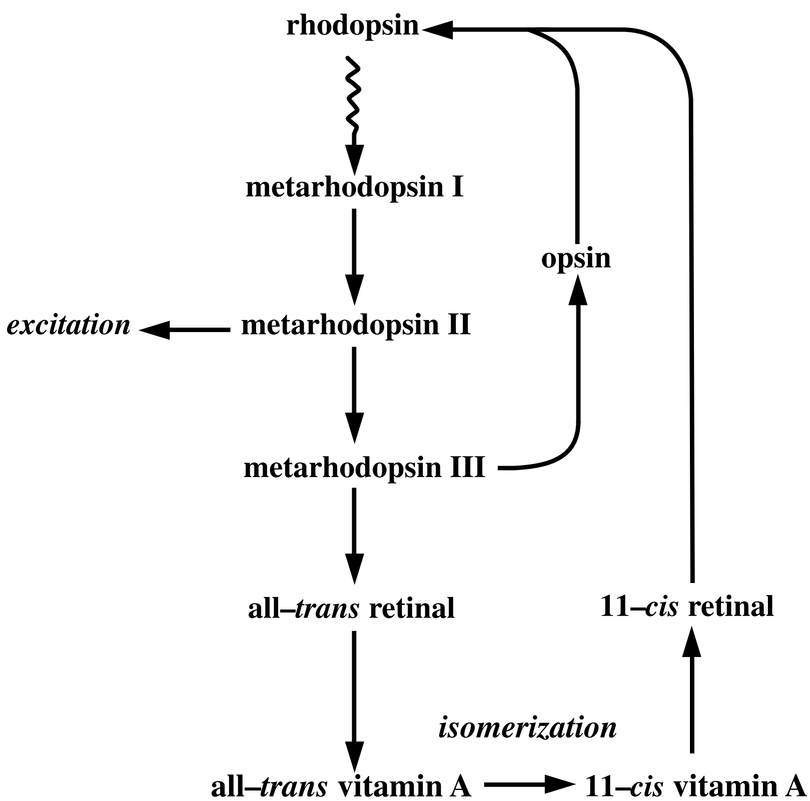

Fig. 5.13: When a photon strikes a rhodopsin

Scheme of the sequence of events that occurs following the absorption of a quantum of light by the rod visual pigment, rhodopsin. Light initiates the conversion of rhodopsin to retinal and opsin through a series of metarhodopsin intermediates. Metarhodopsin II is the active intermediate leading to excitation of the photoreceptor cell. Eventually, the chromophore of rhodopsin, retinal, separates from the protein opsin and is reduced to vitamin A (retinol). For the resynthesis of rhodopsin, the vitamin A must be isomerized from the all-trans to the 11-cis form, and this isomerization takes place in the pigment epithelium overlying the receptors. Vitamin A is replenished in the eye from the blood.

photoreceptors can lead to the development of better electronic and optical devices, as well as improvements in the field of robotics and artificial sensing.

1934–1987 CE **Emile Cioran** (1911–1995, Romania and France). Philosopher. Realized very early that the sense of existential futility can best be cured by the belief in a *cyclical concept of history*, which excludes any notion of the arrival of a new messiah or the continuation of techno-economic progress.

Historical pessimism and the sense of the tragic are recurrent motives in European literature. From Heraclitus to Heidegger, from Sophocles to Schopenhauer, the exponents of the tragic view of life point out that the shortness of human existence can only be overcome by the heroic intensity of living. The philosophy of the tragic is incompatible with the Christian dogma of salvation or the optimism of some modern ideologies. Many modern political theologies and ideologies set out from the assumption that "the radiant future" is always somewhere around the corner, and that existential fear can best be subdued by the acceptance of a linear and progressive concept of history. It is interesting to observe that individuals and masses in our post-modernity increasingly avoid allusions to death and dying. Processions and wakes, which not long ago honored the postmortem communion between the dead and the living, are rapidly falling into oblivion. In a cold and super-rational society of today, someone's death causes embarrassment, as if death should have never occurred, and as if death could be postponed by a deliberate "pursuit of happiness." The belief that death can be outwitted through the search for the elixir of eternal youth and the "ideology of good looks", is widespread in modern TV-oriented society. This belief has become a formula for social and political conduct.

Born in Romania in 1911, Cioran very early came to terms with the old European proverb that geography means destiny. From his native region which was once roamed by Scythian and Sarmatian hordes, and in which more recently, secular vampires and political Draculas are taking turns, he inherited a typically "balkanesque" talent for survival.

Cioran's political, esthetic and existential attitude towards being and time is an effort to restore the pre-Socratic thought, which Christianity, and then the heritage of rationalism and positivism, pushed into the periphery of philosophical speculation. In his essays and aphorisms, Cioran attempts to cast the foundation of a philosophy of life that, paradoxically, consists of total refutation of all living. In an age of accelerated history it appears to him senseless to speculate about human betterment or the "end of history."

"Future," writes Cioran, "go and see it for yourselves if you really wish to. I prefer to cling to the unbelievable present and the unbelievable past. I leave to you the opportunity to face the very Unbelievable."

Before man ventures into daydreams about his futuristic society, he should first immerse himself in the nothingness of his being, and finally restore life to what it is all about: a working hypothesis.

The feeling of sublime futility with regard to everything that life entails goes hand in hand with Cioran's pessimistic attitude towards the rise and fall of state and empires. His vision of the circulation of historical time recalls Vico's *corsi e ricorsi*, and his cynicism about human nature draws on Spengler's "biology" of history. Everything is a merry-go-round, and each system is doomed to perish the moments it makes its entrance onto the historical scene.

One can detect in Cioran's gloomy prophecies the forebodings of the Roman stoic and emperor Marcus Aurelius, who heard in the distance of the Noricum the gallop of the barbarian horses, and who discerned through the haze of Panonia the pending ruin of the Roman empire. Although today the actors are different, the setting remains similar; millions of new barbarians have begun to pound at the gates of Europe, and will soon take possession of what lies inside.

Cioran's philosophy bears a strong imprint of Friedrich Nietzsche and Hindu Upanishads. Although his inveterate pessimism often recalls Nietzsche's "Weltschmerz", his classical language and rigid syntax rarely tolerates romantic or lyrical narrative, nor the sentimental outbursts that one often finds in Nietzsche's prose. Instead of resorting to thundering gloom, Cioran's paradoxical humor expresses something which in the first place should have never been verbally construed.

When one reads Cioran's prose the reader is confronted by an author who imposes a climate of cold apocalypse that thoroughly contradicts the heritage of progress. Real joy lies in non-being, says Cioran, that is, in the conviction that each willful act of creation perpetuates cosmic chaos. There is no purpose in endless deliberations about higher meaning of life. The entire history, be it the recorded history or mythical history, is replete with the cacophony of theological and ideological tautologies. Everything is "éternel retour," a historical carousel, with those who are today on top, ending tomorrow at the bottom.

Cioran's most important books are:

- *On the Heights of Despair* 1934
- *Tears and Saints* 1937
- *A Short History of Decay* 1949
- *The Temptation to Exist* 1956
- *History and Utopia* 1960
- *The Trouble with Being Born* 1973
- *The Bad Demiurge* 1974
- *Anathemas and Admirations* 1987

In "*The Trouble with Being Born*" he explored how our troubles began with the act of being born and the anguish that pure consciousness and lucidity inflicts upon us.

In "*A Short History of Decay*," Cioran explores man's decay, the necessity and futility of rebellion against God and life itself. How we should seek our true hope in nothingness.

In "*Tear and Saints*" he equates religious fanaticism with 'delirium of self-aggrandizement hidden beneath meekness and the will to power masked by goodness.'

Cioran was born as Octavian Goga in the village of Rasinari near Sibiu (Austria-Hungary, present-day Romania), the son of an orthodox priest. He studied philosophy and letters at the Universities of Bucharest (1928–1932) and Berlin (1933–1935) and then worked as a high-school teacher at Brasov (1935–1936). In 1928 he also began an association with the *Iron Guard*, a nationalistic organization which he supported until the early years of *WWII*. This enabled him to obtain a scholarship from the French Institute in Bucharest, that brought him to Paris and he became a cultural councilor at the Romanian Embassy there (1940–1945). He later renounced the organization and frequently expressed regret and repentance for his participation in it. (Some critics have seen his remorse at his participation in the Iron Guard as the source of pessimism which characterized his later work, although others trace it back to events in his childhood[820].)

From 1944 on, Cioran wrote exclusively in French. Sometimes during the 1950's he met Simone Bouc, who became his lifelong companion.

He led a quite and solitary life of study and composition. Though he was highly regarded by Parisian literary circles, he was not well known to the rest of the world, and he sustained himself through his work as a translator or reader for various publishing houses.

---

[820] In 1935 his mother is reputed to have told him that if she had known he was going to be so unhappy, she would have aborted him.

He lived in the same small apartment in the Latin Quarter of Paris from 1960 on. In his later life, Cioran withdrew from social life and gave up writing altogether in 1987. Alzheimer's disease began slowly deteriorating his mind in the 1990's, just as his native country began rediscovering him after the fall of Communism. He fell ill in 1994 and, after a yearlong battle, Emile Cioran finally found his long sought bliss in nothingness.

Worldview XLIX: Emile Cioran[821]

* * *

Life inspires more dread than death — it is life which is the great unknown.

* * *

If, at the limit, you can rule without crime, you cannot do so without injustices.

* * *

In a republic, that paradise of debility, the politician is a petty tyrant who obeys the laws.

* * *

Life is possible only by the deficiencies of our imagination and memory.

[821] The English translation in this section was done by **Tomislav Sunic**. His is also the source of appreciation of Cioran's philosophical life-work as quoted in our article.

* * *

Chaos is rejecting all you have learned, Chaos is being yourself.

* * *

Man starts over again everyday, in spite of all he knows, against all he knows.

* * *

We inhabit a language rather than a country.

* * *

I'm simply an accident. Why take it all so seriously?

* * *

I have no nationality — the best possible status for an intellectual.

* * *

I have always lived with the awareness of the impossibility of living. And what has made existence endurable to me is my curiosity as to how I would get from one minute, one day, to the next.

* * *

To act is to anchor in the imminent future.

* * *

Isn't history ultimately the result of our fear of boredom?

* * *

To want fame is to prefer dying scorned than forgotten.

* * *

Pursued by our origins... we all are.

* * *

For you who no longer possess it, freedom is everything, for us who do, it is merely and illusion.

* * *

To Live signifies to believe and hope — to lie and to lie to oneself.

* * *

Glory — once achieved, what is it worth?

* * *

What does the future, that half of time, matter to the man who is infatuated with eternity?

* * *

Knowledge subverts love: in proportion as we penetrate our secrets, we come to loathe our kind, precisely because they resemble us.

* * *

In most cases we attach ourselves to God in order to take revenge on life, to punish it, to signify we can do without it, that we have found something better, and we also attach ourselves to God in horror of men.

* * *

We understand God by everything in ourselves that is fragmentary, incomplete, and inopportune.

* * *

A people represents not so much an aggregate of ideas and theories as of obsessions.

* * *

We are born to Exist, not to know, to be, not to assert ourselves.

* * *

Knowledge, having irritated and stimulated our appetite for power, will lead us inexorably to our ruin.

* * *

Each of us must pay for the slightest damage he inflicts upon a universe created for indifference and stagnation; sooner or later, he will regret not having left it intact.

* * *

Whenever I happen to be in a city of any size, I marvel that riots do not break out everyday: Massacres, unspeakable carnage, a doomsday chaos. How can so many human beings coexist in a space so confined without hating each other to death?

* * *

Utopia is a mixture of childish rationalism and secularized angelism.

* * *

That history just unfolds, independently of a specified direction, of a goal, no one is willing to admit.

* * *

Society becomes consolidated in danger and it atrophies in peace.

* * *

Authority, not verity, makes the law.

* * *

"What to think of other people? I ask myself this question each time I make a new acquaintance. So strange does it seem to me that we exist, and that we consent to exist."

* * *

"Existing is plagiarism."

* * *

"A self-respecting man is a man without a country. A fatherland is birdlime..."

* * *

"Illusion begets and sustained the world; we do not destroy one without destroying the other. Which is what I do every day. An apparently ineffectual operation, since I must begin all over again the next day."

* * *

History teaches us that: violence and destruction are the main ingredients of history, because the world without violence is bound to collapse.

* * *

In those places where peace, hygiene and leisure ravages, psychoses also multiply. Thus, not "peace and love" will determine the course of tomorrow's history. Unable to put up resistance against tomorrow's conquerors, the fate of Western Europe is doomed.

* * *

"Suffering makes you live time in detail, moment after moment. Which is to say it exists for you. For the others, the ones who don't suffer, time flows, so that they don't live in time; in fact they never have."

* * *

I cannot excuse myself for being born. It is as if, when insinuating myself in this world, I profaned some mystery, betrayed some very important engagement, made a mistake of indescribable gravity.

* * *

1935 CE **Hideki Yukawa** (1907–1981, Japan). Physicist. Proposed that the exchange of virtual quanta (particles) of a hitherto unknown field (*mesons, meson fields*) is the cause of the complex interactions among nucleons (protons and neutrons) in the atomic nucleus. [The name *meson* was coined by

Homi Bhabha (India).] He predicted the rest-mass and spin of this class of particles[822], which were later discovered and named *pions* or π-mesons.

Upon graduating from Kyoto Imperial University in 1929, Yukawa became a lecturer there. In 1933 he moved to Osaka Imperial University, where in 1938 he was awarded the doctorate. He rejoined Kyoto University as professor of theoretical physics (1939–1950), held faculty appointments at the Institute for Advanced Study in Princeton, NJ and at Columbia University in New York city, and became director of the Research Institute for Fundamental Physics in Kyoto (1953–1970). Yukawa was awarded the Nobel prize for physics in 1949.

1935 CE **Arthur Jeffrey Dempster** (1896–1950, U.S.A.). Physicist. Built the first mass spectrometer (1918). Discovered uranium 235, an isotope of uranium that would be used (1942) in producing the first sustained nuclear chain-reaction. Born in Toronto, Canada; taught at the University of Chicago (1919–1950).

1935 CE **Wendell Meredith Stanley** (1904–1971, USA). Biochemist. Worked on purification and crystallization of viruses, thus demonstrating their molecular structure; crystallized tobacco mosaic virus (1935); also studied influenza viruses, for which he developed a preventive vaccine. Corecipient, with **J.H. Northrop** and **J.B. Sumner** of the 1946 Nobel Prize for Chemistry.

Stanley was born in Ridgeville, Indiana. Worked at the Rockefeller Institute for Medical Research (1932–1948) and became professor at the University of California, Berkeley (1948–1971).

Stanley chose to work with the *tobacco mosaic virus* because it was not dangerous to human beings and because characteristic infection could be demonstrated easily and rapidly. From the juice squeezed out of a ton of infected tobacco leaves, Stanley was able to isolate a few milligrams of a *crystalline* material that appeared to him, at first, to be a protein.

---

[822] The successful description of the electromagnetic force in terms of virtual photons suggested to him that the strong nuclear force might be accounted for in a similar manner.

It was known that this force does not decrease gradually toward zero with increasing distance; rather, its range ends abruptly at distance of order 10^{-13} centimeter. From this fact and the uncertainty principle, Yukawa concluded that the particles whose virtual exchange was associated with the strong force field should be all of one, *finite* mass, $m \sim \frac{\hbar}{(10^{-13}\,cm)c} \sim \frac{100\,MeV}{c^2}$, of order two hundred electron masses. Since particles having a mass intermediate between the electron and proton were unheard of at the time this prediction was made, it was received with considerable skepticism.

The substance was a pure, homogeneous *non-cellular* material that could be stored, apparently indefinitely, in a dry state; however, if even one millionth of a milligram of the pure material was suspended in water and spread on a living tobacco leaf, the mosaic disease was produced. Careful chemical analysis of the pure virus showed that it was composed of 95 percent protein and 5 percent *ribonucleic acid*, and nothing else.

Stanley's discovery changed the course of biological thought and research. The virus was not a small bacterium; it was a large molecule. Thus, the problem of viruses fell within the domain of chemistry and physics as well as biology.

The line of demarcation separating the living from the non-living became cloudy, and a new group of scientists (including **Max Delbrück**, **Alfred Hershey** and **Salvador Luria**) entered the field of virology. This new school of virologists turned their attention to a group of viruses that attack bacteria, celled *bacteriophages*.

Microwave Technology

In 1935, British scientists led by **Robert Alexander Watson-Watt** *(1892–1973), developed the first pulse-radar* (Radio Detection and Ranging), *capable of detecting aircraft at ranges up to 27 km. Spurred by the growing threat of war, the British quickly recruited many of their best scientists and developed* PPI *radar (Plane Position Indicator) and efficient multicavity magnetrons to generate microwaves.*

By the time WWII *began in September 1939, the British had installed a chain of large radar warning stations on their shores. They also developed* GCI *(Ground Controlled Interception) radar and Airborne Interception radar for night fighter planes. During the Battle of Britain, these radars enabled a small force of British fighter planes and antiaircraft artillery to fight off the massive German air attacks.*

Magnetrons are vacuum tube devices which generate or amplify high-frequency electromagnetic waves. In ordinary vacuum tubes the period of the voltage or current cycle is long compared with the transit time required for an electron to travel from cathode to anode. However, at frequencies of *the order of 100 MHz the transit time becomes comparable with the period of the oscillations themselves. It then becomes dependent upon the space charge, and hence modulated by the oscillations.*

This effect, in conjunction with the effect of the interelectrode capacitance, will tend to nullify the control action of the grid. Thus, if the frequency of the signal is so high that the electric field experienced by an electron changes significantly during the time of transit, ordinary vacuum tubes cannot be used.

The magnetron *(like the* klystron *and the* traveling-wave tube*) utilizes the transit-time in their operation to sustain and amplify oscillations above 1000 MHz; in each of these devices, a stream of electrons is subjected to electric* and *magnetic fields precisely arranged so that an exchange of energy occurs between the signal and the electrons. The net result is that power supplied by a d–c source is converted to a–c power at the signal frequency and amplification is obtained.*

The Hull magnetron *(1921) underwent two basic modifications on its way from serving as a mere diode to becoming an efficient generator of microwave radiation. In its first use as an oscillator, the anode of the valve was split into two segments (1927) and a high-frequency resonant circuit was connected between the anode segments. This was known as the '*Split-Anode Magnetron*'. An electron emitted from the cathode at the center of the cylinder was then subjected to 3 different fields:*

(1) a d–c radial electric field E accelerating it toward the peripheral anode;

(2) a d–c axial magnetic field $B > B_c$, (B_c being a critical field value) affecting radial and azimuthal motion in a plane perpendicular to the axis;

(3) intense high-frequency field across the gaps of the anode segments.

Assuming first that both segments of the anode are at the same potential V_b and that the cathode is negligibly thin, each electron moves with an approximately constant speed $v = \sqrt{\frac{2e}{m}V_b}$ in a circular orbit of radius $r = \frac{mv}{eB}$ and period of revolution ('transit-time') $\tau = \frac{2\pi r}{v} = \frac{2\pi m}{eB}$. Under these conditions the electron neither gives nor takes energy from its surrounding.

Now suppose we activate the resonant tank circuit across the anode gaps; since $B > B_c$, an incoming electron in its circular orbit nearly grazes the anode. Depending on the polarity of the tank circuit, the incoming electron will be either accelerated or decelerated by the momentary field across the gap. If it is accelerated it will induce a current in the resonant circuit that will extract *energy from the circuit. If it is retarded at the gap, it will instead induce a current which delivers energy to the tank circuit.*

If, when the electron approaches the gap again, the tank circuit has oscillated through one cycle, then the electron is again retarded at the gap, and the whole process is repeated. In successive cycles the electron approaches the anode less closely, owing to its repeated losses of kinetic energy, and finally it comes to rest somewhere between the anode and the cathode and is removed by special arrangements.

Over time, the external circuit gains more AC energy from the electrons which are retarded at the gaps than it losses to electrons which are accelerated at the gap. The magnetron can therefore maintain oscillations in the tuned circuit connected across its anode segments. The AC oscillation energy comes from the high DC voltage supply, which sets up the radial accelerating field near the cathode. As the electrons pass through this field, the current which they induce flows between the cathode and the anode as a whole, resulting in a transfer of energy from the battery to the electrons, which in turn transfer part of this energy, at the frequency of the transit-time*, to the tank circuit.*

In the next stage in the development of the magnetron (1941), the tank circuit was replaced by a cavity, or several cavities. The anode now consisted of a solid block of copper, in which an even *number of identical cylindrical cavities were drilled, symmetrically arranged. In such a configuration, cavity communicates by means of a slot, with a central cylindrical hole housing an oxide-coated nickel cathode.*

These cavities are capable of entering into resonance at the desired oscillation frequency; a coupling loop, inserted in one of the cavities, suffices to energize a coaxial cable waveguide. Oscillations of the charge take place around the inner circumference of the cylinder, and set up an intense electric field over the narrow gap. The anode potential V_b is over 10,000 volts, and the axial magnetic flux density B is about 1000 Gauss.

Under static conditions no electrons would reach the anode, and there would be a cylindrical space-charge distribution of diameter less than the inner diameter of the anode.

This space-charge would, in effect, circulate round the cathode with an angular velocity depending on the anode potential and the magnetic flux density. But theory suggests that, when the cavity system produces a transient oscillation, the electric field of the resonators draw out the space-charge into a form rather like the spokes of a wheel. Then, the electrons swinging past the gaps in the cavities interact with the electric fields across those gaps.

Under certain conditions of flux density and anode potential the resonators gain energy from the electrons, and their oscillations grow to a steady amplitude. Neighboring segments of the anode must be at potentials of opposite sign at any given instant, each segment changing from maximum positive potential to maximum negative potential, and back again, once per cycle; in *other words — the configuration of the fields and currents rotates at* $\left(f/\frac{1}{2}N\right)$ *revolutions per second, where* f *is the frequency and* N *the number of cavities.*

The cavity magnetron is not suitable for producing an amplitude-modulated signal, because the high anode voltage is fixed by the conditions for oscillation. It was developed as a generator of pulses, for use in RADAR. Each pulse lasts for a few microseconds, with wavelengths between 10 cm and 3 cm (frequencies between 3000 and 10,000 MHz). Typical peak power of 150 kilowatts at a pulse rate of 1000 per sec were attained during WWII.

Today, high operating efficiencies are possible and microwave tubes find application in television transmission, satellite communication, industrial heating, home cooking (e.g. microwave oven), medical imaging, radiation therapy and high-energy physics.

1935 CE, Sept. 04 '*Labor Day*' Hurricane[823] struck the Florida Keys. One of the greatest storms to hit the United States in the 20^{th} century. The barometer fell to 669.3 mb, the lowest reading ever recorded in the Western Hemisphere. More than 400 persons were killed in the storm. Winds reached 320 km/hr in the Florida Keys.

Violent Storms

As with many other natural catastrophes, hurricanes and tornadoes attract a great deal of attention. Although these phenomena are relatively rare, they command a fascination that ordinary weather events cannot provide. Furthermore, because of the death and destruction that these storms leave

[823] The Caribbean word *huracan* was introduced by the Portuguese, Spanish and Dutch explorers of the 15^{th} and 16^{th} centuries into many European languages.

in their wake[824]*, they have been and continue to be an important focus of atmospheric research.*

Storms vary in areal size, wind velocity and total energy input:

- *In a tornado, wind may exceed* 650 *km/hr. It is usually less than* 2 *km wide and lasts for a few minutes. Its kinetic energy is typically* 4×10^{17} *erg, and its total energy is* 10 *to* 100 *times greater.*
- *In a hurricane (tropical cyclone), wind may be above* 300 *km/hr, its areal size may be* 800 *km in diameter and it may last for as much as a week or so. Its kinetic energy is about* 4×10^{23} *erg, and its total energy may reach* 4×10^{24} *erg.*
- *A cyclone (nearly circular area of low pressure which commonly form outside the tropics in the middle latitudes and slowly moves inland across the coast) usually has winds below* 80 *km/hr, an areal size of more than* 1500 *km in diameter and duration of perhaps a week. Its kinetic energy is on the average* 4×10^{24} *erg, while its total energy is about* 4×10^{25} *erg.*

The major portion of the energy in atmospheric systems is expended in overcoming the effects of friction and in heating the air inside and outside the systems. Thus, the input energy of an average hurricane may be equivalent to more than 10,000 *atomic bombs of the kind that destroyed Nagasaki (10 KT).*

There are various sources of energy for atmospheric vortices. Heat contained in the air and earth's surface, and the sinking of heavier air when it moves over lighter air are important factors. But the major contribution comes from heat released when water vapor condenses to form clouds[825]*. In hurricanes and cyclones there are indeed widespread areas of cloudiness and*

---

[824] Enormous amounts of destruction and damage can be caused by one tropical cyclone, particularly in coastal areas. For example, on 12 November 1970 a tropical cyclone moving up the Bay of Bengal hit the coast of Bangladesh, sending a 6-meter surge ahead of it, which moved into a low-lying convergent coastline at the time of high-tide. The resultant hurricane storm tide destroyed the island of Bhola, over 500,000 people died and some 4.7 million people were affected by the disaster.

[825] In a single *thunderstorm* about 5 km in diameter, there may be 500,000 tons of condensed water in the form of water droplets and ice crystals. In the course of producing these particles, there would have been released about 3×10^{14} calories. This is equal to about 10^{22} erg.

rainfall. They indicate the release of enormous amounts of heat of condensation (latent heat).

Tornadoes appear as pendent funnels which dip downward from the base of existing clouds, and approach the ground in an irregular fashion. These are intense centers of low pressure having a whirlpool-like structure of winds rotating around a central cavity, where centrifugal forces produce a partial vacuum. Pressures within the center of some tornadoes have been estimated to be 100 *millibars less than immediately outside the storm. Because of such tremendous pressure gradients, it is estimated that wind speeds may reach* 650 *km/hr or more. Air sucked into the vortex of the storm is rapidly lifted and cooled adiabatically. The resulting condensation creates the pale and ominous-looking funnel cloud, which may darken as it moves across the ground, as it picks up dust and debris.*

The most striking feature of the tornado is the velocity of the wind, which in localized regions of the funnel may reach peak speeds close the speed of sound. The circulation of these winds is always counterclockwise (dust-devils usually spin clockwise!). The nearly total destruction wrought by tornadoes is linked to the combined effects of the exceedingly strong winds and the partial vacuum in the center of the storm. The winds may rip apart everything in the path of the storm, and the abrupt pressure drop may cause some building to literally explode[826].

Although meteorologists still do not know how and why tornado funnels form where they do, they can specify the conditions usually associated with their development throughout the spring: continental Canadian polar air from the arctic may still be very cold and dry, whereas maritime tropical air from the Gulf of Mexico is very warm and moisture laden. The greater the contrast, the more intense the storm. Since these two contrasting air masses are most likely to meet in the central United States, it is not surprising that this region generates more tornadoes than any other area in the country, and, in fact, the world.

Tornado warning is effected by visual sightings, conventional radar and recently by Doppler radar[827] *through which the frequency of the reflected*

---

826 *Tornado stories*: in 1931 a tornado carried an 83-ton railroad coach and its 117 passengers 24 meters high through the air and dropped them in a ditch; The force of the wind during a tornado in Clarendon, Texas, in 1970, was enough to drive a wooden stick through a 4-centimeter metal pipe; Turkeys and chickens were stripped clean of their feathers, but remained alive! Thin pieces of straw were blown into three trunks or fence posts.

827 Nowadays, *Doppler radar* is used to detect the initial formation and subsequent development of a *mesocyclone*, an intense rotating wind system in the lower

signal is compared to that of the original pulse. These frequency changes are then interpreted in terms of speed forward or away from the radar unit.

Tropical cyclones develop in very humid air with temperature over $26\,^{\circ}C$*, so they happen mostly in the summer and early autumn, when the seas and the air above them are at their warmest. First, the warm sea heats the air above. A current of very warm, moist air rises quickly above the sea, creating a center of very low pressure on the surface below. Trade winds rush in towards this low-pressure center and whirl upwards. As they rise they cool, and the huge amounts of water vapor they contain condense and form towering cumulus and cumulonimbus clouds.*

Hurricanes are whirling tropical cyclones having wind speeds reaching 320 *km/hr — the greatest storms on earth. Out at sea they can generate* 15*-meter waves capable of inflicting destruction hundred of kilometers from their source. Should a hurricane smash into land, strong winds coupled with extensive flooding can cause great loss of life and catastrophic damage. [These awesome storms form in all tropical waters (except those of the south Atlantic) between the latitudes* $5\,^{\circ}$ *and* $20\,^{\circ}$*, and are known in each region by a unique name: in the western Pacific they are called typhoons, and in the Indian Ocean they are called cyclones.]*

Although hurricanes are most noted for their destruction, some parts of the world, especially eastern Asia, rely on them for much of their precipitation. (Consequently, while a resort owner in Florida dreads the coming of the hurricane season, a farmer in Japan welcomes its arrival.)

Hurricanes average 600 *kilometers in diameter and often extend* 12 *kilometers above the ocean surface. From the outer edge of the hurricane to the center, the barometric pressure on occasion drops* 60 *mb. This steep pressure gradient generates the rapid, inward spiraling winds. As the inward rush nears the core of the storm, it is deflected upward. Upon ascending the air condenses, generating the cumulonimbus clouds that constitute the doughnut-shaped inner structure of the hurricane called the eye-wall.*

Near the top of the hurricane the airflow is outward, carrying the rising air away from the storm center, thereby providing room for more inward flow at the surface. At the center of the storm is the spectacular eye. Averaging 20 *kilometers in diameter, this zone of calm and scattered cloud cover is*

---

part of a thunderstorm that precedes tornado development. It can provide an average *warning* time of 21 minutes before tornado touchdown, as compared to 2 minutes at most by visual observations. Doppler radar also helps meteorologists gain new insights into thunderstorm development and air hazards that plague aircraft.

unique to the hurricane. The air within the eye slowly descends and heats by compression, making it the warmest part of the storm.

A hurricane can be described as a heat engine that is fueled by the energy liberated during the condensation of water vapor (latent heat). The enormous amounts of energy involved in a single storm is evident when we consider that it is equal to the total amount of electricity consumed in the United States over a 6-month period.

The release of latent heat warms the air and provides buoyancy for its upward flight. The result is to reduce the pressure near the surface — which encourages a more rapid inward flow of air. To get this engine started, a large quantity of warm, moisture-laden air is required and a continual supply is needed to keep it going.

Hurricanes develop most often in late summer, when the water has reached $27\,^{\circ}C$ *or more and is thus capable of providing the warm, moist air required. This fact is thought to account for the fact that the coolest tropical ocean, the South Atlantic, does not experience hurricanes.*

For the same reason, hurricane formation is confined to the warm sectors of the oceans, which are located not more than 20 *degrees on either side of the equator. On the other hand, hurricanes are not known to form within* 5 *degrees of the equator, because at low latitudes the Coriolis force is too weak to initiate the necessary rotary motion.*

Although the exact mechanism of formation is not completely understood, it is known that smaller tropical storms initiate the process. *These initial disturbances are regions of low-level convergence and lifting. Many tropical disturbances like these occur each year and move westward across the warm oceans, but only few develop into full-fledged hurricanes. It is believed that the upper-level airflow acts to further* intensify selected *storms by "pumping out" the rising air as it reaches the top of the storm, thus encouraging influx of warm moist air at the surface, which ascends and releases latent heat to fuel the storm.*

It seems that if the air is "pumped out" at the top faster than it is being replaced at the surface, the storm intensifies. However, if the rising air is not removed, the convergence at the surface will "fill" the storm center, equalizing the pressure differences, and the storm will die. Whenever a hurricane moves onto land, it loses its punch rapidly, for its source of warm water-laden air is cut off. Also, the added frictional effect of land causes the wind to move more directly into the center of the pressure low, helping to eliminate the large pressure differences.

North Atlantic hurricanes develop in the trade winds, which generally move these storms from east to west at about 25 *km/hr. Then, hurricanes* *curve poleward and are deflected into the westerlies, which increase their forward motion.*

Damage caused by hurricanes can be divided into three categories: (1) wind damage, (2) storm surge, and (3) inland fresh water flooding. Most of the devastating damage is caused by the storm surge, which is a dome of water 65 *to* 80 *kilometers long that sweeps across the coast near the point where the eye makes landfall. The torrential rains that accompany most hurricanes represent a third significant threat — flooding: as it moves inland, the storm can yield* 30 *centimeters of rain and drop* 100 *cubic kilometers of rain water over a radius of some* 200 *kilometers.*

One of the most awesome of natural atmospheric phenomena, similar in many respects to the tornado, is the firestorm. This often develops when a forest wild fire becomes organized by a cyclonic circulation. The highly unstable air (greatly exceeding the dry adiabatic rate[828]*) pulls in the surrounding air and develops a massive fire of terrifying proportions. An organized firestorm*

---

828 Near the earth's surface most processes are non-adiabatic, namely: heat is readily exchanged between the ground and the air above. When the ground looses heat during the night, the air in contact with it is cooled. When there is enough moisture in the air, and there is little and no wind, the air temperature may be lowered to the point where *dew forms* (the dew-point temperature).

If there is just enough air motion to produce gentle stirring, so that additional air can be cooled by mixing or direct contact with the cold ground, the condensed moisture — *fog* — can attain a thickness of 100 m or more. However, because air is a poor conductor of heat, this exchange is virtually nonexistent above a few thousand meters. Thus, some other mechanism must operate during *cloud formation*.

As an airmass *rises*, pressure in it decreases and in response it expands. The expansion requires an expenditure of energy; since temperature is a measure of internal energy, this use of energy causes the airmass temperature to drop; this drop is 10 °C for each kilometer of ascent. A mass of rising air cools at this rate, known as the *dry adiabatic lapse rate* (DALR).

Conversely, sinking air is compressed and warms at the same rate. This activity determines the altitude at which a cloud will form or evaporate. When water molecules in the gaseous state condense, they lose some of their kinetic energies to the air; they release what is called *latent heat*. With water, this is a large amount of energy — nearly 600 kilocalories for each kilogram of condensed water, depending on the temperature and increasing as the temperature decreases.

Now, if air rises long enough, it will inevitably cool sufficiently to cause condensation. From this point along its ascent, latent heat stored in the water vapor *creates its own localized wind pattern which often becomes so violent as to fell trees, tear burning limbs from them, and scatter ambers from the upper levels of the convective column far and wide, thus starting new fires.*

When an intensive low-level jet-stream is over the region, an extremely dry subsiding air with a persistent wind velocity of 15–25 *m/sec can initiate a* blowup. *This may become a firestorm if a convective column develops and generates its own inflow winds. This occurred, for example, in* 1910 *in western Montana and eastern Idaho.*

Forecasting the evolution and movement of these systems remains one of the major unsolved problems of meteorology today.

---

will be liberated. Although the air will continue to cool after condensation begins, the released latent heat works against the adiabatic process, thereby reducing the rate at which air cools from $10\,^\circ$C/km to the *saturated lapse rate* (SALR). It may be as low as $6\,^\circ$C/km, depending on the rate of release of latent heat. These lapse rates are referred to as being *adiabatic*, which means a temperature exchange process where there is no loss or addition of heat to or from an element of air molecules by its surroundings. No exchange of heat, momentum or water occurs with the environmental air molecules, and a parcel of air will heat or cool at a rate which is predictable and independent of environmental temperature.

For a vertical motion of air in the atmosphere, the temperature changes that take place are approximately adiabatic, as air is a poor conductor of heat, and diffusional mixing of a parcel with its surrounding is usually low. The air parcel will therefore tend to retain its own thermodynamic identity, which distinguishes it from the surrounding air.

The change of temperature of the environment with respect to the height is referred to as the *environmental lapse rate* (ELR, measured in $^\circ$C/km).

The atmosphere is said to be *absolutely stable* if $\text{ELR}<\max\{\text{DALR},\text{SALR}\}$, so that the rising parcel of air is always cooler and heavier than the surrounding air, and convection is suppressed.

On the other hand, the atmosphere is said to be *absolutely unstable* if $\text{ELR}>\max\{\text{DALR},\ \text{SALR}\}$, so that any air parcel cooling at the DALR will always be warmer and less dense than the surrounding air. Its buoyancy will give it an upward impulse, so that convection is encouraged. This motion will stop at a level of equilibrium where $\text{ELR}=\text{SALR}$.

1935–1937 CE **Nathan N. Rosen** (1909–1992, USA and Israel). Theoretical physicist. Worked with Albert Einstein on the foundations of quantum mechanics. Together with **Boris Podolsky**[829] (1896–1966) they concocted the ‘ *Einstein-Podolsky-Rosen Paradox*’ (1935) based on an idea of Rosen. It is a logically impeccable conclusion which casts a spotlight on some peculiarities of quantum mechanics.

Behind the title of the EPR paper, *Can the Quantum Mechanical Description of Physical Reality Be Regarded as Complete?*, is an attempt to demonstrate that quantum mechanics represents only an *incomplete* description of physical reality and therefore is unable to get beyond the formulation of statistical regularities.

Rosen was born in Brooklyn, New York, obtained his ScD at MIT (1932) and was a member of the Institute of Advanced Study (1934–1935). He collaborated with **Einstein** on the singularity-free solutions of the combined gravitational and electromagnetic field equations (1935), on the GTR two-body problem (1936), and on gravitational lenses (1937).

[829] Born in Taganrog, Russia. Emigrated to the United States (1913) and did his Ph.D. at CalTech (1928). He was a member of the Institute of Advanced Study (1934–1935) when the Einstein-Podolsky-Rosen collaboration took place. He later became research professor at the Xavier University in Cincinnati.

1935 CE '*The Einstein–Rosen Bridge*'[830]

Barely a few months after Einstein wrote down the field equations of the General Theory of Relativity, the first exact solution was found by Karl Schwarzschild (1916). He had shown that it is always possible to find a coordinate system in which the most general spherically symmetric solution of the vacuum field equation is obtained via the metric line element.

In relativistic units ($c = 1$),

$$ds^2 = \left(1 - \frac{2m}{r}\right) dt^2 - \left(1 - \frac{2m}{r}\right)^{-1} dr^2 - r^2(d\theta^2 + sin^2\theta\, d\,\varphi^2) \qquad (1)$$

with

$$m = G\,M$$

Thus, if we interpret the Schwarzschild solution (SS) as due to a point particle situated at the origin, then the constant m is simply the mass of the particle in relativistic units. It is clear from (1) that m has the dimensions of length.

We notice that the SS becomes *singular* at $r = r_s = 2GM$, known as the *Schwarzschild radius* of the mass M.

Imagine a body so small and massive that the radius r_s lies outside it, in empty space. The SS then holds down to this radius and actually displays a singularity. The question then arises as to whether this singularity is real or just an artifice of the coordinate system used. **Kruskal** (1960) found a coordinate system that allows us to avoid talking about a *Schwarzschild singularity*, if we are willing to allow the world an *unusual topology*. To exhibit this reinterpretation of the Schwarzschild singularity, he introduced a new set of coordinates r', θ, φ, t', defined by

$$\left.\begin{aligned} r'^2 - t'^2 &= T^2\left(\tfrac{r}{2GM} - 1\right)e^{\left(\frac{r}{2GM}\right)} \\ 2r'\,t'/(r'^2 + t'^2) &= tan\,h\left(\tfrac{t}{2MG}\right) \end{aligned}\right\} \qquad (2)$$

where T is a arbitrary constant. The SS (1) then becomes

$$ds^2 = F^2(dt'^2 - dr'^2) - r^2(d\theta^2 + sin^2\theta\, d\varphi^2); \qquad F^2 = \frac{\varphi r_s^3}{T^2\, r}\, e^{-\frac{r}{r_s}} \qquad (3)$$

where r is now to be understood as a function of $r'^2 - t'^2$ defined by (2). The metric is nonsingular as long as $r'^2 > t'^2 - T^2$.

Hence, during the time interval $0 < t' < T$, the metric is a perfectly smooth finite function of r' for all real r'. The space described by (3) is therefore *singularity–free*, but consists of two identical sheets $r' > 0$ and $r' < 0$, joined in a smooth way by a branch point at $r' = 0$. When t' reaches the time T, the two sheets detach from each other, and thereafter the metric has a real singularity at $r' = \pm\sqrt{t'^2 - T^2}$, that is, at $r' = 0$. This is unavoidable since the curvature becomes infinite at that point. However, even so, the metric has no singularity at the radius $r' = t'$ that corresponds to the Schwarzschild radius $r = 2\,G\,M$.

If we consider the submanifold $t' = 0$ in the Kruskal solution (3), then the line–element is given by $ds^2 = -F^2 dx'^2 - r^2(d\theta^2 + sin^2\theta\, d\varphi^2)$. As we move along the x'–axis from $+\infty$ to $-\infty$, the value of r decreases to a minimum $2m$ at $x' = 0$ and then increases again as $x' \longrightarrow -\infty$. We can draw a cross–section of this manifold corresponding to the equatorial plane $\theta > \frac{\pi}{2}$, in which case (3) reduces further to $ds^2 = -(f^2 dx'^2 + r^2\, d\varphi^2)$.

In their joint paper (1935), Einstein and Rosen showed that implicit in the formalism of GTR is a curved–space structure that can join two distant regions of space–time through a tunnel–like curved spatial shortcut. The purpose of their paper was not to promote faster–than–light travel, but to attempt to explain fundamental particles like electrons as space–tunnels threaded by electric lines of force.

Kerr (1968) found an exact solution of Einstein equation describing a realistic dying star – a spinning black hole. Because of the conservation of angular momentum, as a star collapses under gravity it spins faster. A spinning star could collapse like a particle into an infinitely thin disc which would remain stable because of the intense centrifugal force pushing outwards, canceling the inward force of gravity. The astonishing feature of such a black hole was that if an object fell directly into the thin disc perpendicular to its axis it would not be crushed but instead be sucked completely through the Einstein–Rosen bridge to a parallel universe. However, it is not clear how safe it would be to enter the bridge or how stable the doorway would be. **Steven Hawking** and **Roger Penrose** have studied (1970) the effects of these strange Kerr black holes. They have found, for example, that the neck of the Einstein–Rosan bridge may actually bend around and come out somewhere else in the universe. Thus, if rockets are sent directly through the black hole, at right angles to the disc, they would not emerge on the other side of the black hole, but on the other side of the universe! In this sense, the bridge could serve as a convenient passageway to the other side of space.

Special Relativity only applies locally. Wormholes allow superluminal (faster–than–light) travel by ensuring that the speed of light is not exceeded locally at any time. While traveling through a wormhole, subluminal (slower–than–light) speeds are used. If two points are connected by a wormhole, the time taken to traverse it would be less the time it would take a light beam to make the journey if it took a path through space outside the wormhole. However, a light beam traveling through the wormhole would always beat the traveler.

However, it has never been proven that wormtails exist and there is no experimental evidence for them. They are currently more *science–fiction* than they are science fact. Indeed, they play pivotal roles in science–fiction where faster–then–light travel is possible though limited, allowing connection between regions that would be otherwise unreachable within conventional timelines.

Yet, one should always keep in mind that the wormhole idea came from Einstein Theory of General Relativity using a spacetime coordinate system on a highly curved space in the vicinity of a black hole (Schwarzschild geometry).

‘WORMHOLE’ TIMELINE (1915–1988)

1915 **Albert Einstein** created his General Theory of Relativity.

1916 **Karl Schwarzschild** produced the first exact solution of Einstein field equation for a non–rotating spherically symmetric small mass (star) in empty space. His solution exhibits two singularities: one at the mass’ center (origin, $r = 0$) and the other at the critical radius $r_s = \frac{2GM}{c^2}$. For many years this solution was thought to apply only to ordinary stars and the critical radius remained a mere mathematical curiosity in the minds of most theorists. In retrospect, Schwarzschild’s solution is now called ‘the Schwarzschild *black hole*’.

1916 **Ludwig Flam** (1885–1964, Austria) realized that Einstein’s equations allowed (via the Schwarzschild solution) a second solution, now known as a *white hole*[831] (a black hole running backwards in time just as a black hole swallows thing irretrievably, so a while hole spits them out).

1930 **Subrahmanyan Chandrasekhar** (1910–1995, USA) discovered the *Chandrasekhar limit* — the minimum mass above which a star will ultimately collapse into a neutron star or a black hole. The ensuing prediction of the inescapable collapse of massive stars lead eventually to accept the concept of black holes and their associated structures.

1935 **Albert Einstein** and **Nathan Rosen** (1909–1995, USA and Israel) used Schwarzschild black hole solution as a model for elementary particles (e.g., the electron). In this way, they thought, GTR could be used to explain the mysteries of the quantum world in the framework of a unified field theory. They started with the standard

[831] GTR is time–symmetric: it does not know about the second law of thermodynamics, and it does not know about which way cause and effect go. The white hole arises from the negative square root solution inside the horizon. The negative square root solution outside the horizon represents *another universe*.

black holes solution (Schwarzschild), which resemble a large vase with a long throat. They then cut the throat, and merged it with a another black hole solution that was flipped over (a white hole). This smooth configuration is free of the singularity at the origin and might act like an electron. This concoction is known as the *Einstein–Rosen bridge*.

While the Einstein–Rosen idea of representing an electron as a virtual black hole was not accepted, cosmologists today speculate that in theory the 'Einstein–Rosen bridge' can act as a "tunnel" in space–time between *two different universes* (inter–universe) or between two remote points in the same universe (intra–universe). These connecting passage are now called 'wormholes'.[832]

[832] The Kruskal metric does not have a direct physical meaning. The name "wormhole" comes from an analogy used to explain the phenomenon. If a worm is traveling over the skin of an apple, then the worm could take a shortcut to the opposite side of the apple's skin by burrowing through its center, rather than traveling the entire distance around, just as a wormhole traveler could take a shortcut to the opposite side of the universe through a topologically nontrivial tunnel.

In physics, a wormhole is a hypothetical topological feature of spacetime that is basically a 'shortcut' through space and time. Spacetime can be viewed as a 2D surface, and when 'folded' over, a wormhole bridge can be formed. A wormhole has at least two mouths which are connected to a single throat or tube. If the wormhole is traversable, matter can 'travel' from one mouth to the other by passing through the throat. While there is no observational evidence for wormholes, spacetimes-containing wormholes are known to be valid solutions in General Relativity.

The term wormhole was coined by the **John Wheeler** in 1957. However, the idea of wormholes was invented already in 1921 by the **Hermann Weyl** in connection with his analysis of mass in terms of electromagnetic field energy.

Intra-universe wormholes connect one location of a universe to another location of the same universe (in the same present time or unpresent). A wormhole should be able to connect distant locations in the universe by creating a shortcut through spacetime, allowing travel between them that is faster than it would take light to make the journey through normal space. Inter-universe wormholes connect one universe with another. This gives rise to the speculation that such wormholes could be used to travel from one parallel universe to another. A wormhole which connects (usually closed) universes is often called a *Schwarzschild wormhole*. Another application of a wormhole might be time travel. In that case, it is a shortcut from one point in space and time

The 'wormhole' joining the two separate universes is the 'Einstein–Rosen bridge'.

The Einstein–Rosen work was disturbing to many physicists of the time because such a 'tunnel' through space–time, could in principle allow the transmission of information faster then the speed of light in violation of one of the key postulates of Special Relativity.

1960 **Martin David Kruskal** (1925–2006, USA) invented *Kruskal Coordinates*, used in GTR to explain black holes and lay out their complete space–time structure. Since then, progress in the theory of black holes has been very rapid and they are presently accepted as real phenomena almost universally.

1962 **R.W. Fuller** and **J.A. Wheeler** has given a topological interpretation of the Einstein–Rosen metric and shown that the Einstein–Rosen bridge space–time structure was dynamically unstable in field–free space. They proved that if such a wormhole somehow opened, it would close up again before even a single photon could be transmitted through it, thereby preserving Einsteinian causality.

1963 **R. Kerr** found an exact solution of Einstein's equations describing a *spinning black hole*.

1988 **K.S. Thorne** and his associates suggested that traversable wormholes could exist and that exotic[833] forms of energy threaded through a wormhole might keep it open.

---

to another. In string theory, a wormhole has been envisioned to connect two D-branes, where the mouths are attached to the branes and are connected by a flux tube. Finally, wormholes are believed to be a part of spacetime foam. There are two main types of wormholes: *Lorentzian wormholes* and *Euclidean wormholes*. Lorentzian wormholes are mainly studied in General Relativity and semiclassical gravity, while Euclidean wormholes are studied in particle physics. Traversable wormholes are a special kind of Lorentzian wormholes which would allow a human to travel from one side of the wormhole to the other.

[833] Here "exotic" means that the stress energy must exceed the equivalent rest mass energy density: for a specific gravity of unity, the required stress is a little over 13×10^{15} psi!

They also concluded that what is needed is a field with *negative* equivalent mass density. This could be provided by employing the Casimir effect[834]. It remains, however, unclear whether such arrangements are physically feasible.

[834] Two identical, perfectly conducting spherical plates are placed one on each side of the throat. Each carries a homogeneous electric charge, so that they repel each other. According to the quantum–mechanical analysis of *Casimir*, the phenomenon of virtual particle pair–production causes the time–averaged energy density of the region between the plates to be *negative*.

Quantum Mechanics – Conceptual problems, Philosophical issues[835]

"I am convinced that quantum mechanics is not a final theory. I believe this because I have never encountered an interpretation of the present formulation of quantum mechanics that make sense to me. I have studied most of them in depth and thought hard about them, and in the end I still can't make real sense of quantum theory as it stands."

(Lee Smolin, 1997)

I. Introduction

Quantum Mechanics grew out of a series of anomalies in the picture of matter and light offered by Newtonian classical physics – in particular associated with blackbody radiation, the photo-electric effect, and the need to devise a model of the atom consistent with atomic spectra and the newly discovered subatomic particles.

Important aspects of Quantum Mechanics include its inherently statistical nature, at the heart of which lie the uncertainty and complementarity principles which sets limits on our knowledge of physical systems. Other key aspects are:

- *the ability of particles and systems to behave in two or more classically-contradictory ways (including e.g. "being in two places at the same time")*[836]*;*
- *a certain* irreducible disturbance *inflicted upon a system by observing it;*
- *very accurately reproducible values for certain observable dynamic variables (a curious counterpoint to the uncertainty principle); and*
- *high* correlations *between some observables that seem to (but do* not*) contradict their high* individual *randomness.*

The implications of the theory for the nature of reality have been and are much discussed. Most quantum theorists accept an intrinsic element of probability in the empirical predictions of fundamental physics; the need to see systems as wholes rather than merely dissecting them into their simplest components; and that not all of a quantum system's classical dynamical variables actually exist as numbers (even unknown *numbers!) except if, where and when they are actually measured.*

The empirical basis for the development and acceptance of quantum physics lies in such phenomena as blackbody radiation, the photoelectric effect, the specific heats of solids and the robustness and discreteness of the structure and the emission spectra of atoms and molecules, chemical reactions rates and energetics, condensed matter physics, and a host of other phenomena whose ranks swells yearly. All of these remain unexplainable in terms of classical physics.

In 1901, ***Max Planck*** *solved the blackbody problem by proposing that emitted or absorbed EM energy is quantized: it is released or taken up in discrete, not continuous, amounts. The quantization of light as 'photons' by* ***Albert Einstein*** *in 1905 explained the photoelectric effect, and the similar quantization of elastic waves as "phonons" allowed him to use a blackbody-like derivation to explain the specific heat of crystalline solids two years later. Furthermore, the particle/wave duality introduced into electromagnetic theory by this development — as well as the fact that photons move at the speed of light and are thus inherently relativistic — precipitated the discovery of both* non-relativistic quantum mechanics *and* relativistic quantum field theories.

[836] When an experiment is actually performed to *decide* the issue, though, it is resolved only at the price of destroying the original state and replacing it by a stochastic ensemble of new states.

In 1913 **Niels Bohr** *predicted the emission spectrum for hydrogen with a simple 'planetary' model of the atom in which the angular momentum of the orbiting electron, and thus the sizes and energies of its orbits, are quantized.*

In 1924, **Louis de Broglie** *attributed wave-like behavior to material particles and showed how this can lead to Bohr's quantization conditions. Based on this idea,* **Erwin Schrödinger** *developed the wave equation which has proved to be foundational for quantum mechanics;* **Werner Heisenberg** *formulated the uncertainty principle (and an alternative, but mathematically equivalent formulation to that of Schrödinger); and* **Wolfgang Pauli** *discovered the exclusion principle. The empirical discovery and theoretical understanding of the* spin *concept (***Stern***,* **Gerlach***,* **Goudsmit***,* **Uhlenbeck***,* **Dirac***,* **Landé** *and others) extended quantum mechanics to internal (non-spacetime) degrees of freedom.*

By the end of the 1920's (nonrelativistic) quantum mechanics was basically complete, and the 1930's and 1940's saw the development of Quantum Electrodynamics (QED) – the first, and most successful, relativistic QFT (Quantum Field Theory).

Still, almost a century later, major conceptual problems in interpreting quantum mechanics stubbornly persist:

- *The Schrödinger wave propagates continuously in time but 'collapses' discontinuously (in a process not described by the Schrödinger equation) when a few-particle quantum system interacts with a classical (i.e. mesoscopic or macroscopic) system (often called 'the* measurement problem*');*

- *The Schrödinger equation describes the propagation of the wave function, but this is a complex variable; itself not directly measurable, whose squared modulus represents statistical information about the quantum system potentially obtained via interactions of a whole ensemble of identical quantum systems with a measuring device;*

- *A composite quantum system displays a holistic character entirely unlike classical composite systems: once interacting, now vastly separated, particles continue to act in some ways as though they remained part of a single system — a feature underscored by the "EPR" paradox in the 1930s and* Bell's theorem *in the 1960s and now referred to as "quantum entanglement";*

- *'Chance' in quantum mechanics (i.e., quantum uncertainty and quantum statistics) works in strikingly different ways from classical chance. It actually gives rise, in a 'bottom-up' way, to the basic features of the* *classical world, including the robustness of atoms, the periodic table, and other properties of matter, chemistry, optics, and life.*

II. Historical Timeline of Quantum Mechanics 1925–1989

1926 *While Shrödinger's equation for the quantum wave function serves admirably as a vehicle by which to predict the outcome of laboratory experiments, the wave function itself has defied all attempts to give it an interpretation in terms of physically observable entities in a single (as opposed to an ensemble of copies of a) quantum system. It remains today as much of an ontological mystery as it was the day Schrödinger first wrote his equation.*

In fact, Schrödinger himself became so exasperated with Niels Bohr's persistent attempts to get him to admit that his wave function had no physical interpretation that he once blurted out, "I am sorry I ever started to work on atomic theory" — strong words from the man who in 1933 was awarded the Nobel Prize in Physics for "new insights into atomic theory."

1930 *Bohr's Copenhagen Interpretation (CHI).*

Probably the biggest mystery of the quantum world unveiled by ***Schrödinger***, ***Bohr***, ***Heisenberg***, ***Born***, ***Wigner*** *and others in the 1920s is what we now call the quantum measurement problem.*

The values of attributes (position, momentum and spin) of quantum objects such as photons, electrons, atoms, etc. are all arguments of the Schrödinger wave function. But until a measurement of one of these attributes is actually made, the wave function describes merely the likelihoods of the possible outcomes of such a measurement. Once a measurement is actually taken, of course, the range of potential outcomes of the corresponding attribute is replaced by a single outcome, which we term the result of the measurement.[837]

[837] *Other* attributes may remain "fuzzy", and even the just-measured attribute becomes progressively more fuzzy (uncertain) after the measurement.

The problem here is that prior to the measurement, the wave function exists as a kind of mathematical wave of probability. Yet as soon as we make an observation, this wave "collapses" to a single point with respect to the measured attribute – the outcome of the measurement. The essence of the measurement problem is to ask how this collapse comes about and what it actually means in physical terms. In short, what's so special about the act of a measurement?

The CHI makes a distinction between the observer and the observed; when no one is watching, a system evolves deterministically according to the Schrödinger wave-equation (though its classical attributes are fuzzy, correlated *via classically-impossible quantum statistics, and do not usually enjoy objective existence as numbers — even as* unknown *numbers). When, however, someone*[838] *is observing, the complex waveform (state) of the system "collapses" to an ensemble of other, observed states, which is why the act of observing changes the system. In this way the observer is accorded a* special status, *not given to any other object in quantum theory.*

Quantum mechanics can be interpreted philosophically in a variety of conflicting ways, and so far we know of no experimental basis for choosing definitively between them. These include ontological indeterminism *(**Heisenberg**),* ontological determinism *(**Einstein**, **David Bohm**),* many worlds *(**Everett**), or as involving* consciousness *(**von Neumann**, **Eugene Wigner**, **Roger Penrose**).*

All of these interpretations challenge classical-physics ontology, with its core concepts of waves, particles and locality, as well as a critical realist philosophy of nature.

The Copenhagen Interpretation cannot explain the observer itself, but it is now generally agreed that any large enough (mesoscopic or macroscopic) sample of matter, while obeying its own (vastly complicated) Schrödinger equation, interacts with a few-particle (nanoscopic or sub-atomic) quantum system as would the "ideal observer" of the Copenhagen Interpretation.

---

[838] The "observer" need not be sentient, or even a recording device. Any classically-describable (i.e. many-mody) body which interacts with the "observed" quantum system and is irreversibly affected by this interaction, qualifies as an observer.

_1935_ *The EPR Paradox:* **Einstein** *and his colleagues claimed to have demonstrated the existence of* hidden variables *(fundamental elements of reality) which quantum theory fails to take into account, thus showing that the theory is* incomplete.

At the basis of EPR is the notion that if two systems are in isolation from each other for some time, then a measurement on the first can produce no real instantaneous change *of the second (no causal influence travels faster than light). This is Einstein's '*locality principle*' (separateness).*

Bohr*'s reply to this was that 'locality' was not allowed, i.e. quantum mechanics does not permit an ontological separation between the observer and the observed, even after they have separated. They are parts of a* single system. *In other words, Bohr's claim was that the EPR thought experiment does not demonstrate the incompleteness of quantum theory, but rather the naiveté of assuming* local *conditions in atomic systems. Once connected ("entangled"), atomic systems never separate.*

_1952–1966_ ***David Bohm*** *(1917–1992, USA) developed a* hidden variable[839] *interpretation of quantum mechanics which works just as well as the CHI, but gives a completely different view of quantum theory. According to his view, particles always have well-defined positions and velocities, but any attempt to measure these properties will destroy information about them by altering the* pilot wave *associated with the particles. Thus, measuring the position of an electron will immediately alter the shape of the pilot wave everywhere, affecting the future behavior of the electron.*

Bohm further developed the idea that everything is connected to everything else, and affected instantaneously by everything that happens to everything else, through the pilot-wave.

In later developments of his idea, Bohm proposed that the basic underlying order of the world consists of a field made up of an infinite number of overlapping waves, and that the overlapping of waves produces local effects which we perceive as particles. These ideas are strongly reminiscent of ***Feynman****'s*

---

[839] *Hidden variables*: A hidden level of deterministic dynamics as opposed to genuinely intrinsic uncertainty. In recent years a number of key experiments have been performed to test this point. They have confirmed that uncertainty is indeed inherent in quantum systems.

sum-over-histories ("path integrals") approach to quantum mechanics[840].

1957 **Hugh Everett III** *(1930–1982, USA) developed his 'many-worlds' interpretation (MWI), which is a daring proposal to reconcile the continuity of the Schrödinger equation with the discontinuity of the quantum measurements process.*

According to this interpretation, whenever multiple viable possibilities exist for the results of the measurement of a particular attribute — whether the set of possibilities is finite, discrete-infinite or continuum-infinite in its size — the world – and in particular the measured and measuring systems – splits into a multiplicity of worlds, one world for each different possibility (in this context, the term "worlds" refers to what most people call "universes"). In each of these worlds, everything is identical, except they each have a distinct outcome of the measurement of the attribute in question. Note that the entangled quantum wavefunction of both observed and observing system split individually, although their combined ("holistic") wavefunction continues to evolve continuously, in accordance with its Schrödinger equations.

From the moment a given split occurs, the branch universes – at least for ideal measurements – develop independently, and no communication is possible between them, so the people

---

[840] The formulation of quantum mechanics developed by **Feynman** in terms of path integrals builds on the familiar Lagrangian concept of the action of a trajectory in space and time and appears to be much closer to classical concepts than the Schrödinger or Heisenberg formulations. In Feynman's formulation, the *probability amplitude* of any quantum-mechanical process can be represented as a coherent superposition of contributions of all possible spatio-temporal paths that connect the initial and the final state of the system. The weight of each path is a complex number whose phase is equal to the classical action along the path, divided by Planck's constant. Even though this approach turned out to be very useful in quantum mechanics and almost indispensable in quantum field theory, it is nevertheless difficult to work with except in certain approximations — due to mathematical and computational difficulties with the quantum version of the *Wiener measure* (in path-space) which underlies path integrals.

Instead of saying that '*the photon*' travels by every possible route to a mirror and then up to the observer to make a reflected image, **Bohm** says that 'the pilot-wave' travels by every possible route, and then 'tells' the photon which path to actually follow.

living in those worlds (and splitting along with them) may have no idea that this is going on.

An advantage of the MWI is that it does away with the need for either an intelligent observer or a measuring device 'outside the system' to collapse wave functions and make reality real; indeed, the wave function of an observer (be it sentient or mechanical) is entangled (continuously and in accordance with the overall Schrödinger equation) with that of the observed system, and their mutual entanglement appears *to the observer as a collapse of the observed* system's *wavefunction — and with the same probability distribution of the measurement outcome as predicted by CHI (i.e., the squared modulus of the relevant Hilbert-space projection of the observed system's wavefunction).*

The MWI consists of two parts:

i. *A mathematical theory which yields evolution in time of the quantum state of the (single) universe.*
ii. *A prescription which sets up a correspondence between the quantum state of the universe and our (sense-perception and instrumental) experiences.*

Part (i) is essentially summarized by the Schrödinger equation. It is a rigorous mathematical theory and is not problematic philosophically although in practice it is always necessary to make various approximations — due to the immense number of quantum degrees of freedom of any realistic measuring device. Part (ii) involves, for any realistic case, a detailed quantum-thermodynamical treatment of the irreversible measurement process.

Everett demonstrated that observations in each world obey all the usual conventional statistical laws predicted by the probabilistic Born interpretation, by showing that the Hilbert space's inner product (and corresponding norm) has a special property which allows us to makes statements about the worlds where quantum statistics break down. The norm of the vector of the subset of entangled worlds where experiments contradict the Born interpretation ("non-random" or "maverick" worlds) provides a measure of these worlds which vanishes in the limit as the number of probabilistic trials goes to infinity, as is required by the definition of probability.

Thus we, as observers, are overwhelmingly likely to observe the familiar, probabilistic predictions of quantum theory to hold. Everett-worlds, where the Copenhagen Interpretation of probability rules breaks down, are never realized — or rather, *are as likely to be realized as a tepid glass of teas is likely to spontaneously re-heat at the expense of the ambient air's thermal fluctuations!*

From the MWI viewpoint, the universe is like a tree that branches and re-branches into myriads of new sub-branches with every passing zeptosecond (zepto $= 10^{-21}$*), and each of these new branch universes has a*

slightly different sub-atomic "history". Because an observer happens to have followed one particular path through the diverging branches of this universe-tree, he never perceives the splitting. Instead he interprets the resolution of the myriad of possibilities into one particular outcome as a Copenhagen-style collapse. But the observer plays no active role in the splitting. Events at the quantum level, of course, must lead to consequences in the every-day world, and one set of such consequences happens to be the irreducible quantum randomness of the sequence of empirical measurements recorded by our brains and instruments.

It seems that the majority of the opponents of the MWI reject it because, for them, introducing a very large number of worlds that we do not see is an extreme violation of Ockham's principle: "Entities are not to be multiplied beyond necessity".

However, in judging physical theories one could reasonably argue that one should not multiply physical laws beyond necessity either (such versions of Ockham's Razor has been applied in the past), and in this respect the MWI is the most economical theory (since it avoids wavefunction collapse as a separately-posited process). Indeed, it has all the laws of the standard quantum theory, but without the collapse postulate.

It is commonly thought that Many-Worlds is an un-falsifiable — and hence unprovable hypothesis, experimentally indistinguishable from the Copenhagen Interpretation.

1964–1966 **John S. Bell** *(1928–1990, Ireland). Developed an ingenious inequality principle* to test the questions raised by the EPR *paradox. The Bell inequality sets an upper limit upon the statistical correlations of certain observable pairs, each pair measured upon two quantum-entangled systems, instantaneously, and once they are too far to classically interact.*

To derive his inequality, Bell used certain facts and ideas on which everyone could agree, except for Einstein's condition of locality, which he assumed to be true.[841]

Now, if experiments showed the inequality was violated, this would mean that one of the premises in his derivation was false. Bell chose to interpret this to mean that nature is non-local if experiments would (as they did, starting in the 1980's) show the inequality to be violated; but his theorem also allows the alternate interpretation, according to which a set of attributes (dynamical variables) of a quantum system does not always even exist as numbers in case they are not measured. (This implies a violation of classical physical reality.)

The problem of the nature of locality, raised by EPR, clearly demanded some form of empirical investigation. To bring it into a form suitable for testing involves a modest degree of reformulation. The basic principles are threefold:

1. *Reality: Regularity of phenomena is due to an underlying physical reality. This requires that regularity should be the touchstone for telling reality from illusion.*
2. *Locality. This is what we are particularly keen to probe. In accord with STR it states that any influence of A upon B must not propagate between them faster than the velocity of light.*
3. *Induction: It is possible to reach conclusions valid for all systems of a given type from a consistent set of observations on a large sample of systems of that type.*

   Whatever may be the logical difficulties of a principle of induction, as a methodological strategy it is essential for science. Since we can never investigate all protons (say), any general statement about them whatsoever must depend upon a principle of this sort.

Note that the empirical violation of Bell's inequality imply that if one insists upon 1 and 3, quantum mechanical experiments produce results that are inconsistent with classical notions of causality.

[841] A position with which **Bohm** et al. would disagree.

1983 ***Alain Aspect*** *and his collaborators in Paris, obtained experimental verification of the* violation *of Bell's Inequality. This could be interpreted to mean that in spite of the local appearances of phenomena, the fabric of our world is actually supported by an invisible "infrastructure" of quantum reality which is unmediated and allows communication faster than light, even instantaneously. However, such communication is not necessarily capable of being used to* send information *or otherwise* effect causation *faster than light-speed, and communications of the latter two types can be proven to be* impossible *in mathematically consistent relativistic Quantum Field Theories*[842]*. No physical experiment to date – despite occasional claims to the contrary, which are based on misconceptions – has succeeded in configuring any causation at super-luminal (faster than light) speeds.*

1989 ***Steven Weinberg*** *suggested an experiment that would conclude whether or not there is a nonlinear term in the Schrödinger equation; the experiment was performed, and stringent upper bounds on the magnitude of such a term were thence deduced.*

1935–1939 CE **Gerti Theresa Cori, nee Radnitz** (1896–1957, U.S.A.) and **Carl Ferdinand Cori** (1896–1984, U.S.A.). Biochemists. A Prague-born American man-and-wife team. Studied *carbohydrate metabolism* and discovered (1936) how cells use and convert food into energy — a process now called the *Cori cycle*. Shared the Nobel prize in physiology or medicine (1947) with **B.A. Houssay**.

Gerti Radnitz was born in Prague to Jewish parents. She entered the Medical School of the German University of Prague and received her M.D. in 1920. Carl Cori was also born in Prague. His father — Dr. Carl Cori, was director of the Marine Biological Station in Trieste. His grandfather, Ferdinand Lippioh was a professor of Theoretical Physics at Prague. Carl

[842] Many physicists ask themselves: can we live with the preposterous concept of *action-at-a-distance* — even if only *correlation*, not information transfer or event causation, are involved?

met Gerti when they studied medicine together. He also got his M.D. in 1920 and married Gerti in the same year.

The couple emigrated to the U.S. (1922). They were on the staff of N.Y. State Institute for Study of Malignant Diseases (1922–1931), and then on the faculty of Washington University (1931–1957).

They discovered (1936) a *phosphated* form of glucose, known as the *Cori ester*; discovered (1938) the enzyme *phosphorylase*, and synthesized glycogen (1939). Their most important discovery was that glycogen in the body is not *hydrolyzed* (breaking the chemical bond by the addition of the elements of water), but is instead broken down by the use of phosphoric acid (*phosphorolysis*)

1935–1945 CE **Konrad Zuse** (1910–1995, Germany). Mechanical and civil engineer. Pioneer digital computer builder, who worked with electromechanical relay machines (having no *electronic* components). Because of his war-time isolation and his own reluctance to publish his work he was, for a long time, largely unknown.

Thus, his early machines had essentially no influence on the field although they included, in an elementary way, many of the features of modern computers. Throughout his life he received little understanding and support from the German government, industry, or academia. Not until 1960 (when it finally became clear to German leaders in the field that computing machinery was important) was he recognized as Germany's chief claim to fame in the modern history of computing.

Zuse was born in Berlin-Wilmersdorf to the family of a Prussian civil servant. He entered (1927) the Technical College in Berlin-Charlotterburg, majoring in both mechanical and civil engineering (1935).

During 1935–1938 he built two successive machines. The first, Z1, had the size of a large dining-room table, including metal sheets, glass plates, crank arms, gear-wheels and a program-cylinder — the first program-controlled computing machine. The second, Z2, was built with electromagnetic relays. In working with these machines, Zuse was able to develop and test in both theory and practice the basic laws of switching techniques, and his concepts of the design of a computer. During WWII he was developing remote-controlled flying bombs.

His first machine that really worked, the Z3, was completed in 1941. It was based on 2064 relays, used a 22-bit word and was controlled via an

8-track punched-celluloid film tape[843]. *Input* was through a keyboard and *output* was displayed on a lamp strip including a binary point. Its speed was approximately 3 sec for multiplication, division, or taking the square root of a number. The machine was demonstrated but never put into continuous operation. It was destroyed in a 1944 air raid. Zuse reconstructed it in 1960.

In his book *Calculating Space* (1969), Zuse proposed that the physical laws of the universe are discrete by nature, and that the entire universe is just an output of a giant deterministic *cellular automaton*.

1935–1948 CE **Frits** (**Frederik**) **Zernike** (1888–1966, Holland). Physicist. Invented the method of *phase contrast* and applied it in the optical *phase-contrast microscope*. The method is used to render visible a *transparent* object whose index of refraction differs slightly from that of a surrounding transparent medium. Phase contrast is particularly useful in microscopy for examination of living organisms; sections of biological materials examined under an optical microscope are often almost, or totally, transparent[844].

---

843 The same ideas were occurring at the same time to other pioneers who were making similar plans and inventions, e.g. **H.H. Aiken** (1937–1944 USA), **Stibitz** (1940) and **Atanasoff** (1942, USA).

844 Because they do not absorb any of the indecent light. An object can be "seen" because it stands out from its surroundings — it has a color, tone, or lack of color which provides contrast with the background. This kind of structure is known as an *amplitude object* because it is observable by dint of variations which it causes in the amplitude of light waves. The wave which is either reflected or transmitted by such an object becomes *amplitude* modulated in the process. In contradistinction, it is often desirable to "see" *phase objects*, i.e., ones which are transparent, thereby providing practically no contrast with their environs and altering only the phase of the detected wave. The *optical thickness* of such objects generally varies from point to point (periodically or otherwise) as either the *refractive index* or the actual thickness, or both, vary.

As such materials have almost no effect on the amplitude on the light that passes through them, and since the eye (or any similar observing instrument) only distinguishes changes in intensity, such objects are invisible. (Strictly speaking, *some* details of the phase structure are always seen due to the finite size of the aperture. These can even be enhanced by a slight defocusing of the instrument.)

This is the problem which led biologists to develop techniques for *staining* transparent microscope specimens, thereby converting phase objects into amplitude objects. But this approach is unsatisfactory in many respects as, for example, when the stain kills the specimen whose life processes are under study, as is all too often the case.

A direct method for distinguishing between regions of different optical thickness (and therefore different biological compositions) is by *phase contrast microscopy*, for which Zernike was awarded the Nobel prize for physics in 1953:

The phase contrast microscope changes the phase between the light waves passing through the specimen and those not passing through it. This action turns phase objects into amplitude objects. Consequently some parts of the specimen appear brighter and the other parts darker than normal. Thus, the parts of a transparent object that vary in thickness or have different refractive index (or both), can be seen.

Zernike was born in Amsterdam. During 1915–1920 he was assistant astronomer at the University of Groningen, and afterwards a professor of physics there.

In 1938, Zernike gave a significant augmentation of the theory of *partial coherence* for quasi-monochromatic fields.

Theoretically, the phase-contrast method is a special case of *Abbe's theory* of image formation in paraxial optical systems. According to Abbe, the object acts as a diffraction grating, so that not only every element of the *aperture of the objective*, but also every element of the *object* must be taken into account in determining the complex disturbance at any particular point in the *image plane*.

Expressed mathematically, the transition from object to image involves two *Fraunhofer-type integrations*. The first over the area A of the object plane (x, y) covered by the object:

$$U(\xi, \eta) = C_1 \iint_A F(x, y) e^{-ik\left[\frac{\xi}{f}x + \frac{\eta}{f}y\right]}\, dx\, dy,$$

where F is the given transmission function of the object, U is the diffraction pattern over the back focal plane of the objective, f is the distance of this focal plane from the objective lens, and C_1 is a constant. Every point in the focal plane may be considered to be a center of a coherent secondary disturbance, whose strength is proportional to the amplitude at that point. The light waves that proceed from these secondary points will then interfere with each other and will give rise to the image $V(x', y')$ of the object in the image plane of the objective, whose typical coordinates are (x', y'). The image is given by the double Fourier integral

$$V(x', y') = C_2 \iint_B U(\xi, \eta) e^{-ik\left[\frac{x'}{D'}\xi + \frac{y'}{D'}\eta\right]}\, d\xi\, d\eta.$$

Here B is the object's aperture in the focal plane, while D' is the distance between the focal and image planes. The approximation

$$F(x, y) = e^{i\Phi(x,y)} = 1 + i\Phi(x, y) + O[\Phi^2]$$

leads to $U = U_0 + U_1$, where $U_0 = C_1 \iint_A e^{-\frac{ik}{f}(\xi x+\eta y)} dxdy$ represents the light distribution that would be obtained in the focal plane if no object were present, whilst $U_1 = C_1 \iint_A (F-1) e^{-\frac{ik}{f}(\xi x+\eta y)} dxdy$ represents the effect of *diffraction* (i.e. the interaction of the light with the object under study).

Now, the *direct light* U_0 corresponds to the central order of diffraction, and will be concentrated only in a small region B_0 in the focal plane around the axial point $\xi = \eta = 0$. On the other hand, a very small fraction of the diffracted light will, in general, reach this region, most of it being diffracted to other parts of the plane.

Suppose that the region B_0 (through which the *direct light passes*) is covered by a *phase plate* (a thin transparent material by means of which the *direct wave* is retarded or advanced by one quarter of a period relative to the diffracted spectra). The effect of this plate may be described by a transmission function $h = ae^{i\alpha}$, where $a = 1$ for a non-absorbing plate and $a < 1$ for an absorbing plate. Consequently, the new form of U will be $U'(\xi, \eta) = hU_0(\xi, \eta) + U_1(\xi, \eta)$ and $V(x', y') = V_0(x', y') + V_1(x', y')$ where

$$V_0 = hC_2 \iint_B U_0(\xi, \eta) e^{-\frac{ik}{D'}(x'\xi + y'\eta)} d\xi d\eta,$$

and

$$V_1 = C_2 \iint_B U_1(\xi, \eta) e^{-\frac{ik}{D'}(x'\xi + y'\eta)} d\xi d\eta.$$

Now, the aperture B greatly exceeds in size the region B_0, and U_0 is practically zero outside B_0. Thus both V_0 and V_1 may be given infinite integration limits, with $U_0 = 4\pi^2 C_1 \delta\left(\frac{k}{f}\xi\right)\delta\left(\frac{k}{f}\eta\right)$. Therefore $V_0 = Ch$; $V_1 = C\left[F\left(\frac{x'}{M}, \frac{y'}{M}\right) - 1\right]$ on the strength of the Fourier integral theorem, with $C = C_1 C_2 f^2 \frac{4\pi^2}{k^2}$. Finally, since $\frac{f}{D'} = -\frac{1}{M}$ (M = magnification between object plane and image plane) we find $V_1 = C\left[F(x, y) - 1\right]$. Inserting $F(x, y) - 1 \approx i\Phi(x, y)$, it follows that the intensity in the image plane is given by

$$I(x', y') = |V|^2 \approx |Ch + V_1|^2 \sim |C|^2 \left[a^2 + 2a\Phi(x, y)\sin\alpha\right].$$

For a phase plate $\alpha = \pm\frac{\pi}{2}$, and hence $I(x', y') = |C|^2\left[a^2 \pm 2a\Phi(x, y)\right]$. The intensity changes are directly proportional to the phase variations of the object. With a plate that absorbs a fraction a^2 of the direct light, the ratio of the second term to the first term has the value $\pm\frac{2\Phi}{a}$, so that the contrast of the image is enhanced.

In general, when the *phase of the central order is retarded* w.r.t. the diffraction wave, regions of the object which have greater optical thickness will appear brighter than the mean illumination. When the phase of the central order is advanced, regions of greater optical thickness will appear darker.

Optical Coherence[845] *(1865–1938)*

Light from a real physical source is never strictly monochromatic, since even the sharpest spectral line has a finite width. Moreover, a physical source is not a point source, but has a finite extension consisting of many elementary radiators (atoms); because of the quantized nature of the radiation process, light is emitted via electron transitions in the form of individual photons, which for our present purpose can be represented by finite wave trains.

Moreover, since the atoms are in random thermal motion, the frequency spectrum will be broadened by the Doppler effect. In addition, the atoms suffer collisions, which interrupt the wave trains and again tend to broaden the frequency distribution. The total effect of all of these mechanisms is that each spectral line has a bandwidth $\Delta\nu$ *rather than one single frequency. The temporal extent of the pulse is of the order* $\Delta t \sim \frac{1}{\Delta\nu}$ *and is referred to as the coherence time. The associated length* $\Delta x = c\Delta t$ *is the coherence length*[846].

In an ideal monochromatic wave field the amplitude of the vibration at any point is constant, while the phase varies linearly with time. A real source can

- Beran, M.J. and G.B. Parrent, Jr., *Theory of Partial Coherence*, Prentice-Hall, 1964, 193 pp.

[846] *White light* has a frequency range from 0.4×10^{15} Hz to about 0.7×10^{15} Hz, that is, a bandwidth of about 0.3×10^{15} Hz. The coherence time is then roughly 3×10^{-15} sec, while the coherence length is 9×10^{-5} cm — a spatial extent only a few wavelengths long.

be visualized in the time domain as being composed of wave packets, bearing random phase relation to each other. In general, the Fourier spectrum of a single packet will differ from that of the light beam composed on N wave packets, because in the latter the amplitude and phase undergo irregular fluctuations. If, however, we restrict the time interval of the observed pulse to be small compared to the reciprocal of the effective width of the spectrum (i.e. the coherence time), then, within such a time interval the amplitudes of the spectral components will remain substantially constant; in this time interval the light behaves like a monochromatic wave with the mean frequency. This will happen whenever the source is quasi-monochromatic, i.e. if the bandwidth is small compared to the mean frequency. In effect, the coherence time is loosely the temporal interval over which we can reasonably predict the phase of the light wave at a given point in space.

The same characterization can be viewed somewhat differently. Imagine that we have two separate field points P_1 and P_2 to which light arrives from a quasi-monochromatic point source. If the coherence length $\Delta x = c\Delta t$ is much larger than the longitudinal separation between the points, the disturbances at P_1 and P_2 will be highly correlated. On the other hand, if this longitudinal separation were very much greater than the coherence length, many wave trains, each with an unrelated phase, would span the gap between P_1 and P_2. In that case, the disturbance at the two points in space would be independent at any given time. The degree to which a correlation exists is sometimes spoken of alternatively as the amount of longitudinal coherence. Whether we think in terms of coherence time (Δt) or coherence length $(c\Delta t)$, the effect still arises from the finite bandwidth of the source.

The idea of spatial coherence is most often used to describe effects arising from the finite extent of ordinary light sources.

The theory of optical interference is based on the principle of linear superposition of electromagnetic vector fields. According to this principle, the electric field $\boldsymbol{E}$ produced at a point in empty space jointly by several different sources is equal to the vector sum $\boldsymbol{E} = \boldsymbol{E}_{(1)} + \boldsymbol{E}_{(2)} + \boldsymbol{E}_{(3)} + \cdots$, where $\boldsymbol{E}_{(j)}$ are the fields produced at the point in question separately by the different sources. The same is true for magnetic fields. Consider the monochromatic, linearly polarized plane waves with corresponding fields $\boldsymbol{E}_{(1)} = \boldsymbol{E}_1 e^{i(\boldsymbol{k}_1\cdot\boldsymbol{r}-\omega t+\varphi_1)}$, $\boldsymbol{E}_{(2)} = \boldsymbol{E}_2 e^{i(\boldsymbol{k}_2\cdot\boldsymbol{r}-\omega t+\varphi_2)}$ etc. Here the quantities φ_1 and φ_2 have been introduced to allow for any phase differences between the sources of the two waves, so that $\boldsymbol{E}_j$ are real.

If the phase difference $\varphi_1 - \varphi_2$ is constant, the two sources are said to be mutually coherent. The intensity of radiation at a point between two sources is proportional to the square of the amplitude of the light field at the point *in question. Therefore, the intensity of the interference pattern between two sources is proportional to*

$$I = |\boldsymbol{E}|^2 = \boldsymbol{E}\cdot\boldsymbol{E}^* = (\boldsymbol{E}_{(1)} + \boldsymbol{E}_{(2)})\cdot(\boldsymbol{E}^*_{(1)} + \boldsymbol{E}^*_{(2)})$$

$$= |\boldsymbol{E}_1|^2 + |\boldsymbol{E}_2|^2 + 2\boldsymbol{E}_1\cdot\boldsymbol{E}_2\cos\theta = I_1 + I_2 + 2\boldsymbol{E}_1\cdot\boldsymbol{E}_2\cos\theta;$$

$$\theta = \boldsymbol{k}_1\cdot\boldsymbol{r} - \boldsymbol{k}_2\cdot\boldsymbol{r} + \varphi_1 - \varphi_2.$$

Since θ depends on $\boldsymbol{r}$, periodic spatial variations in intensity occur. These variations are the familiar interference fringes that can be seen when two mutually coherent beams of light are combined. If the sources of the two waves are mutually incoherent, then the quantity $\varphi_1 - \varphi_2$ varies with time in a random fashion. The result is that the mean value of $\cos\theta$ is zero, and there is no interference. (This will also happen if the polarizations are mutually orthogonal, i.e. $\boldsymbol{E}_1\cdot\boldsymbol{E}_2 = 0$.)

The classical experiment that demonstrates interference of light from a point source was first performed by **Thomas Young** *in 1802. In his 2-slit experiment $\theta \simeq -\frac{kyh}{x}$, where h = slit separation, x = slit-screen distance, and y = coordinate of a point on the far screen. If $|\boldsymbol{E}_1|^2 = |\boldsymbol{E}_2|^2 = I_0$, we shall have $I = 2I_0\left[1+\cos\left(\frac{kyh}{x}\right)\right]$ with bright fringes maxima at $y = 0, \lambda\frac{x}{h}, 2\lambda\frac{x}{h}, \cdots$ where $\lambda = \frac{2\pi}{k}$ = wavelength.*

In order to adequately describe a wave field produced by a finite polychromatic source, it is desirable to introduce some measure for the correlation that exists between the vibrations at different points in the field. We must expect such a measure to be closely related to the sharpness of the interference fringes which would result on combining the vibrations from the two points. We expect sharp fringes when the correlation is high (e.g. when light arrives at two separate field points from a very small source of narrow spectral range), and no fringes at all in the absence of correlation.

We describe these situations by the terms coherent and incoherent respectively. In general, neither of these situations is realized and we may speak of vibrations which are partially coherent. In this case, the amplitudes and phases usually vary with time such that the instantaneous light intensity at a given point fluctuates rapidly. It would then seem meaningful, to define the intensity as a time average.

In the case of two fields $\boldsymbol{E}_1$ and $\boldsymbol{E}_2$, the intensity I can accordingly be expressed as

$$I = \langle\boldsymbol{E}\cdot\boldsymbol{E}^*\rangle = \langle(\boldsymbol{E}_1 + \boldsymbol{E}_2)\cdot(\boldsymbol{E}^*_1 + \boldsymbol{E}^*_2)\rangle = \langle|\boldsymbol{E}_1|^2 + |\boldsymbol{E}_2|^2 + 2Re(\boldsymbol{E}_1\cdot\boldsymbol{E}^*_2)\rangle.$$

The angular brackets denote the time average $\langle f \rangle = \lim_{T\to\infty} \frac{1}{2T}\int_{-T}^{T} f(t)dt$*. It will be assumed that all quantities are* stationary *(time average is independent of the origin of time). Also, for convenience, the optical fields will be assumed to have the same polarization so that their vectorial nature can be ignored. Then* $I = I_1 + I_2 + 2\text{Re}\langle E_1 E_2^* \rangle$, *where* $I_1 = \langle |E_1|^2 \rangle$, $I_2 = \langle |E_2|^2 \rangle$.

Consider the general problem of coherence at some given field-point between waves from two source-points $\boldsymbol{x}_1$ *and* $\boldsymbol{x}_2$ *emitted at different times. Then, define the* mutual coherence function *(Zernike, 1938)*

$$\Gamma_{12}(\tau) = \Gamma_{12}(\boldsymbol{x}_1, \boldsymbol{x}_2, \tau) = \langle E_1(\boldsymbol{x}_1, t) \cdot E_2^*(\boldsymbol{x}_2, t+\tau) \rangle,$$

where E_1 *is the optical disturbance at the point* $\boldsymbol{x}_1$, E_2 *the optical disturbance at the point* $\boldsymbol{x}_2$, *and* $\tau = t_2 - t_1$ *is given by* $\Delta\ell/c$ *(where* $\Delta\ell$ *is the optical path difference between the two beams and* c *is the speed of light in vacuum).*

A special case of interest arises when Young's experiment is repeated with a partially coherent source (say, quasi-monochromatic with a spectral width $\Delta\nu$ *that is very small compared to the mean frequency* ν*, and also such that* $\Delta x \ll c/\Delta\nu$*). In this case one can consider two fields arriving from the same point* $\boldsymbol{x}_1 = \boldsymbol{x}_2$*) over different optical paths, which makes* E_1 *different from* E_2.

Defining the self-coherence *functions*

$$\Gamma_{11}(\tau) = \langle E_1(\boldsymbol{x}_1, t) \cdot E_1^*(\boldsymbol{x}_1, t+\tau) \rangle,$$

$$\Gamma_{22}(\tau) = \langle E_2(\boldsymbol{x}_1, t) \cdot E_2^*(\boldsymbol{x}_1, t+\tau) \rangle$$

as the complex autocorrelation of the fields due to the two beams, we find $\Gamma_{11}(0) = I_1$, $\Gamma_{22}(0) = I_2$. *Therefore,*

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\text{Re}\{\gamma_{12}(\tau)\}$$

where

$$\gamma_{12}(\tau) = \frac{\Gamma_{12}(\tau)}{\{\Gamma_{11}(0)\Gamma_{22}(0)\}^{1/2}}$$

is known as the complex degree of coherence *(in general, an approximately periodic function of* τ*). In terms of* $|\gamma_{12}(\tau)|$, *we have the following types of coherence:* $|\gamma_{12}| = 1$, *complete coherence;* $|\gamma_{12}| = 0$, *complete incoherence;* $0 < |\gamma_{12}| < 1$, *partial coherence (by the Cauchy–Schwarz inequality we always must have* $0 \le |\gamma_{12}| \le 1$*).*

Michelson *(1890) introduced the concept of* visibility *of the interference fringes — defined as the ratio*

$$\mathcal{V} = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}.$$

In terms of the degree of coherence it is equal to $\frac{2\sqrt{I_1 I_2}}{I_1+I_2}|\gamma_{12}|$. *In particular, if* $I_1 = I_2$, *then* $\mathcal{V} = |\gamma_{12}|$, *i.e., the fringe visibility is equal to the degree of coherence, and the latter is then simply measurable.*

For the Young experiment, one can specify the analytic form of the fields E_1 *and* E_2 *as:* $E_1 = K_1 V_1\left(t - \frac{r_1}{c}\right)$, $E_2 = K_2 V_2\left(t - \frac{r_2}{c}\right)$, *where* K_1 *and* K_2 *depend on the size of the slits and* r_1 *and* r_2 *are the respective distances from slits* S_1 *and* S_2 *to the field-point* P, *and* $V_1(t)$, $V_2(t)$ *are* stationary *random functions which describe the light oscillations at* S_1 *and* S_2 *respectively. Using the previous definitions, the intensity at* P *is given by*

$$I(P) = \left\langle\left|K_1 V_1\left(t - \frac{r_1}{c}\right) + K_2 V_2\left(t - \frac{r_2}{c}\right)\right|^2\right\rangle = I_1 + I_2 + 2\sqrt{I_1 I_2}|\gamma_{12}|\cos\Phi_{12},$$

where

$$\Phi_{12} = \arg\left[\Gamma_{12}(0)\right] + \frac{2\pi}{\lambda}(r_1 - r_2).$$

Because of the stationarity condition; γ_{12} *depends only on* $\tau = \frac{r_1}{c} - \frac{r_2}{c}$ *and not on* $\frac{r_1}{c}$ *and* $\frac{r_2}{c}$ *explicitly.*

Also, since only quasi-monochromatic light is being considered, the experiment is restricted to small path differences $r_1 - r_2 \ll \frac{c}{\Delta\nu}$.

When Young's experiment is performed with very narrow-bandwidth extended sources, spatial coherence *effects will predominate. The optical disturbances at the slits* S_1 *and* S_2 *will differ, and the fringe pattern will depend on* $\Gamma_{12}(0)$. *By examining the region about the central fringe where* $r_1 = r_2$, $\gamma_{12}(0)$ *can be determined. In this case, spatial coherence results primarily from* angular source size considerations. *Thus,* $\Gamma_{12}(0)$ *plays a central role in the measurement of stellar diameters. On the other hand,* $\Gamma_{11}(\tau)$ *is a measure of* temporal coherence.

The first investigations which had a close bearing on the subject of partial coherence appear to be due to ***Emile Verdet*** *(1865 to 1869), who demonstrated that the light from 2 pinholes in a screen illuminated by the sun will interfere in Young's experiment if the separation of the pinholes is less than about* $\frac{1}{20}$ *mm.* ***Laue*** *(1907) gave a quantitative measure for partial coherence. Theoretical interest in this subject lay dormant until it was revived in the* 1930*'s by* ***P.H. van Cittert*** *(1934, 1939) and* ***Zernike*** *(1938).*

These authors determined the theoretical complex degree of coherence $\gamma_{12}(P_1, P_2; \tau = 0)$ *for two points* P_1 *and* P_2 *on a planar screen illuminated by an* extended *quasi-monochromatic primary source, having the shape of a portion of a plane* σ *parallel to the screen. Assuming that the medium between the source and the screen is homogeneous, that the linear dimensions of* σ *are small compared to the source-screen distance, and that the angular* *dimensions of the source as seen from any point on the screen are small, it is found that*

$$\gamma_{12}(P_1, P_2; \tau = 0) = \frac{1}{\sqrt{I(P_1)I(P_2)}} \int_\sigma I(S) \frac{e^{i\overline{k}(r_1 - r_2)}}{r_1 r_2} dS,$$

where

$$I(P_1) = \int_\sigma \frac{I(S)}{r_1^2} dS, \quad I(P_2) = \int_\sigma \frac{I(S)}{r_2^2} dS.$$

Here $\overline{k}$ is the average wave-number in the medium, $I(S)$ is the intensity flux per unit area (flux) of the source, and r_1, r_2 are the respective distances between a typical source point S and the points P_1 and P_2 on the screen. The above result also incorporate the assumption that the coherence time from all point sources is larger than the time difference for all paths between the source and the points of observation.

It can be shown that γ_{12} is the spectral amplitude diffraction-pattern at P_1 (centered on P_2) when we replace the source by a diffraction aperture in an opaque screen of the same size and shape as the source (Huygens-Fresnel diffraction).

This result is known as the van Cittert-Zernike theorem[847]*. Establishing a coordinate system $O(\xi, \eta)$ at the source S, and a parallel one $O'(x, y)$ on the screen, the above integral can be reduced to the form*

$$\gamma_{12} \approx \frac{\iint_\sigma I(\xi, \eta) e^{-i\overline{k}(p\xi + q\eta)} d\xi d\eta}{\iint_\sigma I(\xi, \eta) d\xi d\eta} e^{i\Psi},$$

where

$$p = \frac{x_1 - x_2}{r}, \quad q = \frac{y_1 - y_2}{r}, \quad \Psi \simeq \overline{k}(OP_1 - OP_2);$$

$$r = OO'; \quad P_1 = (x_1, y_1); \quad P_2 = (x_2, y_2).$$

For a uniform circular source of diameter d, we find $\gamma_{12} \approx \frac{2J_1(v)}{v} e^{i\Psi}$, J_1 being the Bessel function of the first kind and first order, and $v = \frac{\pi}{\lambda} \frac{d}{r} \overline{P_1 P_2}$.

---

[847] Apart from its theoretical significance, the theorem is particularly important from a computational point of view because the coherence calculation is normally more difficult than the calculation of the corresponding diffraction pattern. Note that the theorem ties up two Fourier transform pairs, namely, the *coherence-intensity pair* (visibility-brightness) to the *diffraction pattern-aperture pair*.

The function $\left|\frac{2J_1(v)}{v}\right|$ *decreases steadily from the value of unity when* $v = 0$ *to the value zero when* $v = 3.83$*; thus, as the points* P_1 *and* P_2 *are separated more and more, the degree of coherence steadily decreases and there is a complete incoherence when* P_1 *and* P_2 *are separated by the distance* $\overline{P_1P_2} = 1.21\ \frac{\lambda}{(d/r)}$. *For the sun* $\frac{d}{r} \sim 0\,^\circ 32' \sim 0.009$ *radian, and consequently* $\overline{P_1P_2} = 0.06$ *mm, as found by* ***Verdet*** *(1869) for* $\lambda = 5500$ *Å.*

1935–1952 CE **Alan Mathison Turing**[848] (1912–1954, England). Mathematician and logician. One of the founders of modern automata theory, computer logic and artificial intelligence.

During 1935–1937, Turing developed theories for an idealized computing device which can be considered as the theoretical prototype of present day digital computers (known today as a *Turing machine*). His specifications were:

(1) The machine has a *finite*, discrete set of different internal states.

(2) The input data is not restricted in size, i.e. no limit is placed on the amount of information that the machine can process.

(3) The calculational procedure (algorithm) is the same *finite* set of instructions no matter how big the data stream.

(4) The machine must be allowed to call upon an unlimited external storage space for its calculations[849]. [The question of whether the storage space be regarded as internal or external is just a technicality. The internal part could be the *hardware* and the external part the *software*.]

(5) The device 'reads' a *tape* with marks on it. These marks comprise a linear sequence of squares. Each square is either blank or a single mark (say, the symbols '1' and '0'). The machine reads one square at a time,

849 The marvels of modern computer technology have provided us with electronic storage devices which can be treated as unlimited for most practical purposes.

and after each operation moves just one square to the right or left (as determined by the algorithm).

(6) The device could also place new marks on the tape where required and could obliterate old ones. The tape will keep running back and forth through the device so long as further calculations need to be performed. When the calculation is finally completed, the device comes to a halt and the answer to the calculation is displayed on that part of the tape which lies to one side of the device.

Problems that could be solved by the machine, were called by Turing '*computable*'.

In 1936 Turing solved Hilbert's 23^d problem by showing that there is no unique way to prove or disprove all logical statements.

In 1952 Turing originated the mathematical theory of *morphogenesis*, the development of pattern and form in living organisms. The main goal was to show how a uniform and symmetric structure could evolve, through a combination of diffusion and chemical reaction, into a strongly asymmetrical structure with a definite pattern. Though this work was left unfinished, it is a major contribution to mathematical biology. Through his equations[850], Turing introduced the concept of *diffusion-driven instability* (known today as *Turing instability*). He showed that the presence of diffusion induces small spatial perturbations into a uniform-mixture steady state. It is this instability that eventually determines how the pattern or mode are selected. His work, however, went unnoticed by the embryologists and chemists of his time.

In 1953, Turing suggested a new method for the determination of the number of zeros of the Riemann zeta function in a given range.

Alan Turing was born in London, the son of a British member of the Indian Civil Service who was away from his children during most of their childhood. Turing was educated at King's College, Cambridge. He completed his Ph.D. at Princeton University (1938). During WWII he played a significant role in breaking the German "Ultra" codes.

In 1945 he joined the staff of the National Physical Laboratory to lead the design, construction, and use of a large electronic digital computer that was named the Automatic Computing Engine (ACE). In 1948 he became deputy director of the Computing Laboratory at the University of Manchester, where the Manchester Automatic Digital Machine (MADAM, as referred to by the press), the computer with the largest memory capacity in the world at that

time, was being built. *His efforts in the construction of early computers and the development of early programming techniques were of prime importance.*

He also championed the belief that computers could be constructed that would be capable of thought, and even proposed that machine thought could more closely resemble human thought if a random element could be introduced. Turing's papers on this subject are widely acknowledged as the foundation of research in artificial intelligence.

Turing was arrested for violation of British homosexuality statutes in 1952. He died of potassium cyanide poisoning while conducting electrolysis experiments. An inquest concluded that it was self-administered but it is now thought by some to have been an accident.

Chemical Patterns, Clocks and Waves[851]

"Has it a clock? Or is it a clock?"

Collin S. Pittendrigh (1957)

Nonlinear systems, that is, systems governed by a set of nonlinear equations (algebraic, functional, ordinary differential, partial differential, integral, stochastic or a combination of these) are used to describe a great variety of phenomena, in the social and life sciences, as well as the physical sciences and engineering. The theory of nonlinear systems has applications to problems of economics, population growth, ecosystems, the propagation of genes, the physiology of nerves, the regulation of heart-beats, chemical reactions, phase

[851] For further reading, see:

transitions, elastic buckling, the onset of turbulence, celestial mechanics, earth sciences, electronic circuits and many other phenomena.

Nonlinear system display certain characteristics that differ radically from those of linear systems. One finds, in particular, that as a parameter changes slowly a solution may change either slowly and continuously or abruptly and discontinuously. In many applications of the theory of nonlinear systems we are interested in enduring rather than transient phenomena, and so in steady states. Thus, steady solutions *of the governing equations are of special importance.*

Of these steady solutions, only the stable *ones, (i.e., those which, when slightly disturbed, are little changed afterwards), correspond to states which persist in practice, and so are usually the only ones observable. It follows that a state may change abruptly not only if it ceases to exist but also if it becomes unstable as parameters change.*

Another general phenomenon associated with nonlinearity is that as a result of an instability, a small cause may have a large effect *— in the sense that a small disturbance at a given instant may grow and become significant, to the extent that after a long time the behavior of the system depends substantially on the nature of the disturbance, however small it was.*

For example, a spherical pendulum with the bob finely balanced directly above its point of suspension, may be destabilized by a gentle breath on it; further, the direction and timing of the ensuing motion of the pendulum depend strongly on the very small disturbance of the unstable position of equilibrium[852]*.*

A bifurcation *occurs where the solutions of a nonlinear system change their qualitative character as a parameter changes. In particular, bifurcation theory is about how the number of steady solutions of a system depends on parameters. The theory of bifurcations, therefore, concerns all nonlinear systems and thus has a great variety of applications. Bifurcations of a nonlinear system and the onset of instability of a solution usually occur at the same critical value of a parameter governing the system.*

The word bifurcation *was coined by* ***J.H. Poincaré*** *(1885). In the study of self-gravitating spinning fluids (relevant to planetary formation) he found that a sequence of pear-shaped figures of equilibrium branches off the sequence of* Jacobi ellipsoids*, just as Jacobi ellipsoids branch off the* Maclaurin spheroids*. However, the significance of bifurcations first came to be recognized in the*

852 **E.N. Lorenz** described this in a metaphor in which an unstable prairie atmospheric condition might be triggered by the flutter of the wings of a butterfly in a distant jungle, and thereby a devastating tornado might arise.

18^{th} *century. The work of* **L. Euler** *(1744) on the equilibrium and buckling of an elastic column under load, and the work of* **J. le Rond d'Alembert** *(1747) on the figures of equilibrium of a rotating mass of self-gravitating fluid, are the foundations of bifurcation theory.*

The ideas of bifurcation theory arose slowly and imperceptibly at first, being almost as old as algebra itself. At the simplest, we may view the quadratic equation $x^2 - a = 0$ *as an example. If we examine the real solutions of this equation as a* function of the parameter a *(real), we find that there are two for* $a > 0$, *one for* $a = 0$ *and none for* $a < 0$. *This situation can be visualized by a drawing of a parabola in the* (x, a) *plane (*bifurcation diagram*). The point* $a = 0$ *is a* bifurcation point*, since there the qualitative character of the solutions change (in this case, the* number *of solutions).*

A less trivial example is the ODE $\frac{dx}{dt} = a - x^2$, *where the* number *and* character *of the solutions depend critically both on* a *and on the initial value* $x(0) = x_0$.

If we define an equilibrium point *(or* steady-state point*) as that point in the* (a, x_0) *plane for which* $x(t)$ *is time-independent, then these points lie on the parabola* $x^2 = a$. *The branch* $x = +\sqrt{a}$, $a > 0$ *corresponds to* stable *solutions, while the branch* $x = -\sqrt{a}$, $a > 0$ *consists of unstable solutions. The point* $(0, 0)$ *is* unstable*. It is obvious from the explicit expression*

$$x(t) = \begin{cases} \frac{x_0 + \sqrt{a}\tanh(t\sqrt{a})}{1 + x_0\tanh(t\sqrt{a})/\sqrt{a}} & , \quad a > 0 \\ \frac{x_0}{1 + x_0 t} & , \quad a = 0 \\ \frac{x_0 - \sqrt{-a}\tan(t\sqrt{-a})}{1 + x_0\tan(t\sqrt{-a})/\sqrt{-a}}, & \quad a < 0 \end{cases}$$

that the solution may become infinite after a finite time, and the value of t *at the singularity will depend on* x_0 *as well as on* a. *The point* $(0, 0)$ *is a* bifurcation*, since the number of steady solutions and their character changes as* a *increases through zero.*

The previous equation can be generalized into the form $\frac{dx}{dt} = F(x)$. *In the case where the variable* x *represents a position, the latter equation may be considered as an appropriate expression of the second law of dynamics in the presence of very high damping. Similar equations are often encountered in the thermodynamics of irreversible processes and in this case the term* $F(x)$ *is often called a 'generalized force'.*

If an explicit form of the potential function $V(x)$ *can be found such that* $F(x) = -\frac{dV}{dx}$, *then the stability can be determined from the sign of* $\frac{d^2V}{dx^2}$. *For example,* $F(x) = -Kx - K_1x^3$ $(K_1 > 0)$ *corresponds to the potential* $V(x) = \frac{K}{2}x^2 + \frac{K_1}{4}x^4$. *If* $K > 0$, *the origin* $x = 0$ *will be a point of stable* *equilibrium. If, however* $K < 0$, *the origin will be unstable, and two new stable points will be located at* $x_0^{(1,2)} = \pm\sqrt{\frac{|K|}{K_1}}$. *Clearly, there is a bifurcation at* $K = 0$ *of the single stable solution into two stable and one unstable solutions.*

*An important branching of a time-periodic solution from a steady state is known as a Hopf bifurcation (**E. Hopf**, 1942). For example, the system* $\dot{x} = -y + (a - x^2 - y^2)x$, $\dot{y} = x + (a - x^2 - y^2)y$, *is stable at its steady-state solution* $x = 0$, $y = 0$ *provided* $a < 0$. *The exact solution of this system is*

$$r^2(t) = \begin{cases} \frac{ar_0^2}{r_0^2 + (a - r_0^2)e^{-2at}}, & a \neq 0 \\ \frac{r_0^2}{1 + 2r_0^2 t} \quad , & a = 0 \end{cases}$$

where $x + iy = re^{i\theta}$, $\theta = \theta_0 + t$, *and* $r = r_0$, $\theta = \theta_0$ *at* $t = 0$. *The solution is written as* $x(t) = r(t)\cos(t + \theta_0)$, $y(t) = r(t)\sin(t + \theta_0)$. *For* $a \leq 0$, *all solutions vanish as* $t \to \infty$. *However, for* $a > 0$ *the origin becomes an unstable focus while a new stable periodic solution* $x = \sqrt{a}\cos(t + \theta_0)$, $y = \sqrt{a}\sin(t + \theta_0)$ *arises as a increases through zero. Such a solution is called a limit cycle, because it is a periodic solution approached by other solutions in the limit as* $t \to \infty$. *It is represented by a closed curve, in this case the circle* $x^2 + y^2 = a$, *in the phase plane of the orbits. Thus, the periodic solutions bifurcate from the null solution as a increases through zero.*

Suppose that $\ddot{x} = f(x, \lambda)$, *represents the equation of motion of a unit mass under the influence of a force* f, *where* x *is the displacement of the particle and* λ *is a parameter. Equilibrium points of the mass are given by* $f(x, \lambda) = 0$. *If there exists a function* $V(x, \lambda)$ *such that* $F(x, \lambda) = -\frac{\partial V}{\partial x}$ *for each value of* λ, *then* $V(x, \lambda)$ *is the potential energy of the system and equilibrium points correspond to stationary values of the potential energy.*

We expect a minimum of the potential to correspond to a stable equilibrium point, and other stationary values (the maximum and points of inflexion) to be unstable. In fact, V *is a minimum at* $x = x_1$ *if* $\frac{\partial V}{\partial x}$ *changes from negative to positive on increasing through* x_1; *this implies that* $f(x, \lambda)$ *changes sign from positive to negative as* x *increases through* $x = x_1$. *Hence the curve* $f(x, \lambda) = 0$ *in the* (λ, x) *plane is the locus of all equilibrium points.*

Suppose we shade the entire domain in which $f(x, \lambda) > 0$. *If a segment of the curve has shading below it, the corresponding equilibrium points are stable, since for fixed* λ, f *changes from positive to negative as* x *increases. Bifurcation points mark transition from stable to unstable points on* $f(x, \lambda) = 0$. *As* λ *varies through such points, the equilibrium point may split into two or more equilibrium points, or several equilibrium points may merge into a single one.*

Bifurcation points are therefore diagnostic of the dynamic behavior of a parameter-dependent system in which both the number and stability of equilibrium points may vary with the parameter(s).

Bifurcation is often associated with what is called symmetry breaking. A symmetry of a nonlinear system manifests itself as invariance of the set of all solutions under some group of transformations, but it does not necessarily follow that each solution is itself invariant. Symmetry is broken at a bifurcation if all solutions are symmetric where a parameter is greater (or less) than a critical value but some are asymmetric when the parameter is less (or greater) than that value.

Also, oscillations occur in many applications, so periodic solutions and their stability are important too. Further, unsteady solutions may occur which are seemingly random functions of time with stationary statistical properties; these are chaotic solutions or, more precisely, strange attractors. A chaotic solution also may be stable in the sense that it persists even (with changed detailed behavior but unchanged statistical properties) when the solution is perturbed slightly at some time.

The observed patterns and ordered structures of living organisms have long been a puzzle to biologists and were crying out for an explanation based on the physicochemical laws of nature.

A nonlinear partial differential equation of major importance in modern theoretical biology and nonequilibrium thermodynamics is the reaction-diffusion equation. The equation of conservation of matter for the flux of material $\boldsymbol{J}$*, concentration* c *and sources* f*, reads*

$$\frac{\partial c}{\partial t} + \operatorname{div} \boldsymbol{J} = f(c, \boldsymbol{r}, t).$$

Substituting $\boldsymbol{J} = -D \operatorname{grad} c$ *(Fick's law), we find an equation for* $c(\boldsymbol{r}, t)$*:*

$$\frac{\partial c}{\partial t} = f + D\nabla^2 c$$

for fixed diffusivity D*. This equation is referred to as the reaction-diffusion equation.*

Such a mechanism was proposed as a model for the chemical basis of morphogenesis by Turing (1952), and has been widely studied since 1970*. Examples for its application will be discussed next. They involve the complex behavior of those chemical systems exhibiting self-organization phenomena, such as the formation of stationary spatial structures or periodic oscillatory states.*

• *Spatial pattern formation*. *Morphological order is the most conspicuous attribute of living species. Leaves, branches, skin, hair, legs, all appear with a well-defined order and relationship with respect to each other. Moreover, this morphological order and its sequential unfolding in space and time is engraved in the tiny seeds and minute fertilized eggs.*

Whatever pattern one chooses to focus on in the animal or plant worlds, it is almost certain that the process that produced it is unknown. Although the mechanism must be genetically controlled, the genes themselves cannot create the pattern. They only provide a blueprint, or recipe, for the pattern generation. The problem is then to discover how genetic information is physically translated into the necessary pattern and form as manifested in the phenotype.

H.A.E. Driesch *(1867–1941, Germany), a biologist and philosopher, proposed (1895) that morphogenesis (the birth of forms) is the consequence of the onset of various gradients of unspecified nature in the developing embryo. In order to substantiate these ideas,* ***Turing*** *(1952) suggested that during stages in the development of an organism, chemical constituents generate a* prepattern *that is later interpreted as a signal for cellular differentiation. In other words, cells are pre-programmed to react to chemical concentration so that the cell can read out its position in the coordinates of chemical concentration and differentiate, undergo appropriate cell shape change, or migrate accordingly. Such chemical substances have been called* morphogens.

According to Turing, the prepattern *is generated through the processes of reaction and diffusion such as to produce a steady state heterogeneous spatial patterns.*

Consider two chemicals with the respective concentrations $C_1(\boldsymbol{r}, t)$ *and* $C_2(\boldsymbol{r}, t)$. *Let* $R_1(C_1, C_2)$ *be the generally nonlinear rate of production of* C_1, $R_2(C_1, C_2)$ *the rate of production of* C_2, *and* $\{D_1, D_2\}$ *the respective diffusion coefficients of the chemicals.*

The governing system of equations is then of the form

$$\frac{\partial C_1}{\partial t} = R_1(C_1, C_2) + D_1\nabla^2 C_1,$$

$$\frac{\partial C_2}{\partial t} = R_2(C_1, C_2) + D_2\nabla^2 C_2.$$

Turing explained why this system is expected to form spatial patterns: If in the absence of diffusion $(D_1 = D_2 = 0)$ C_1 *and* C_2 *tend to a stable uniform steady state* $\left(\frac{\partial C_1}{\partial t} = \frac{\partial C_2}{\partial t} = \nabla C_1 = \nabla C_2 = 0\right)$, *then this equilibrium may be disturbed by the addition of the diffusion terms, provided* $D_1 \neq D_2$ *and certain other conditions hold. This instability,* driven by diffusion, *is precisely the cause of the formation of the spatial patterns.*

To see intuitively how this pattern is formed due to diffusion, it is sufficient to consider the one-dimensional case and with the simplest form of R_1 *and* R_2*, namely* $R_1 = aC_1 + bC_2, \quad R_2 = cC_1 + dC_2;$ *i.e.,*

$$\frac{\partial C_1}{\partial t} = aC_1 + bC_2 + D_1\frac{\partial^2 C_1}{\partial x^2},$$

$$\frac{\partial C_2}{\partial t} = cC_1 + dC_2 + D_2\frac{\partial^2 C_2}{\partial x^2}.$$

Assume small deviations from equilibrium: $C_1 = C_{10} + U, \quad C_2 = C_{20} + V$*. Clearly, if at time* $t = 0$*,* $U = V = 0$ *for all values of* x*, then* U *and* V *will continue to be zero. If this equilibrium is disturbed, then for most values of the constants* $\{a, b, c, d, D_1, D_2\}$ *equilibrium will be restored and* $\{U, V\}$ *will tend to zero everywhere as* t *increases. Consequently, no spatial pattern will emerge.*

Surprisingly, however, there are values of the constants for which the homogeneous equilibrium is unstable: Let $a > 0$*,* $c > 0$*,* $b < 0$*, and* $D_2 > D_1$*. These inequalities will guarantee the following traits: if the concentration* U *rises above its equilibrium level, the rate of synthesis of both* U *and* V *will rise; if the concentration of* V *rises, it leads to destruction of* U*;* V *diffuses faster than* U*.*

Suppose now that the homogeneous equilibrium is disturbed by a small local rise *in* U*. This will lead to further rises in both* U *and* V*, but* V *has diffused out further. At those new regions where* V *has penetrated, but* U *hasn't yet,* C_1*, will be reduced and fall below its equilibrium value* ($U < 0$)*. This in turn will lead to destruction of morphogen* V*, so that a 'trough' will developed on either side of the initial peak.*

These troughs will cause the developments of further peaks, and so on until a standing wave *has developed, whose 'chemical wave-length' will depend on the values of the constants defining the rates of reaction and diffusion. The morphogen* C_1 *is known as* activator*, while* C_2 *is the* inhibitor*. A reaction-diffusion system thus exhibits diffusion-driven instability or* Turing instability *if the homogeneous steady state is stable to small perturbations in the absence of diffusion but unstable to small* spatially varying *perturbations when diffusion is present. A particular pattern will depend on the analytical form of* $R_1(C_1, C_2)$ *and* $R_2(C_1, C_2)$*.*

For the case of boundary conditions enforcing spatial periodicity with period $\Delta x = 1$*, Turing gave an explicit general solution to the one-dimensional* *linear PDE set* ((X_0, Y_0) *are concentrations at uniform equilibrium);*

$$\frac{\partial X}{\partial t} = a(X - X_0) + b(Y - Y_0) + M_x \frac{\partial^2 X}{\partial x^2},$$
$$\frac{\partial Y}{\partial t} = c(X - X_0) + d(Y - Y_0) + M_y \frac{\partial^2 Y}{\partial x^2},$$

in the form of an infinite Fourier-series

$$X(x,t) = X_0 + \sum_{n=-\infty}^{\infty} (A_n e^{p_n t} + B_n e^{p'_n t}) e^{inx},$$
$$Y(x,t) = Y_0 + \sum_{n=-\infty}^{\infty} (C_n e^{p_n t} + D_n e^{p'_n t}) e^{inx}$$

where $\{p_n, p'_n\}$ *are the roots of the quadratic*

$$(p - a + M_x n^2)(p - d + M_y n^2) = bc$$

and

$$A_n(p_n - a + M_x n^2) = bC_n,$$
$$B_n(p'_n - a + M_x n^2) = bD_n.$$

The Fourier coefficients can be considered as the spectral amplitudes of the standing wave pattern, and depend on the six parameters $\{a, b, c, d, M_x, M_y\}$.

• *Chemical clocks. In* 350 *BCE an officer in the army of Alexander the Great noted that the leaves of certain plants were open during daytime and closed at night. Until the* 1700*'s such rhythms were viewed as passive responses to a periodic environment, i.e., the succession of light and dark cycles due to the natural day length. In* 1729*, the astronomer* ***Jean Jacques d'Ortous de Mairan*** *(1678–1771, France) conducted experiments with a plant and reported that its periodic behavior persisted in a total absence of light cues. Although his results were disputed at first, further demonstrations and experiments by the botanist* ***Wilhelm Friedrich Philipp Pfeffer*** *(1845–1920, Germany), during* 1875–1915*, gave clear evidence in support of the observations that many physiological rhythms are endogenous (independent of any external environmental influences).*

We now know that most organisms have innate 'clocks' that govern peaks of activity: seasonal periodicities of plants, heart-beat of animals and circadian rhythms (periodic phenomena which appear with a period of approximately one day), and menstrual cycles are familiar manifestations of temporal *organization in nature. These large-scale rhythmic behaviors require the co-operation of a great many cells.*

In the last decades of the 19^{th} *century, a mathematical formalism for the description of* self-organized states *was developed for the study of planetary motion by* ***J.H. Poincaré*** *(1881 to 1889);* ***A.M. Lyapunov*** *(1892 to 1906), and* ***I. Bendixon***[853] *(1901). Concurrently, interest grew in the study of non-linear differential equations that originated in the fields of engineering and the applied sciences [****G. Duffing*** *(1918),* ***B. van der Pol*** *(1922),* ***V. Volterra*** *(1926)].*

Until the beginning of the 20^{th} *century, all laboratory chemical reactions were performed in closed systems: Various reactants were combined in a vessel, forming a closed thermodynamic system, in such proportions as to keep the reaction* initially *very far from equilibrium. In such conditions the quantity of the new-formed products increased gradually until the mass action law is satisfied at an* equilibrium state*. However, in* 1916 ***T.H. Morgan****, while experimenting with a reaction medium that contained hydrogen peroxide, formic acid, and sulfuric acid, observed a* periodic *release of carbon monoxide.*

Earlier (1910), ***A.J. Lotka*** *suggested a theoretical reaction which exhibits damped oscillations. Indeed,* ***W.C. Bray*** *(1921) discovered decaying oscillations in the concentrations of iodine in a hydrogen peroxide – iodate ion (*IO_3^-*) reaction. This interesting and important work was dismissed and widely disbelieved since, among other criticisms, it was mistakenly thought to violate the second law of thermodynamics.*

Thus, these few 'abnormal' oscillating chemical reactions went almost unnoticed by most chemists until the 1960*'s, when a few oscillatory biochemical processes were discovered that operate on the cellular level. For example, the synthesis of some proteins by cells follows an oscillatory pattern.*

The development by ***Prigogine*** *(1947) of the thermodynamics of far-from-equilibrium processes was a great leap forward in our understanding of biological systems. It showed that thermodynamic methods can predict the onset of spatio-temporal order in an open chemical system. Moreover, such systems must necessarily evolve according to nonlinear kinetics, and therefore must be described by nonlinear coupled partial differential equations of the type that produces* limit cycles*.*

Therefore, the fact that a great number of chemical processes in living organisms produce the observed spatio-temporal order is in complete accord with the macroscopic laws of nonequilibrium thermodynamics.

---

[853] **Ivar Otto Bendixon** (1861–1935, Sweden). Mathematician. His important memoir (1901) supplemented some of Poincaré earlier work.

The fact that predator-prey type equations hold for certain autocatalytic chemical reactions, leads to the conclusion that chemical 'clocks' must exist. However, in the Lotke-Volterra model, the period of oscillation is a function of the initial prey and predator populations, and therefore essentially arbitrary (because it is amplitude dependent). The oscillation frequency of any clock worthy of the name, must be independent *of the externally determined initial conditions and is, rather, self-determined by the intrinsic characteristics of the system itself.*

The initial conditions may only influence the behavior of the system during the transient which precedes the establishment of the oscillating state. Periodic oscillations, when they correspond to a limit cycle *behavior, may be considered as* self-organization *phenomena.*

One mathematical model of reactions which exhibited an oscillatory behavior corresponding to a limit cycle is the so-called Brusselator *(Prigogine and Lefever, 1968). This trimolecular model is the most widely known theoretical model of chemical instability phenomena, although it does not represent a actual chemical reaction. It corresponds to the scheme of reaction in four steps:*

$$\overline{A}\xrightarrow{k_1}\overline{X},\qquad \overline{B}+\overline{X}\xrightarrow{k_2}\overline{Y}+\overline{D},\qquad 2\overline{X}+\overline{Y}\xrightarrow{k_3}3\overline{X},\qquad \overline{X}\xrightarrow{k_4}\overline{E},$$

where the k's are rate constants.

The concentrations of the initial and final products ($\overline{A}$, $\overline{B}$, $\overline{D}$ and $\overline{E}$) are kept constant, whereas the two components $\overline{X}$ and $\overline{Y}$ have concentrations that change with time, and also have different observable properties (e.g., colors). Since $\overline{A}+\overline{B}\to\overline{D}+\overline{E}$ in the complete process, $\overline{X}$ and $\overline{Y}$ have the role of intermediates. Their only function is that of mediating the conversion of the reagents $\overline{A}$ and $\overline{B}$ into the products $\overline{D}$ and $\overline{E}$ without undergoing any permanent transformation at the end of the reaction cycle.

Note that the third step is a trimolecular autocatalytic step which is necessary for oscillatory behavior. In the above scheme, the reverse reactions were ignored because the conditions of irreversibility are realized by holding the concentrations of $\overline{A}$, $\overline{B}$, $\overline{D}$, $\overline{E}$ far from their equilibrium values.

The reaction-diffusion equations corresponding to the above scheme are (t being ordinary time)

$$\frac{\partial\overline{X}}{\partial\bar{t}}=\overline{D}_1\nabla^2\overline{X}+\left\{k_1\overline{A}-(k_2\overline{B}+k_4)\overline{X}+k_3\overline{X}^2\overline{Y}\right\},$$

$$\frac{\partial\overline{Y}}{\partial\bar{t}}=\overline{D}_2\nabla^2\overline{Y}+\{k_2\overline{B}\,\overline{X}-k_3\overline{X}^2\overline{Y}\}.$$

With the scalings $t = k_4\bar{t}$, $X = \sqrt{\frac{k_3}{k_4}}\overline{X}$, $Y = \sqrt{\frac{k_3}{k_4}}\overline{Y}$, $B = \frac{k_2}{k_4}\overline{B}$, $A = \frac{k_1}{k_4}\sqrt{\frac{k_3}{k_4}}\overline{A}$ $D_1 = \frac{1}{k_4}\overline{D}_1$, $D_2 = \frac{1}{k_4}\overline{D}_2$, *the reaction-diffusion equations acquires the nondimensional form*

$$\frac{\partial X}{\partial t} = \left\{A - (B+1)X + X^2Y\right\} + D_1\nabla^2 X,$$
$$\frac{\partial Y}{\partial t} = \{BX - X^2Y\} + D_2\nabla^2 Y.$$

These equations are first investigated without the diffusion terms ('well-stirred' Brusselator). It is then found that the system has only one stationary state at $X_0 = A$, $Y_0 = \frac{B}{A}$. *This steady state becomes unstable (via a Hopf bifurcation) for* $B > 1 + A^2$, *provided that B remains fairly close to* $1 + A^2$. *Thus, for* $A = 1$, $B = 2$, *the equilibrium point* $\left(A, \frac{B}{A}\right)$ *is stable. However, as soon as B is increased to 2.2 it is seen that this point is unstable, a limit cycle appears, and a chemical oscillation develops.*

As B is further increased to the value 3, the limit cycle is still present although its form has changed. The period of the Brusselator in the vicinity of the bifurcation $(B \approx 1 + A^2)$ *is* $\frac{2\pi}{A}$.

In the presence of one-dimensional diffusion (unstirred Brusselator), in the x direction say, it can be shown that instability may arise in different ways: In addition to the above Hopf bifurcation there is the possibility of a Turing bifurcation in which a pattern of a standing wave arises. Finally, the limit cycle may also be space dependent and lead to a traveling concentration wave $\Big[B \geq 1 + A^2 + (D_1 + D_2)\pi^2\frac{m^2}{L^2}$ *where m is an integer and L is the length of the system*$\Big]$.

As a chemical clock (absent diffusion), the Brusselator mimics the experimentally observed chemical oscillations in a somewhat more complicated system, found by **B.P. Belousov** *and* **A.M. Zhabotinsky** *(1958, 1964). Their system shows a spectacular oscillatory change of colors from red to blue. Since chemical reactions are at the foundations of biological events, this model may offer also an understanding of the action of biological clocks (such as the control mechanism of the heart).*

Indeed, a biochemical clock which seems to behave like a limit cycle oscillator occurs in glycolysis and is readily studied in yeast cells. The question of whether these and other rhythms, such as opening and closing of plants, are limit cycles or harmonic oscillations has not been resolved yet.

• *Chemotaxis: The diffusion-reaction equation is also adequate to model natural phenomena of chemical signaling that occurs on all levels of the living world (insects, animals, leukocyte cells, single-cell amoebae, etc.). The chemically directed motion of cells up the gradient of concentration of a chemical is known as chemotaxis. For example, a large number of insects and animals rely on an acute sense of smell for conveying information between members of the species. When a bacterial infection invades the body it may be attacked by movement of cells toward the source as a result of chemotaxis.*

Let $n(\boldsymbol{r},t)$ *be the concentration of the moving cells, and* $a(\boldsymbol{r},t)$ *the concentration of an attractant chemical which gives rise to the cell motion up its gradient. We start from the conservation equation for* $n(\boldsymbol{r},t)$, *namely* $\frac{\partial n}{\partial t} + div\boldsymbol{J} = f(n)$, *where* $f(n)$ *represents the growth term for the cells, and* $\boldsymbol{J} = D\,\mathrm{grad}\,n + n\chi(a)\,\mathrm{grad}\,a$ *is the total flux of the cells: it has the ordinary diffusion contribution* $\{D\,\mathrm{grad}\,n\}$, *plus the extra chemotactic flux due to the presence of the attracting chemical that increases with the number of cells, with the gradient of the chemical attractant concentration and with a factor* $\chi(a)$ *that is a function of the attractant concentration.*

Since the attractant is a chemical, it also diffuses and is produced, partially perhaps, by the moving cell itself (amoebae, say). It obeys the equation $\frac{\partial a}{\partial t} = g(a,n) + \mathrm{div}(D_a\,\mathrm{grad}\,a)$, *where* D_a *is the diffusion coefficient of* a *and* $g(a,n)$ *is the source term. The combined set of equations for* n *and* a *define a diffusion-chemotaxis process. The balance between the stabilizing diffusion term and the destabilizing chemotaxis term could result in some steady-state spatial patterns in* n *and* a, *and in some unsteady wave-like spatially heterogeneous structures.*

Turing Machines, or — What is a Computation?

Although people have been computing for millennia, it has only been since 1936 CE that we have possessed a satisfactory answer to the above title question. Along with the development of modern computers, has emerged a new branch of applied mathematics — theory of computation: the application of mathematics to the theoretical understanding of computation. The foundations of this theory were laid by ***Emil Post*** *(1920),* ***Alan Turing*** *(1935) and* ***Alonzo Church*** *(1936).*

There are many different styles of mathematics. At one extremity is the pure existence proof, asserting that an object with certain properties must necessarily exist, *but giving no method to find it. This is part of* dialectic mathematics *— a rigorously logical science, where statements are either true or false and where entities either do or do not exist. It is an intellectual game played according to rules about which there is a high degree of consensus. Dialectic mathematics invites* contemplation *and generates* insight. *It originated with the Greeks. Throughout most of the 19th century, mathematics has been existence-oriented.*

At the other end is algorithmic mathematics[854] *— a tool for solving problems by means of a perfectly definitive procedure guaranteed to calculate*

---

[854] *Algorithm*: a step-by-step recipe (instruction set) for performing some kind of calculation: e.g. the algorithmic solution to the equation $x^2 = 2$ is $x_{n+1} = \frac{1}{2}\left(x_n + \frac{2}{x_n}\right)$, $n = 1, 2, \ldots$. The corresponding dialectic solution uses the function $y = x^2 - 2$. Since $f(1) = -1$ and $f(2) = 2$, as x moves continuously from 1 to 2, y moves continuously from negative to positive values. Hence, *somewhere* between 1 and 2 there is an $x = x_0$ such that $y = 0$, i.e. $x_0^2 = 2$.

The details of the argument are supplied by the properties of the real number system and of continuous functions defined on that system. The first significant algorithm is to be found in **Euclid's** Book Seven where he taught us how to calculate the highest common factor of two numbers.

For some particularly simple Diophantine equations (**Diophantos of Alexandria**, ca 250 CE), there are known algorithms (e.g. for linear and quadratic equations in at most two unknowns). The name *algorithm* is associated with **Al-Khowarizmi**, who outlined (ca 825 CE) the rules for performing basic arithmetic operations, using numbers expressed in the Hindu decimal notation that we use today.

exactly what is required, if and only if one waits long enough. The rules of the game may vary according to the urgency of the problem at hand (we never could have put a man on the moon if we had insisted the trajectories should be computed with dialectic rigor). Algorithmic mathematics invites action *and generates* results. *The mathematics of Babylon and the ancient orient was all of the algorithmic type.*

Between the two extremes are constructive techniques *which provide a more explicit description of the desired results or objects then in pure existence proofs.*

The problem of transcendental numbers *illustrates all three styles well. Cantor's existence proof exhibits not a single transcendental. It merely observes that since there are more reals than algebraic numbers, transcendentals must exist. At the intermediate level are transcendence proofs for* specific *numbers, such as:* π, e, $2^{\sqrt{2}}$. *An algorithm for transcendence would be a general method of deciding, for any number whatsoever, whether it does or does not satisfy an algebraic equation. No such technique is known.*

There have been extensive philosophical arguments about the value and nature of these types of result. Does a pure existence proof really convey any useful information? One school of modern mathematics, the Constructionism, *take a very restrictive position and refuses to consider any non-constructive arguments at all. Others believe that in order to calculate something, it is* useful *to know in advance that it exists.*

Throughout most of the 19th century, mathematics has been existence-oriented. Then, at the turn of the 20th century (and especially since 1936) there occurred a partial shift back to constructive, or algorithmic, points of views.

Indeed, **David Hilbert** *(1928) proposed a problem (known as the* "Entscheidungs problem" *— the decision problem) as a fundamental problem of the newly developing field of mathematical logic. It can be stated as follows: a finite list of statements called* premises *is given together with an additional statement called the* conclusion. *The logical structure of the statements is to be explicitly exhibited in terms of "not", "and", "or", "implies", "for all" and "there exists".*

Hilbert wanted a computing procedure (algorithm) for testing whether or not the conclusion can be deduced (using the rules of logic) from the premises. Hilbert regarded this problem as especially important because he expected *that its solution would lead to a purely mechanical technique for settling the truth or falsity of the most diverse mathematical statements. (Such statements could be taken as the conclusion, and an appropriate list of axioms as the premises to which the supposed computing procedure could be applied). The end result of his programme would thus lead to a rigorous proof of the consistency of systems such as: logic; logic combined with set theory; or arithmetic.*

However, research during 1930–1936 showed that there are problems that had no algorithmic solution! First, ***Gödel*** *(1930) showed that there are true statements in arithmetic that can never be proved. In other words — one cannot prove that arithmetic is consistent. At about the same time,* ***Alan Turing*** *was working in mathematical logic, with a view to clarifying the notion of computability. He discovered that certain very natural questions have no answer whatsoever, i.e. — there is no solution using any method available to human beings.*

Turing based his precise definition of computation on an analysis of what a human being does when he computes. Such a person is following a strict set of rules which can be carried out in a completely mechanical manner.

In this process (be it long division, algebraic manipulations or steps in solving a calculus problem) there are irrelevant parts which are logically unnecessary and are included only to speed up specific operations. Turing described an idealized computer (Turing machine) with the most rudimentary structure possible.

Imagine an infinite tape (one dimensional paper) divided into square cells, passing under a head which can be in a finite number of initial states. The head can read what is on the tape, and optionally write symbols 0 *and* 1 *on it. Only* 0 *and* 1 *are required since any information can be encoded using just* 0*s and* 1*s (e.g. a Morse code with* 0 *representing a dot and* 1 *a dash).*

The machine behavior is controlled by a kind of computer program (Turing-Post program). This consists of a sequence of numbered steps, each step being one of seven instructions:

Instruction	*Programming Language Statement*
Write the symbol 1	`PRINT 1`
Write the symbol 0	`PRINT 0`
Move the tape forward one cell	`GO RIGHT`
Move the tape backward one cell	`GO LEFT`
{ Observe the symbol currently scanned and *choose* the next step accordingly	`GO TO instruction` i `IF 1 IS SCANNED` `GO TO instruction` j `IF 0 IS SCANNED`
Stop	`STOP`

In order that a particular Turing-Post program begin to calculate, it must have some "input" data. That is, the head begin scanning at a specific square of a tape already containing a sequence of zeros and ones. The machine processes the data according to the program, and then stops.

Turing showed that anything *a computer can calculate, can also be computed by a Turing machine. Moreover, he showed (1936) how to construct a* universal *machine capable of simulating the action of* any *program in* any *Turing machine. This is equivalent to saying that any computer, given enough time and memory, can be programmed to simulate any other computer. So, for theoretical purposes, we may think of all computers as capable of being emulated by Turing machines [Church-Turing thesis]. This also implies that there exists a single Turing-Post program which can compute everything* that *is computable.*

At this point we may define *an algorithm to be a Turing-Post program that eventually* halts *no matter what input is presented to the Turing machine who runs it. Clearly, an important property of an algorithm is that it should eventually* stop *with a definite answer. A calculation that may go on forever is not of much use. However, a Turing-machine may, in principle go on forever (e.g. 'move right looking for* 1*s' will not stop if there are no* 1*s' to the right of the head).*

In light of this possibility there arises the Halting Problem *for a particular Turing-Post program: to distinguish between initial inputs which lead to the program's eventually halting and initial inputs which lead the program to run forever. In other words, is there a method for determining* in advance *which input data leads the program to halt and which do not.*

The answer is no*. The halting problem is* unsolvable *(undecidable). Turing proved this in 1936 indirectly by* reductio ad absurdum*. Thus, a problem is* undecidable *if there exists no algorithm to solve it, and the undecidability of the Halting Problem places definite limits on the applicability of algorithms.*

Another problem which proved to be unsolvable was the 'word problem' of ***Axel Thue*** *(1908): Is there an algorithm for deciding, for any given alphabet and a set of production rules, whether or not any given two words are equivalent*[855]*? Emil Post proved (1947) that the unsolvability of the halting problem leads to the existence of an unsolvable word problem. Work on unsolvable word problems has turned out to be extremely important, leading to unsolvability results in different parts of mathematics such as group theory and topology.*

Yet another problem that eventually turned out to be unsolvable first appeared as the $10th$ *in a famous list of* 23 *problems posed by David Hilbert in 1900: he challenged to determine whether or not any given Diophantine equation has integer solutions*[856]*. Here the name refers to any algebraic equa-*

---

855 Any string of letters is called a *word* of the alphabet. Given two arbitrary words on the alphabet, the problem is of determining whether one can be transformed into the other by a sequence of substitutions that are legitimate using the given rules. Unsolvability means here that no computational process exists for determining whether or not two words can be transformed into one another using the given rules.

Example: given an alphabet of three symbols a, b, c, and three rules encoded by the equations $ba = abc$; $bc = cba$; $ac = ca$, we can obtain other equations by substitution such as

$$\mathbf{ba}c = abcc$$
$$b\mathbf{ac} = \mathbf{bc}a = c\mathbf{ba}a = \mathbf{ca}bca = \mathbf{ac}bca = cab\mathbf{ca} = cab\mathbf{ac} = ca\mathbf{bc}a = cacbaa$$

(the letter strings in boldface type are the symbols about to be replaced). In this context questions can be raised such as: Can we deduce from the three equations listed above that

$$bacabca = acbca?$$

856 *Examples*: The equation $4x - 2y = 3$ has no solution in integers because the l.h.s. would have to be even while the r.h.s. is odd. On the other hand the equation $4x - y = 3$ has infinitely many solutions in integers (e.g. $x = 1$, $y = 1$; $x = 2$, $y = 5$). The Pythagorean equation $x^2 + y^2 = z^2$ has also infinitely many integer solutions, but $x^n + y^n = z^n$ for $n > 2$ has none. Likewise $x^2 + y^2 = 2$, considered as a Diophantine equation, has only 4 solutions $(1, 1)$; $(1, -1)$; $(-1, 1)$; $(-1, -1)$. If we change the equation just slightly, say to $x^2 + y^2 = 3$ there are no integer solutions at all. Thus, a Turing machine might work forever on this equation without producing any solution. From the point of view of a computer — the equation is unsolvable.

tion in one or more variables, with integer coefficients (the adjectival use of the word Diophantine refers not to the equation so much as to the kind of solution which is sought). The problem stayed open until 1970, when ***Yuri Matijasevich*** *used the Fibonacci numbers to prove that there cannot be an algorithm of the kind requested by Hilbert.*

There is perhaps no better example of the limited computability by computers than a mathematical problem [raised by ***Karl Menger***[857]*(1930)] which has resisted all attempts at a general solution via traditional methods. It is known as the Traveling Salesman Problem (TSP): given a network of cities and roads, find a tour that takes the salesman (tourist) to each city exactly once such that the total distance traveled is minimized. The order in which the cities are visited is of no importance (sometimes it is required that the tour begins and ends at the same location).*

The only known algorithm for solving the problem is the laborious uninsightful one of trying every possibility, and a computer can be easily programmed to do just that. To date, no faster algorithm has been found, not even a theory, except for special cases. Nor has anyone been able to prove the impossibility of a faster algorithm (this field of endeavor is known as complexity theory).

But the listing of all possible routes is practical only for a modest number of locations; If there are N *locations to visit, then there are* $N! \approx \left(\frac{N}{e}\right)^N \sqrt{2\pi N}$ *possible different itineraries, which will obviously lead to an exponential-time algorithm*[858]*. Already for* $N = 10$ *there are* $3,628,800$ *possible routes. This can be achieved by a modern computer, but when we go up to* $N = 25,$ *the*

---

[857] (1902–1985, Austria and USA). Mathematician. Born in Vienna and completed his Ph.D. on *dimension theory* (1924). Forced by the Nazis (1938) to leave his chair of geometry at the University of Vienna and immigrated to US. Even after the war, the ex-Nazis at the University of Vienna told him that he was unwanted there... He worked at the University of Notre Dame (1938–1948) and then spent the rest of his career at the University of Illinois.

[858] An *algorithm* (a Turing-machine program) is said to run in *polynomial time* if there are fixed integers A and k such that for input data of length n, the computation is complete in at most An^k steps (for any value of n). For example: the *addition* of two numbers, each with $\frac{n}{2}$ digits (input data of length n), involves exactly n steps (allowing for carries). Thus the above definition is valid with $A = k = 1$. In the *multiplication* of two $\frac{n}{2}$-digit numbers there are $\frac{n^2}{4}$ basic digit multiplications, $\frac{n^2}{4}$ carry–and–add operations, and the finally $n-1$ 3 digits addition steps as encountered in an addition problem; this add up to $\frac{n^2}{2}+n-1$ steps in all. Since $\frac{n^2}{2}+n-1 < n^2$, the above definition holds with $A = 1$, $k = 2$.

number of routes to consider mounts to 16×10^{25} *while for* $N = 100$, *of order* 3×10^{161} *single–digit decimal arithmetic calculations must be performed for all possible tours, requiring of order* 10^{145} *years on today's fastest supercomputers. While a tour of* 25 *cities is quite realistic for a real-life salesmen, not many salesmen need to visit* 100 *cities, yet the TSP is important because it has far wider applications*[859] *than just in the travel industry.*

Algorithms which require n^n or $n!$ steps to handle data of length n (say, the number of cities in the TSP) are *exponential time* algorithms.

For an algorithm to be efficient (fast), it should run in polynomial time, provided of course that A and k are modest (values like $A = 10^{10}$ and $k = 100$ are hardly likely to be 'efficient' in any real sense). Assuming that a computer performs one basic operation in 10^{-6} sec, the dependence of the computation time on the data size for a number of exponential and polynomial time models is roughly as follows:

Size of data:	Run times for given computation complexity formula:				
n	n	n^2	n^3	2^n	3^n
10	10^{-8} s	10^{-7} s	10^{-6} s	10^{-6} s	$5.9 \cdot 10^{-5}$ s
20	$2 \cdot 10^{-8}$ s	$4 \cdot 10^{-7}$ s	$8 \cdot 10^{-6}$ s	10^{-3} s	3.5 s
30	$3 \cdot 10^{-8}$ s	$9 \cdot 10^{-7}$ s	$2.7 \cdot 10^{-5}$ s	1 s	57 hours
40	$4 \cdot 10^{-8}$ s	$1.6 \cdot 10^{-6}$ s	$6.4 \cdot 10^{-5}$ s	18.3 m	389 years
50	$5 \cdot 10^{-8}$ s	$2.5 \cdot 10^{-6}$ s	$1.25 \cdot 10^{-4}$ s	13 days	23 My
60	$6 \cdot 10^{-8}$ s	$3.6 \cdot 10^{-6}$ s	$2.16 \cdot 10^{-4}$ s	36.6 years	1.4 trillion years

Note that 1.4×10^{12} years exceeds by about three order of magnitude the current estimate of the age of the universe.

859 *For example*, electronic circuit board manufacturers have to drill as many as $65,000$ holes on their boards using laser drills. Finding the best way to drill the holes turns out to be a TSP, since it involves finding the shortest tour that visits each hole exactly once. And in fact, a team of academic and industrial researchers recently established a record for the TSP by finding the exact minimal distance path for visits of 3038 cities, where the "cities" were indeed holes drilled on a printed circuit board.

So, arriving at a solution by listing all the possibilities is obviously out of the question except when a small number of locations are involved. Modern computers, however, were able to solve specific *instances of the problem using special ad-hoc methods. Thus, a smart algorithm (1970) needed to examine only* 61 *relevant cases out of a vast number of* 33×10^{49} *possibilities. Another specific problem was solved (1979) for* 318 *locations.*

The Catastrophe Paradigm (1937–1972)[860]

Classical physics is essentially a theory of smooth behavior according to Newton's laws of motion. This is certainly manifested in the awe-inspiring stable motion of the planets in their courses around the sun. However, in our daily experience here on earth we meet other phenomena: water suddenly boils, ice melts, the earth quakes, bridges collapse, buildings fall, hearts fail, stock markets crash, wars erupt. The back of a camel is stable, we are told, under the load of n *straws, but breaks suddenly under a load of* $n + 1$.

All these are sudden *changes caused by* smooth *alterations in the situation. Such changes are far more difficult to predict and analyze than the stars in their courses and the sciences (from physics to economics and psychology) are still developing the analytical techniques to handle such abrupt behavior.*

There are numerous kinds of "jump" phenomena. There are forces that build up until friction can no longer hold them: when friction gives way an earthquake results. There is a critical population density below which certain creatures grow up as grasshoppers, above which as locusts: this is why locusts, when they do *occur, do so in a huge swarm.*

---

[860] To dig deeper, see:

- Poston, T. and I. Stewart, *Catastrophe Theory and Its Applications*, Dover, 1996, 491 pp.
- Woodcock, A. and M. Davis, *Catastrophe Theory*, Avon, 1980, 151 pp.

A cell suddenly changes its reproductive rhythm and doubles and redoubles, cancerously. In engineering, for example, the gradual buildup strain on the structure of a bridge can eventually result in a sudden collapse. These phenomena occur also in economical and psychological events. They are named catastrophes[861]*, to convey the feeling of abrupt and dramatic changes, and the subject has (since 1973) become known as catastrophe theory.*

It is an attempt to describe those situations in which small gradually changing forces lead to large abrupt changes, or otherwise stated — the treatment of a continuous action producing a discontinuous result. It is capable of dealing with evolution of many natural phenomena that proceed by a series of gradual changes that are triggered by, and in turn trigger, large-scale changes.

Consider the potential function of a system having two variables $V(x, y; \alpha, \beta)$, *where* α, β *are some parameters which characterize the strengths of interaction between various parts of the system (properties of materials, amount of heat being supplied or extracted, etc.).*

For fixed values of α, β, *an equilibrium state of the system is determined by the equation* $\operatorname{grad} V = 0$ *(i.e.* $\frac{\partial V}{\partial x} = \frac{\partial V}{\partial y} = 0$*) and by the behavior of the scalar* $\Delta = ab - h^2$, *where* $a = \frac{\partial^2 V}{\partial x^2}$, $b = \frac{\partial^2 V}{\partial y^2}$, $h = \frac{\partial^2 V}{\partial x \partial y}$ *at the equilibrium point(s). In the regular case* $(\Delta \neq 0)$ *there are two possibilities: either the system stays near equilibrium and the potential* V *increase from its equilibrium state for every conceivable tiny change in* x, y ($\Delta > 0$, $\frac{\partial^2 V}{\partial x^2} > 0$; *stable) or there is no increase in* V *for some small alternation to* x, y *and the system tends to move away from equilibrium* ($\Delta \neq 0$, $\frac{\partial^2 V}{\partial x^2} < 0$ *or* $\Delta < 0$; *unstable).*

---

[861] The word's overtones of disaster are, for most applications, misleading. 'Catastrophe theory' is in fact a model (paradigm), not yet an explanation. It is, in fact, an assemblage of mathematical and physical ideas.

'Catastrophe theory' is *not* the first mathematical method capable of treating divergent phenomena. The buckling of a beam one way or the other as stress increases is just such a phenomena, and was first analyzed by **Euler** (1744). Many similar problems of elasticity were well understood in their own terms by engineers long before 'catastrophe theory' was proposed, and for these we cannot expect the new mathematics to render new practical information — only a reformulation. 'Catastrophe theory' will, however, shed light on more complicated cases.

Choosing (without loss of generality) the origin at equilibrium,

$$V(0,0) = V_x(0,0) = V_y(0,0) = 0,$$

the Taylor-series expansion for V near the origin will take the form

$$V = \frac{1}{2}(ax^2 + 2hxy + by^2) + \textit{ higher order terms.}$$

Now, it is well known that the curve $ax^2 + 2hxy + by^2 = F$, where F is constant, is a conic section. If $\Delta = ab - h^2 > 0$ then it is either an ellipse (if $aF > 0$) or has no real points (if $aF < 0$). If $\Delta = ab - h^2 < 0$ then it is a hyperbola, with the sign of aF determining which of the two principal axes is the transverse axis. By considering the intersections of the surface $z = V(x, y)$, with planes $z = \pm\epsilon$, where $|\epsilon|$ is small, the above conditions follow.

In the neighborhood of a non-degenerate critical point $(\Delta \neq 0)$, the function of one variable *can be closely approximated by a parabola, opening upwards for a minimum or downwards for a maximum. The generalization for a function of two variables is that near a non-degenerate critical point it can be closely approximated either by an elliptic paraboloid $(\Delta > 0$, for a maximum or a minimum) or a hyperbolic paraboloid (for saddle point, $\Delta < 0)$.*

Consider, however, the physical situation where the parameters α, β are not fixed any longer: A slight adjustment in the environment will result in small deviations of α, β from their original values. Now, there are two possibilities; either the state of the system will be modified a little, or it will be transformed dramatically. In the latter case a catastrophe *occurs and the set of values for which this happens is said to be the* catastrophe set*. In the former case the state may be called* regular *because it is not affected much by small perturbations.*

Let this state of equilibrium be perturbed by a small variation of the parameters $\alpha \to \alpha + \delta\alpha$, $\beta \to \beta + \delta\beta$, and let the corresponding induced disturbance in the variables at the equilibrium state shift the system to a new equilibrium state *$x \to x + \delta x$, $y \to y + \delta y$. A Taylor expansion then yields:*

$$\begin{aligned}
&\frac{\partial}{\partial x}V(x+\delta x, y+\delta y; \alpha+\delta\alpha, \beta+\delta\beta) \\
&\quad = \frac{\partial}{\partial x}V(x,y;\alpha,\beta) + \delta x\frac{\partial^2}{\partial x^2}V(x,y;\alpha,\beta) + \delta y\frac{\partial^2}{\partial x\partial y}V(x,y;\alpha,\beta) \\
&\quad + \delta\alpha\frac{\partial^2}{\partial\alpha\partial x}V(x,y;\alpha,\beta) + \delta\beta\frac{\partial^2}{\partial\beta\partial x}V(x,y;\alpha,\beta) + \text{higher order terms;}
\end{aligned}$$

$$\frac{\partial}{\partial y}V(x+\delta x, y+\delta y; \alpha+\delta\alpha, \beta+\delta\beta)$$
$$= \frac{\partial}{\partial y}V(x,y;\alpha,\beta) + \delta x\frac{\partial^2}{\partial y\partial x}V(x,y;\alpha,\beta) + \delta y\frac{\partial^2}{\partial y^2}V(x,y;\alpha,\beta)$$
$$+ \delta\alpha\frac{\partial^2}{\partial\alpha\partial y}V(x,y;\alpha,\beta) + \delta\beta\frac{\partial^2}{\partial\beta\partial y}V(x,y;\alpha,\beta) + \text{higher order terms.}$$

The first term on the r.h.s. of each equation vanishes on account of the equilibrium condition. The new *equilibrium will be worthy of its name if in each equation, the sum of the remaining terms will vanish for the* given *changes $\delta\alpha$ and $\delta\beta$. This leaves us with a set of two equations in the two unknowns δx and δy in terms of $\delta\alpha$ and $\delta\beta$ (higher terms in the Taylor expansion being neglected),*

$$\delta x\frac{\partial^2 V}{\partial x^2} + \delta y\frac{\partial^2 V}{\partial x\partial y} = -\delta\alpha\frac{\partial^2 V}{\partial\alpha\partial x} - \delta\beta\frac{\partial^2 V}{\partial\beta\partial x}, \qquad \textit{and}$$

$$\delta x\frac{\partial^2 V}{\partial x\partial y} + \delta y\frac{\partial^2 V}{\partial y^2} = -\delta\alpha\frac{\partial^2 V}{\partial\alpha\partial y} - \delta\beta\frac{\partial^2 V}{\partial\beta\partial y}.$$

If the determinant of the coefficients matrix $\Delta = \begin{vmatrix} V_{xx} & V_{xy} \\ V_{xy} & V_{yy} \end{vmatrix}$ *on the l.h.s. (known as the Hessian) is non-zero, there is a unique solution of the above system:* $\delta x = a_{11}\delta\alpha + a_{12}\delta\beta$, $\delta y = a_{21}\delta\alpha + a_{22}\delta\beta$, *where a_{ij} are constants. Thus, the smaller the perturbations $\delta\alpha$ and $\delta\beta$, the smaller δx and δy, and the equilibrium state is regular. In contrast, if* $\Delta = 0$, *a general solution of the above system contains an arbitrary element which does not depend on $\delta\alpha$, $\delta\beta$, because it satisfies the homogeneous system of equations. Hence δx, δy cannot be forced to go to zero with $\delta\alpha$, $\delta\beta$ and there is a* catastrophe.

Thus, an equilibrium state is catastrophic or regular according as the Hessian of the potential function does or does not vanish. The points for which $\Delta = 0$ *therefore have an* inherent structural instability, *since there will be functions arbitrarily close to them with* $\Delta > 0$ *and with* $\Delta < 0$ *and these will be in general of different type.*

Now, Δ can vanish for two quite distinct reasons: first, all three *second order partial derivatives may be zero at the origin, and it is then clear that $V(x,y)$ is degenerate in both the x-direction* and *the y-direction. Second, we could have* $\Delta = 0$ *because* $V_{xx}V_{yy} = (V_{xy})^2$ *but not all the derivatives vanish separately. In that case* $|ax^2 + 2hxy + by^2|$ *is a* perfect square, *which allows us to write*

$$V(x,y) = \pm\frac{1}{2}(px+qy)^2 + \textit{ higher order terms,}$$

where $p = \sqrt{|a|}$, $q = \sqrt{|b|}$.

The form of the expansion suggests that we rotate the axes, transforming to new coordinates u, v *given by* $u = \frac{px+qy}{\sqrt{p^2+q^2}}$, $v = \frac{qx-py}{\sqrt{p^2+q^2}}$. *In the* u, v *system* $V(u,v) = \pm\frac{1}{2}(p^2+q^2)u^2$ *(parabolic cylinder). Consequently, the values of the first and second partial derivatives at the origin are*

$$\frac{\partial V}{\partial u} = \frac{\partial V}{\partial v} = \frac{\partial^2 V}{\partial u \partial v} = \frac{\partial^2 V}{\partial v^2} = 0,$$

$$\frac{\partial^2 V}{\partial u^2} = \pm(p^2+q^2) \neq 0.$$

Thus, V *has either a minimum or a maximum in the* u *direction. In any other direction* $w = u\sin\theta + v\cos\theta$, *we have at the origin* $\frac{dV}{dw} = \sin\theta\frac{\partial V}{\partial u} + \cos\theta\frac{\partial V}{\partial v} = 0$ *and*

$$\begin{aligned}\frac{d^2V}{dw^2} &= \sin^2\theta\frac{\partial^2 V}{\partial u^2} + 2\sin\theta\cos\theta\frac{\partial^2 V}{\partial u\partial v} + \cos^2\theta\frac{\partial^2 V}{\partial v^2} \\ &= \sin^2\theta\frac{\partial^2 V}{\partial u^2} = \pm\sin^2\theta(p^2+q^2).\end{aligned}$$

Hence V *has the same behavior in the* w*-direction as in the* u *direction, provided that* $\theta \neq 0$. *Thus, the problem has been reduced, by a single coordinate transformation, to the study of a function of one variable only.*

This result can be extended to a potential depending on n *variables and* k *parameters* $V(x_1,\dots,x_n;\alpha_1,\dots,\alpha_k)$ *with a critical point at the origin. We make an expansion in terms of the state variables near equilibrium*

$$V = V_0 + \sum_i a_{ij}x_ix_j + \sum_{i,j,\ell} b_{ij\ell}x_ix_jx_\ell + \sum_{i,j,\ell,m} c_{ij\ell m}x_ix_jx_\ell x_m$$

correct to the 4^{th} *order. The coefficients* a_{ij}, $b_{ij\ell}$, $c_{ij\ell m}$ *will depend on* $\alpha_1,\dots,\alpha_k$ *in general. It can be shown that the axes can be rotated until only the squares among the quadratic terms are left. (There are standard techniques for doing so based on matrices, the details of which are not of immediate concern.) After the rotation*

$$V = V_0 + \sum_{i=1}^{n}\lambda_iX^2 + \sum_{i,j,\ell} B_{ij\ell}X_iX_jX_\ell + \sum_{i,j,\ell,m} C_{ij\ell m}X_iX_jX_\ell X_m$$

where $\lambda_1,\lambda_2,\dots,\lambda_n$ *are known as eigenvalues. The number of non-zero eigenvalues depends on the rank of the Hessian matrix of* V, *namely* $\left[\frac{\partial^2 V}{\partial x_i\partial x_j}\right]$.

If the rank is n (i.e. its determinant does not vanish), then all $\lambda_i \neq 0$ and V is structurally stable.

If, on the other hand, the rank of the Hessian is $n-r$ for some $r>0$, then there exists a coordinate transformation which permits us to write V in the form $V=\lambda_{r+1}x_{r+1}^2+\lambda_{r+2}x_{r+2}^2+\cdots+\lambda_n x_n^2+$ higher order terms. The structural instability is confined to the variables $x_1, x_2, \ldots, x_r$ and can be analyzed in terms of these variables alone. The remaining variables can be ignored. The number r, known as the corank of the Hessian, is the number of directions in which the function is degenerate. It also denotes the number of kinds of catastrophes which can occur.

It can be shown that when only one of the eigenvalues vanishes, the potential near equilibrium is reducible in most cases to one of four canonical potentials:

$$V = c_1 x + x^3 \qquad \textit{(fold)}[862];$$

---

[862] Example: *Equilibrium of a picture frame*. A rectangle of width $2a$ and depth $2h$ is suspended by an inextensible string of length 2ℓ (with $\ell > a$) attached to its upper corners and passing over a smooth pin c. Since the only force which does any work is gravity, the potential energy of the frame is determined by the depth of the frame's center of gravity below the suspension point.

Hence the potential energy

$$V(x,\theta;a,\ell,h) = -mg\left\{\left[\sqrt{\ell^2-x^2}\sqrt{1-\frac{a^2}{\ell^2}}+h\right]\cos\theta + x\sin\theta\right\},$$

where x is the distance of the center of side $2a$ (facing the suspension point c) from the perpendicular passing through the suspension point on this side, and θ is the angle at c between this perpendicular line and the vertical; m is the mass of the frame and g is the acceleration of gravity. There are two state variables x and θ because each can be varied independently of the other.

From the equilibrium equation $\frac{\partial V}{\partial x}=0,\ \frac{\partial V}{\partial \theta}=0$ we deduce that equilibrium is reached whenever $\sin\theta = 0$ or $\sqrt{1-\frac{x^2}{\ell^2}} = \frac{h}{a^2}\sqrt{\ell^2-a^2}$. The condition $\sin\theta=0$ implies that $x=0$, which is the expected symmetrical configuration where the frame is horizontal.

The second condition can be realized only if $h\sqrt{\ell^2-a^2}\le a^2$. Then there are two configurations, one on either side of the vertical. There are, therefore, 3 positions of equilibrium. It can be proved that the side positions, whenever they exist, are stable, but the central position is stable only when there are no side positions ($h\sqrt{\ell^2-a^2}>a^2$). When $h\sqrt{\ell^2-a^2}=a^2$, the Hessian determinant vanishes for the central position and a fold catastrophe ensues.

$$V = c_1x + c_2x^2 \pm x^4 \qquad (cusp);$$
$$V = c_1x + c_2x^2 + c_3x^3 + x^5 \qquad (swallow\text{-}tail);$$
$$V = c_1x + c_2x^2 + c_3x^3 + c_4x^4 + x^6 \qquad (butterfly).$$

If two eigenvalues can pass through zero, three additional catastrophes can occur:

$$V = x^3 + y^3 + axy + bx + cy \qquad (hyperbolic\ umbilic);$$
$$V = x^3 - 3xy^2 + a(x^2 + y^2) + bx + cy \qquad (elliptic\ umbilic);$$
$$V = x^2y + y^4 + ax^2 + by^2 + cx + dy \qquad (parabolic\ umbilic).$$

When three eigenvalues disappear, a further four catastrophes can be present — but when more than three can vanish, unlimited possibilities become available.

Thus, Catastrophes are bifurcations *between different equilibria, or fixed point attractors. Due to their restricted nature, catastrophes can be classified based on how many control parameters are being simultaneously varied. For example, if there are two controls, then one finds the most common type, called a "cusp" catastrophe. If, however, there are more than five controls, there is no classification.*

The foregoing ideas had their origin at the end of the 19th *century, when* ***Henri Poincaré*** *(1881 to 1895) linked calculus and topology (then called "*analysis situs*", analysis of location) to create* qualitative *dynamics and then applied it to unsolved problems of planetary motion. This may seem strange; after all, dynamics had been a firmly quantitative field since Newton. But Newton's methods yielded explicit solutions only for the interaction of two bodies — for example, the sun and the earth, or the earth and the moon. When three or more bodies are involved, the equations of motion cannot be solved directly, and even approximate solutions require tedious, complex procedures. Around* 1800 ***Pierre Simon de Laplace*** *had tried at length — but without success — to show that all the two-body attractions of the solar system added up to a stable dynamic system, a grand perpetual-motion machine that would run forever.*

Poincaré set out to show that even if quantitative solutions were impossible, it was still possible to make progress on important questions: does a complex, many-body system return periodically to the same arrangement? Does a slight perturbation simply "nudge" the whole system, or does it lead eventually to qualitatively different behavior, such as a planet spiraling into the sun or colliding with another planet? Though he did not fulfill Laplace's earlier hopes, Poincaré inaugurated a valuable new approach.

His fellow mathematicians saw its value, but thought it arbitrary because it was adapted to a particular physical problem rather than being part of a general method. Indeed, as late as 1937 *E.T. Bell, a historian of mathematics, summed up the state of the art in the words: "...few have mastered his weapons, and some, unable to bend his bow, insinuate that it is worthless in a practical attack".*

But in the very same year the mathematicians ***A.A. Andronov*** and ***L.S. Pontryagin*** *built on Poincaré's ideas in their general definition of structural stability. They made mathematical questions out of Poincaré's physical ones. Given the equations describing any dynamical system, they said, the crucial question was how the stable solutions for these equations were distributed topologically. Was a stable state of the system part of a continuous range, or an "island" surrounded by instability? Would a small quantitative change alter the solutions slightly, or produce very different new ones, or perhaps leave none at all?*

At about the same time, ***Marston Morse*** *was renewing the topological approach to the* calculus of variations*, making it possible to find the maxima and minima of whole family of curves.*

Interestingly enough, the ideas of Poincaré found fertile ground in biology. ***Conrad Hall Waddington*** *(1905–1975, England) was the first scientist of stature to acclaim catastrophe theory (1930). He came to these ideas through his exploration of the evolution of embryos before birth*[863]*. He studied processes of* morphogenesis *that transform an apparently uniform ball of cells into a layered structure of differentiated tissues. These investigations revealed much about the chemical signals of morphogenesis, including the surprising discovery that many substances — even some not normally found in organisms — can act as* triggers *for the same complex sequence of events. Waddington suggested (1940) the desirability of a theory of a generally topological kind, which would be appropriate to biological forms. Such a theory was eventually developed by* ***René Frédéric Thom***[864]*; he used it to illuminate singularities of differentiable mappings.*

---

863 As early as 1917, **D'Arcy Thompson** had shown that the shape of a fish or of an animal's skull, drawn on a rectilinear grid, could be altered by a continuous, smooth transformation to that of a related fish or skull in the animal's evolutionary predecessor. Although Thompson did not develop quantitative mathematics for this visual relationship, he exerted pervasive influence on three generations of scientists.

864 French mathematician (b. 1923). Developed the theory (1966) and expounded it in his book "*Structural stability and Morphogenesis*" (1972). It has attracted publicity as well as some controversy.

Catastrophe theory is a special branch of dynamical systems theory. It has been applied to widely differing situations such as embryo development, stability of ships at sea and social interactions between human beings and animals. Although catastrophe theory was intended primarily as a mathematical language for biology, it turned out to be an efficient mathematical tool that also provides a common language for physical and psychological processes.

1935–1972 CE **Israel Moiseyevich Gelfand** (b. 1913, Russia). Mathematician. Generalized and extended classical mathematics by the use of infinite dimensional, yet geometric ideas.

Gelfand was born to Jewish parents in Krasnye Okny, near Odessa, in the Ukraine. He went to Moscow at the age of 16, before completing his secondary education. There he took a variety of different jobs (such as a door keeper at the University library). In 1932 he was admitted as a research student under Kolmogorov and presented his thesis (1935) on abstract functions and linear operators. He became a professor at Moscow State University (1943). In 1990 he emigrated to the United States, becoming Distinguished Visiting Professor at Rutgers University.

His achievements:

- Developed (1938) the theory of *commutative normed rings* which are of crucial importance in functional analysis and modern physics. Revealed close connections between Banach's general functional analysis and classical analysis.

- Developed the representation theory of *locally compact groups*[865], important in relativity theory and quantum mechanics (e.g. the Lorentz groups). His work in this area unifies the treatment of classical Lie groups (ubiquitous in physics) with their analogues in algebraic geometry. In particular, his work has led to essential mathematical methods in *the study of symmetries* of fundamental particles.

---

[865] For further reading, see:
 – Gelfand, I.M., R.A. Minlos and Z.Y. Shapiro, *Representation of the Rotation and Lorentz Groups and their Applications*, Pergamon Press: New York, 1963.

- Contributed to the life sciences through his mathematical studies of *neuro-physiology* and *cell biology.*
- Developed *integral geometry*, which studies in geometric terms transformations by integrals of functions on a given space.
- Worked (with Naimark) on *non-commutative normed rings* and the theory of representations of *non-commutative groups.* He later advanced the theory of *group representations* and the *cohomology* of infinite dimensional Lie Algebras.
- Contributed to the theory of *generalized functions* (used in solving differential equations of mathematical physics).

1935–1973 CE **Leo Strauss** (1899–1973; Germany and USA). Political philosopher. Created the '*Straussian*' school of political science. No other conservative thinker has inspired a following remotely comparable, in size, continuity, and influence, to that of Leo Strauss. This school has its own interests, ideas, and purposes, which are clearly distinct from mainstream conservatism. His extraordinary influence as a leader has been demonstrated by his many students who have succeeded him in the field of political philosophy.

Strauss was born in Kirchheim, Hesse, Germany. He was brought up in an orthodox home, where the 'ceremonial' laws were rather strictly observed, but where there was little Judaic knowledge. Further identification as a Jew came early to Strauss, when refugees from the Russian Pogroms passed through his village.

In the Marburg Gymnasium (1905–1916) he was exposed to the message of *German Humanism* and read Schopenhauer and Nietzsche. He was exposed to political Zionism in 1917. During 1917–1918 he was conscripted into the German Army. He then studied philosophy, natural science and mathematics (1919–1921) at the Marburg University under the guidance of **Husserl**, **Heidegger** and **Hermann Cohen**, and received his Ph.D. there (1921). In 1932 he left Germany and eventually came to the United States. He taught at the new New-York School for Social Research during 1938–1949, then at the University of Chicago from 1949 to 1967, Claremont Men's College in 1968–69, and St. John's College until his death in 1973. Leo Strauss was the Robert Maynard Hutchins Distinguished Service Professor Emeritus in Political Science at the University of Chicago.

Strauss is the author of fifteen books, in which he set himself to investigating the fundamental problems of political philosophy. Among them: *Philosophy and Law* (1935); *Natural Right and History* (1953); *What is Political Philosophy* (1959); *Liberalism Ancient and Modern* (1968).

Strauss, an ethnic Jew and refugee from Nazi Germany, looked at the regnant liberalism of mid-century America, and saw the Weimar Republic: morally weak, incapable of self-preservation. His prophecy was fulfilled by the ignominious collapse of the liberal establishment, both political and academic, in the face of the New Left.

In the Straussian view, philosophy inadvertently exposed men to certain hard truths, truths too hard for them to bear: that there are no gods to reward good or punish evil; that no one's *patria* is really any better than anyone else's; that one's ancestral ways are merely conventional. This leads to nihilism, epitomized by the listless, meaningless life of bourgeois man, or to dangerous experiments with new gods – gods like the race and the *Fuehrer*.

Straussianism poses questions that need to be asked: what is the relation of nature to culture? Can society be founded on rational principles? Has Enlightenment brought about its own fall? How did this happen? What can be salvaged from the wreck?

Strauss' own answers are:

(1) A return to treating old books *seriously*, reading them carefully and with an effort to understand them as their *authors* did, rather than as History does.

(2) A recognition of the *political* nature of philosophy, that most philosophers who wrote did so with a political purpose.

(3) A recognition that the greatest thinkers often wrote both *exoteric* and *esoteric* teachings, either out of fear of persecution or a general desire to present their most important teachings to those most receptive to them. This leads to an attempt to discern the *esoteric* teachings of the great philosophers from the clues they left in their writings for careful readers to find.

(4) A recognition of the dangers that historicism, relativism, eclecticism, scientism, and nihilism pose to philosophy and to Western culture generally, and an effort to steer philosophy away from these devastating influences through a return to the seminal texts of Western thought.

(5) Careful attention paid to the dialogue throughout the development of Western culture between its two points of departure: Athens and Jerusalem. The recognition that Reason and Revelation, originating from these two points respectively, are the two distinct sources of knowledge in the Western tradition, and can be used neither to support nor refute the other, since neither claims to be based on the other's terms.

(6) A constant examination of the most drastic of philosophic distinctions: that between the Ancients and the Moderns. An attempt to better understand philosophers of every age in relation to this distinction, and to learn everything that we as moderns can learn about ourselves by studying both eras.

Worldview L: Leo Strauss

* * *

"The philosopher who, transcending the sphere of moral or political things, engages in the quest for the essence of all beings, has to give an account of his doings by answering the question 'why philosophy?' That question cannot be answered but with a view to the natural aim of man which is happiness, and in so far as man is by nature a political being, it cannot be answered but within a political framework."

* * *

"But let us hasten back from these awful depths to a superficiality which, while not exactly gay, promises at least a quiet sleep ..."

* * *

"Because mankind is intrinsically wicked, he must be governed. Such governance can only be established, however, when men are united — and they can only be united against each other."

* * *

Worldview LI: Allan Bloom

* * *

"As it now stands, students have powerful images of what perfect body is and pursue it incessantly. But deprived of literary guidance, they no longer have any image of a perfect soul, and hence do not long to have one. They do not even imagine that there is such a thing."

* * *

"The substance of my being has been informed by the books I learned to care for."

* * *

"Education is the movement from darkness to light."

* * *

"The most successful tyranny is not the one that uses force to assure uniformity but the one that removes the awareness of other possibilities, that makes it seem inconceivable that other ways are viable, that removes the sense that there is an outside."

* * *

"Music is the medium of the human soul in its most ecstatic condition of wonder and terror. Nietzsche, who in large measure agrees with Plato's analysis, says...that a mixture of cruelty and coarse sensuality characterized this state... Music is the soul's primitive and primary speech... without articulate speech or reason. It is not only not reasonable, it is hostile to reason."

* * *

"Rock music has one appeal only, a barbaric appeal, to sexual desire - not love, not eros, but sexual desire undeveloped and untutored."

* * *

Straussianism vs. Liberalism

The modern world is held to be the deliberate creation of the modern philosophers – namely, the Enlightenment*, which gave birth to both scientific-technological progress and the liberal ideology of social-political progress.*

The Enlightenment argued that instead of hiding philosophy, philosophers should reform society to make it more hospitable to philosophy: in particular, by undertaking the project of modern science*, by which reason masters nature and provides material gratifications (safety, health, wealth) to common men; Thus, physical science and technology would provide the know-how, while liberalism would provide the conditions of liberty and equality enabling men to pursue their self-interest.*

The great significance of Strauss for mainstream conservatives is that his is the deepest philosophical analysis of what is wrong with liberalism. Technocratic, legalistic, and empirical criticism of liberalism are all very well, but it is not enough. He believes that contemporary liberalism is the logical outcome of the philosophical principles of modernity, taken to their extremes. In some sense, modernity itself is the problem. Strauss believed that liberalism, as practiced in the advanced nations of the West in the 20th century, contains within it an intrinsic tendency towards cultural and moral relativism, which leads to nihilism. He first experienced this crisis in his native Germany's Weimar Republic of the 1920s, in which the liberal state was so ultra-tolerant that it tolerated the Communists and Nazis who eventually destroyed it and tolerated the moral disorder that turned ordinary Germans against it.

Strauss believed that America is founded on an uneasy mixture of classical (Greco-Roman), Biblical, and modern political philosophy. Conservatives have not failed to note that a significant part of the mischief of liberalism consists in abandoning the biblical element; this story has been told many times and is well represented in Washington. Where Strauss comes in is that he is the outstanding critic of the abandonment of the classical element. His key contribution to fighting the crisis of modernity was to restore the intellectual legitimacy of classical political philosophy, especially Plato and Aristotle.

Strauss' first move, which came as a stunning shock to a 1950s academic world sunk in scientism and desirous of making "political science" substitute for political philosophy, was to reactivate the legitimacy of ancient philosophy as real political critique. It is hard to overstate how unlikely this seemed at the time, it having been a casual article of faith since ancient philosophy had no more to say about modern political problems than ancient physics about modern engineering. Nevertheless he succeeded. When leftists today *feel obliged to denounce Great Books curricula, it is because they know, consciously or unconsciously, that classical thought is very much alive and is a real threat to them.*

The holy grail of Straussian scholarship has been to understand the ancient philosophers not from a modern point of view but from their own. The implication is that we then become free to adopt the ancient point of view towards modern political affairs, freeing us from the narrowness of the modern perspective and enabling us to step back from the distortions and corruptions of modernity. Strauss contends that the modern view of politics is artificial and that the ancient one is direct and honest about the experience of political things.

Strauss was not ignorant of the reasons modern political philosophy had come about. He saw it as a grand compromise made when the demands of virtue made by ancient political philosophy seemed too high to be attainable. Modern political philosophy provides no rational basis for higher human achievement, but it provides a very solid basis for the moderate human achievement of stability and prosperity.

Strauss not only believed that the great thinkers of the past wrote Straussian texts, he approved of this. It is a kind of class system of the intellect, which mirrors the class systems of rulers and ruled, owners and workers, creators and audiences, which exist in politics, economics, and culture. He views the original sin of modern political philosophy, which hundreds of years later bears poisonous fruit in the form of liberal nihilism, to be the attempt to abolish this distinction. It is a kind of Bolshevism of the mind.

The key hidden step in the Machiavellian view, a bold intellectual move that is made logically rigorous and then politically palatable by Thomas Hobbes and John Locke, is to define man as outside nature. Strauss sees this as the key to modernity. Man exists in opposition to nature, conquering it to serve his comfort. Nature does not define what is good for man; man does. This view is the basis for the modern penchant to make freedom and comfort the central concerns of political philosophy, whereas the ancients made virtue the center. Once man is outside nature, he has no natural teleology or purpose, and therefore no natural virtues. Since he has no natural purpose, anything that might give him one, like God, is suspect, and thus modernity tends towards atheism. Similarly, man's duties, as opposed to his rights, drop away, as does his natural sociability. The philosophical price of freedom is purposelessness, which ultimately gives rise to the alienation, anomie, and nihilism of modern life.

Strauss' elitist view of the 'good society' is strikingly similar to the view cultivated for centuries by the Catholic and Orthodox Churches and by Orthodox Judaism, not to mention other religions: there is a small number of *men who know the detailed truth; the masses are told what they need to know and no more.*

What is then the answer to nihilism? Does the restoration of classical political philosophy really re-establish convincing values? Are Aristotle's virtues really virtues? Is Plato's critique of democracy true?

Strauss believed that the great competitor of philosophy is revealed religion. He believed that reason and revelation cannot refute each other. He believed that religion was the great necessity for ordinary men. For him, religion is in essence revealed law, and he took his native Judaism to be its paradigm. Strauss had an ambivalent attitude towards Christianity. On the one hand, Christianity is the only practicable religion for America. On the other hand, Christianity has troubling strands within it, like St. Aquinas' claim that reason and revelation are compatible, for him the precise opposite of the most important truth. It is a commonplace that Christianity is a synthesis of Greek philosophy with biblical theism; Strauss rejects the idea that such a synthesis is possible. For him, religion is at bottom simply dogmatic and unapologetic about it.

Although Strauss was a critic of the natural-right teachings on which the US society is based, he only criticizes modern *natural-rights because he thinks it destroys itself and becomes untenable. As Strauss says, "just because we are friends of liberal democracy does not entitle us to be flatterers of liberal democracy." In his public utterances on contemporary politics he was a conventional conservative patriot who backed the United States against Nazi Germany in WWII and Soviet Russia in the Cold War. He was boldly anti-Communist at a time when most Western intellectuals were dangerously equivocal, if not outright sympathetic.*

What is undeniable is that he did see the United States as the most advanced case of liberalism and therefore the most susceptible to the nihilism he dedicated his life to fighting. But he also saw the United States as partly founded on the classical and Biblical political wisdom that offered an answer. There is no doubt that he saw the United States as the world's only hope. One of the lessons we can draw from him is that the essence of liberal modernity is so problematic that America cannot afford for its essence to adopt liberal modernity, whether that liberalism takes Lockean, classical (in the sense of the 19th century) or postmodern form.

*Strauss held that '*globalism*' (the liberal project of modernity of a universal society consisting of free and equal nations, each consisting of free and equal men and women, with all these nations fully developed as regard to their power of production, thanks to science) is* not *the inevitable culmination of modernity, as its proponents believe, but a* perversion *which would first make nations unfree and then abolish them outright.*

He believed that world citizenship is impossible, as citizenship, like friendship, implies a certain exclusivity, and universal love is a fraud. (If it exists, it is the province only of God.) Good men are patriots or lovers of their patria or fatherland, which must by definition be specific. The United Nations has failed in its fundamental mission: to prevent war.

Strauss' work was extended by his pupil ***Allan David Bloom*** *(1930–1992, USA), social philosopher, humanities scholar and academic educator. His seminal work,* The Closing of the American Mind[866] *(1987) is an open sharp criticism of the leftish analytic philosophy as a movement that originated in post WWII American Universities. To a great extent, Bloom's criticism revolves around the devaluation of the Great Books of Western Thought as a source of Wisdom. However, Bloom's critique extends beyond the university to speak to the general crisis in American Society.* Closing of the American Mind *draws analogies between the United States and the Weimar Republic.*

Bloom saw these social and cultural developments as stemming from a wholesale importation (by European intellectuals that arrived on American shores as emigres and refugees) of the latter day, nihilistic stages of German idealistic philosophy, ultimately traceable to ***Hegel****,* ***Nietzsche****,* ***Marx****,* ***Freud*** *and* ***Heidegger****. The anti-democratic pessimistic and nihilistic ideas of Nietzsche and Heidegger were transformed and 'laundered' by* ***J.P. Sartre*** *and the New Left. When combined with Freud's shallow pseudo–scientific theory of the mind (which forever seeks to explain higher, noble impulses and achievements as repressions and sublimations of lower urges), the result was a worldview and society that would have horrified* both *Nietzsche and the rationalist Enlightenment philosophers who created modernity to begin with. This hybrid post WWII worldview of the West was made possible by a paradoxical combination of:*

- *Advancing and indiscriminate democracy.*
- *Eroding stature of the ideals of the Enlightenment.*
- *An alliance of the revolutionary Left and the old, authoritarian Right – both of which despised that epitomy Democratic Man – the Bourgoise.*

[866] Bloom was born in Indianapolis to Jewish parents. He entered the University of Chicago (1946) and earned his Ph.D. there (1955) under **Leo Strauss**. He later taught at the Universities of Yale, Cornell (1963), Tel-Aviv and Toronto (1978) before returning to Chicago. After Blooms passing, Saul Bellow, his associate at the University of Chicago, implied that Bloom was gay and died of complications of AIDS.

Since the average Everyman is the ultimate ruler in a democracy, he needs to be flattered. And so the Nietzschean right to "kill God", create new gods, and dispense with ordinary right and wrong, morality and cultural standards – rights that Nietzsche meant to reserve for the "inner directed" superior man – were now, in an ironic twist, copiously bestowed upon every person who wanted to rebel against society's 'values' (formerly described with adjectives such as 'right', 'wrong', 'just', 'noble', 'learned' etc.) and 'do his own thing'. People were encouraged to 'find themselves', 'speak truth to power', etc. – anything but be boring Bourgoise, i.e. a 'cog in the machine'. When they follow their untutored whims they are said to be "creative"; every and any predilection that is not at present criminal or contrary to the secular fetish or moralism of the day, is merely "a lifestyle choice" – and the pressure is on to extend compassion, legality or even full societal sanction to "lifestyles" that were formerly merely tolerated – up to and including ideological terrorism (provided, of course, its perpetrators are some flavor of accepted 'Other'!).

This bizarre deification of the undeserving also explains, in Bloom's view, the phenomenon of Rock music — a way for savvy business moguls to tap the immense disposable income–resources adolescents are able to syphon from their parents, by offering a low art form whose drumbeats appeal directly to youngster's tribalism and untutored sexual awakening. Like drugs, much of this music offers a pale simulacrum of the 'highs' normally earned by great and noble achievements. Yet these satisfactions, delivered with the electronic and digital technology achieved by humanity's best thinkers and true rebels over a period of centuries, are readily available to anyone.

And the worst aspect of this European cultural brew, according to Bloom, is that the mental universe of most Americans has come to be delimited by the loan concepts enshrined in the above words. The people who coined these terms and imported them hither were familiar with their Greek, Judeo–Christian and Enlightenment origins, but today's Americans by and large are not. So their intellectual horizons have narrowed. In America's ultra–democracy, the utterances of Rock stars, basketball players, or purveyors of the latest environmental, atheistic or multicultural fads are treated on par with the greatest intellectual canons of Western tradition. Someone raised in this America and schooled in its universities, finds it exceedingly difficult to read the words of Plato, Aristotle, Plutarch, Shakespeare, Locke or Kant and absorb their meaning directly. Rather, they become filtered through the mental fog created by the neologisms of the later German nihilists and their disciples. The deification of any and every individual and his or her rights, development and pleasures in our society, at the expense of common projects (whether a cultural heritage or raising a family), led to inevitable problems in married life – and high divorce rates. That, in combination with the easy, early and consequence–free availability of sexual intimacy, which becomes separated *from* eros *and the cultural longings with which it was formerly associated has – in Blooms experience as a teacher of the young – completely changed the college. It made many students duller and more cynical human beings.*

Bloom hewed to the Straussian approach to social and political philosophy, which contrasted the views of the ancients with those of modernity – and traced the latter to the Enlightenment. In antiquity, the roots of the West's religions *(revealed truth, justice, piety and morality) sprouted in Judea (Moses, Samuel, Elijah, Amos, Hillel, Ben Zakai, Jesus); while* rational philosophy *(logico-mathematical, scientific, aesthetic, moral, economic and socio–political) came into being in Greece, Ionia and the Hellenistic world (Euclid, Pythagoras, Thales, Socrates, Aplaton, Protagoras, Aristotle, Archimedes, Aristarchos, Heron, Ptolemy and the rest).*

When the Church achieved supremacy in Europe, it borrowed logico-rhetorical tools from Aristotle and the Neo–Platonists to codify its theology, but forbade any further independent thinking. The Enlightenment natural and social philosophers adopted ancient Greek rationality and science as their own, further developing them. While their democratic inclinations and morality were Christian (and thus, ultimately, Judaic) in origin, they rebel against the Church's Aristotle-fortified and ossified authority – but not against Aristotle himself (though his theories of physics turned out to be wrong). These thinkers were avowed rationalists; *and while they argued and remonstrated with their ancient colleagues (Francis Bacon replacing the* new republic *for Plato's* republic*), they had no quarrel with the basic Greek approach. Thus, according to him, the Enlightenment was a gigantic, multi–century project to diminish clerical power and educate the European political elites in the ways of democracy.*

Over time, however, several things went awry in this program. The University, which the rationalists converted from theological strongholds to bastions of the liberal arts and sciences, did manage to stand up to the aristocracy and Church. Yet later, it became too eager to please its new master – the common man *– to the point where its properly elitist role gradually eroded. And along with it, so did the kind of liberal education that used to produce thoughtful, responsible national leaderships. Indeed, rationality itself came to be viewed as merely one point of view. And what is worse, many shallow sociological, economic, political and even pseudo-scientific 'theories' came to be spawned, adopted and championed by nominal rationalists. They defend these notions as fervently as their predecessors-in-spirit would champion a religious dogma*[867]*.*

867 As Bloom points out, a rationalized dogma is the only tool that can root out reason itself.

1936 CE *Gravitational lensing*: In the December 04, 1936 issue of *Science*, Albert Einstein published a note entitled "*Lens-like Action of a Star by the Deviation of Light in the Gravitational Field*". In it he predicted a General-Relativistic phenomenon, the observation of which in 1979 provided a new experimental test of GTR. Moreover, it helped astrophysicists and cosmologists to estimate Hubble's constant and determine the amount of invisible matter in the universe (1998). It thus took almost half a century before the cosmos known to us finally reached the dimensions (in the wake of the discovery of *quasars*), and astrophysics the technical sophistication, to render *gravitational lensing* an observable reality.

According to General Relativity, an object in space that is sufficiently massive acts as a *lens* for light coming from more distant objects in the same line of sight with respect to observers on earth. If the configuration of these background and foreground objects is right, the lens effect could produce two or more identical images of the more distant object or even distort its image into an *arc* or complete *ring* about the foreground object's image.

The first actual optical gravitational lens was discovered in 1979 by a British astronomer, Dennis Walsh. The lens in this case is a giant elliptical *galaxy*, and it produces a double image of a more distant *quasar*, since the light of the quasar is deflected to either side of the galaxy located between us and the quasar, thereby producing *two point images*. Both quasar images have the same spectral lines and redshifts, as predicted by GTR. The angular separation between the two quasar images is 6 seconds of arc.

A few other such phenomena have since been observed, including the 1998 discovery of an "Einstein ring" produced by a perfect alignment of nearer and farther objects. Astronomers used a network of radio telescopes in Britain and the *Hubble Space Telescope* (HST) to discover the Einstein ring. This *radio telescope array*, called MERLIN, found the ring, and the HST produced an image of it. The ring occurs because two distant galaxies happen to line up almost perfectly with Earth. The closer galaxy's gravitational lens spreads out the light of the more distant galaxy into a complete circle. Vast luminous arcs, or imperfect rings, have also been observed.

Astronomers can use gravitational lenses to determine the amount of matter in a galaxy by measuring how much the galaxy's gravitational field distorts the light of a more distant galaxy behind it. By comparing the gravitational effect of the nearer galaxy with the amount of visible matter in the same galaxy, astronomers can estimate the amount of invisible matter, or *dark matter*, that the nearer galaxy must hold.

The idea was not new: firstly, it is based on Einstein's own second test of GTR, namely the deflection of light by a massive star. Secondly, on his meeting with the astronomer **Freundlich** in Berlin (April 1912), Einstein discussed with him the possibility of a gravitational lensing effect (notes from that period, including his early conclusions on the subject, were indeed found).

Einstein, however, did not publish anything on the subject because he believed that there was no hope in observing this phenomenon. Indeed, the universe, as known to astronomers in the 1910's, essentially consisted of our own galaxy. Under these conditions, the observability of gravitational lensing was, per theory, almost impossible.

Nevertheless, there soon appeared precursor discussions of the idea in published works by others, among them **Oliver Lodge** (1919), **Arthur Eddington** (1920), and **O. Chwolson** (1924). Yet, Einstein himself was reluctant to publish his calculations, and did so only after much hesitation and under persistent badgering by the amateur scientist **Rudi W. Mandl** (1936).

1936 CE, summer First regular television broadcasts were made by NBC in the United States and the BBC in England. FM broadcasts from the Olympic games in Berlin. These constitute the first radio messages from planet earth that made their way past the ionosphere and into outer space (due to their high frequency). By the year 2000, they would reached receivers (if any) 64 light-years away (a distance of ca 6×10^{14} km).

Gravity's Lens – or, the triumph of an amateur's fantasy

In early April 1936, ***Rudolf W. Mandl****, an engineer from the Czech Technical University and amateur astronomer (and a Jewish immigrant refugee from Nazi Europe) walked into the offices of the Science Service in the building of the National Academy of Science in Washington DC. He came with a new idea — a proposed new test of GTR, based on observations during eclipses of stars.*

He was looking for someone to help him publish his ideas and persuade professional astronomers to take up the investigation of his proposal. He was *then invited to plead his case before professor Einstein himself: if the latter found his ideas worthwhile, he could return and seek further help from the NAS.*

Mandl indeed visited Einstein in Princeton on April 17, 1936, presenting him with a quaint combination of ideas from GTR, optics and astrophysics. He proposed a simple model according to which a sufficiently massive astrophysical object could act as a lens *for light coming from a more distant object along the same line of sight w.r.t observers on earth. He speculated that the effects of such a focusing might already have been observed, though not hitherto recognized as such.*

Among the possible effects that Mandl took into consideration were the recently discovered annular shaped nebulae — which he interpreted as gravitational images of distant stars.

The basic GTR consequence that Mandl pointed out to Einstein was that if an observer is perfectly aligned with a both 'near' and a 'far' star, then he will observe the image *of the far star as an* annular ring*, resulting from the bending of its light by the near star.*

Though Mandl's idea was daring, at its core was a valid insight that would eventually (several decades later) become not only an astrophysical confirmation of GTR but an "applied GTR" tool of astrophysics and cosmology.

To grasp the key idea, there is no need to use GTR proper, if one wishes to obtain a quantitative result up to a constant of order unity. In fact, one may employ the same arguments used by **Soldner** *(1804) to derive the deflection of light by a massive star, using only* classical Newtonian gravitational theory *and treating light as consisting of Newtonian non-relativistic corpuscles ("photons").*

Consider a distant point light–source, emitting a beam of earth–directed photons that travel along almost parallel trajectories (rays) with velocity c. Between this lensed object *and the* observer *on earth (eye or telescope) there is a mass M (lensing mass) that bends the rays and focuses them toward the observer. Assume the lensing mass to have the shape of a sphere, with a mass density distribution possessing axial symmetry along the observer's line of sight to the distant mass.*

Assume further that the angles of deflection are small enough such that their tangents can be replaced by the angles themselves (measured in radians). Let: (see Fig. 5.14)

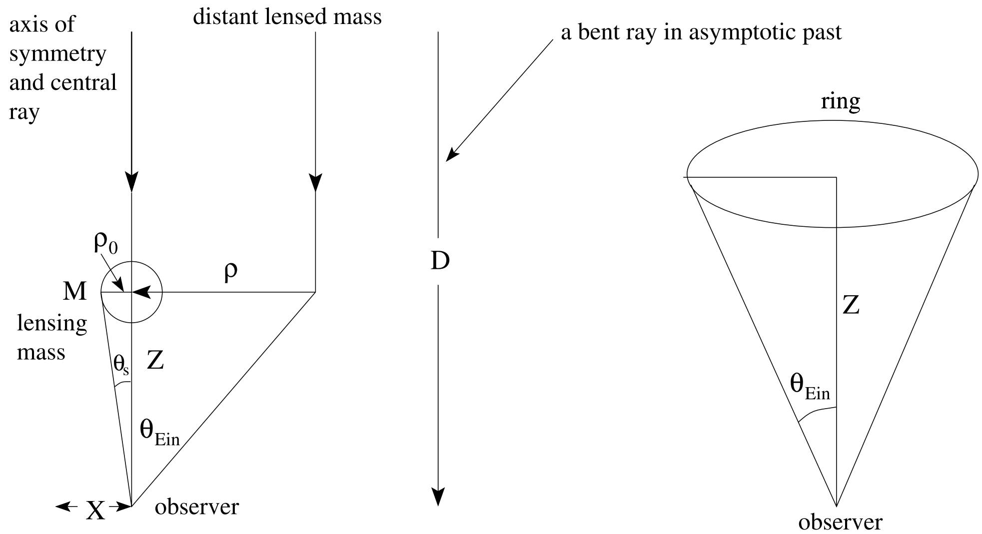

Fig. 5.14: Geometry of a 'gravitational lens'

$Z =$ *distance from center of the lensing mass M to observer on earth;*

$\rho =$ *asymptotic pre-bending distance from unperturbed central ray to a particular bent ray outside the lensing mass (called the "impact parameter" in scattering theory);*

$A_p = \dfrac{GM\rho}{(\rho^2+\xi^2)^{3/2}} =$ *instantaneous transverse gravitational acceleration component (toward the axis of symmetry) per unit photon mass;*

$\delta V_p =$ *photon's impulse (change of transverse momentum) per unit photon mass due to gravitational bending;*

$\xi =$ *variable spatial distance of central ray photon from center of lensing mass.*

In figure (5.14) light rays from a distant object in the background strike a lensing mass in the foreground. The bent rays refers to a cone extrapolated back into asymptotic past. The ring is the image seen by the observer.

In this 'Newtonian approximation' there is no dispersion *because according to the Galilean version of the Equivalence Principle, ray deflections are independent of the photon energy, assuming*[868] *(as we must) that all photons*

[868] A GTR version of this calculation, ignoring optical diffraction effects (permissible since $\lambda_{light} \ll \rho$), would show that the ray's deflection is independent of its frequency, which is to say, of its wavelength λ_{light}. In this calculation, each

move at speed c. It then follows that (in the impulse approximation, i.e. integrating along an undeflected ray):

$$\delta V_p = \int_{-\infty}^{\infty} A_p dt \approx \int_{-\infty}^{\infty} \frac{1}{c} A_p d\xi = \frac{2GM}{c} \int_{0}^{\infty} \frac{\rho d\xi}{(\rho^2 + \xi^2)^{3/2}} = \frac{2GM}{\rho c}.$$

Since the angular deflection is

$$\theta_{Ein} \approx \frac{\delta V_p}{c} \approx \frac{2GM}{\rho c^2} \approx \frac{\rho}{Z},$$

we have in this approximation:

$$\theta_{Ein} = \sqrt{\frac{2GM}{Zc^2}}, \qquad \rho = \sqrt{\frac{2GMZ}{c^2}}.$$

In his GTR, Einstein had already predicted in 1911 that

$$\theta_{Ein} \approx \frac{4GM}{\rho c^2}, \qquad \rho = \frac{2}{c}\sqrt{GMZ}$$

showing that the Newtonian value for θ is in error by a factor of $\sqrt{2} \approx 1.4$.

The above results show that there is just one ray, having one angle and one distance ρ, that bends into the observing instrument on earth for any given value of the azimuth angle. Hence the rays reaching the observer appear to be coming from a circle in the lensing–mass plane (known as the Einstein ring) with radius $Z\theta_{Ein}$. It can be shown that in the general case, when the distant light source is not a point but has some angular extent (and need not be axially symmetric) and rays penetrating through the lensing–mass periphery are considered, the lens creates either a finite-width ring image or two or more separate distorted images, on various sides of the source.

Now, since $\theta_{Ein} \propto \frac{1}{\rho}$, the angle of deflection θ_0 for light rays just grazing the edge of a deflecting object of radius ρ_0 (Fig. 5.14) is related to θ and ρ for a general *ray as follows:*

$$\theta_{Ein} \approx \theta_0 \frac{\rho_0}{\rho} \approx \frac{\rho}{Z},$$

ray's spacetime trajectory is a light-like geodesic in the curved metric induced by the foreground (lensing) mass.

and consequently

$$\theta_{Ein} \approx \sqrt{\frac{\theta_0 \rho_0}{Z}} = \sqrt{\theta_0 \theta_s}, \qquad (1)$$

where $\theta_s \approx \frac{\rho_0}{Z}$ *is the apparent angular radius of the lensing mass as it appears to an earthbound observer. Note that the fiducial grazing ray will not reach earth unless* $\theta_0 = \theta_s = \theta_{Ein}$, *which only holds when the lensing object is at distance* $Z = \rho_0/\theta_0$ *from earth.*

Mandl, who knew from Einstein's GTR result (1911) that $\theta_{Ein} \propto 1/\rho$, *now suggested to Einstein to use (1) as a new independent test of GRT, provided of course that* θ_{Ein}, θ_0, ρ_0 *and* Z *be determined from observations.*

Clearly, θ_{Ein} *could in principle be determined from the radius of the observed Einstein ring and* θ_0 *(the deviation of the grazing ray) could perhaps be determined during an* eclipse *of the lensing mass (assumed to be a star), as done by* **Eddington** *in 1919 for the sun*[869].

In his 1936 note, Einstein was rather skeptic about the experimental confirmation of 'Mandl's equation' on the ground that

"... θ_{Ein} *being of the order of magnitude of one second of arc, the angle* ρ_0/Z *is much smaller. Therefore, the light coming from the luminous circle can not be distinguished by an observer as geometrically different from that coming from the star, but simply will manifest itself as increased apparent brightness of the lensing star".*

Mandl, however, did not yield. His idea was that the lensing effect by the foreground star would result in a considerable brightness increase of the background star's light at the locus of the terrestrial observer, despite the fact that – unlike the case of a common optical lens – gravitational deflection by a massive star does not (even approximately) collect parallel light rays in one single focal point, but rather smears them out along a focal line.

Einstein obliged, and set forth to calculate this intensification. To this end he placed the observer not on the axis of symmetry, but a small distance x *away from it. It can be shown by simple geometrical arguments*

---

869 But then the distant light source used to determine θ_0 cannot, in general, be along the same line–of–sight as are the lensing star and the distant star used to measure θ_{Ein}. If M and ρ_0 are known for the lensing star in question, one could also calculate θ_0 from GTR: $\theta_0 \approx \frac{4G\,M}{\rho_0\,c^2}$.
In modern astrophysics, ρ_0 and/or M are often *deduced* from measurements of magnification and luminosity changes as the lensing mass – sometimes not optically visible at all – passes through earth's line of sight to a distant object (e.g a quasar or galaxy).

that in this case the observer will not see a ring but, instead, two point-like images. The amplification factor will then be approximately (assuming $x/Z << 1, \quad \rho_0/Z << 1$*) proportional to* $1/x$*, and hence cause infinite intensity on the system's axis of symmetry itself (still assuming the lensed object to be infinitely far away, and ignoring wave optics). Furthermore, Einstein noted the curious effect that the amplification at a given point* x increased *with the* increasing *distance from the lensing star.*

Einstein's published note became the classical starting point for the officially recorded research of gravitational lensing. He opened it with the words:

"Some time ago, R.W. Mandl paid me a visit and asked me to publish the results of a little calculation, which I had made at his request..."

In the final section Einstein concluded:

"Therefore, there is no great chance of observing the phenomenon..."

This is the peculiar story of Einstein's double encounter with the idea of gravitational lensing (1911, 1936), and of Mandl's role in the second episode. Einstein's note triggered a number of other papers which further developed the idea, taking it much more seriously than Einstein himself had done.

However, the next major step came a year later, when ***Fritz Zwicky****, then at CalTech, published (1936) two notes in the* Physical Review.

*Referring specifically to Mandl's idea, he claimed that "*extragalactic nebulae*, as a consequence of their masses and apparent dimensions, were much more likely candidates for observation of gravitational lenses" and furthermore: "Present estimates of masses and dimensions of* cluster nebulae *are such that the observability of gravitational lenses effects among the nebulae would be seen"*[870].

In retrospect, Mandl's role in establishing this subject was crucial since he had helped turn gravitational lensing into a theoretical reality long before it became an observed one. What Mandl achieved, in the end, was to introduce a single idea into the canon of accepted scientific knowledge, an idea which

870 Zwicky's "extragalactic nebulae" means, in today's parlance, *galaxies* outside our sun's own (*milky way*) galaxy. By the end of the 20^{th} century, gravitational lensing became a routine tool of "applied GTR". It is used to better observe distant galaxies via the lensing of their light by foreground objects (including brightness and shape changes *and* magnification), as well as to survey dark matter in our galaxy (by the lensing of background stars which they cause), and other applications.

was rejected before only because the effect was deemed to be inaccessible to observations.

It thus happened that Mandl's initiative, persistence[871] *and vision, together with the fact that Einstein lent prominence to it with his 1936 publication, stimulated a broad discussion among astronomers and astrophysicists, and this discussion lasted until the effect was eventually confirmed by observations.*

Mandl's success was a victory of both theory and fantasy, since Einstein's publication stimulated his contemporaries to imagine the strange world of gravitational lensing, and thus to take the effect seriously and explore the conditions under which it might be observable, after all.

Furthermore, this episode shows that science develops not only by the exclusive combination of outstanding scientists working under the auspices of institutions of professional learning. In addition to – and often preceding – specialized theories, it may receive impetus from elementary ideas supplied by non-professionals outside this system.

Mandl's role in the history of gravitational lensing illustrates that innovative explorations in the natural sciences is not necessarily the privilege of a few distinguished scientists and other team members, and that even amateurs can sometimes contribute. After all, Mandl's expectations about the promise of gravitational lensing to provide new observational confirmations of GTR, have obviously been amply fulfilled.

[871] There is evidence that Mandl rather obsessively attempted to enlist professional scientists to his cause. Among them were **William Francis Gray Swann**, director of a center of cosmic ray studies; the Nobel laureate physicist **Arthur Holly Compton** and **Robert Andrews Millikan**; **V.K. Zworykin**, research scientist at the Radio Corporation of America (RCA) and one of the inventors of the first all-electronic television system. Some of them reacted with interest and gave Mandl's ideas some brief consideration, while others excused themselves pleading lack of time or understanding. None of them, in any case, pursued the matter seriously.

1936 CE

- 'Penguin Books' introduced the first *paperback*.
- Fluorescent lighting was introduced.

1936 CE The first *Fields Medal* [872] was awarded at a World Congress in Oslo. It is regarded as mathematics' closest analogue to the Nobel Prize[873] (which does not exist for this field), and awarded every four years by the international Mathematical Union to one or more outstanding researchers. Up to four medals could be awarded at each congress. A prize of 15,000 Canadian dollars goes with the Medal.

The Fields Medal is made of gold, and features the head of Archimedes (287–212 BCE) together with a quotation attributed to him (in Latin rather than his own Greek):

"TRANSIRE SUUM PECTUS MUNDO QUE POTIRI"

("Rise above oneself and grasp the world")

The following table summarizes Field Medals winners during 1936–2002. An asterisk indicates a mathematician of Jewish origin.

---

[872] For further reading, see:

- Devlin, K., *The Millennium Problems*, Basic Books, 2002, 237 pp.

[873] Alfred Nobel did not create a prize in mathematics because he believed only in inventions or discoveries of great *practical* benefit to mankind. It is commonly stated, however, that Nobel decided against a Nobel Prize in mathematics because of anger over the romantic attention of the Swedish mathematician **Gosta Mittag-Leffler** to a woman in his life (perhaps his Viennese mistress, Sophie Hess). There is no historical evidence to support this anecdote.

1936 CE **Heinrich Karl Johann Focke** (1890–1973, Germany). Aircraft designer. Developed the first practical airworthy *helicopter*, FW 61. Began building aircraft (1908); built monoplanes (1919–1920).

1936–1939 CE *The Spanish Civil War.* The prelude to WWII. Started as an internal conflict between a 'popular front' of Socialists, Syndicalists and Communists (known as *Republicans*) against the traditionally pro-monarchist forces — clergy, army and aristocracy (known as *Nationalists*). Had the Spaniards been left alone, the war would hardly have been the major tragedy it turned out to be. But intervention by other countries followed appeals for help by both sides and the war was not to remain a purely Spanish affair: Germany and Italy supported the Nationalists and seized the opportunity to test weapons and men in the field.

The Soviets, in turn, gave materiel and ideological support to the Republicans, but were incapable of matching the aid supplied by the fascists. To assure the survival of the Republicans, the wholehearted cooperation of the democracies was needed. Although public opinion in general supported the Republicans, the governments of France, England and the United States were not willing to risk a general war and remained neutral. (The U.S., for example, prohibited export of arms and munitions to either side in the conflict.) Volunteers from 50 countries did, however, join on the side of the Republicans, but supplies from Germany and Italy finally tipped the scales.

The war lasted almost three years: much of Spain lay in ruins and more than 700,000 died. The war did work for the Nazis in Germany as a diversion to cover their bloodless expansion in central Europe: WWII broke out five months after the Spanish Civil War ended. The big winner of the war was of course El Caudillo himself whose dictatorship lasted for nearly 40 years.

1936–1941 CE **Leopold L. Infeld** (1898–1968; USA, Canada and Poland). Theoretical physicist. Collaborated with **Albert Einstein** at Princeton (1936–8) on the N-body problem in GTR, and with **Max Born** on non-linear corrections to Maxwell's equations in the presence of strong fields.

Infeld was born in Cracow, Poland, and received his Ph.D. in 1921. He came to Princeton's Institute of Advanced Study in 1936, on a scholarship, after a few months in Edinburgh, Scotland, where he worked with Max Born. He later became a professor at the University of Toronto (1938–1950) and Warsaw (1950–1968).

In his work with Albert Einstein and **Banesh Hoffmann** (1906–1986) on the N-body problem, the gravitational field is no longer treated as an external field. Instead, it and the motion of its sources are treated *simultaneously*.

Newtonian celestial mechanics in its axiomatic structure consists of two clearly separate parts: the law of motion, and the law of gravity, which gives rise to the forces that keep the heavenly bodies in their orbits. The two parts stand alongside each other, unconnected. This separation into two strictly distinct sets of laws had not been overcome even by Einstein's initial treatment of motion in the general theory of relativity.

However, by the early 1920s investigations by Lorentz, Eddington, and Levi-Civita suggested that in the general theory of relativity these two sets are not really separate. After two years' work (1938) Einstein, Hoffmann, and Infeld were able to show, in a voluminous publication, that the field equations do in fact contain everything — not only the generation of the gravitational field as spacetime curvature caused by energy-momentum distribution, but also the motions and evolutions of this distributions in response to the gravitational fields.

This obviated the earlier separate "law of motion", according to which masses follow *spacetime geodesics* in the absence of non-gravitational forces; this former axiom of GTR henceforth became merely an *approximation.* Thus the general theory of relativity now described not only space, time, and gravitation, but also, for the first time, the dynamics of matter in response to gravitational fields.

The equations derived by EHI are widely used in analyses of planetary orbits in the solar system.

In the same year as this publication, there also appeared, in April 1938, a book by Einstein and Infeld, *The Evolution of Physics.* This work, reflecting the history of a discipline through the eyes of its greatest representative, owed its genesis not to Einstein's desire to communicate, but to economics at the Institute for Advanced Study.

"Infeld is a splendid fellow. We've done a very pretty thing together," Einstein reported after six months of joint research, but despite his fervent support the institute would not extend Infeld's modest scholarship. "The Institute has treated him badly. But I'll help him prevail here." Einstein, who felt he too had been badly treated by the refusal of a scholarship for his esteemed collaborator, wanted to defray the small sum from his own pocket.

But Infeld, who was embarrassed by that suggestion, had an original idea: How about writing a book together for a wide readership? With Einstein as one of the two authors, it could not fail, so that Infeld's share in the proceeds would secure his livelihood. Infeld found a publisher who paid him an advance, while Einstein planned the contents and the basic structure of the book, which eventually helped Infeld financially.

1936–1944 CE Advent of *information transmission by coaxial cables*. Bell Telephone engineers **Lloyd Espenshied** and **Herman A. Affel** invented the *coaxial cable*. The first line connected New York to Philadelphia (1936). Since 1944, the coaxial cable has been widely used for information transmissions such as long-distance telephone lines, coded, typed, or handwritten information, facsimile (maps, pictures, charts), television programs and computer data. Vast transcontinental and international networks were established[874].

A coaxial cable contains from 8 to 20 *coaxials*. A coaxial contains a *copper tube* with a *copper wire* held in the tube's center by plastic insulators. The *tube* (about 1 cm in diameter) shields the signal from outside electrical interference and prevents the signal from losing strength. The coaxial is wrapped with steel tape for strength, protection, and electrical shielding. The cable includes serial insulated wires, as well as the coaxials. The wires are used for control and maintenance. Amplifiers that strengthen the signals may be placed about 3 km apart. Coaxials may work in pairs: one carries signals in one direction, while the other handles signals in the other direction. In 1975, a fully equipped 20-tube cable could carry 32,400 two-way conversations simultaneously.

1936–1946 CE **John Maynard Keynes** (1883–1946, England). Economist. Most influential world figure in economics since Adam Smith, Ricardo and Marx. His *General Theory of Employment, Interest, and Money* (1936) ranks among the most important books on economics. It changed economic theory and policy, and is the basis of the economic policies of most nations today. His ideas helped to shift emphasis away from *laissez faire*, the classical capitalist economic theory that maintains that government should not interfere in economic affairs.

The basis of Keynesian economics is this: the level of economic activity depends on the total spending of consumers, business, and government. If business expectations are poor, investment spending will be cut, causing a series of reductions in total spending. Consequently, the economy will be led into a depression and stay there. To avoid depression, Keynes surged *increased government spending* and *easy money* (lower interest rates and making money more available for loans). These actions he argued, would encourage investment, increase employment, and enable consumers to spend more. The

[874] Early undersea cables could transmit telegraph signals, but they could not carry the wide frequency range that make up speech. Coaxial cables with built-in amplifiers made long-distance telephony by cable possible. In the US, coaxial cable's reach extended coast to coast in 1951. The first *transatlantic* coaxial telephone cable was laid in 1956. It stretched 3621 km from Clarenville, Newfoundland, to Oban, Scotland.

analysis showed that high levels of demand were essential for both full employment and economic growth.

Keynes was born in Cambridge, England and studied at Cambridge University. He served in the British Treasury (1915–1919) and became a member of the British Peace delegation after WWI (1919). During 1920–1922 he launched a polemical attack on the attitudes and approach of the Victorious Allies, especially in the matter of German reparations[875]. His books on the subject have encouraged appeasement policy pursued by the UK government towards Germany in the 1930s.

Between the world wars Keynes was a financial adviser in London and a professor at Cambridge. He played a large part in the formulation of UK economic strategy during WWII. After the war he helped create a new basis for international monetary and economic cooperation. The outcome was the establishment of the '*World Bank*'.

Today he is best known for the *Keynesian revolution*: the economic theory that recovery from recession is best achieved by a government-sponsored policy of full employment. The integrated economic scheme — based on aggregate demand, short-run relationships among the markets for labor, consumption goods, capital goods and money — is known as *macroeconomics*.

The flip side of Keynes' formula–tightening government spending (including payrolls and social welfare programs) to curb inflationary pressures and stabilize currencies, and *tax cuts* to stimulate the private sector and saving, which in turn can actually increase the tax base – have also been practiced quite effectively, both by international bodies such as the IMF (International Monetary Fund) in developing countries, and – most dramatically – in the UK and the USA starting in the 1980s.

Many Keynsians have blames the 1929 *Stock Market Crash* and subsequent *Great Depression* on too much *laisez faire*. However, the *initial* late–1920s market correction was healthy as long as it affected mainly speculative investment. That it spread to fundamentally solid stocks – and caused widespread hardship and unemployment – may be attributed to both the protectionist tariff polices then in vogue in the U.S, and the pre–Keynsian policies of the US Federal Reserve and the Bank of England. In a series of secret meetings in

---

875 Germany's total obligations were fixed at 29 billion dollars. The total amount of reparation paid was about 6 billion dollars. In return Germany had received a far larger amount in foreign loans. The history of reparations has been compared to a merry-go-round: Germany borrowed American funds to pay reparations to the Allies, who used the money to repay their debts to the United States, who lent the money back to Germany.

Long Island, these institutions formulated a policy of *wage and price freeze*, which may have vastly exacerbated the market correction.

Furthermore, the New Deal policies of the Roosevelt administration were mainly *psychological* in their ameliorative impact in the US; it was only the outbreak of WWII – a decade after the crash and seven years after Roosevelt became president – that rallied Wall Street again and began to ramp up employment.

Mathematics and Economy[876]

Economy[877] *is a study of mankind in the ordinary business of life. Economy can also be defined as the study of human wants and their satisfaction or as the science of wealth and welfare.*

Economics describes the nature of behavior of an economic system. The economic system consists of the rules, principles[878] *and customs, which govern the operation of an economy (e.g. capitalistic system, socialistic system etc.). Economics investigates economic problems with the object of offering solutions. Such problems are the questions and situations arising from the operation of the system, e.g.: labor problems, the problem of taxation, etc.*

The social sciences have an uneasy relationship with mathematics: To some extent, they seek a Newtonian goal of quantification and prediction. Yet the human and environmental variables they must deal with are so many and varied, the possibility of meaningful experiment so limited, and the data so questionable, that the greatest achievements of economics so far are chiefly descriptive rather than analytic. In addition, any theory in the social sciences faces a special problem: the widespread fear that if knowledge is power, then

---

876 For further reading, see:

- Wilmott, P. et al., *The Mathematics of Financial derivatives*, Cambridge University Press, 1999, 317 pp.

877 Derived from the Greek *oikos* (house) + *nemien* (to manage) and means literally: 'household management'.

878 Examples of *economic laws*:

- *Gresham's law* (1553): 'Bad coin drives out good coin'; if someone has two coins of equal face value and debt-paying power, but one is full-bodied and the other a debased coin, the owner's inclination will be to hoard the full-bodied coin and pass on the debased coin. This was how Chancellor Thomas Gresham explained to Queen Elizabeth I why only bad coins remain in circulation whereas newly issued good coins quickly disappeared.

- *Principle of diminishing returns*: If more of one factor (e.g. labor in this case) is increased, while other factors (e.g. capital) are held constant, eventually the marginal product of that factor (labor) in this case must fall.

knowledge in the social sciences could reinforce the power of those who may already have too much.

The most widely used mathematical tools in economy are statistical, *and the prevalence of statistical methods has given rise to abstract and hugely complicated theories. Statistical theories usually assume that the behavior of large number of people is a smooth, average "summing-up" of behavior over a long period of time.*

It is difficult for them to take into account the sudden, critical points *of important qualitative change. The statistical approach leads to models that emphasize the quantitative conditions needed for equilibrium — a* balance *of wages and prices, say, or of imports and exports. These models are ill suited to describe qualitative change and* discontinuity.

Thus, economists of the 19th century believed that in a system of goods and of demand for those goods, prices will always tend toward a level at which supply equals demand. In short, the negative feedback *from the supply/demand relationship to prices leads to a stable equilibrium. Little, however, is said about how equilibria are actually attained.*

Recently, however, economists have argued that is not at all the way the real economy works. Rather, they claim, what we see more often is positive feedback *in which the price equilibria are* unstable. *Economic examples of this situation*[879] *show how paradoxical, unpredictable and surprising behavior can*

[879] Example:

When video cassette recorders (VCRs) started becoming a household item, the market began with two competing formats — VHS and Beta — selling at about the same price. By increasing its market share, each of these formats could obtain increasing returns since, for example, large numbers of VHS recorders would encourage video stores to stock more prerecorded tapes in VHS format.

This in turn would enhance the value of owning a VHS machine, leading more people to buy machines of that format. So by this mechanism a small gain in market share could greatly amplify the competitive position of VHS recorders, thus helping that format to further increase its share of the market. This is the characterizing feature of positive feedback — small changes are amplified instead of dying out.

The feature of the VCR market that led to the situation described above is that it was initially unstable. Both VHS and Beta systems were introduced at about the same time and began with approximately equal market shares. The fluctuations of those shares in the early stages were due principally to things like "luck" and corporate maneuvering.

In a positive-feedback environment, these seemingly random factors eventually *emerge even in simple systems when the components of the system interact in ways that we don't fully understand. Sometimes the complex behavior is due to* nonlinearities *in which the outcome is disproportional to the input; sometimes the problem lies with inherent,* hidden instabilities *in the system. Unlike the behavior of physical and biological systems, the awareness of the participants in the system of the rules of the game, itself influences the system in a very fundamental way, introducing nonlinearities and instabilities.*

To cope with these difficulties, mathematicians during the second half of the 20th century began to view economic processes from new angles, applying methods of the newly developed game theory*,* catastrophe theory *and* deterministic chaos theory*.*

Consider a system such as the national economy. Suppose we're monitoring some measure of the performance of the economy, say the gross national product (GNP). This observed output of the economic system is determined by many factors — interest rates, employment levels, productive capacity and the like. We can think of the economy as a kind of machine; we feed in the value of each of these input quantities and the machine then produces a level of GNP as its output.

Since the economy is a dynamical process, it's reasonable to consider the level of GNP as being a fixed-point attractor of the economic process. Thus for every set of values of the inputs, the economy moves to a particular level of GNP, which can be envisioned as a point in the state-space of the economy. And since every setting of the inputs produces such a point, there is a whole surface of GNP points that the economy may produce — at least one for every level of interest rates, money supply, production facilities and all the rest. Catastrophe theory *is designed to study the geometrical structure of this surface in an overall effort to quantify the stability of changes in the systems.*

Generally speaking, if we change the inputs just a bit, the corresponding level of GNP will also shift by only slightly. But occasionally we will encounter a combination of input values such that if we change them by only a small amount, the corresponding output will shift discontinuously to an entirely new region of the GNP surface. Such a value of the inputs is called a catastrophe

---

tilted the market toward the VHS format until it acquired enough of an advantage to take over essentially the entire market. But it would have been impossible to predict at the outset which of the two systems would ultimately win out. The two systems represented a pair of unstable equilibrium points in competition, so that unpredictable chance factors ended up shifting the balance in favor of VHS. In fact, if the common claim that the Beta format was technically superior holds any water, then the market's choice did not even reflect the best outcome from an economic point of view.

point. In colloquial terms, we might think of the catastrophe points as the straws that break the economy's back.

As it turns out, these catastrophe points arise at just those input levels where there is more than one possible fixed point to which the system can be attracted. And the jump discontinuity is a reflection of the system's "deciding" to move from the region (attraction basin) of one attractor to that of another. Catastrophe theory *shows that there are only a small number of inequivalent ways in which these jumps can take place, and it provides a standard picture for each of the different geometries that the surface of attractors can display.*

Another example is the problem of competition and prices: if production is cheaper in large quantities, the industry tends to be dominated by one company (monopoly) *or by a few* (oligopoly)*. Oligopoly can adopt one of the three strategies. Firstly, it can form a cartel (production and prices determined by negotiation) which as far as the consumers are concerned, acts like a monopoly.*

Second, one or more firms can initiate a round of predatory price-cutting to force weaker companies out of the market.

Third, in some circumstances, firms can merge, reducing the level of competition to the benefit of the remaining members. Even when these strategies are employed, manufacturers are generally unable to raise prices indefinitely since prices are affected by the elasticity of demand *too, and prices depend simultaneously on competition between producers* and *elasticity of demand. The dependence of the price on the elasticity of demand and number of producers is mathematically represented by an* equilibrium surface *displaying a* bifurcation set of the 'cusp' type.

The most interesting feature of this model[880] *is its prediction of two price ranges, one high and one low, in conditions of low to moderate elasticity of demand and moderate competition.* Transitions *between these ranges would be dramatic in cases of very low elasticity of demand (e.g. when alternative*

---

[880] An example in which the formation of an oligopoly had a dramatic impact on price was the establishment of OPEC (association of oil producing and exporting countries). These nations had previously sold their oil competitively, but in 1973 they began to set prices in concert as an oligopoly. The price of crude oil went from $2.12 per barrel in January 1973 to $7.61 per barrel a year later, and to $10.50 per barrel by January 1975. Consumption fell by 14 percent in Belgium and the Netherlands, 10 percent in West Germany, and 3.5 percent in the United States. But the elasticity of demand for oil, in the short run at least, was low, and the merchants of OPEC had little difficulty in selling all they chose to produce.

source of energy becomes readily available). A more complex model, one based on the 'butterfly' catastrophe surface, would be needed in order to describe the interaction of monopolies and oligopolies.

A third economical example concerns inflation and unemployment*, which is inevitably bound up with politics: Empirical studies have suggested that there is a trade-off between these levels, and political parties accuse each other of sacrificing those out of work to the goal of lowered inflation, or conversely of sacrificing economic stability to the goal of full employment.*

More recently, both economists and politicians have recognized that the expectation *of future inflation is an important factor. If a high level of inflation is the norm, then workers begin to demand higher wages to offset the increased cost of living they believe will come during the period of contract. These higher wages themselves have an inflationary impact. This phenomenon suggests that a qualitative model for inflation should include the* expected inflation rate *as one control factor and* unemployment *as the other. We meet again the 'cusp' bifurcation set, which predicts a dramatic drop in inflation rate under conditions of a drastic increase of unemployment coupled with high inflation rate.*

Catastrophe theory is also useful in assessing the "fine tuning" of quantities such as money supply (which affects inflation via loan rates) and the government's expenditure for goods and services (which increases employment by raising total demand). The value of models based on this theory lies in its indication that the sequence *in which the control factors are altered can, at any given moment, be at least as important as their quantitative levels.*

The above examples serve to show that there is an enormous gulf between the highly simplified static *economists' models and the complex world to which they are applied.*

Another important problem concerns the interpretation of price – fluctuations: When analyzing prices of commodities, securities, or financial instruments in a variety of markets, a commonly used assumption is that many of the fluctuations observed in the market prices (known as "noise") are the result of purely stochastic (i.e. random) processes. One recognizes, of course, the effects on prices of external influences such as political developments, weather (especially important in commodities markets), and a variety of macroeconomic factors. In addition, there are other well-understood, time-dependent influences such as time to delivery of a future contract. But aside from these effects, the prevailing wisdom can be represented by a stochastic process; once the underlying trends are subtracted out, the remaining price fluctuations often appear to be random.

Furthermore, there was a conviction that small, transient changes had nothing to do with large, long-term changes: small-scale ups and downs during *a day's transactions are just noise, unpredictable and uninteresting; long-term changes are determined by deep macroeconomic forces, such as the trends of war and recession. Yet, that dichotomy was found to break down in many cases*[881]*. Evidence was found that tiny changes and grand ones were bound together across all scales and that within the most disorderly realms of data lurked an unexpected kind of order.*

A simple example serves to show how chaos may enter an economic system: suppose we have a simple market with just one commodity with time-dependent price $p(t)$ *such that*

$$p(t+1) = Ap(t) - Ap^2(t).$$

This is the well-known logistic map, which for $A > A_c \approx 3.57$ *renders* $p(t)$ *chaotic*[882] *except in isolated A-intervals. For* $A > 4$*, the iteration of the map diverges for most initial conditions. This behavior can easily be mistaken for randomness, for even if we apply some sophisticated statistical methods to the iterations of this map, we are not assured of finding any structure! Many chaotic systems pass as random under common statistical tests*[883]*.*

---

881 **Bachelier** (1900) claimed that successive price changes are statistically independent and follow, in the first approximation, the one-dimensional Brownian motion.

Mandelbrot (1963) analyzed cotton price data at the New York City Cotton Exchange, 1880–1940, and interpreted this data as having a *fractal structure* with dimension $D = 1.7$, thus bearing the first evidence for *scaling* in economic, i.e. curves of daily changes and monthly price changes corresponded perfectly! Moreover, the degree of variation had remained constant over a tumultuous period of 60 year period that saw two world wars and a depression.

882 The discretization of the first-order *differential equation* $\dot{x} = F(x)$ leads to a first-order *difference equation* $x_{n+1} = F(x_n, c)$. In this form, the dynamics can be equally well viewed as a sequence of mapping $F\colon x_n \to x_{n+1}$. The dynamics of the difference equation is much richer than the first-order ODE because it is free from the continuity restrictions of differential equations; x_n can 'jump around' on the real axis, whereas a non-periodic $x(t)$ can only pass a point once if $\dot{x} = F(x)$. This freedom makes it possible for the difference equation to exhibit several interesting types of bifurcation sequences, leading to various forms of coherent or 'chaotic' behavior, depending on the magnitude of the control parameter c.

883 A simple test, though, will help to differentiate between randomness and deterministic chaos in the case of the logistic map; we construct a two-dimensional graph of $p(t+1)$ against $p(t)$ for a set of integer t-values in a given interval. If the values of $p(t)$ were really random, then our 2-dimensional plot would look like a scatter of points. On the other hand, a plot constructed from a lo-

Thus, depending on the value of A, *the nonlinear regularity mechanism (i.e., the term* $-Ap^2(t)$ *in the equation) could create all kinds of interesting price movements as a function of time, even random-looking ones.*

It may be that in a nonlinear market, the price movement may not be solely due to the new information affecting the market but may result partly from the nonlinear dynamics of the market itself, and these may indeed be vastly more complicated than that of the simple logistic map.

To complicate matters still more, the environment in which a market exists is not static. Changes take place in societies and economies on all time scales, from seconds to millennia. A financial market, coupled to other markets and to the society at large, will, in some enormously complex way, reflect in its prices all these changes over all time scales. These markets have exquisitely intricate self-regulatory mechanisms, reflecting the effects of human psychology, social behavior and, to some extent, rational thought.

A final example involves an economic system which defies any mathematical formulation:

Consider the curve $y = ax^{\alpha}(100 - x)^{\beta}$ *which purports to relate the percentage tax-rate* x *to the government's revenue* y *(known as the Laffer Curve). If there is too much taxation, people will not work as hard for a salary and look for other non-cash benefits, so the revenue will drop. However, data for the U.S. economy over the past* 50 *years reveals a 'neo-Laffer curve' which resembles the former only near the trivial points* $x = 0,\ 100$, *but looks totally chaotic in between these points.*

These results show that there is no Tax Rate – Government Revenue map, because there is no causal connection; human nature is presumably too complicated for such a connection to be deterministic. What is indeed fortunate, and often amazing, is that some complicated systems do appear to have dynamics which can be approximated by simple first order models, and we often do not have any profound physical understanding as to why this occurs.

1936–1949 CE **Eugène Louis Felix Néel** (1904–2000, France). Physicist. Predicted a fourth type of magnetism — *antiferromagnetism* (in addition

gistic map will render a *parabola*! A fair number of financial and economic data series have been analyzed using these methods, and there is significant evidence for the existence of underlying nonlinear processes in economics and finance.

to dia- , para- , and ferromagnetisms). He argued for a crystal model in which two lattices having their magnetic fields acting in opposite directions are interlaced. Their opposite magnetic fields would cancel, leaving the crystal with little observable magnetic field. His predictions were verified by experiment (1938), and further confirmed by neutron diffraction techniques (1949).

Later, Néel successfully predicted magnetization configurations in thin films and near surfaces. He also explained the strong magnetism found in ferrite materials such as magnetite (1948), demonstrating that if the magnetic field of one of the two lattices (mentioned above) were stronger than the other, there would be an observable magnetic field (*ferrimagnetism*). His work on ferromagnetic materials saw great application in the *coating of magnetic tape*, as well as in the processing of permanent magnets for motors and of *magnetic storage media* used by computers. He was awarded the Nobel Prize for Physics jointly with **Alfven**.

Néel was born in Lyons and graduated from the Ecole Normale Supérieure. He was later Professor of Physics at Strasbourg University (1937–1940) and Grenoble (1940).

1936–1949 CE **Matvei Petrovich Bronstein** (1906–1938, Soviet Union), **Jacques Solomon** (1908–1942, France) and **Carl Bryce Seligman DeWitt** (1923–2004, Belgium) — theoretical physicists and pioneers of *quantum gravity*, made the first approaches to quantize general relativity in an overall effort to unify gravity with quantum theory.

Bronstein entered Leningrad University (1926), graduated (1929) and joined the Leningrad Physico-Technical Institute (1930), where he worked with **Ioffe**, **Frenkel**, **Fock**, **Tamm** and **Landau**. In 1935 he presented his Doctoral Thesis on "Quantizing Gravitational Waves", to Vladimir Fock and Igor Tamm. In 1936, the work was published in Russian[884], as well as in a condensed German version[885].

On Aug 6, 1937, Bronstein was arrested in Kiev on the charge of "active involvement in a Leningrad counterrevolutionary organization" and was ex-

[884] Bronstein, M.P., "*Kvantovanie gravitatsionnykh voln [Quantization of gravitational waves]*", Zhurnal Eksperimentalnoy i Teoreticheskoy Fiziki G, pp. 195–236, 1936.

[885] Bronstein, M.P, "*Quantentheorie schwacher Gravitationsfelder*", Physikalishe Zeitschrift der Sowjetunion, 9, pp. 140–157, 1936.

ecuted by a Soviet NKVD firing squad on Feb 18, 1938[886,887]. His grave is unknown and references to his name disappeared from the annals of Soviet physics for several decades. Only 20 years later did his widow, the writer Lydia Chukovskaya, learned the exact date of his death.

Bronstein was first to claim that there is an essential difference between quantum electrodynamics and the quantum theory of the gravitational field. He indeed showed that general relativity and quantum theory are *fundamentally* difficult to unify. In that he disagreed with **Pauli** and **Heisenberg** (1929) who believed that the gravitational field could eventually be easily quantized along the lines of QED.

Indeed, Bronstein realized the intrinsic difference: in QED, an infinite charge density in the test body is, in principle, conceivable, whereas in the case of gravitation, the test body's gravitational radius should not exceed its real linear dimensions. Bronstein then derived [long before **Wheeler** (1955)] the intrinsic limitations of the quantization of the gravitational field, related to *Planck's scales*[888].

---

[887] Gorelik, G.E., *Matvei Bronstein and quantum gravity: 70th anniversary of the unsolved problem*, Physics – Uspekhi, 48(10), pp. 1039–1053, 2005.

[888] In his doctoral thesis (1935), Bronstein carried out the quantization of the linearized Einstein equations by the Fermi method, developing the quantum analogue of Einstein's quadrupole radiation formula, and deducing the Newtonian law of attraction from the interchange of longitudinal gravitational quanta. He then proceeded to some critical reflections on the physical significance of his results.

He carries out an analysis of the measurability of the (linearized) Christoffel symbols, which he takes to be the components of the gravitational field. By analogy with the then-recent Bohr-Rosenfeld analysis of the measurability of the electromagnetic field components, he shows that there are limitations on the measurability of the gravitational field components implied by the uncertainty relations between position and momentum of a test body, the acceleration of which is used to measure the gravitational field. *But he notes that there is an additional gravitational complication, which has no electromagnetic analogue:* To measure the components of the electromagnetic field, it is permissible to introduce electrically neutral test bodies, which have no effect on the field being measured. But in the gravitational case, due to the universality of gravitational interactions, the effect of the energy-momentum of the test bodies on the gravitational field cannot be neglected — *even in the linear approximation.* Bronstein derives an expression for the minimum uncertainty in a measurement of a component of the Christoffel symbols that depends inversely on the mass

At least one physicist outside the Soviet Union acknowledged, and indeed extended, Bronstein's views. In 1938 the French physicist **Jacques Solomon** after summarizing Bronstein's argument concluded:[889]

"In the case *when the gravitational field is not weak, the very method of quantization based on the superposition principle fails, so that it is no longer possible to apply a relations such as [the equation setting a lower limit on the measurability of the linearized field strength] in an unambiguous way... Such considerations are of a sort to put seriously in doubt the possibility of reconciling the present formalism of field quantization with the non-linear theory of gravitation.*"

In one of the many tragic ironies of history, both of these pre-war advocates of the need for a radically different approach to quantum gravity perished prematurely. Jacques Solomont was a Communist militant active in

---

density of the test body, just as Bohr-Rosenfeld's corresponding result does on the charge density r of the test body. He then states what he sees as the crucial difference between the two cases:

"*Here we should take into account a circumstance that reveals the fundamental distinction between quantum electrodynamics and the quantum theory of the gravitational field. Formal quantum electrodynamics that ignores the structure of the elementary charge does not, in principle, limit the density of ρ. When it is large enough we can measure the electric field's components with arbitrary precision. In nature, there are probably limits to the density of electric charge... but formal quantum electrodynamics does not take these into account... The quantum theory of gravitation represents a quite different case: it has to take into account the fact that the gravitational radius of the test body ($k\rho V$) must be less than its linear dimensions $k\rho V < V^{1/3}$.*

...The elimination of the logical inconsistencies connected with this result requires a radical reconstruction of the theory, and in particular, the rejection of a Riemannian geometry dealing, as we have seen here, with values unobservable in principle, and perhaps also rejection of our ordinary concepts of space and time, modifying them by some much deeper and nonevident concepts."

In summary, he raised the problem of the measurability of the quantized gravitational field, arguing that, in addition to limits imposed by the uncertainty principle, in general relativity there is an 'absolute limit' to the accuracy with which the components of the linearized affine connection within a given volume can be measured. He suggested that the application of the formalism of quantum field theory might not yield the desired fusion of quantum theory and gravitation, calling for 'a radical reconstruction of the theory'.

889 Solomon, Jacques, "*Gravitation et Quanta*", Journal de Physique et de Radium, 9, pp. 479–485, 1938.

the underground resistance to the German occupation of France. He was arrested together with his wife, Helene Langevin, in March 1942 and was killed by the Germans on May 23, 1942; she was sent to Auschwitz, but survived the war.

Between them, Stalin and Hitler saw to it that the post-World-War-II discussion of quantum gravity took place without what could have been two significant voices.

Carl Bryce Seligman (1923–2004, USA) (changed his name to **DeWitt** in the 1950's) was a theoretical physicist best known for formulating canonical quantum gravity. It was one of the first approaches to quantizing general relativity[890]; for formulating the Wheeler-deWitt equation for the wavefunction of the universe. He is also known for advancing the formulation of the Hugh Everett's many-worlds interpretation of quantum mechanics.

Seligman was born to Jewish parents in Dinuba, CA. He received his bachelor's, master's and doctoral degrees from Harvard University. Afterwards he worked at the Institute for Advanced Study, the University of North Carolina at Chapel Hill and the University of Texas at Austin.

1936–1956 CE **Alonzo Church** (1903–1995, USA). Mathematical logician. Made important contributions in mathematical logic and theoretical computer science. Published the first precise definition of a calculable function, thus advancing the systematic development of the theory of algorithms. The mathematical analysis of computation is generally credited independently to Alan Turing and Alonzo Church. The *Church Theorem* (1936) extends the work of Gödel (1930) by showing that there is no decision procedure for arithmetic, i.e., there is *no algorithm* for a class of quite elementary arithmetical questions. In this sense, Church's theorem connects the *Turing halting problem* in computer science to Gödel's incompleteness theorem. The *Church-Turing Thesis* (not yet proved false or true) maintains that all computers are equally powerful problem solves (notwithstanding the fact that some computers will be able to solve problems *faster* than others). Thus, the Church-Turing thesis says that, given sufficient resources (time and memory), there is nothing that one computer can do, that any other can not (eventually).

Church was educated in Princeton and remained there for 40 years (Ph.D. 1927). He spent a year at Harvard (1925) and another year at Göttingen,

Germany (1926). He created the λ-*calculus*[891] (1930), which today is an invaluable tool for computer scientists, and then showed that any other computational scheme could be described in terms of it.

1936–1956 CE **Samuel Eilenberg** (1913–1998, Poland and USA). Mathematician. A leading topologist in the 20th century. Introduced the concepts of *functor* (1942), *category* (1945), *homological algebra* (1956) and contributed to the theories of *homotopy groups* and *fiber bundles* (1952).

Eilenberg was born in Warsaw to Jewish parents. He was educated at the University of Warsaw (Ph.D. 1936). He left Poland for the United Stated (1939) and held positions at the universities of Princeton, Michigan, Indiana and Columbia (1947–1998).

The New Geometry — Algebraic and Differential Topology[892] *(1900–1970)*

(A) Overview

Topology is an area of pure mathematics that deals with those properties of objects which are not affected by continuous deformation. This discipline is

[891] A logical language used to formalize the very general concept of a function. It is a formal mathematical system to investigate functions, function application and recursions. It has influenced many programming languages and has a good claim to be the prototype programming language ('denotational semantics').

[892] To dig deeper, see:

- Flegg, H.G., *From Geometry to Topology*, Dover, 2001, 186 pp.
- Stewart, I., *Concepts of Modern Mathematics*, Dover, 1995, 339 pp.
- Henle, M., *A Combinatorial Introduction to Topology*, Dover, 1994, 310 pp.
- Arnold, B.H., *Intuitive Concepts in Elementary Topology*, Prentice-Hall, 1963, 182 pp.
- Alexandroff, P., *Elementary Concepts of Topology*, Dover, 1961, 57 pp.

also called "rubber sheet geometry" since the properties that are of interest to a topologist are those that would be invariant on a stretchable rubber sheet.

Thus, geometric properties such as length *and* local curvature *are not of interest to a topologist, but the number of* holes *in an object* is *a topological property.*

In ordinary Euclidean geometry*, one may move objects around, rotate and flip them over, but one is not allowed to stretch or bend them. This leads to the concept of '*congruence*' in that geometry. Two objects in plane geometry are congruent if one can be laid on top of the other such that they match exactly.*

In projective geometry *(invented during the Renaissance to understand perspective drawing), two objects are considered the same if they are both views of the same object. For example, if one looks at a plate on a table from directly above the table, the plate looks round like a circle. But if one walks away a few feet and looks at it, it looks elongated, like an ellipse*[893]*. The ellipse and circle are projectively equivalent.*

In topology, any continuous change which can be continuously undone is allowed. So a circle is the same as a triangle or a square, because you just 'pull on' parts of the circle to make corners and then straighten the sides, to change a circle into a polygon. Then you just 'smooth it out' to turn it back into a circle. These two processes are continuous in the sense that during each of them, nearby points at the start are still nearby at the end.

The circle is not *topologically the same as a figure 8, however, because although one can squash the middle of a circle together to make it into a figure 8 continuously, when one tries to undo it, one has to* break *the connection in the middle and this is discontinuous: a set of points that are all infinitesimally near the center of the 8 end up split into two branches, on opposite sides of the circle, a finite distance apart.*

Another example: a plate and a bowl are the same topologically, because one may just flatten the bowl into a plate. At least this is true if one uses clay which is still soft and has not been fired yet. Once they are fired they become Euclidean rather than topological, because one cannot flatten the bowl any longer without breaking it.

---

893 This is one reason it is hard to learn to draw. The eye and the brain work projectively. They look at the elliptical plate on the table, and think it's a circle because they know what happens when one looks at things at an angle. To learn to draw, one has to learn to draw an ellipse even though the brain is saying 'circle', so one can draw what one really sees, instead of 'what one knows it is'.

Thus, what distinguishes different kinds of geometry from each other are the types of transformations *that are allowed before one considers that something has changed.*

In two dimensions, topologists imagine that figures can be stretched and pulled as though they were drawn on an infinitely thin, infinitely stretchable material that can be deformed in any way (not including tearing, perforating, or gluing). Some properties *that are important in Euclidean geometry such as distance, measurement of angle, or straightness, have no topologically invariant meaning. Other properties, such as whether lines intersect or whether figures are* closed *(like the letter "O") or* open *(like the letter "U") remain important.*

In order to deal with these problems that don't rely on the exact shapes of objects, one must be clear about just which properties these problems do rely on. From this need arises the notion of topological equivalence. *In two dimensions, a triangle, a square, and a circle are all topologically equivalent.*

In three dimensions, the surfaces of a cube, a pyramid, and a sphere are topologically equivalent. A stretchable "skin" that covers any one of them can be readjusted to cover any of the others. The surfaces of a doughnut and a coffee mug are topologically equivalent — each is a three-dimensionally embedded, closed oriented (2-sided) surface with a single hole in it (the doughnut hole or mug handle).

Indeed, a topologist is sometimes said to be a person who does not know the difference between a coffee mug and a doughnut, since if these are made out of plastic clay, either of them can be continuously deformed into the other without tearing apart contiguous regions or pinching together disjoint regions: the hole in the handle of the mug corresponds to the hole in the doughnut, while the cupped part can be flattened and rounded.

Similarly, the set of all possible positions of the hour hand of a clock is topologically equivalent to a circle (i.e., a one-dimensional closed curve with no intersections – which can be embedded in two-dimensional space); the set of all possible positions of the hour and minute hands taken together is topologically equivalent to the surface of a torus *(i.e., a two-dimensional surface that can be embedded in three-dimensional space by sweeping a circle such that its center traces along a closed curve), and the set of all possible positions of the hour, minute, and second hands taken together is topologically equivalent to a closed three-dimensional manifold (the* three-torus*).*

Topologists do not limit themselves to the two- and three-dimensional worlds with which we are familiar via direct sense-perception. Many of the concepts and theorems in topology deal with multi-dimensional manifolds *which may exist only in the imagination, or as formal mathematical constructs.*

Topologists, then, are interested in a variety of surfaces and, more generally, "hyper-surfaces" (and their intrinsically-defined versions, manifolds). They try to understand exactly what it is that distinguishes one hypersurface from another, and to understand the relationships that a hypersurface can have with the higher-dimensional ("host-" or "target-") space that it is embedded in. The mathematical study of knots *is a branch of topology.*

Topology is relevant to the study of spatial objects such as curves, surfaces, maps, electrical or neural circuits, organizational or flow charts, configurations of electromagnetic fields, fluid flow patterns, the space we call our universe, the spacetime of general relativity, fractals, knots, manifolds (smooth intrinsic spaces that can be continuously patched from regions of a Euclidean space), configuration and phase spaces that are encountered in physics (such as the space of hand-positions of a clock or the space of possible positions and velocities of a system of stars and planets), symmetry groups such as the collection of ways of rotating a rigid body, *etc.*

Topology is divided into several (overlapping) parts, including graph theory *(or, more generally,* combinatorial topology*); general* point-set topology *(including* real analysis*);* measure theory*; and the* topology of manifolds*. The latter is further subdivided into* algebraic topology *and* differential topology*, and* low-dimensional topology*. In algebraic topology, tools from* abstract algebra *are used to study the global property of manifolds.*

One of the strengths of algebraic topology has always been its wide applicability to other fields. Nowadays that includes physics, differential geometry, algebraic geometry, and number theory.

As an example of this applicability, we present a simple topological proof that every non-constant polynomial $p(z)$ *with complex coefficients has at least one complex zero. Consider a circle of radius* R *and center at the origin of the complex plane. The polynomial function transforms this into a closed curve in the complex plane. If this image curve ever passes through the origin, we have our zero. Otherwise, suppose the radius* R *is very large. Then the highest power of* $p(z)$ *dominates and hence* $p(z)$ *transforms the circle into a curve (the* image curve*) which winds around the origin the same number of times as the degree of* $p(z)$.

This is called the winding number *of the image curve around the origin. It is always an integer and it is defined for every closed curve which does not pass through the origin. Winding numbers of closed curves form an* additive group*; if we concatenate two closed curves, their winding numbers add to yield that of the resultant curve. This is an example of how abstract algebra gave Algebraic Topology its name.*

If we deform the image curve subject to this last constraint, the winding number has to vary continuously but, since it is constrained to be an integer, it cannot change and must be a constant – unless the curve is deformed through the origin. The above argument thus shows that if $p(z)$ has no root (zero), the winding number of the image curve equals the degree of $p(z)$ for any *finite value of R. Now deform the image curve, by shrinking the radius R to zero and suppose again that the image never passes through the origin, that is to say we never hit a zero of the polynomial.*

The image curve becomes very small and if, as $R \to 0$, it tends to a (non-origin) point, it must have winding number 0 around the origin, in that limit. If the image curve does shrink to the origin, the origin is a zero of $p(z)$. If not, the winding number is 0 for sufficiently small R. Combining this fact with the large-R limit treated above, we deduce that the polynomial must have degree 0, in other words it is a constant. We have thus used algebraic topology *to prove, by contradiction, that a polynomial of nonzero degree must have at least one zero (root) in the complex plane.*

The winding number of a curve illustrates two important principles of algebraic topology. First, it assigns to a geometric object, the closed curve, a discrete-valued invariant, the winding number, which in this case is an integer. Second, when we deform the geometric object subject to certain constraints, the winding number does not change; hence it is called an invariant of deformation or, synonymously, an invariant of homotopy.

Modern algebraic topology *is the study of the global topological properties of spaces (especially manifolds) by means of abstract algebra. Poincaré was the first to link the study of spaces to the study of algebra by means of his fundamental group. This is a generalization of the concept of winding number which applies to any manifold.*

To get an idea of what algebraic topology is not *about, consider the fact that we live on the surface of a sphere (namely the earth), but locally this is difficult to distinguish from living on a flat plane. One way of telling that we live on a sphere is to measure the sum of the three angles of a triangle, the vertices of which are 3 points (loci) on the earth's surface, and the* sides *of which are segments of great circles (shortest-length curves) between the 3 possible pairs among these vertices. For a small triangle on earth's surface, this sum is slightly more than 180 degrees. For a large triangle, it is much more. This tells us that we live on a surface with what is called positive curvature. But, since we can use arbitrarily small triangles to measure curvature, it is a local property, not a global one. It properly belongs to the field known as* differential geometry.

Algebraic topology is concerned with the whole surface, and starts with the obvious fact that the surface of a sphere is a finite area with no boundary, *while the flat plane does not have this property. It expresses this fact by assigning various deformation-invariant groups to these and other spaces.*

One class of such groups consists of homotopy groups; another kind comprises homology groups[894]*. These groups are all discrete, and they are invariant in the sense that they do not change if the space is continuously deformed.*

One of the homotopy groups assigned to a sphere is an infinite Abelian group which corresponds to the topologically distinct ways in which a sphere can be wound about another sphere. The corresponding group for a plane, for example, is the trivial group (consisting of the identity element alone). Other homotopy groups have elements representing the various (deformation invariant) distinct ways in which an n-dimensional hypersphere (the n-sphere – denoted S^n) can wrap around the manifold in question.

The fact that these discrete groups may be different for different topological spaces, tells us that the spaces are globally different. Algebraic topology includes, but is not confined to, the study of spaces of dimensions two or three. It includes, for example, the contemplation of the shape of the three dimensional universe itself, or of the shape of the four dimensional spacetime of General Relativity, or whether two closed curves (or other embedded manifolds) can "link" each other in n dimensions; or the shape of the group manifold of all rotations in $\mathbb{R}^n$; the global study of phase-space trajectories of nonlinear dynamical systems; etc.

The concept of continuous deformation can be illustrated by the following examples. Consider again a coffee cup (with a handle) and a doughnut. If they are both made of some pliable substance like modeling clay, they can be deformed continuously (without ripping) one into the other. This is reflected in the fact that they have the same homotopy and homology groups, that is, their homotopy groups and homology groups are topological invariants. On

---

[894] For a manifold M of dimension n, there are $n + 1$ additive *homology groups*, denoted $H_m(M, \mathbb{Z})(m = 0, ..., n)$, with $\mathbb{Z}$ the ring of integers (signed or zero); $\mathbb{Z}$ is sometimes replaced with a different ring or field (e.g. the rationals or reals). H_m consists of a set of m-dimensional *closed* and *oriented* submanifolds of M, for which group addition is defined in the sense of set union. The additive inverse of a submanifold is the same submanifold, but with its orientation reversed; the zero (unit) element of the additive group H_m is represented by any m-dimensional submanifold continuously deformable to infinitesimal neighborhoods of a point in M. Two-m-submanifolds are considered *equivalent* if their difference is the boundary of some $(m+1)$-dimensional submanifold; thus the elements of each homology group H_m are actually *equivalence classes* of m-submanifolds.

the other hand, a doughnut cannot be continuously deformed into a sphere. This means that their homotopy and/or homology groups are different.

(B) History[895]

Topology as a subject began to take shape between 1850 and 1900 in the works of these mathematicians: ***G.F.B. Riemann*** *(1826–1866),* ***J.B. Listing*** *(1808–1882),* ***A.F. Möbius*** *(1790–1868),* ***E. Betti*** *(1823–1892),* ***C. Jordan*** *(1838–1922),* ***Gustav Roch*** *(1839–1866),* ***F. Klein*** *(1849–1925) and* ***H. Poincare*** *(1854–1912).*

Although concepts that we now consider part of topology, were expressed and used by these mathematicians, algebraic topology as a part of rigorous mathematics (i.e., with precise definitions and correct proofs) only began in 1900 with the works of: ***M. Fréchet*** *(1878–1973),* ***M. Dehn*** *(1878–1952),* ***H. Lebesgue*** *(1875–1941),* ***E. Cartan*** *(1869–1951) and* ***F. Hausdorff*** *(1868–1942).*

At first, algebraic topology grew very slowly and did not attract many mathematicians; until 1920 its applications to other parts of mathematics were very scant and often shaky. This situation gradually changed with the introduction of more powerful algebraic tools, and the vision of Poincare (1895) of the fundamental role topology should play in all mathematical theories began to materialize. The main characters in this saga were: ***O. Veblen*** *(1880–1960),* ***L.E.J. Brouwer*** *(1881–1966),* ***S. Lefschetz*** *(1884–1972),* ***H. Weyl*** *(1885–1955),* ***J.W. Alexander*** *(1888–1971),* ***L. Vietoris*** *(1891–2002),* ***M. Morse*** *(1892–1977),* ***K. Reidemeister*** *(1893–1971),* ***E. Cech*** *(1893–1960),* ***H. Hopf*** *(1894–1971),* ***P.S. Alexandrov*** *(1896–1982),* ***K. Kuratowski*** *(1896–1980),* ***P. Uryson*** *(1898–1924),* ***J. Schauder*** *(1899–1943),* ***O. Zariski*** *(1899–1986),* ***K. Menger*** *(1902–1985),* ***W. Hodge*** *(1903–1975),*

---

[895] Some enlightening statistics:

(i) A remarkable longevity among topologists: of 36 men born between 1878–1911, *nine* (25 percent) reached age above 92 and one reached the ages of 110!

(ii) Of the 56 'top topologists' listed here, at least 12 are European Jews. Hausdorff and Schauder were murdered by the Nazis (1942–3) and Hurewicz fell from atop a Mexican pyramid (1956). Thus, the advice "be a good topologist and live longer" must be heeded with caution.

***B.L. van der Waerden** (1903–1996), **G. de Rham** (1903–1990), **H. Cartan** (b. 1904), **J.W.C. Whitehead** (1904–1960), **W. Hurewicz** (1904–1956), **H. Freudenthal** (1905–1990), **C. Ehresmann** (1905–1979), **K. Borsuk** (1905–1982), **J. Leray** (1906–1998), **J.A.D.E. Dieudonné** (1906–1992), **A. Weil** (1906–1998), **K. Seifert** (1907–1996), **H. Whitney** (1907–1989), **L. Pontryagin** (1908–1988), **C. Chevalley** (1909–1984) and **N. Steenrod** (1904–1960).*

*Since 1945, the growth of algebraic and differential topology and its applications has been exponential and shows no sign of slackening. Some of the leading exponents were (are): **S. MacLane** (b. 1909), **S.S. Chern** (b. 1911), **S. Eilenberg** (1913–1998), **K. Kodaira** (1915–1997), **E.S. Spanier** (1921–1996), **A. Borel** (b. 1923), **R. Thom** (1923–2002), **J.P. Serre** (b. 1926), **A. Grothendiek** (b. 1928), **S. Smale** (b. 1930) and **J.W. Milnor** (b. 1931).*

The growth of general point-set topology, which we review next, has been largely driven by the ever-deepening studies of the real-number system starting in the 19th century. This field is an indispensable foundation of measure theory — which in turn is needed in defining and generalizing the concept of integration, as well as in the various branches of Functional Analysis. Measure theory also underlies the theory of probability and stochastic processes. Point-set topology underlies the topology of manifolds, as well as: the theory of function spaces, transforms, differential and integral equations and linear operators — as well as the rest of Functional Analysis.

(c) Basic Concepts

Topological spaces are structures which enable the formalization of intuitive concepts such as *convergence*, *connectedness* and *continuity*.

Formally, a topological space is a set X together with a set T of so-called *open subsets* of X satisfying these axioms:

1. The *union* of any collection of open sets an element of T is also an element of T.

2. The *intersection* of any finite set of elements (sets) in T is also in T.

3. X itself and the *empty set* are in T.

The set T is also called a topology on X. The sets in T are referred to as open sets, and their complements in X are called closed sets. Roughly speaking, open sets are thought of as neighborhoods of points; two points are considered "close" in a pre-metric sense if there are "many" open sets that contain both of them.

A function (also called a map) between topological spaces is said to be continuous if the inverse image of every open set is open. This definition is an attempt to capture & generalize the intuition that points which are "close together" get mapped to points which are likewise "close together".

Examples of topological spaces:

- *The set (also algebraic field) of real numbers $\mathbb{R}$: its open sets are unions of (possibly infinitely many) open intervals. This is in many ways the most basic topological space, and the one that guides most of our human intuition.*
- *More generally, every interval in $\mathbb{R}$ is a topological (sub) space, and so are the product Euclidean spaces $\mathbb{R}^n$.*
- *The set (field) of complex numbers $\mathbb{C}$: the open sets are (finite or infinite) unions of open discs.*
- *Any metric space can be turned into a topological space if we define a set to be open if and only if it is a (possibly infinite) union of open balls. This applies to $\mathbb{R}^n$, but also to such useful infinite dimensional spaces as Banach spaces and Hilbert spaces studied in functional analysis. Such infinite-dimensional spaces are very important in both classical and quantum physics.*
- *Manifolds (whether intrinsic or embedded); in particular, surfaces.*
- *A simplex – a type of convex object that is very useful in computational geometry. In 0, 1, 2 and 3 dimensional spaces the simplices are, respectfully: the point, line segment, triangle and tetrahedron.*
- *Simplicial complexes. A simplicial complex is made up of simplices. Many geometric objects can be modeled by simplicial complexes, and such discretizations are a cornerstone in the computerized numerical simulation of mechanical, quantum-mechanical, electromagnetic, thermal, and chemical behavior of physical systems on all scales of space and time, from sub-nuclear to cosmological.*

In topology, two geometrical objects (or "spaces") are called homeomorphic if, roughly speaking, each may be reversibly deformed into the other by a sequence of stretching and bending operations; cutting is also sometimes allowed, but only if the two parts are later glued back together along exactly the same cut. For example, a square and a circle are homeomorphic. A partially hollowed solid ball containing a smaller solid ball is homeomorphic to a hollowed cube with a solid cube (or ball) embedded inside of it.

If two objects are homeomorphic, there exists a continuous, one-to-one function (also called a map, mapping or transformation) which maps points from the first object to corresponding points of the second object, such that every point in the 2nd ("target") object is reached (an onto map) and the inverse map is continuous as well. Such a function is called a homeomorphism; intuitively, it maps points in the first object that are "close together" to points in the second object that are close together, and points in the first object that are not close together to points in the second object that are not close together.

Topology is the study of those properties of objects that do not change when homeomorphisms are applied.

For a formal definition, suppose X *and* Y *are topological spaces, and* f *is a function from* X *to* Y. *Then* f *is a homeomorphism iff all the following hold:*

1. f *is a bijection (i.e. one-to-one and onto),*
2. f *is continuous,*
3. *the inverse function* f^{-1} *also is continuous.*

If there exists a homeomorphism $f : X \to Y$, *then* Y *is said to be homeomorphic to* X *(or to be a homeomorph of* X*). In this case,* Y *is also homeomorphic to* X, *since* f^{-1} *is a homeomorphism as well — and we say that* X *and* Y *belong to the same homeomorphism class.*

Topological spaces can be broadly classified according to their degree of connectedness, their degree of compactness and the degree of separability of their points.

A space is metrizable if it is homeomorphic to a metric space. A space is locally metrizable if every point has a metrizable neighborhood.

Metric spaces were defined and investigated by **Fréchet** *in 1906, and Hausdorff spaces by* **Felix Hausdorff** *in 1914, and the current concept of topological space was described by* **Kuratowski** *in 1922.*

An n-dimensional manifold is a topological space that is locally homeomorphic to the "ordinary" space $\mathbb{R}^n$. An example is the surface of the ordinary two-dimensional sphere, which modern mathematicians often refer to as the 2-sphere (denoted S^2). It is topologically distinct from a plane, although simply–connected open patches of it are homeomorphic to $\mathbb{R}^2$. To make precise the notion of "locally homeomorphic" one uses overlapping local coordinate systems or charts, as will be described in detail below. Every manifold has a dimension — the number of coordinates needed in every local coordinate system.

The (partially) overlapping local charts on a manifold are assumed to be compatible in certain senses; in consequence one can talk about directions, tangent spaces, curves, submanifolds, differentiable functions and tensors on that manifold — as well as other optional attributes such as orientation, metric, metric signature, complex- and spin-structures, connections, etc. Manifolds on which directions and differentiable tensors exist are called differentiable. In order to measure lengths and angles, to parallel-transport a tensor or to define intrinsic curvature, a metric tensor is needed and one defines Riemannian manifolds.

Differentiable manifolds are used in mathematics to describe geometrical objects and geometrical (or other dynamical) degrees of freedom; they are also the most natural and general setting in which to study differentiability. In physics, examples of differentiable manifolds are the configuration and phase spaces in classical mechanics, four-dimensional pseudo-Riemannian manifolds used to describe spacetimes in the General Theory of Relativity (GTR), and fiber bundles with spacetime manifolds as their bases. Fiber bundles — of which more below — are differentiable manifolds, and they are also the natural topological and geometric frameworks for describing the space of possible field configurations in space and time — e.g. in GTR; QED (Quantum Electrodynamics); adiabatically evolving quantum-mechanical systems; and in quantum field dynamics of Non-Abelian Gauge Theories (important in sub-nuclear physics and Big-Bang cosmology).

Manifolds inherit many of the local properties of Euclidean space. In particular, they are locally path-connected, locally compact[896], and locally metrizable. The idea of the n-dimensional manifold was introduced by ***Riemann*** *in*

896 A manifold is locally compact *iff* every *open cover* of an open neighborhood homeomorphic to $\mathbb{R}^n$ can be replaced with a *finite* open cover. An "open cover" of a neighborhood N is a collection of open sets U_α, $\alpha \in I$, whose union covers N; i.e. N is a subset of this union. The *finite open cover* in question must be a finite subset of $\{U_\alpha\}$, i.e. a set $\{U_{\alpha_1}, \dots, U_{\alpha_k}\}$ with $k \geq 1$ a finite integer and $\alpha_j \in I$ for $j = 1, 2, \dots, k$.

1854. He also introduced the topological concept of connectivity *(1851, 1857) in the context of Riemann surfaces.*

In order to discuss differentiability of functions, one needs more structure than a topological manifold provides. We start with a topological manifold M *without boundary. An* open set *of* M *together with a homeomorphism between that open set and an open ball in* $\mathbb{R}^n$ *is called a coordinate* chart[897]*. A collection of charts which cover* M *is called an* atlas *of* M*. Suitably composing the defining homeomorphisms of two overlapping charts in the intersection of their open sets provides a* transition map *from a subset of* $\mathbb{R}^n$ *to some other subset of* $\mathbb{R}^n$*. If all these maps are* k *times continuously differentiable, then the atlas is termed a* C^k *atlas.*

Example: The unit two-dimensional sphere S^2 *(commonly embedded in* $\mathbb{R}^3$*) can be covered by two charts: the complements of the north and south poles*[898] *with their associated coordinate maps —* stereographic projections *centered at the south and north pole, respectively.*

Two C^k *atlases are called* equivalent *if their union is also a* C^k *atlas. This is an* equivalence relation*, and a* C^k manifold *is defined to be a manifold together with an equivalence class of* C^k *atlases. If all the transition maps are infinitely differentiable, then one speaks of a* smooth *or* C^∞ *manifold; if they are all* analytic*, then the manifold is an* analytic manifold*.*

A smooth atlas provides local coordinate systems such that the change-of-coordinate functions (within chart overlaps) are smooth. These coordinate systems allow one to define differentiability and integrability of functions on M *(e.g. maps from* M *into* $\mathbb{R}$*, or* $\mathbb{C}$*, or any* $\mathbb{R}^n$[899]*).*

On differentiable manifolds per se*, there are no notions of length, volume or angle. In order to introduce these, one needs a way to measure the lengths*

---

[897] In most definitions of charts, the homeomorphism is between an open set of M and all of $\mathbb{R}^n$. This is equivalent: many open subsets of $\mathbb{R}^n$, including all open balls, are themselves homeomorphic to the full $\mathbb{R}^n$. Thus for instance, the open interval $(0,1)$ in $\mathbb{R}^1 = \mathbb{R}$ can be mapped onto all of $\mathbb{R}$ via

$$x \to f(x) = \ln x + \frac{1}{1-x} \quad ,$$

and f is one-to-one, onto, continuous, and its inverse is also continuous.

[898] By the complement of a pole we mean the (open) set of all points of S^2 except for that pole.

[899] Manifolds "locally looks like" *Euclidean space* R^n and are therefore inherently finite-dimensional objects. To allow for infinite dimensions, one may consider *Banach manifolds* which locally look like *Banach spaces*; or *Fréchet manifolds*, which locally look like *Fréchet spaces*.

and angles of and between tangent vectors of curves on M. A Riemannian manifold is a differentiable manifold (at least C^3) on which the tangent spaces are equipped with inner products in a differentiable fashion.

In differential geometry, one attaches to every point P of a differentiable manifold a tangent space: a real vector space (denoted T_p) which intuitively contains the possible "directions" in which one can pass through the given point. For example, if the given manifold is a 2-sphere embedded in $\mathbb{R}^3$, one can picture the tangent space at a point as the plane which touches the sphere at that point and is perpendicular to the sphere's radius through the point. In general, as in this example, all the tangent spaces have the same dimension, and it equals the manifold's dimension. However, the definition just provided for tangent spaces is inadequate since it is non-intrinsic — i.e. it relies on a particular embedding of the manifold. The following intrinsic definition is thus used instead: T_p is the n-dimensional vector space of linear differential operators (directional derivatives), acting on any differentiable function $f : M \to \mathbb{R}$ on a chart to which the point $p \in M$ belongs. It can be shown that the local tangent-spaces, thus defined, do not depend upon the particular chart or atlas used.

Once the local tangent spaces of the differentiable manifold have been introduced, one can define vector fields[900], which are abstractions of the velocity field of hypothetical particles moving on the manifold. A vector field attaches to every point of the manifold a vector from the tangent space at that point, in a smooth manner. Such a vector field serves to define (in any given chart) a system of first-order (and in general nonlinear) ordinary differential equations on the manifold: a particular solution to such a system is a differentiable curve on the manifold, $g : \mathbb{R} \to M$, such that for any differentiable function $f : M \to \mathbb{R}$, the ordinary derivative of the composite function $f \circ g : \mathbb{R} \to \mathbb{R}$ at a given argument $t \in \mathbb{R}$, $(f \circ g)'(t)$, is the above-mentioned element of T_p, where $p = g(t)$. While the system of differential equations defining the intersection of the curve with a given coordinate-chart is chart-dependent, the curve itself does not depend on the atlas or its charts.

[900] Vector fields, in turn, can be used to define a general *tensor field* on the differentiable manifold, with arbitrary numbers of *covariant* and *contravariant* indices. If the manifold is Riemannian, any covariant (subscript) index can be *raised* into a contravariant (superscript) index by using the metric tensor, and vice versa. A vector field is a particular case of a tensor field with a single, contravariant index. A skew-symmetric (i.e. completely antisymmetric) with m covariant indices ($0 \le m \le n = \dim M$) is called an *m-form*; Cartan's *exterior calculus* deals with these forms, as do the cohomology theory of de Rham and Hodge theory. A 0-form is simply a scalar field (a mapping $\varphi : M \to R$).

The ordered pairs of manifold points p and corresponding tangent spaces T_p for all points $p \in M$, can be "glued together" to form a new differentiable manifold of twice the dimension: the tangent bundle of the manifold. This is an example of a vector fiber bundle. The original manifold M is called its base while T_p are its fibers. A given vector field is a particular section of the tangent bundles. More generally, any type of tensor field is a section of the corresponding tensor bundle — a vector fiber bundle over the base manifold (M), whose fiber is again a vector space. The tangent bundle can be constructed for any differential manifold, whether or not it is Riemannian (i.e. endowed with a metric); if a metric exists, it can be viewed as an internal product in each tangent space. The tangent bundle — or indeed any other fiber bundle — can be endowed with a connection, by which is meant a rule specifying how to glue together (in a smooth manner) the fibers erected above neighboring base-manifold points. A connection provides atlas-independent definitions of how to parallel-transport and covariantly differentiate a vector (or any other tensor) field. For a Riemannian base-manifold M, one possible connection on a bundle is the Christoffel connection, constructed from the metric tensor.

Differential geometry is the study of Riemannian manifolds and manifolds with additional or alternative local geometrical structures (e.g. fiber bundles). Differential geometry deals with metrical notions on manifolds, while differential topology deals with those nonmetrical, global attributes of manifolds which are expressible in terms of local entities (including connections and metric–tensor related quantities, when those exist).

Differential topology and differential geometry are both intimately linked to the theory of differential equations.

*The fundamental group, also called the Poincaré group or the first homotopy group, (**Poincare**, 1895) is one of the basic concepts of algebraic topology.*

To grasp the general idea, take some manifold and some point in it, and consider all the loops at this point — directed paths which start at this point, wander continuously about the manifold, and eventually return to the starting point. Two loops can be combined together in an obvious way: travel along the first loop, then along the second. The set of all the loops with this method of combining them forms the fundamental group, provided we consider two loops to be the same if one can be deformed into the other without breaking.

Thus, each element in the fundamental group is an equivalence class of loops. It is an additive group, with the "sum" of two loops being their combination (composition) as described above. The unit (zero) group element is the class of loops that can be continuously shrunk to the starting point (base-point).

Although the fundamental group in general depends on the choice of base-point, it turns out that, up to an isomorphism, this choice makes no difference if the manifold X is path-connected.

In many spaces, such as R^n, there is only one homotopy class of loops, and the fundamental group is therefore trivial. A path-connected space with a trivial fundamental group is said to be simply connected.

A more interesting example is provided by the circle. It turns out that each loop homotopy class of the circle consists of all loops which wind around the circle a given number of times (which can be zero, positive or negative, depending on the direction of winding). The sum (composition) of a loop which winds around m times and another that winds around n times is a loop which winds around the circle $m + n$ times. So the fundamental group of the circle is isomorphic to $\mathbb{Z}$, the additive group of integers. Knowledge of the fundamental group of the circle can be used to provide a topological proof of the Fundamental Theorem of Algebra, as sketched above.

Unlike many of the other groups associated with a manifold or other topological space, the fundamental group need not be Abelian. An example of a space with a non-Abelian fundamental group is a figure 8 (two circles joined at one point). The fundamental group of a figure 8 is just the free group with two generators — roughly speaking, each loop of the 8 corresponds to one of the generators. The figure 8 is not a manifold (there is no chart containing the intersection point at which the two loops meet); but the closely related 2-torus (the direct product of two circles), which is a manifold, has the same non-Abelian fundamental group as does the figure-8 space.

It can be shown that the Abelianization of the fundamental group of a nonempty path-connected space is isomorphic to the first homology group of the space — which is another important concept in algebraic topology. Thus, the first homology group of the figure 8 space (or the 2-torus) is isomorphic to the direct product $\mathbb{Z} \times \mathbb{Z}$, i.e., the additive group of integer-coordinate square lattice points in the plane.

A topological group G is a group which is also a topological space such that the group multiplication

$$G \times G \quad \rightarrow \quad G$$

and the taking of inverses

$$G \quad \rightarrow \quad G^{-1}$$

are continuous maps. Here, $G \times G$ is viewed as a topological space by using the product topology – in which the direct product of two open sets of G is defined as an open set of $G \times G$.

Examples:

The real numbers $\mathbb{R}$, *together with addition as group operation and its ordinary topology, form a topological group. More generally, the Euclidean* n*-space* $\mathbb{R}^n$ *with addition and standard topology is a topological group. More generally still, all topological vector spaces, such as Banach spaces or Hilbert spaces, are topological groups.*

The above examples are all Abelian. Important examples of non-Abelian topological groups are given by most Lie groups (topological groups that are also manifolds), for instance the group $GL(n,\mathbb{R})$ *of all invertible* n*-by-*n *matrices with real entries. The topology on* $GL(n,\mathbb{R})$ *is defined by viewing* $GL(n,\mathbb{R})$ *as a subset of the Euclidean space* $\mathbb{R}^{n\times n}$.

All the examples above are Lie groups (if one views the infinite-dimensional vector spaces as infinite-dimensional "flat" Lie groups). An example of a topological group which is not a Lie group is the rational numbers $\mathbb{Q}$ *under addition. This is a countable space and it has the discrete topology. For a non-Abelian example, consider the subgroup of rotations of* $\mathbb{R}^3$ *generated by two rotations by rational multiples of* 2π *about two different axes, or the group of allowed operations on a Rubick's Cube (for which the generating rotations on any one of the cube's 6 faces are by angles that are integer multiples of* $\frac{\pi}{2}$*).*

In mathematics, an isomorphism is a type of bijective (onto and one-to-one) mapping between two abstract structures, in a manner such as to preserve the structure (whether group or algebra operations, internal products, etc).[901]

If there exists an isomorphism between two structures, we call the two structures isomorphic. Isomorphic structures are essentially the same; they are equivalent, in the abstract sense.

For example, if one object consists of a set X *with an ordering* $\leq$ *and the other object consists of a set* Y *with an ordering* $\sqsubseteq$, *then an isomorphism from* X *to* Y *is a bijective*[902] *function* $f\colon X \to Y$ *such that*

$$f(u) \sqsubseteq f(v) \qquad \text{iff} \qquad u \leq v.$$

Such an isomorphism is called an order isomorphism.

Or, if on these sets the binary operations $*$ *and* $\circ$ *are defined, respectively, then an isomorphism from* X *to* Y *is a bijective function* $f\colon X \to Y$ *such that*

$$f(u) \circ f(v) = f(u * v)$$

[901] If the one-to-one hypothesis is relaxed, one speaks of a *homomorphism*.

[902] i.e. one-to-one and *onto* — the latter means every element in Y is $f(x)$ for *some* x in X.

for all u, v in X. When the objects in questions are groups, such an isomorphism is called a group isomorphism.

In 1904, ***H. Poincare*** *put forward the Poincare Conjecture: Any compact orientable 3-dimensional manifold with trivial fundamental group must be homeomorphic to a sphere S^3.*

The conjecture admits a natural extension to n dimensions for any positive integer n. For $n \geq 5$, this conjecture was proved by ***Stephen Smale*** *(1959) and for $n = 4$ by* ***Michael Freedman*** *(1981).* ***Simon Donaldson*** *proved (1982) that $\mathbb{R}^4$ admits more than one differentiable structure (i.e. it admits non-equivalent C^k atlases for some $k \geq 1$). Donaldson's result is of interest to physicists, as it sheds light on the possible structures of 4-dimensional spacetime.*

(D) Global Analysis (1828–1968)

Differential geometry studies the local properties (e.g. curvature) of smooth manifolds. Differential topology studies the global properties of manifolds by reducing them to local properties. The study of differential operators on a smooth manifold reveals deep relationships between the geometry and the topology of the manifold on the one hand; and the (local and global) solutions of differential equations on this manifold, on the other.

Global analysis studies the global nature of differential equations on Riemannian manifolds (including infinite-dimensional manifolds and manifolds with singularities). In addition to local tools from ordinary and partial differential equation theory, global techniques include the use of fiber bundles and topological spaces and mappings, as well as optimization procedures. Analysis here means the study of ordinary and partial differential operators on vector bundles over differentiable manifolds.

The ideas of global analysis evolved over more than a century, from Green's theorem (1828), Gauss' divergence theorem (1839) and Stokes' theorem[903]

[903] Given an oriented surface S bounded by a directed curve C encircling S in a positive (counter-clockwise) sense, and a vector field $\boldsymbol{F}$,

$$\iint_S \boldsymbol{n} \cdot \operatorname{curl} \boldsymbol{F} dS = \int_C \boldsymbol{F} \cdot \frac{d\boldsymbol{r}}{ds} ds = \int_C \boldsymbol{F} \cdot d\boldsymbol{r},$$

where $\boldsymbol{n}$ is a unit vector normal to S and $\boldsymbol{r}(s)$ is a parametric representation of C.

*(**Kelvin**, 1850; **Stokes**, 1854) to the Atiyah-Singer index theorem (1963–1968 and later works), through the intermediary steps of:*

- *Cauchy's residue theorem (1831).*
- *Gauss-Bonnet theorem for the Euler characteristic of surfaces (Bonnet 1848; Chern's generalization, 1943–1945).*
- *Riemann-Roch theorem*[904] *for algebraic curves (Roch, 1864) and its generalization by **F. Hirzebruch** in his Signature theorem (1954) and by **A. Grothendieck** (1957) to arbitrary projective varieties in n dimensions.*
- *The Betti connectivity numbers (1870).*
- *The Poincare topological theory of nonlinear differential equations (1881).*
- *The Brouwer fixed-point theorem (1907).*
- *The Lefschetz fixed-point*[905] *theorem (1927).*
- *The Pontryagin*[906] *abstract harmonic analysis of functions defined on locally compact groups (1934).*
- *The Hodge index theorem and theory of harmonic integrals (W.V.D. Hodge 1903–1975; 1935).*

---

904 *Riemann-Roch theorem* (1864): deals with functions on a Riemann surface of genus p. Essentially, the theorem determines the maximal number of linearly independent meromorphic functions on the surface that have at most a specified finite set of poles. It thus links complex analysis with algebraic geometry.

905 A *fixed point* of a mapping $F : X \to X$ from a set X to itself is a point $x \in X$ for which $F(x) = x$. Proofs of the existence of fixed points and methods for finding them are important mathematical problems having applications in physics and engineering. Depending on the structures defined on X, and the properties of F, there arise various fixed-point principles. Of greatest interest is the case when X is a topological space and F is continuous.

906 **Lev Semenovich Pontryagin** (1908–1988, Russia). Blinded by accident at the age of 14, his mother *Tatyana Andreevna Pontryagina* dedicated her life to help him became a mathematician. She worked as his secretary, reading scientific works to him. The contingent development of mathematics depends on a wide array of influences, other than the talents of the mathematicians themselves — such as economic and social factors and the acts of non-mathematicians such as Tatyana Andreevna.

Topological invariants in two dimensions

A 2D cell is a figure in two dimensions that is topologically equivalent to a discs. Figures that can be constructed from cells by gluing and pasting them together along their edges are called complexes. *In this way, complicated figures can be built from simple ones. Clearly, the number of cells that constitute a given figure is not uniquely determined: e.g., a spherical surface can be built from just two cells, for instance the northern and southern hemispheres of a globe or (alternatively) two hourglass-shaped cells such as those sewn together to make a baseball; or alternatively by eight cells, each having the shape of a quarter of a hemisphere.*

We call a cell a polygon *when a finite number of points on its boundary are chosen as* vertices. *The vertices on a polygon's boundary partition it into* edges. *A* polyhedron *is a 3D complex that is topologically equivalent to a ball (interior of a 2-sphere). Given a polyhedron, let F stand for the number its 2D cells (faces), E the number of distinct edges, and V the number of distinct vertices.* Euler's formula *for polyhedra then states that $V-E+F=2$ (**Descartes** 1639, **Euler** 1751). This formula states that no matter how a sphere may be divided into polygons, the sum $V-E+F$* always *equals 2. This number is a topological property of the sphere and is called its* Euler characteristic. *Clearly, this applies to any* connected map *on a sphere that has V vertices, E edges and F faces. If a map on a sphere with p handles has V vertices, E edges and F faces, and if each face is simply connected, then the above formula becomes: $V-E+F=2-2p$.*

If we remove one of the faces of a polyhedron, the remainder is topologically equivalent to a 2D cell (disc) and so may be flattened into a plane. By removing one face and leaving edges and vertices intact, the sum $(V-E+F)$ has been decreased by one; and it can be proved in general for a complex equivalent to a disc that $V-E+F=1$.

Both the sphere and the torus can be triangulated, *i.e., covered with a finite number of topological triangles (cells with 3 edges and 3 vertices each) which fit together along their edges. (It does not matter topologically that the triangles are not flat, or that the edges are not straight.) More generally, a* surface *(2D manifold) is a topological space which is triangulable, connected, compact and without any boundary, i.e. it has no edge belonging to only a single triangle. (Examples: sphere, torus, Klein bottle, projective plane.) The Möbius strip is not a surface in this sense, because it has an edge. The plane is not a surface, because it is not compact — i.e. it cannot be built up from a finite number of triangles. On any compact surface we can draw maps (partitions into polygonal cells) and we can count its faces, edges, and vertices. For a given surface S the number $V-E+F$ can be shown to*

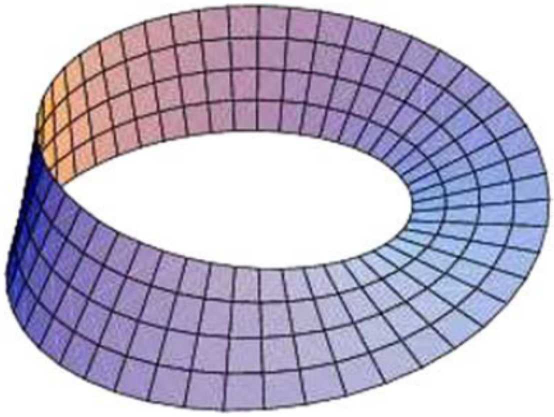

Fig. 5.15: The Möbius strip

be independent of the map we choose. It is known as the Euler (or Euler-Poincaré) characteristic of the surface, and is denoted by $\chi(S)$. *It is a topological invariant* because it is the same for all topologically equivalent spaces.

In particular, for any polyhedron homeomorphic to a sphere $\chi = 2$. *For closed orientable surfaces* $\chi = 2 - 2g$, *where* g *is the genus.*

For closed Riemannian orientable manifolds of even dimension, the Euler characteristic can also be found by integrating a scalar constructed from the curvature tensor, via the Gauss-Bonnet theorem for the 2-dimensional case and its generalization for higher dimensions.

Other topological invariants for closed (boundary-less) surfaces are:

- *First Betti number* (b_1): *The maximum number of simultaneous cuts that can be made without dividing a surface into disjoint pieces. This number — just one of the Betti numbers — can be defined for manifolds of any dimension, and is related to the homology and cohomology groups of algebraic topology & differential topology. The following surfaces have the corresponding first Betti numbers: plane lamina (0); sphere (0); cylinder (1); Möbius strip (Fig. 5.15) (1); projective plane (1); torus (2); Klein bottle (2).*

  Note that $b = h - 1$, *where* h *is the connectivity,*

- *genus* (g): *for a connected orientable surface it is equal to the number of handles (e.g., sphere has* $g = 0$ *and a torus has* $g = 1$*).*

- *orientability.*

Extensions to higher dimensions.

The building blocks of 3-dimensional complexes are points, edges, polygons and polyhedral solids. The latter is any subset of 3-dimensional space that is topologically equivalent to a spherical ball and whose boundary surface has been divided into faces, edges and vertices (i.e., the boundary surface of a polyhedron). A 3-dimensional complex is a topological space made up of polyhedral solids glued together along faces. The concept of complex can similarly extended iteratively to any higher dimension.

It can then be shown that Euler's formula $V - E + F = 1$, *valid for an open region of disc topology in two dimensions, can be generalized to an* n*- dimensional manifold having the ball topology; it then becomes the Euler-Poincaré* formula,

$$F_0 - F_1 + F_2 - \cdots \pm F_n = 1,$$

where F_m *is the number of* m*-dimensional 'faces' of the complex (map) into which the manifold has been partitioned. Thus, in 3 dimensions*

$$\chi = V - E + F - S = 1$$

where $S = F_3$ *is the number of polyhedral solids in the complex. For a tetrahedron we have:*
$V = F_0 = 4, \quad E = F_1 = 6, \quad F = F_2 = 4, \quad S = F_3 = 1.$

The Euler-Poincaré characteristic and Betti numbers

Another, related expression for the Euler characteristics of an n*-dimensional manifold — one that does not depend on the segmentation of the manifold into a complex — relates* χ *to the manifold's* $n+1$ *Betti numbers* $b_m (o \leq m \leq n)$*. These non-negative integers are, like the Euler–Poincaré index* χ*, topological invariants of the manifold.*

b_m *is the cardinality of two isomorphic groups — the m-th homology group and its m-th cohomology group. It can be shown that*

$$\chi = b_0 - b_1 + \cdots + (-1)^n b_n$$

This applies to any boundary-less and oriented manifold of dimension n*.*

Gauss-Bonnet Theorem and its generalizations (1848–1943)

This theorem in differential geometry and differential topology is an important statement about surfaces which connects their intrinsic geometry *(local curvature) to their* topology *(Euler characteristic).*

Let M *be a compact, orientable two-dimensional Riemannian manifold with boundary* ∂M*. Denote by* K *the* Gaussian curvature *at a general point on the surface, and by* K_g *the* geodesic (extrinsic) curvature *at a general point on* ∂M*. Then*

$$\int_M K dA + \int_{\partial M} K_g ds = 2\pi\chi(M) \tag{1}$$

where dA *is an area-element on* M, ds *is an* arc *element on* ∂M, *and* $\chi(M)$ *is the* Euler characteristic *of* M*. If the manifold does not have a boundary, the integral* $\int_{\partial M} K_g ds$ *can be omitted. Thus, the* integral curvature *of a closed orientable surface* M *of genus* g *does not depend on the shape of the surface and is equal to*

$$\int_M K dA = 4\pi(1-g). \tag{2}$$

This result makes it possible to express topological *properties of the surface — in this case the genus* g *(which remains invariant under arbitrary continuous deformations) — in terms of quantities of differential geometry (here, the integral curvature).*

If M *is open (i.e. has a boundary), the geodesic (extrinsic) curvature at a given point along the (closed) curve* ∂M *is the reciprocal of the radius of curvature of* ∂M *at that point, in a locally flat 2D coordinate system. Thus,* $K_g \equiv 0$ *if* ∂M *is a geodesic of the Riemann surface* M*. For example, if* M *is a portion of a unit-radius sphere defined by* $0 \leq \theta \leq \alpha < \frac{\pi}{2}$ *(in spherical polar coordinates),* ∂M *is the circle of latitude* $\theta = \alpha$ *(not a geodesic);* $K_g = \cot\alpha$ *uniformly on* ∂M, *and* $K = 1$ *uniformly on* M*. We thus have in this case* $\int_M dA = 2\pi(1-\cos\alpha)$, $\int_{\partial M} ds = 2\pi\sin\alpha$*. Thus, the Gauss-Bonnet theorem for this open surface yields:*

$$\int_M K dA + \int_{\partial M} K_g ds = 2\pi(1-\cos\alpha) + 2\pi\sin\alpha \cdot \cot\alpha = 2\pi = 2\pi\chi(M).$$

And indeed, since M *is topologically equivalent to a disc, its Euler characteristic is* $\chi(M) = 1$.

If one bends or deforms the manifold M, its Euler characteristic will not change, while its curvature at given points will. The theorem then requires, somewhat surprisingly, that the integral of all curvatures will remain the same.

In 1943, **Carl B. Allendoerfer** *and* **André Weil** *generalized the Gauss-Bonnet theorem to n-dimensional spaces. Also in that year, it was further generalized by* **S.S. Chern** *for a closed Riemannian manifold of dimension $2n$. He presented the Euler characteristic as an integral of a certain formal polynomial derived from its Riemann curvature tensor:*

$$\int_M Pf(\Omega) = 2^n \pi^n \chi(M), \tag{3}$$

where $Pf(\Omega)$ is the Pfaffian polynomial[907] *of Ω and Ω is the curvature 2-form matrix (in Cartan's exterior calculus). For $n = 1$ (2 dimensions)*

$$\Omega = \begin{bmatrix} 0 & K \\ -K & 0 \end{bmatrix} \omega, \quad Pf \begin{bmatrix} 0 & K\omega \\ -K\omega & 0 \end{bmatrix} = K\omega,$$

where $\omega = \sqrt{\det g}\ dx^1 \bigwedge dx^2$ is the volume 2-form, g the surface's metric tensor, (x^1, x^2) coordinates in the local chart, and "$\bigwedge$" the Cartan wedge

---

[907] The *determinant* of a skew-symmetric square *matrix* X with elements x_{ij} can always be written as the square of a *polynomial* of degree n in the variables x_{ij}. This polynomial is called the *Pfaffian* of the matrix, and denoted $Pf(X)$. The Pfaffian is non vanishing only for $2n \times 2n$ skew-symmetric matrices. Thus

$$\det(X) = \begin{vmatrix} 0 & x_{12} & x_{13} & \cdots & x_{1n} \\ -x_{12} & 0 & x_{23} & \cdots & x_{2n} \\ -x_{13} & -x_{23} & 0 & \cdots & x_{3n} \\ \vdots & \vdots & \vdots & & \vdots \\ -x_{1n} & -x_{2n} & -x_{3n} & \cdots & 0 \end{vmatrix} = \begin{cases} [Pf(X)]^2 & n \text{ even} \\ 0 & n \text{ odd} \end{cases}$$

For example:

$$Pf \begin{bmatrix} 0 & x_{12} \\ -x_{12} & 0 \end{bmatrix} = x_{12};$$

$$Pf \begin{bmatrix} 0 & x_{12} & x_{13} & x_{14} \\ -x_{12} & 0 & x_{23} & x_{24} \\ -x_{13} & -x_{23} & 0 & x_{34} \\ -x_{14} & -x_{24} & -x_{34} & 0 \end{bmatrix} = x_{12}x_{34} - x_{13}x_{24} + x_{23}x_{14}$$

product $(dx^2 \bigwedge dx^1 = -dx^1 \bigwedge dx^2)$. *Since* $\int_M K\omega = \int_M KdA$ *in standard (non-Cartan) notation, we recover equation (1).*

Atiyah-Singer Index Theorem (ASIT)

In the beginning, mathematics was used to count (arithmetic), e.g. for bookkeeping, planning and trade; or to describe shapes (geometry), e.g. for measuring a plot of land, for cutting out fabric for a dress, or for building a bridge. Modern applications of mathematics are often concerned with modeling — and thereby predicting — the evolution over time of complex, composite systems, such as oil and gas flow in porous rocks under the North Sea, how queues of text messages in a cellular network can best be resolved, or what the weather will be like this weekend.

Since the time of Newton and Leibniz, these mathematical models have often been described by systems of differential equations. *To use mathematics for the intended application, one seeks to find the* solutions *of such systems. The Atiyah-Singer Index Theorem (ASIT) is a fundamental insight that essentially says that we can find out* how many solutions *the system has by just knowing some simple pieces of information about the geometry of the space being modeled. Thus although the index theorem is a purely mathematical result, which links together analysis and topology, it can be used as a tool in many applications of mathematics.*

The subject of mathematics can coarsely be divided into four areas: algebra, analysis, topology/geometry, and logic. Mathematics is a diverse language that can describe, discuss and model many different objects, processes and problems, and the four areas tend to focus on different aspects of these objects. Nonetheless, there are no clear boundaries between them.

In analysis, *an entity is studied by first partitioning it into small pieces, and thereafter reassembling them (synthesis). Emphasis is put on the limiting case when the pieces become arbitrarily small, and simultaneously arbitrarily numerous. Keywords: differentiation, integration and calculus.*

In topology *and* geometry *one studies how an object can have a shape, or a spatial aspect. In particular, in topology one emphasizes properties of the whole global shape and properties unchanged under continuous, reversible deformations, rather than the local or deformation-sensible attributes of the object. If the shape is described by some notion of distance, angle, straightness etc., then we usually talk about* geometry.

The Index theorem (actually a class of related theorems) marked the birth of the mathematical field of global analysis. *One reason for seeking such a* *theorem was the attempt to unify all the aforementioned types of concepts into one formula. Such a formula had been conjectured earlier (1960) by* ***Israel Gelfand*** *in the context of the homology invariance of the index of a Fredholm operator. Given the examples from Hodge theory, Cauchy-Riemann operators in several variables, and the topologists' work on the Riemann-Roch Theorem at the time, the required concepts were perhaps 'in the air' by 1960.*

Thus for instance, from 1946, ***Salomon Bochner*** *(1899–1982) and his colleagues & students found novel connections between homology & cohomology theories on the one hand, and the local differential geometry of the corresponding manifold on the other.*

For example, Bochner proved that if a smooth Riemannian manifold M *has a positive-semidefinite Ricci curvature scalar which is positive at a point, then the manifold's first Betti number,* b_1*, vanishes. This has two implications. From the homology point of view,* $b_1 = 0$ *means there is no closed curve along which the manifold* M *can be cut while remaining connected. From the (de Rham) cohomology viewpoint,* b_1 *is the number of linearly independent 1-forms on* M *that are closed modulo exact forms. In other words, in Cartan's exterior calculus,* b_1 *is the dimension of the vector space of 1-forms* V *that are closed (i.e. satisfy* $d\mathrm{V} = 0$*), provided we regard two solutions* $\mathrm{V}_1, \mathrm{V}_2$ *of this differential equation as identical if their difference is exact - i.e.* $\mathrm{V}_1 - \mathrm{V}_2 = d\phi$ *for some scalar (0-form)* ϕ*.*

Before launching into technical examples of the use of ASIT in contemporary mathematical physics, we define a few necessary general concepts. We also provide the reader with a very simple and easily visualized example that will set the stage for what follows.

A brief statement of the simplest version of ASIT is:
Let $E(f) = 0$ *be an elliptic system of differential equations, defined over a closed, smooth, oriented* n*-dimensional manifold* M*. Then*

$$\text{analytical index } (E) = \text{topological index } (E)$$

where the analytical index is

$$\text{analytical index } (E) = \begin{array}{l} \text{dimension of the kernel of } E \\ - \text{dimension of co-kernel of } E \end{array}$$

and the topological index of E *is an explicit expression that characterizes the topology of the manifold.*

In formulating the theorem we start with two vector bundles over the base manifold M*, and an elliptic operator* E *mapping smooth sections of one vector bundle into smooth sections of the other vector bundle. If the sections are tensor fields then the fibers of the corresponding bundles are related to* *the local tangent-spaces of M, as discussed above. But, in general, a bundle's fiber need not have anything to do with its base manifold. Thus, for instance, in particle-physics applications, the electromagnetic or chromodynamic field tensors are curvature 2-forms in bundles whose fibers are* internal *(non-spacetime) spaces, acted upon by (Abelian or non-Abelian) Lie-group symmetries. The elliptic property of E is expressed in terms of its* symbol *— an algebraic entity derived from the coefficients of the highest-order derivatives in the operator E. Thus, if E is a generalized Laplacian, its symbol is a positive-definite quadratic form. The symbol is itself a section of a fiber bundle and is required to be non-singular.*

The differential (or pseudo-differential) operator E is a Fredholm operator. As such it has an index (called its analytical *index above). This is the difference between two integers. The first is the dimension of the* kernel *(or* null-space*) of E — i.e. the number of linearly independent solutions of the system of differential equations $Ef = 0$, where f is a section of the first bundle. This integer is denoted as $\dim\ker(E)$. (The solutions f can be viewed as generalized harmonic functions.) The second integer, denoted $\dim\operatorname{coker}(E)$, is the dimension of the vector space of linear constraints on sections $g = Ef$ of the* second *bundle, where f is now an arbitrary section of the first bundle.*

The index problem *is the following: compute the index of E using only the symbol s and* topological *data derived from the manifold and the vector bundles. The Index Theorem solves this problem. Its precise statement requires K-theory, as well as a background in* functional analysis *and pseudo-differential operators in the manifold setting (*global analysis*).*

A simple case is illustrated by a famous paradoxical etching of ***M.C. Escher****, "Ascending and Descending" (Fig. 5.16), where the people, always going uphill along the parapet, still manage to circle the castle courtyard. The index theorem would have told them this was impossible.*

To see this, we follow a hooded walker as he goes around, up or down the square staircase. Here the spatial (base) manifold M is a square, while the walker trajectory (section of the first vector-bundle) is a function $f(x)$ that equals the height above ground at each point x along M. The square M is parameterized by a coordinate x (at least two charts are needed, and we may choose $0 \leq x < 2\pi$ in one of them). The operator E is taken to be differentiation: $Ef = df/dx = f'(x)$. The differential equation $Ef = 0$ then has the 1-dimensional space of solutions $f(x) = C$, with C an arbitrary real constant; thus $\dim\ker(E) = 1$. On the other hand, $\dim\operatorname{coker}(E)$ also equals 1, since the differential equation $g(x) = f'(x)$ imposes the single constraint $\int_0^{2\pi} g(x)dx = 0$ (this followed from the fact that $f : M \to R$ is a single-valued function along the square). Thus, the analytical *index of E is $1 - 1 = 0$; and it can be shown that the corresponding* topological *index vanishes as well. In*

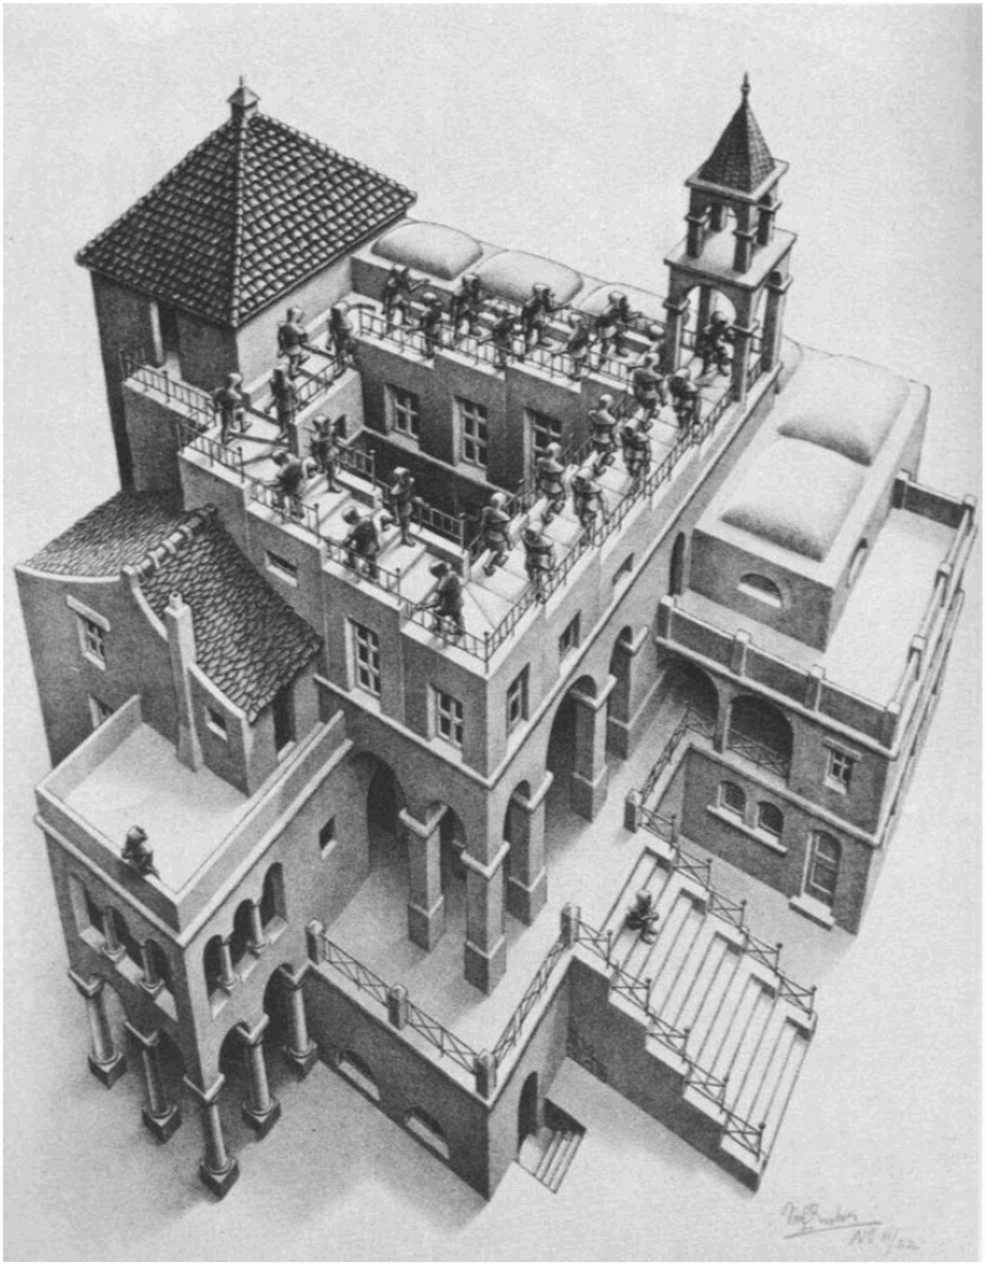

Fig. 5.16: M.C. Escher's "Ascending and Descending"

particular, the wanderer cannot ascend nor descent all the time, since that would imply $f'(x) > 0$*, contradicting the constraint* $\int_0^{2\pi} f'(x)dx = 0$.

Michael Francis Atiyah *(b. 1929) and* ***Isadore M. Singer*** *(b. 1924) shared the Field Medal (2004) for their discovery. They brought together topology, geometry and analysis and built new bridges between mathematics and theoretical physics.*

The ASIT is a topological formula for the Fredholm index of a linear, elliptical pseudo-differential operator (e.g. a "Dirac Operator") in terms of characteristic classes (differential-topological invariants) of the underlying bundle. The ASIT covers all the particular cases mentioned above, by means of specific choices of the linear operator and associated fiber bundle.

In the particular case of the Dolbeault Operator on complex manifolds this is the theorem of Riemann-Roch; while for the Chern-Gauss-Bonnet formula, the ASIT is applied to a vector bundle of smooth differential forms, with the (Dirac) operator being the square-root of the Hodge Laplacian.

We have seen that for an even-dimensional, closed (boundary-less), oriented, smooth and compact Riemannian manifold M*, the manifold's Euler characteristic,* $\chi(\mathrm{M})$*, can be expressed as an integral over* M *of an* n*-form constructed from the matrix curvature 2-form, where* $n = \dim \mathrm{M}$.[908] *On the other hand, we have seen that* $\chi(\mathrm{M})$ *can* also *be expressed as an alternating sum of the manifold's Betti numbers. The equality of these two expressions for* $\chi(\mathrm{M})$ *is one of the many useful consequences of the Atiyah-Singer Index Theorem — as we now proceed to discuss. The mathematical framework for this particular application of ASIT is the theory of exterior forms (skew-symmetric covariant tensors) and their cohomology classes on Riemannian manifolds, as developed by* **Cartan**, **de Rham**, *and* **Hodge**.

We will describe how ASIT works for this case, presenting more details for the 2-dimensional (Gauss-Bonnet) case. We will follow the more recent heat-kernel approach to proving ASIT, which utilizes ideas from physics. (The original proof of the Atiyah-Singer and related Index Theorems relied on K-theory and the theory of characteristic classes).

The Cartan exterior derivative operator, denoted "d", maps the vector space of m*-forms into that of* $(m+1)$*-forms; Thus for instance, if* $\phi : \mathrm{M} \to \mathrm{R}$ *is a scalar field (0-form), then* $d\phi$ *is a 1-form (in any particular chart* $d\phi = \frac{\partial \phi}{\partial x^k} dx^k$ *where the summation convention is understood). Or, if* ϕ_1, ϕ_2 *are two 0- forms, then* $\phi_1 d\phi_2$ *is a 1-form and we have* $d(\phi_1 d\phi_2) = d\phi_1 \bigwedge d\phi_2$*, a 2-form. Here we have used the fact that the operator* d^2 *vanishes identically (which,*

[908] The requirement that M be *compact* can be relaxed if the metric is chosen such that its deviation from the Euclidean case has *compact support* on M.

in ordinary vector calculus in flat 3-D space, yields the well-known results: $\operatorname{div}\operatorname{curl} = 0$ *and* $\operatorname{curl}\operatorname{grad} = 0$*).*

Another key mapping defines the Hodge dual. If V *is an* m*-form* $(0 \le m \le n)$*, then its Hodge dual* $^*V$ *(an* $(n-m)$*-form) is defined so that* $V \to {}^*V$ *is a linear map at any point* $p \in M$ *and* $^*(dx^1 \wedge dx^2 \wedge \ldots \wedge dx^m) = dx^{m+1} \wedge \ldots dx^n$ *in any positive-orientation chart for which the metric is Euclidean at* p*. (Such a chart can be added to any atlas for any point* p*, since* M *is* orientable *and* Riemannian*). This Hodge duality (or star)operation, like exterior differentiation, is chart-independent, and thus they are covariant (and truly geometric) operations. They can be combined to yield a third important operation (map), the* δ derivative*, defined as follows: if* W *is an* m*-form,* δW *is an* $(m-1)$*-form and*

$$\delta W = (-1)^{mn+n+1}\ {}^*d({}^*W).$$

It is easily shown that $^*({}^*\mathrm{W}) = (-1)^{m(n-m)}W$ *and therefore,* δ^2 *vanishes identically (just as* d^2 *does).*[909]

Hodge duality is also used to define an internal product *on exterior forms: if* V, W *are two forms,* $\langle V, W\rangle = 0$ *unless they have the same rank (i.e. they are both* m*-forms for some* m*); and if they do,*

$$\langle V, W\rangle \equiv \int_M V \wedge\ {}^*W,$$

where $\wedge$ *denotes the Cartan wedge-product. (Here the integrand* $V \wedge {}^*W$ *is an* n*-form; only* n*-forms can be integrated on an* n*-dimensional manifold). It is easy to prove that* δ *is the* adjoint *of the operator* d *relative to this internal product.*

For any m*-form* V*,* $\langle V, V\rangle \equiv \|V\|^2 \ge 0$*, and vanishes* iff $V = 0$*.*
The Hodge Laplacian *is defined as follows:*

$$\Delta = (d+\delta)^2 = d\delta + \delta d$$

Acting on any smooth m*-form, it yields another such form. For any* m*-form* V[910]*, we have (using that* d, δ *are each other's adjoint):*
$\langle V, \Delta V\rangle = \langle dV, dV\rangle + \langle \delta V, \delta V\rangle = \|dV\|^2 + \|\delta V\|^2$*. Therefore, due to the properties of the norm listed above,* Δ *is a* positive semi definite elliptic *operator, and any* harmonic m*-form* V *(i.e. satisfying* $\Delta V = 0$*) also satisfies*

---

909 d acting on an n-form yields 0, as it must since no $(n+1)$-forms, exist – and for a similar reason, $\delta\phi = 0$ for any 0-form (scalar) ϕ.

910 From now on all forms and the metric will be assumed smooth.

$dV = \delta V = 0$[911]. *If the manifold M is compact, it can be shown that the spectrum of Δ (i.e. the set of its eigenvalues $\lambda_j; j = 0, 1, \ldots$) is discrete and infinite. If nonzero harmonic form(s) exist for any m then the lowest eigenvalue is $\lambda_0 = 0$. Since Δ is self-adjoint, any two of its m-forms eigenfunctions V, W are orthogonal ($\langle V, W\rangle = 0$) if they correspond to distinct eigenvalues. And the m-form eigenfunctions having the same eigenvalue (if more that one) can also be rendered mutually orthogonal, via the familiar Gramm-Schmidt procedure.*

The mathematical tools just described readily lead to some powerful results. The Hodge decomposition theorem guarantees that any m-form U can be written as $U = dV + \delta W + U_0$, where V, W are an $(m-1)$- and $(m+1)$-form respectively, and U_0 is a harmonic m-form.[912] *This, in turn, can be used to show that b_m, the m-th Betti number of M (an integer topological invariant which counts the generators of the m-th homology group), is also the number of linearly-independent harmonic m-forms.*

In order to apply the ASIT to the Betti numbers, we must first select the operator E and the (first) vector bundle it acts upon. We erect this bundle upon the base manifold M, with its fiber being the vector space of formal sums of all types of even rank forms (0-, 2-, … through n-forms, if $n = \dim M$ is assumed even). And we choose: $E = d + \delta$.

*E maps any section of the above-defined bundle into a formal sum of odd-rank forms; thus, if v is a 4-form, Ev is the formal sum of a 3-form and a 5-form. E is a type of generalized Dirac operator, and is (in a sense) the "square root" of the Hodge Laplacian operator Δ. E maps the above–defined bundle (whose sections are formal sums of even-rank forms) into a second bundle which the ASIT requires: namely, the vector bundle whose sections are formal sums of odd-rank forms (1-forms, 3-forms, … $(n-1)$-forms).
The adjoint of E, which we denote $E^\dagger$, is also $d + \delta$, but it acts on sums of odd-rank forms to yield even-rank forms.*

As noted above (from here on we assume $n = \dim M$ to be even),

$$\chi(M) = b_0 - b_1 + \ldots + b_n = \sum_{k=0}^{n/2} b_{2k} - \sum_{k=0}^{n/2-1} b_{2k+1} \equiv b_{even} - b_{odd}$$

---

[911] Any form satisfying $dV = 0$ is called *closed*; any m-form V which can be written $V = dW$ for some $(m-1)$-form W is said to be *exact*. All exact forms are closed, since $d^2 = 0$ as noted above.

[912] In flat 3-D space this implies the *Helmholtz* theorem – familiar from ordinary vector calculus – according to which any vector field vanishing at infinity is the sum of a *curl* and a *grad*.

Here b_{even} is the number of linearly-independent, even-rank harmonic forms; while b_{odd} is the same for odd-rank harmonic forms. Since $\Delta = E^2$, it is easily shown that:

$$b_{even} = \dim\ker E, \qquad b_{odd} = \dim\operatorname{coker} E,$$

and we thus conclude that the Euler characteristic $\chi(M)$ is the analytical index of the generalized Dirac operator E:

$$\chi(M) = \text{analytical Index}(E)$$

It remains to express the RHS in terms of a topological index – in this case, the Euler-Poincaré characteristic of the tangent bundle $T(M)$ of the base manifold; this characteristic , in turn, is an integral over M of an n-form built from the Riemann-curvature matrix 2-form, as we saw earlier.

*We conclude with a demonstration of how the Heat Kernel method (**E.Getzler** 1983) can be used to express the analytical index of E as an integral over a curvature-dependent n-form. To that end, we restrict our attention to $n = 2$, i.e. M is a closed, compact, 2-D orientable surface; in this case the ASIT should reduce to the Gauss-Bonnet theorem for the boundary-less case.*[913]

A well-known theorem in 2-D differential geometry guarantees that an atlas exists on M such that, in each chart, the metric tensor is

$$g_{ij} = e^{\varphi(\xi,\eta)}\delta_{ij} \qquad 1 \le i \le 2, \quad 1 \le j \le 2$$

where δ_{ij} is the Kronecker delta and φ is a function (assumed smooth) of the chart's two coordinates:

$$x^1 \equiv \xi, \quad x^2 \equiv \eta.$$

We then have $\det g = \exp(2\varphi)$, and the local Ricci scalar is

$$R = e^{-\varphi}\left(\frac{\partial^2\varphi}{\partial\xi^2} + \frac{\partial^2\varphi}{\partial\eta^2}\right)$$

Now, it can be shown[914] *that for any number $t > 0$,*

$$\textit{Analytical Index}(E) = \operatorname{Tr}(e^{-tE^\dagger E}) - \operatorname{Tr}(e^{-tEE^\dagger}), \tag{4}$$

[913] Versions of the ASIT for manifolds *with* boundary have also been proven; for instance, the *Atiyah–Singer–Patodi* theorem.

[914] Eq. (4) follows from the fact that the nonzero spectra of the operator $E^\dagger E$ and $EE^\dagger$ are *positive* and *identical*, so all contributions to the two traces *cancel* except the zero-eigenvalue (i.e. *harmonic*) terms. These terms are t-independent, and thus the RHS of (4) is also t-independent.

Where the trace of any matrix-differential operator A acting on vector functions $v_j(\xi,\eta) \quad (i,j=1,\dots s$ for some integer $s\geq 1)$, is

$$\mathrm{Tr}(A)=\sum_{k=0}^{\infty}\Big\langle \Psi_k, \quad A\Psi_k\Big\rangle. \tag{5}$$

Here $\Psi_k(k=0,1,\dots)$ is an infinite, orthogonal basis of scalar function on the chart:

$$\sum_{k=0}^{\infty}\Psi_k(\xi,\eta)\Psi_k(\xi',\eta')=\frac{I}{\sqrt{\det g}}\delta(\xi-\xi')\delta(\eta-\eta'), \tag{6}$$

with $\delta()$ the Dirac delta-function.

Now, for any vector function $v_j(\xi,\eta)$ (a section of the first bundle over the given chart), the vector

$$w_j(\xi,\eta|t)\equiv\sum_{j'}(e^{-tE^{\dagger}E})_{jj'}v_{j'}(\xi,\eta)$$

solves the following parabolic PDE (generalized heat equation):

$$(\frac{\partial}{\partial t}+\Delta)w_j(\xi,\eta|t)=0 \tag{7}$$

with the initial condition: $w_j(\xi,\eta|0)=v_j(\xi,\eta)$. (Here $\Delta=d\delta+\delta d$ is the Hodge Laplacian. A similar PDE results for the second term on the RHS of (4).)

For a flat chart ($\varphi=0$) Eq. (7) is the standard heat equation (in two dimensional space). But a general surface need not be flat (in any chart); in that case, (7) reduces — for each m-form component of the vector bundle — to a heat equation with inhomogeneous heat conductivity. Such PDE's do not, in general, admit exact closed-form solutions. Fortunately, however, the RHS of (4) — and thus the sought-after index formula — does not depend on t; so the heat kernel method consists of finding small-t asymptotic expansions in t for the solutions of (7), and then taking the $t\to 0^+$ limit — in which the leading few terms in the asymptotic expansion become exact! Using these techniques, it can be proven without too much difficulty that the Gauss-Bonnet formula is indeed reproduced[915]*:*

[915] Eq. (7) is solved for initial conditions $v_j(\xi,\eta)$ that are Dirac delta-functions at a point P on M; and then the trace operation (5), together with (6), results in an integral over P — as seen in Eq. (8).

$$\chi(M) = b_0 - b_1 + b_2 = b_{\text{even}} - b_{odd} = \frac{1}{2\pi} \sum_{charts} \int_{chart} \left(\frac{\partial^2 \varphi}{\partial \xi^2} + \frac{\partial^2 \varphi}{\partial \eta^2} \right) d\xi d\eta$$
$$= \frac{1}{2\pi} \sum_{charts} \int_{chart} R\sqrt{\det g}\, d\xi \wedge d\eta = \frac{1}{2\pi} \int_M k dA, \tag{8}$$

where $k(P)$ is the Gaussian curvature at a point P of the surface M, and the sum over charts is done in such a manner as to compensate for multiple counting where charts overlap.

However, it is important to notice that the ASIT is much more general than all the more specialized theorems above. For example, a typical corollary which is not contained in the previous results is the index theorem for the spinor Dirac operators on the spin bundle of a curved spacetime manifold in the presence of electromagnetic (and other gauge) fields. This index theorem and the others mentioned above are of key importance in particle physics, Quantum Field Theory (QFT), quantum gravity and string theory.

Nowadays there are several extensions of the ASIT in many different directions. But index theorems are not the only object of research in global analysis. For example: scattering theory on noncompact manifolds, holomorphic torsion, trace formulas and analysis on locally symmetric spaces are all active fields of research. Applications of global analysis can be observed in almost all fields of pure mathematics, theoretical physics *and equilibrium theory in* microeconomics.

(e) Physics and Topology

In the 1970's and 1980's, theoretical physics underwent a significant transformation: the traditional tools of mathematical physics (real and complex analysis), which deal with space-time configurations and phase-space manifolds mainly locally, *were supplemented by topological approaches (more precisely, methods from* differential and algebraic topology*), that account for the* global *(holistic) structure of spacetimes, configuration and phase-spaces, function spaces, and other manifolds based upon spacetime (such as e.g. fiber bundles, whose* local *differential geometry also became important in physics, and whose fibers often involve non-spacetime ("internal") spaces). This trend was seen in:*

- *Geometrical phases in adiabatic Quantum Mechanics.*
- *The rise of Non Abelian Gauge theories.*

- *Solitons, instantons, path integrals, functional differential equations, symmetry breaking and gauge-fixing and anomalies in gauge theories and condensed-matter systems.*
- *Theory of defect-mediated phase-transition in condensed matter, QFT (Quantum Field Theory) and the particle-physics era in early-universe cosmology.*
- *Kaluza-Klein theories (microscopic extra dimensions and geometrization of non-gravitational forces), supergravity theories, and string and superstring theories.*
- *Attempts to develop Grand Unified QFT's and a theory of Quantum gravity.*
- *Nonlinear dynamics and chaos theory.*

As before, mathematicians forged the tools for the new physics. Thus, for example, De Rham's theorem *in cohomology (1931) and the work of* ***Chern*** *on* characteristic classes *and* fiber-bundles *(1943), became an important tools for understanding non-Abelian gauge theories (Yang-Mills theories) and quantized fields in curved spacetime. The work of* ***E. Calabi*** *(1954) on Kähler manifolds with Ricci flat metric and vanishing first Chern class became of importance in* superstring theory.

While most of the algebraic, differential-geometric and topological tools adapted for use in quantum physics are classical in nature, some — such as Quantum Groups *(Hopf algebras),* Virasoro *and* Kac-Moody *algebras, and the so-called* graded Lie algebras *of supersymmetry and supergravity — are inherently quantum-mechanical insofar as their relevance to physics goes.*

1936–1960 CE **Hans Adolph Rademacher** (1892–1969, Germany and USA). Mathematician. Made significant contributions to analysis and number theory. His most famous result (1936) is his derivation of an explicit asymptotic formula for the growth of the *partition function* (the number of representations of a number as a sum of natural numbers). This answered questions posed by **Leibniz** and **Euler** and followed results obtained by **Hardy** and **Ramanujan**. In addition he derived other important results in measure theory, complex analysis, geometry and numerical analysis.

Rademacher was born in Wandsbeck (near Hamburg) and was a student of Carathéodory and Landau at Göttingen (Ph.D. 1916). He then held academic appointments in Berlin, Hamburg and Breslau. Because of his pacifist views he was forced by the Nazis out of his professorship in Breslau and left Germany (1934). He spent the rest of his life in the United States, mostly at the University of Pennsylvania.

1936–1962 CE **Harold Marston Morse** (1892–1977, USA). Mathematician. Established connections between topology and equilibrium points in the calculus of variations, and applied such ideas to *minimal surfaces*. Contributed to what is now called *Global Analysis*, i.e. the study of differential equations, ordinary and partial, from a topological point of view. This development owes much to the calculus of variations since the problems of this field have an especially global character from the outset. *Morse function*, *Morse Lemma*, *Morse equality* and *Morse theory* are named after him.

Marston Morse was born in Waterville, Maine, and educated at Colby College (B.A., 1914) and Harvard (Ph.D., 1917). He taught at Harvard briefly before entering military service in World War I and again immediately thereafter. He then held positions at the universities of Cornell (1920–1925) and Brown (1925–1926). In 1926 he returned to Harvard, where he remained until his appointment to the Institute for Advanced Study in 1935. In 1962 he was appointed Emeritus Professor at the Institute and in 1965–1966 served as Visiting Professor at the Graduate Center of City University of New York.

Euler's relation for polyhedra inscribed in a sphere is $V - E + F = 2$ (V = number of vertices; E = number of edges; F = number of faces). For the hemisphere (topologically equivalent to a sphere with one hole) we have $V - E + F = 1$ (e.g. for a three-sided pyramid that is missing its base $V = 4$, $E = 6$, $F = 3$). On the other hand Morse discovered that for a hemispherical bowl with n equilibrium points $\{P_1, P_2, \dots, P_n\}$ with the corresponding *characteristic numbers*[916] $\{\lambda_1, \lambda_2, \dots, \lambda_n\}$ we have $\sum_{i=1}^{n}(-1)^{\lambda_i} = 1$ (Morse's Equation).

Morse connected this equation with the existence of n *minimal surfaces* (surfaces of locally-minimal area) that span a given contour. First, he assigned to each of the minimal surfaces a characteristic number λ_i analogous in meaning to the characteristic numbers in the bowl, in such a way that $\lambda_i = 0$ corresponds to a *stable* minimal surface with minimal area. A consequence

[916] *Characteristic number* of an equilibrium point is equal to the maximal number of mutually perpendicular directions in which the height from equilibrium point diminishes. Thus, for example, a stable point (minimum potential energy) has $\lambda = 0$, while a saddle point has $\lambda = 1$.

of Morse's equation is that the existence of n minimal surfaces of minimal area that span a given contour implies that there must be another $(n-1)$ *unstable* minimal surfaces bounded by the same contour.

The relation $\sum_i(-1)^{\lambda_i} = V - E + F$ reflects a profound statement that connects topology with the concept of equilibria in the calculus of variations. Morse's equation is forced upon us by some mathematical structure hidden within the topological nature of the bowl.

1936–1965 CE **Max Horkheimer** (1895–1973, Germany and USA). Social philosopher. Regarded philosophy as culture criticism and maintained that the enlightened spirit of modern man destroys itself by striving for a pleasant and fair existence. Accordingly, the ills of modern society are caused by the misuse and the misunderstanding of reason. If people use true reason to critique their societies, they will be able to identify and solve their problems.

Horkheimer was born in Stuttgart to an assimilated Jewish family. He left High School (1911) to work in his father's factory and then participated (1917–1918) in WWI. He enrolled in the University of München (1919) and studied philosophy and psychology, obtaining his Ph.D. degree in 1925. There he struck a lasting friendship with **Theodor Adorno** with whom he collaborated throughout his life. In 1930 he founded, with **Herbert Marcuse** the Frankfurt (Main) *Institute for Social Research*, and was appointed the full professor for social philosophy. The Nazis closed the institute (1933) and Horkheimer emigrated to the USA via Switzerland. In 1949 he returned to Frankfurt, where the Institute was reopened (1950). He returned to America to lecture at the University of Chicago (1954–1959). He died in Nürnberg (1973). His most important publications are

- *Authority and the Family* (1936).
- *Traditional and Critical Theory* (1937).
- *Eclipse of Reason* (1947).
- *The Dialectic of Enlightenment* (1947).
- *Critique of Instrumental Reason* (1967).

The last book deals with the concept of "reason" within the history of Western philosophy. Horkheimer defines true reason as rationality. He details the difference between objective and subjective reason and states that we have moved from the objective to the subjective. Objective reason deals with universal truths that dictate that an action is either right or wrong. Subjective reason takes into account the situation and social norms. Actions that produce the best situation for the individual are "reasonable" according to subjective reason. The movement from one type of reason to the other occurred when thought could no longer accommodate these objective truths or when it judged them to be delusions. Under subjective reason, concepts lose their meaning. All concepts must be strictly functional to be reasonable. Because subjective reason rules, the ideals of a society, for example democratic ideals, become dependent on the "interests" of the people instead of being dependent on objective truths.

Horkheimer's programmatic essay on 'Traditional and Critical Theory' (1937) enshrined the ambitions of the Institute. It described the necessity of integrating philosophy and social science, and of developing a relationship of integrity between critical theory and political practice. In later years, Horkheimer's vision became increasingly dark and gloomy. His later writings evince the difficulty — even the impossibility — of fulfilling the original ambition and programme of the Frankfurt School[917]. The result is an increasingly sharp critique of 'enlightened' reason and Western rationality. The *Dialectic of Enlightenment* (1947), written in collaboration with Adorno, was the first and most powerful statement of this theme.

1937 CE **Arne Wilhelm Kaurin Tiselius** (1902–1971, Sweden). Biochemist. Developed new methods of separation of colloids though *electrophoresis*[918] and used it for studying proteins.

---

917 The "*Frankfurt School*" aimed to put philosophical ideas to the task of diagnosing social problems. It was comprised extraordinarily by a distinguished collection of leftists, mostly Jewish, philosophers and social thinkers that gathered in the *Institute of Social Research* at the University of Frankfurt. After the war, when most of its members returned from exile, the institute was led by **Theodor Adorno** and **Max Horkheimer**. Horkheimer's chair was given to **Jurgen Habermas** (1964).

918 *Electrophoresis*: A technique for the analysis and separation of colloids, based on the movement of charged colloidal particles in an electric field. There are various experimental methods. In one the sample is placed in a U-tube and a buffer solution added to each arm, so that there are sharp boundaries between buffer and sample. An electrode is placed in each arm, a voltage applied, and the motion of the boundaries under the influence of the field is observed. The rate of migration of the particles depends on the field, the charge on the particles, and on other factors, such as the size and shape of the particles. More simply, electrophoresis can be carried out using an adsorbent, such as a strip of filter paper, soaked in a buffer with two electrodes making contact. The sample is placed between the electrodes, and a voltage applied. Different components of

Tiselius was born in Stockholm. He studied at the University of Uppsala (1925–1930), specializing in chemistry under **Svedberg** (Ph.D. 1930). He was a professor at Uppsala, 1938–1968. Awarded the Nobel Prize for chemistry (1948) for his studies concerning the nature of *serum proteins.*

Electrophoresis became widely developed in the 1940s and 1950s when the technique was applied to molecules ranging from the largest proteins down to amino acids or even inorganic ions.

1937–1940 CE **George Robert Stibitz** (1904–1995, USA). Mathematician, computer scientist and inventor. Father of the modern digital computer. Designed and built the *Complex Number Calculator*, the world's first *electrical* digital computer. The design began in April 1939 and the end product first ran on January 08, 1940. Its "brain" consisted of 450 electromechanical telephone relays and 10 cross-bar switches, and it could find the quotient of two eight digit complex numbers in about 30 seconds. Three teletypewriters provided input to the machine.

Born in York, PA, Stibitz earned a Ph.D. in applied mathematics (1926) and a Ph.D. in physics from Cornell University (1930). He then joined Bell Telephone Laboratories (1930), serving as a mathematical consultant. Stibitz's interest in computers arose from an assignment to study the magneto-mechanics of telephone relays; he turned his attention to the binary circuits controlled by the relays, to the arithmetic operations expressible in binary form, and, in November 1937, to the construction of a two-digit binary adder based on relays, flashlight bulbs, and metal strips cut from tin-cans.[919]

In 1940, Stibitz performed a spectacular demonstration at the Dartmouth (NH) meeting of the American Mathematical association: Leaving his computer in New York City, he took a teleprinter to the meeting and proceeded to connect it to his computer via telephone — the world's first demonstration of remote computing. During WWII he designed program-controlled calculations for the military, but these were soon to be outmoded by the development of *electronic* digital computers.

---

the mixture migrate at different rates, so the sample separates into zones. The components can be identified by the rate at which they move. This technique has also been known as *electrochromatography.*

Electrophoresis is used extensively in studying mixtures of proteins, nucleic acids, carbohydrates, enzymes, etc. In clinical medicine it is used for determining the protein content of body fluids.

919 The machine, called "Model K" (because most of it was constructed on his kitchen table), worked on the principle that if two relays were activated, they caused a third relay to become active, where this third relay represented the resultant of a binary operations.

Thereafter he developed a precursor of the electronic digital microcomputer (1954) and eventually applied computer systems development to a wide variety of topics in biomedicine. He became professor of physiology at the medical school of Dartmouth College (1966).

1937–1944 CE **Isidor Isaac Rabi** (1898–1988, U.S.A.). Experimental physicist. Perfected the technique of *molecular beams* and made it into a potent tool for measuring magnetic properties of molecules and atomic nuclei *with great accuracy*. For this he was awarded the Nobel prize for physics (1944).

Rabi was born in Rymanov, Poland, to Jewish parents and was brought at the age of one year to the United States. He studied at Cornell and then at Columbia University (Ph.D. 1927). Rabi spent the next two years in Europe, including some time in the laboratory of Otto Stern, where he acquainted himself with the technique of molecular beams. In 1929 he joined the faculty at Columbia. From 1940 to 1945 he was associate director of the *M.I.T. Radiation Laboratory*. He returned to Columbia after WWII.

Rabi and his collaborators introduced for the first time the induction of radio-frequency resonance in magnetic moment measurements. In their original experiments on nuclear moments, the beam was first deflected in an *inhomogeneous* field $\boldsymbol{B}_A$ and a particular component was selected by passing the beam through a slit.

This component then traversed a *homogeneous* field $\boldsymbol{B}_B$, which introduced no deflection, and was finally deflected back to the axis of the apparatus by a third field $\boldsymbol{B}_C$, which was inhomogeneous with the gradient opposed to that of $\boldsymbol{B}_A$. A beam detector was placed to record the arrival of atoms which traversed the three fields *with their spin and magnetic moment fixed throughout*.

A small magnetic field oscillating with a high frequency was then imposed on the beam in the homogeneous field region ($\boldsymbol{B}_B$) and the frequency was varied until the beam signal showed a sharp "resonance" dip. This dip was due to *defocusing* of the beam and indicated that the spin orientation was significantly affected in the $\boldsymbol{B}_B$ region.

1937–1949 CE **William Webster Hansen** (1909–1949, USA). Physicist. Co-inventor[920] of the *Klystron tube* and founder of microwave electronic technology. Contributed to developments on Doppler radar, aircraft blind-landing systems, electron acceleration (SLAC), and nuclear magnetic resonance.

---

920 With the **Varian** brothers. **Edward Leonard Ginzton** (1915–1998, USA) applied the Klyston in satellite communications, airplane and missile guidance systems, telephone and television transmission, and other important applications (1942–1959). He succeeded Hansen in the Directorship of the Stanford

Hansen was born in Fresno, California. He received his doctorate in physics from Stanford University (1933) and joined the faculty there (1934). Hansen was a professor of physics and Director of the Microwave Laboratory at Stanford (1939–1949).

He invented the high-quality cavity resonator on which the linear electron accelerator depends. During WWII he worked in New York on defense applications of physics and electronics, including *radar*.

1937–1955 CE **Emilio Gino Segrè**[921] (1905–1989, Italy and USA). Experimental nuclear physicist. Discovered the first synthetic element *technetium* (1937), the new element *astatine* (1940) and the *antiproton* (1955).

Segrè was born in Tivoli, near Rome, and educated at Rome University, studying engineering and then physics (Ph.D. 1928). He remained at the university, working with Fermi until 1936, when he became a professor at Palermo. But in 1938 he was dismissed from this post and forced into exile by the Fascist government.

Apart from wartime research at Los Alamos on the Manhattan Project he worked from 1938 at the University of California at Berkeley, where he became professor (1947). In that year Segrè started work on proton-proton and proton-neutron interaction, using a cyclotron accelerator at Berkeley. This was how he created and detected the antiproton (antiparticle of the proton with identical mass but negative electric charge), which reconfirmed the relativistic quantum theory of Paul Dirac. He shared the 1959 Nobel Prize for Physics with his co-worker **Owen Chamberlain** (b. 1920).

1937–1964 CE **Arthur Erdélyi** (1908–1977, U.S.A. and England). Mathematician. A leading figure in American mathematics in the post-war development of the subject. Contributed to many fields in mathematical analysis. Among them: special functions[922], operational calculus, asymptotic expan-

---

Microwave Laboratory (1949–1959). Under Ginzton's supervision, the preliminary design of the SLAC accelerator was completed in 1961.

921 **Segre** (also **Segri**) — an Italian Jewish family of rabbinical scholars since the 14th century. Members of the family in modern times include: **Corrado Segre** (1863–1924, Mathematician); **Arturo Segrè** (1874–1928, Historian); **Beniamino Segrè** (1903–1977, Mathematician).

922 He derived (1937) the integral representation of a multipole spherical eigenfunction: $h_\ell^{(2)}(k_c r)P_\ell^m(\cos\theta) = \frac{i^{m-\ell+1}}{k_c}\int_0^\infty J_m(k\Delta)e^{-\nu_c|z-z_0|}P_\ell^m\left(\frac{i\epsilon\nu_c}{k_c}\right)dk$, where $r^2 = \Delta^2 + (z - z_0)$, $\nu_c = \sqrt{k^2 - k_c^2}$, $\epsilon = \mathrm{sgn}(z_0 - z)$, J_m is the Bessel function of the m^{th} order, P_ℓ^m is the associated Legendre function, and $h_\ell^{(2)}$ is the spherical Hankel function of the second kind.

sions, integral equations and integral transform theory. Headed an international team of applied mathematicians that issued the encyclopedic source books on Higher Transcendental Functions and Integral Transforms (five volumes), which summed up all the accumulated lore in that field since Euler.

Erdélyi was born in Budapest, Hungary to Jewish parents. He then continued his studies in Brno, Czechoslovakia. The German occupation put him in mortal danger, but thanks to **Edmund Whittaker**, he was able to come to Edinburgh in 1939. In 1949 he moved to the California Institute of Technology, where he directed the famous Bateman project. He returned to the University of Edinburgh in 1964.

1937–1966 CE **Nahum Il'ich Akhiezer** (1901–1980, Russia). Mathematician. Made important contributions to function theory and approximation theory. Created the Kharkov school of mathematics.

Akhiezer was born in Cherikov, Belarus, to a Jewish family. He graduated (1924) from Kiev University an taught there until 1933. He then moved to the Kharkov Polytechnic Institute (1941–1956). From 1956 till the end of his life he worked at Kharkov State University.

1938 CE **Ladislau** and **Georg Biro** (Hungary) patented the ball-bearing point pen.

History of Writing Instruments — from the bamboo reed to the ball-point pen (3100 BCE–1938 CE)

ca 100,000 BP Early humans developed *symbolic thinking* manifested in linguistic speech capacity.

ca 3100 BCE First fully developed system of *word-writing*: Sumerians in Mesopotamia used *split bamboo reed* as stylus to write words and numbers on *wet clay tablets*. Only a few hundred words were used.

ca 3000 BCE Advent of *pictographic writing* on papyrus in Egypt; soot mixed with water served as ink.

ca 2700 BCE **Tien-Lcheu** (China) invented "Indian Ink" — a mixture of soot from pings smoke, lamp oil mixed with gelatin of donkey skin and musk.

ca 2200 BCE Oldest extant document written on *papyrus*.

ca 1500 BCE Origin of the oldest *phonetic alphabet* in the Sinai peninsula.

ca 1313 BCE The Phoenician **Cadmus** invented the *Phoenician alphabet* and the *written letter*.

ca 1300 BCE Chinese's pictographic language has a vocabulary of ca $50,000$ words.

ca 1200 BCE *Ink* becomes common in China.

ca 600 BCE Final stages of current *Hebrew alphabet* and writing.

ca 530 BCE A *library* in Greece.

ca 400 BCE Development of *Greek alphabet*. They employed a writing stylus made of either *metal*, *bone* or *ivory* to place marks upon *wax-coated tablets*. These tablets were made in hinged pairs that could be closed to protect the scribe notes.

Chinese write on silk.

ca 300 BCE *Greeks* created the *calamos* ($\kappa\alpha\lambda\alpha\mu o\varsigma$): a *reed pen* suitable for *parchment* and *ink*. They converted bamboo stems (of marsh grasses) into a form of fountain pen, cutting one end into a form of pen nib or point. A writing fluid (ink) was poured into the stem, then the reed was squeezed, forcing fluid to the nib.

ca 200 BCE *Parchment* developed in the city of Pergamum (now in Turkey); a superior writing material made of animal skin.

ca 50 BCE Men discovered that the sharpened goose *quills* (large feathers) made excellent writing instruments. [The word *pen* comes from the Latin *penna* which means *feather*.]

ca 79 AD A *bronze pen* in Pompei.

ca 100 AD *Wood-fiber paper* invented in China.

ca 400 AD A stable form of *ink* was developed — a composite of iron salts, nut-galls and gum; this basic formula was to last for centuries.

ca 600 AD *Books* printed in China.

ca 700–711 Chinese *wood-fiber paper* became known in Japan (700 CE); brought to Spain by the Arabs (711 CE).

ca 700 AD *Quill-pen* introduced in Europe; it was to remain predominant for over a thousand years.

The strongest quills were those extracted from living birds in the spring – from the five outer left-wing feathers (carved outwards and away when used by right-handed writer). Birds used were: goose, swan, eagle, owl, hawk, turkey. Quill-pens lasted for only a week before it was necessary to replace them.

The early European *parchment* was made from animal skin, which required much scraping and cleaning.

During the centuries that followed, metal points, often called *nibs*, were added to the quill. The nib-tips did not wear out as fast as quill-tips.

ca 765 AD *Picture books* printed in Japan.

ca 1000 AD Mayas in Yucatan, Mexico, make writing paper from tree bark.

1436 AD Invention of the *printing press* with replaceable wooden or metal letters by **Johannes Gutenberg** (Germany).

1565 AD Invention of the *pencil.*

1650–1685 Some pens were made entirely out of *metal*, sometimes with *precious stones* as the tip.

ca 1700 AD Advent of *fountain pens.*

1750–1850 The Industrial Revolution heralded the doom of the quill-pen. It began with *steel nibs* that could be inserted into a holder (1750). Then, the whole pens were made in the form of a *metal tube or barrel* (1809); *machine-made pens*, *gold-pens* (1810–1820); In 1822 horn and tortoise-shell were patented to the formation of pen-nibs, the points of which were rendered durable by small pieces of diamond or ruby, or by attaching small piece of thin gold sheet over the end of the tortoise-shell. By 1850, pen manufacturers were using alloys of *rhodium*, *osmium* and *iridium* to make very hard tips.

1884 AD **Lewis Edson Waterman** (US) patented one of the first *practical fountain pens*. The pen was filled with ink squeezed from an eyedropper.

1886 AD **John Loud** (US) invented a ball-point pen.

1913 AD **W.A. Sheaffer** (US) developed a lever-fill fountain pen.

1927 AD Disposable ink cartridges for fountain pens were developed.

1938 AD **Ladislau and Georg Biro** (Hungary) patented the *ball-bearing point pen*.

1945 AD First commercially successful ball-point pens.

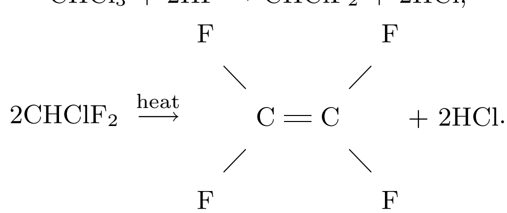
1951 AD Marker pens.

1938 CE **Roy J. Plunkett** (1910–1994, USA). Engineer at Du Pont, U.S.A., accidentally invented *Teflon*[923] (or PTFE), a polymer of tetra-fluoro-ethylene[924] (Poly-Tetra-Fluoro-Ethylene) that does not occur in nature. Plun-

[923] The name Teflon is derived by combining the chemists' name for tetrafluoroethylene — *tef* — with an arbitrary suffix — *lon* — that Du Pont chose for its products, as in nylon, orlon, etc.

[924] Tetrafluoroethylene is prepared in the following manner:

$$CHCl_3 + 2HF \rightarrow CHClF_2 + 2HCl;$$



$$\text{Polimerization yields} \quad n(CF_2 = CF_2) \xrightarrow[\text{pressure catalyst}]{\text{heat}} (CF_2CF_2)_n.$$

kett had been looking for a new kind of refrigerant, a gas to be used in air conditioners, to suck out the heat. He thought he was mixing together a batch of *tetrafluoroethylene* and *freon* (CCl_2F_2). But instead of finding the gas in his steel reactor bottle as expected, he found a white powder; inside the tank the gas molecules had formed into long chains.

Teflon became known to the public only in 1946 because it had been kept as a military secret during WWII; scientists working on the first nuclear bomb — the Manhattan Project — needed it for making gaskets that could resist the corrosive uranium hexafluoride (UF_6), used in the separation of uranium isotopes.

Teflon is an unusual plastic, which is extremely resistant to flames, oxidation and strong acids or bases. Its chemical and thermal stability ($-240\,°C$ to $260\,°C$) can be traced to two features. One is the considerable strength of the $C{=}C$ and $C{-}F$ bonds, which keeps the molecules from decomposing even when moderately heated. The second feature is the match between the sizes of the fluorine and carbon atoms, which result in the fluorine atoms forming an almost continuous sheath around the carbon atom chain, protecting it from chemical attack. In effect, the fluorine atoms act as chemical insulation around the carbon-atom "wire".

PTFE consist of very long chains, composed of about 50,000 $\{— CF_2 —\}$ groups each, with very little cross-linking between them. As a result, the molecules pack together to give a dense, compact solid with a high melting point. Grease and oil do not form bonds with PTFE, so surfaces coated in it are "nonstick" and PTFE feels slippery to the touch. Its molecules pack together so densely that the solid does not absorb water, and hence it is an excellent electrical insulator.

The chemical industry uses Teflon in corrosion-resistant gaskets, valve packing, cable insulation, bearings, fry pan coating, clothing and artificial body parts.

1938 CE, Oct 24 *Wages and Hours Law* became operative in the United States of America. It provided for humane wages, an 8 hours working day and a maximum of 40 weekly hours in industries affecting interstate commerce. It also prohibited child labor.

1938–1939 CE **Hans Albrecht Bethe** (1906–2005, U.S.A.). Physicist. Proposed a new theory for the energy production mechanism, important in some main-sequence stars: the nuclear fusion of hydrogen into helium, catalyzed by carbon nuclei[925]. This theory was confirmed by a combination of laboratory nuclear collision experiments and astrophysical observations. Moreover, it is believed today that nuclear reactions in the interior of very hot stars are the source of continual heavy-element build up; once the star's hydrogen is all fused into helium, ^4H nuclei proceed to fuse into Beryllium, Carbon and heavier elements.

Bethe also applied classical mathematical methods to the calculation of electron densities in crystals, the order-disorder states of alloys, the operational conditions of reactors and the ionization processes in shock waves.

---

[925] Our sun is a nuclear furnace that turns mass into energy. Every second it converts over 657 million tons of hydrogen into 653 million tons of helium. The missing 4 million tons of mass are discharged into space as radiant energy. The earth receives only about one two-billionths of this. It has been estimated that in 15 minutes our sun radiates as much energy as mankind consumes in all forms, during an entire year. Solar fusion of ^1H into ^4He is mostly *direct*, with Bethe's CNO (Carbon-Nitrogen-Oxygen) cycle accounting for only a few percent of fusion reactions; but the CNO mechanism dominates in hotter main-sequence stars.

The sun is approximately 150×10^6 km from earth, 1.392×10^6 km in diameter and has a mass of approximately 2×10^{30} kg. It is an 'average' star in size, brilliance and age. There are more than 10^{11} stars in our sun's own galaxy, the Milky Way. Light energy, with a temperature of about 5800 degrees Kelvin is received on earth, from the sun. It takes light 8.3 min to travel from sun to earth. Supposing no major change in the sun's stability will occur until about 10^{-3} of its present total mass has melted away in nuclear reactions, it could keep going for 1.7×10^{10} years at the present rate of generating radiation. However, astrophysical theory predicts a gradual increase in solar power output, which will wreak havoc with earth's biosphere as early as 10^9 y from now. It also predicts that solar-core hydrogen will run out ca 5×10^9 y from now, leading to a collapse that will cause hydrogen in outer shell into fusion, followed by a dramatic *expansion* and *cooling* of the sun, and core burning of helium. In this *red giant phase* (starting ca 7×10^9 y from now) the expanding sun will engulf and incinerate the inner planets, possibly including earth. The present power output of the sun is 3.6×10^{23} kilowatts. The upper limit of the solar power available on the surface of the earth is about 1.6×10^{14} kilowatts. Solar power alone should thus be sufficient, in principle, to satisfy the energy requirements of man for the foreseeable future. In fact, most of our present energy consumption, whether in the form of hydroelectric power, food, lumber, or fossil fuels, can be traced back to solar energy.

Bethe was born in Strasbourg. He was educated at the Universities of Frankfurt and Münich, where he obtained his Ph.D. in 1928. He worked with **Fermi** in Rome (1931) and lectured on physics at the University of Tübingen (1933). Because his mother was Jewish, he was forced to leave Germany at the beginning of the Nazi regime. After a stay in Manchester, he emigrated to the United States in 1935 and settled at Cornell University, where he was a professor from 1937 to 1975, and a professor emeritus thereafter.

During 1943–1946 he headed the Division of Theoretical Physics of the Manhattan Project in Los Alamos, NM, and made important contributions to the development of the theory of the atomic nucleus and nuclear reactions. He received the Nobel prize for physics in 1967.

1938–1939 CE **Russell Harrison Varian**[926] (1898–1959, U.S.A.) and his brother **Sigurd Fergus Varian** (1901–1961, U.S.A.). Physicists. Invented the *klystron* for the generation and amplification of microwaves, during their research into RF electronics at Stanford University. Russell and Sigurd were born in Washington, D.C. and Syracuse, N.Y., respectively; Russell became president of *Varian Associates* (1948–1959).

---

- Varian, Dorothy, *The Inventor and the Pilot*, Pacific Books, 1983, 314 pp.

The Klystron[927]

Two separate principles are combined in the klystron oscillator: the velocity modulation of an electron beam, and the use of cavity resonators as tuned circuits. When the wavelength to which a circuit is tuned is not much greater than the physical dimensions of the circuit, a coil and a condenser arrangement becomes impracticable, and must be replaced by a length of transmission line in a coaxial-line triode. At still shorter wavelengths even quarter-wave lines become awkwardly small and, in their turn, are replaced by cavity resonators. In general the wavelength corresponding to the fundamental mode of a cavity is of the order of magnitude of its linear dimensions.

A resonant cavity is a high frequency descendant of the parallel resonant LC *circuit. Such an* LC *circuit will resonate at a very high frequency* ω_0 *if the inductance* L *and capacitance* C *are very small since* $\omega_0 = \frac{1}{\sqrt{LC}}$. *A relatively high frequency* LC *circuit might consist of two parallel plates joined by a single inductive turn of wire.*

In order to reduce the inductance, more turns may be added in parallel. The closed surface may be thought of as an infinite number of turns in parallel and represents a minimum value of inductance. The resulting cavity is a region of space surrounded by conducting walls.

The high-frequency currents in a cavity flow effectively only in a narrow layer of the inner surface, the width of which is known as the skin depth. (At 10,000 MHz the skin depth is of the order of 10^{-4} *cm for copper.) The energy is stored in the electric and magnetic fields within the cavity. Unlike an* LC *circuit, a cavity may have many resonant frequencies, each associated with a different mode of oscillation. These frequencies are functions of the cavity geometry, as are the fundamental frequency and harmonics of an acoustic organ pipe.*

The electromagnetic energy involved in the excitation of a mode of oscillation, oscillates between energy stored in the magnetic field and energy stored in the electric field. The oscillating fields induce currents in the cavity walls, which may dissipate energy in the form of heat since the walls are resistive. In a steady-state condition, the supply of exciting energy must be equal to the

---

[927] To dig deeper, see:

- Hemenway, C.L. et. al., *Physical Electronics*, Wiley, 1962, 396 pp.
- Parker, P., *Electronics*, Edward Arnold: London, 1950, 1050 pp.

power lost in the cavity walls. The ratio of the stored energy to the energy dissipated in a cycle of oscillation is called the Q *of the circuit. The* Q*'s of cavities have typical values of* 10^4*. A high* Q *value also means a sharp tune or narrow bandwidth response.*

Coupling of electromagnetic power into and out of resonant cavities is sometimes achieved by means of a small loop of wire, which couples with the magnetic field within the cavity and joins to an external coaxial transmission line.

When an electron beam passes near an electrode connected to an impedance, a current may flow through the impedance only if the velocity of the electrons, as they pass near the electrode, is time dependent (modulated). This is so because an electron beam is equivalent to a current, and a d–c current delivers no a–c power by induction.

Velocity modulation is achieved by impressing a small a–c component of velocity on a d–c electron beam. This may be done by allowing the beam to pass through two grids across which a small a–c voltage is applied. As the electrons leave the modulating grids, the faster electrons move away from the slower electrons behind and overtake the slower electrons ahead. The numerical density of electrons further along the beam is no longer uniform, and the beam is said to be bunched*. Because of this bunching the beam current has acquired an a–c component. Thus, the velocity modulation imparted to the beam in passing through the grids gives rise to current modulation further along the beam.*

A–c power may be extracted *from the current-modulated electron beam by allowing it to pass through a second pair of grids connected to an external load impedance. The beam induces currents in the impedance and loses energy. In* klystrons*, the grids and impedances have the physical form of resonant cavities, in order to velocity – modulate an electron beam and extract useful a–c power at high frequencies.*

Details of the mechanism are as follows: An electron gun sends a beam of electrons into a tube connecting of two resonant cavities. The cavities are separated by a region called the drift space. The ends of the reentrant parts of the cavities may be wire grids. The cavity nearer to the gun is called the input or buncher cavity*. The signal couples to the RF magnetic field of the input cavity by means of a coaxial line, which has its center conductor joined to a small loop within the cavity. The input signal appears as an a–c voltage between the grids of the buncher cavity, and velocity-modulates the beam.*

Let us suppose that the electrons, upon entering the input cavity have been accelerated through a potential V_0 *and that a small a–c voltage* $V_1 \cos \omega t$ *is established between the grids and the cavity. The velocity* v *of the electrons as they emerge from the cavity is* *given by* $v = \sqrt{2\eta V} = \sqrt{2\eta}(V_0 + V_1 \cos\omega t)^{1/2} \approx v_0 \left(1 + \frac{V_1}{2V_0}\cos\omega t\right)$, *where* $v_0 = \sqrt{2\eta V_0}$, $\eta = e/m_e$ *and* $V_1 \ll V_0$ *is assumed, provided the time for the electron beam to pass between the grids is small compared with a period of an a–c cycle.*

In the drift space, bunching occurs: faster electrons start to pass slower ones, with the result that the beam current reaches a large value once each cycle*. But the current is* not *sinusoidal and contains many harmonics. For that reason, the position of the maximum a–c current of the fundamental mode is* not *located at the position of maximum bunching.*

The modulated beam passing through the output cavity induces a net a–c current on the inside surface of the cavity walls. This induced current initiates the oscillations of the cavity when the modulation is first turned on. The amplitude of the output cavity oscillations builds up at the expense of the electron's d–c kinetic energy. In a steady-state condition, the energy lost by the electrons equals the sum of the power delivered to the load and the energy dissipated in the cavity walls.

The relative phase is such that when the number of electrons crossing the gap is largest, the oscillating electric field of the cavity retards the electrons and extracts energy from the beam. On the average, power is delivered to the output cavity because more than half *the electrons pass through the cavity when the phase of the electric field is such as to* decelerate *the electrons and* less than half *the electrons pass through the cavity when the field is* accelerating*.*

To summarize, the klystron is an energy converter: The d–c kinetic energy of the electrons is converted to the a–c energy of the electromagnetic fields in the cavity. [In contradistinction, the magnetron *converts the d–c* potential energy *of electrons to a–c energy.] Power amplification in the klystron is achieved because only a small amount of a–c power is required to velocity modulate the electrons, and a large amount of output power is supplied by the kinetic energy of the electrons. The power amplification of a klystron can reach the order of 1000 or greater.*

The output cavity is connected to a load impedance by means of a coaxial line so that when the cavity is excited, a–c power is delivered to the load impedance. A collector electrode, maintained at output cavity potential, intercepts the beam as it emerges from the output cavity. Both cavities generally have the same resonant frequency.

1938–1943 CE Swiss chemists **Albert Hoffmann** and **Arthur Stoll** discover and name (1938) *lysergic acid diethylamide*, or LSD. Hoffman discovered (1943) that LSD is hallucinogenic. LSD became widely used as hallucinogen in the 1960's.

1938–1947 CE **Chester Carlson** (1906–1968, U.S.A.). Physicist and inventor. Invented *xerography* — an electrostatic process for copying printed material, using photo conductive materials (e.g. selenium compounds) to form an image. Carlson was born in Seattle, Washington.

By the age of 14, Carlson was supporting his invalid parents, yet he managed to earn a college degree from the California Institute of Technology, Pasadena, in 1930. After a short time spent with the Bell Telephone Company, he obtained a position with the patent department of P.R. Mallory Company, a New York electronics firm.

Plagued by the difficulty of getting copies of patent drawings and specifications, Carlson began in 1934 to look for a quick, convenient way to copy line drawings and text. Since numerous large corporations were already working on photographic or chemical copying processes, he turned to electrostatics for a solution to the problem. Four years later he succeeded in making the first xerographic copy.

Carlson obtained the first of many patents for the xerographic process in 1940, and over the next four years tried unsuccessfully to interest someone in developing and marketing his invention. More than 20 companies turned him down. Finally, in 1944, he persuaded Battelle Memorial Institute, Columbus, Ohio, a non-profit industrial research organization, to undertake developmental work. In 1947 a small firm in Rochester, NY, the Haloid Company (later the Xerox Corporation), obtained the commercial rights to xerography, and 11 years later Xerox introduced its first office copier. Carlson's royalty rights and stock in Xerox Corporation made him a multi-millionaire.

1938–1979 CE **Oscar (Ascher) Zariski**[928] (1899–1986, U.S.A.). Mathematician. Developed an abstract theory of *algebraic geometry*; abandoning topological and analytical methods he turned to modern algebra as a means of elucidating basic geometric ideas, introducing the notions of *valuation*, *integral closure* and *saturation*. He found strong links between the algebra of polynomials and the geometry of curves.

---

[928] For further reading, see:

- Parikh, C., *The Unreal Life of Oscar Zariski*, Academic Press: New York, 1991, 264 pp.

Zariski was born in Kobrin, White Russia, son of a Jewish Talmudic scholar in what was then known as the Pale of Settlement. He spent his first eleven years in a traditional, almost exclusively Jewish society. During 1914–1918 he attended the gymnasium (high school) in Chernigov and from 1918 to 1920 he was a student at the University of Kiev.

In 1921 he moved to the University of Rome, Italy, which was at that time the most important center of algebraic geometry in the world. There he came under the influence of the algebraic geometers **Guido Castelnuovo** (1865–1952), and **Federigo Enriques** (1871–1946) [Enriques, brother-in-law of Castelnuovo, was a descendant of Spanish Jews, whose ancestors were expelled from Spain in 1492].

In 1926 Zariski received a Rockefeller foundation fellowship[929], but the rise of Fascism in Italy forced him to leave Rome. He applied to Zürich and Jerusalem, but both universities hired older men. On the recommendation of **S. Lefschetz** he joined in 1927 the faculty of mathematics of the John Hopkins University of Baltimore, U.S.A. In 1940 he moved to Harvard, where he remained for the rest of his life.

Zariski was a man caught up in many of the central conflicts of the 20^{th} century. He was torn between an allegiance to an intellectual world that ignored the politics of race and his emotional need to find safety for those members of his family who escaped the Nazi Holocaust. Intellectually, he was torn between a love of the free-spirited, creative Italian vision of geometry and his appreciation of the need for strict logical rigor which he found in the Bauhaus-like school of the abstract German algebraists. Zariski called geometry "the real life" and he lived intensely in the world of mathematics. This commitment led him safely through the turbulence of his 'unreal life'.

---

[929] A member of the Harvard Mathematics Department, **G.D. Birkhoff**, had been asked by the Rockefeller Foundation to stop in Rome to discuss the work of the fellows. Zariski remembered, however, that their discussions were not confined to mathematics:

"*Is it difficult for a Jew to become a student at Harvard*?" Zariski asked one evening. "*No, not at all*", Birkhoff replied with no trace of embarrassment, "*although of course we naturally keep a certain proportion. The Jewish population is about* 3% *and we admit only* 3%". "*Then you must have very large classes*", said Zariski, but Birkhoff didn't smile.

Sources of Stellar Energy – the Advent of Nuclear Astrophysics[930] (1939–1957)

The main problem that baffled all astrophysicists concerned with stellar structure and evolution in the 1920*'s and the* 1930*'s, was the unknown source of stellar energy. It was generally agreed that energy is derived from transformation of mass into energy, according to Einstein's law* $E = mc^2$, *where* E *is the amount of energy released,* m *is the mass transformed, and* c *is the velocity of light in vacuum. However, the actual process involved was not known. In* 1919, ***Jean Perrin*** *put forward the notion that the synthesis of Helium from hydrogen is capable of supplying the quantity of energy that is required for the permanent radiation of the sun.*

In 1927, ***A. Eddington*** *showed that the temperatures near the center of the sun must be much greater than had previously been thought. Yet Eddington rejected the transmutation of elements as a possible source of stellar energy. As research into stellar structure and nuclear processes progressed, the alternative rejected by Eddington was shown to be feasible.*

When a gas is heated to temperatures of the order of 10^7 *to* 10^8 *degrees Kelvin, its particles gain (according to the Maxwellian energy distribution) so much energy that the collisions of nuclei can initiate thermonuclear reactions. Such temperatures occur in the interior of the sun and other stars, as astrophysicists have found. Indeed,* ***George Gamow*** *(1904–1968, U.S.A.),* ***Robert d'E Atkinson*** *(England) and* ***Fritz Houtermans*** *(1903–1966, Germany)*[931] *hypothesized already in* 1929 *that thermonuclear processes produce*

---

930 To dig deeper, see:

- Shirokov, Yu.M. and N.P. Yudin, *Nuclear Physics*, Mir Publication: Moscow, 1982, Vols I-II (445 pp. + 303 pp.)
- Harwit, M., *Astrophysical Concepts*, Wiley, 1973, 561 pp.

931 All three met at Göttingen in 1928: Gamow arrived from Leningrad, Atkinson was a young British physicist and Houtermans had finished his Ph.D. thesis in 1927 under **James Franck**. In their joint 1929 paper, Atkinson and Houtermans put forward the idea that nuclear reactions are the source of stellar energy, namely, that near the sun's center, hydrogen nuclei might fuse together to produce helium nuclei in a reaction that would convert a tiny amount of mass into a very large amount of energy.

Houtermans' own account of the denouement: 'That evening, after we had finished our essay, I went out for a walk with a pretty girl. As soon as it grew *the heat and light from the sun. A more detailed account was given by* ***Carl von Weizsäcker*** *(b.* 1912*, Germany) in* 1936*.*

---

dark the stars came out, one after another in all their splendor. "*Don't they shine beautifully*?" cried my companion. But I simply stuck out my chest and said proudly: "*I've known since yesterday why it is that they shine*"'.

Friedrich Georg Houtermans was born in Zoppot, near the then-German Baltic port of Danzig. He was reared in Vienna as an only child by his mother, who was half-Jewish. Fleeing Nazi Germany in 1933, he went to England. Soon, driven by idealism, he emigrated to the Soviet Union (1933), but fell victim to one of Stalin's purges (1934). He spent a couple of years in prison, where the NKVD had knocked out all his teeth and kept him in solitary confinement for months; his wife, with their two small children, managed to escape to the U.S.A.

When Germany made its temporary pact with the Soviet Union in 1939, it included an exchange of prisoners, and Houtermans was handed to the Gestapo. **Max von Laue**, one of the few German scientists with the prestige and courage to stand up to the Nazis, managed to free Houtermans and arrange for him to work with a wealthy German inventor, Baron **Manfred von Ardenne**, who had studied physics and who maintained a private laboratory in Lichterfelde, outside Berlin. Ardenne was pursuing uranium research independently of Heisenberg and the War Office. To raise funds for the work, he had approached the German Post Office, which commanded a large unused budget for research. The Minister of Posts, imagining himself handing Hitler the decisive secret weapon for the war, had funded the building of a million-volt van de Graaff and two cyclotrons, all under construction in 1941. Until they came on line, Houtermans turned his attention to the *theory of nuclear chain reactions*.

By August 1941, he had independently worked out all the basic ideas necessary to create a bomb. He discussed them in a 39-page report, "*On the question of unleashing chain reactions*", that considered fast-neutron chain reactions, critical mass, U^{235}, isotope separation, and element 94, which the Americans had already secretly named "*plutonium*". Houtermans discussed his ideas privately with **von Weizsäcker** and **Heisenberg**, but kept his report out of reach of the War Office, for whom Heisenberg was working on the very same problem!

However, Houtermans redeemed himself from Heisenberg's fate by making surreptitious contact with the Fermi group in Chicago. Long before completing the first nuclear reactor in December 1942, the Chicago group received a cable from Switzerland sent by someone at Houtermans' direction. "*Hurry up*", it said tersely. "*We are on the track*".

After the war, physics research in Germany was severely hindered by the Allied Control Commission. These restrictions went so far as to decree an upper limit of 10^9 ohm on resistors. In 1952 Houtermans became a professor at the University of Bern.

From the equation $\frac{1}{2}mv^2 = \frac{3}{2}kT$, *it is seen that the average kinetic energy of a nucleus at the sun's center* $(T \simeq 1.4 \times 10^7\ K)$ *is equivalent to only* 2000 *eV. In spite of the corresponding low value of the mean particle energy, as compared with the millions of eV of particles accelerated in laboratories, protons at that temperature can still initiate a sufficient number of nuclear reactions per second, for three reasons. Because of the Maxwellian distribution, there is always a small fraction of particles with kinetic energy far higher than the mean thermal energy. Furthermore, the very large volumes of stellar cores lead to such a high number of collisions that even reactions with a small probability occur with sufficient frequency. And – last but not least – when two hydrogen-isotope nuclei collide,* quantum tunneling *has a finite probability of occurring: this is a process via which, even if the nuclei's relative speed is insufficient for them to classically overcome their mutual Coulomb potential barrier, the* uncertainty *principle sometimes allows them to "borrow" the requisite kinetic energy for a brief time. Once safely past the Coulomb repulsion barrier, the nuclei's short-range nuclear attraction forces take over and allow the exothermic fusion reaction to proceed. Two protons fuse into a deuteron hydrogen isotope (with a positron and neutrino emitted), as well as other stellar nuclear fusion reactions.*

Two strongly exothermal nuclear reactions were definitely established. The balance of the first reaction cycle *results in the fusion of* 4 *protons to a* ${}^4_2He$ *nucleus with the simultaneous emission of* 2 *positrons and* 2 *neutrinos:*

$$4{}^1_1H \rightarrow {}^4_2He + 2e^+ + 2\nu_e.$$

Energy is released since the mass of four protons is $4 \times 1.00723 = 4.02892$ *atomic mass units, which is larger by* 0.02741 *than the mass of the product* ${}^4He$ *nucleus (4.00151). Therefore, in this reaction, an energy of about* 25 *MeV per helium nucleus is liberated, which corresponds to* 1.5×10^8 *kCal/gram or* 6×10^8 *kCal/mole. The neutrinos released during the reaction are responsible for about ten percent of the energy flux from the sun.*

The next step was the realization that only reactions with capture of protons by light nuclei play a notable part in the interior of stars. The final insight was supplied by ***H.A. Bethe*** *(1939). He showed that the most important source of energy in the heaviest and hottest main-sequence stars is the so-called "carbon-nitrogen-oxygen cycle", in which carbon, nitrogen and oxygen serve as catalysts for the conversion of four hydrogen atoms into one helium atom.*

The CNO cycle occurs in our sun, but is negligible there due to the sun's core temperature, which is low enough to favor direct fusion of hydrogen into helium. But the CNO-catalyzed fusion rate increases extremely rapidly with core temperature, and thus is dominant for main-sequence stars somewhat *hotter than the sun. There are several variants of the CNO cycle; they all occur in stars with relative rates determined by core temperatures. One common CNO cycle proceeds as follows:*

$$\begin{aligned} &{}^{12}_{6}C + p \rightarrow {}^{13}_{7}N, && {}^{13}_{7}N \rightarrow {}^{13}_{6}C + e^{+} + \nu_e, \\ &{}^{13}_{6}C + p \rightarrow {}^{14}_{7}N, && {}^{14}_{7}N + p \rightarrow {}^{15}_{8}O, \\ &{}^{15}_{8}O \rightarrow {}^{15}_{7}N + e^{+} + \nu_e, && {}^{15}_{7}N + p \rightarrow {}^{12}_{6}C + {}^{4}_{2}He, \end{aligned}$$

with the overall *reaction being again*

$$4p \rightarrow {}^{4}He + 2e^{+} + 2\nu_e \ .$$

In addition to dominating helium production in many stars, the CNO mechanism also plays a role in nova explosions, and in the production of heavier elements in post-main-sequence stars.

The presence of these elements in the sun and stars was proved spectroscopically.

1938–1939 CE **Robert Julius Oppenheimer** (1904–1967, U.S.A.). Theoretical physicist and scientific administrator. Laid the foundation for a 'general-relativistic' theory of stellar structure and gave first concrete description of a 'black hole'.

With his graduate student **Robert Serber** (1909–1997, U.S.A.) he studied the relative influence of nuclear and electromagnetic forces in neutron stars (1938).

With his graduate student **George M. Volkoff** (b. 1914, U.S.A.) he put forward (1938) a model of a static spherical star consisting of an ideal high-density 'Fermi fluid' of neutrons[932]. He found that the star is *stable* whenever its mass is not greater than one-third of the solar mass [present day value is 0.7 solar masses, known as the *Oppenheimer-Volkoff limit*]. The model incorporated an equation of state with the GTR equation of hydrostatic equilibrium.

With his graduate student **Hartland Snyder** (1913–1962, U.S.A.), he initiated the study of black-hole physics (1939). They formulated the process

[932] Neutrons, like electrons, when closely packed into a sufficiently small volume, resist further compression because of the *Pauli exclusion principle*.

of *gravitational collapse* of a neutron star and showed that when all thermonuclear sources of energy are exhausted, a sufficiently heavy neutron star will reach a state where its weight will overcome the sum of all opposing forces [centrifugal force due to fast spin, radiation and degeneracy pressures, thermal motion and blast-off of outer material].

On the other hand, the increasing density reduce the energy carried off by escaping radiation due to Doppler period-lengthening caused by the inward motion of collapse, gravitational red-shift due to increased gravity and bending of light rays seeking to escape[933].

An outside observer perceives the collapse as slowing down when the *Schwarzschild radius* $\left(R_S = \frac{2GM}{c^2}\right)$ is approached[934]. As perceived by such an observer, the collapse virtually comes to a standstill — a state of equilibrium. For an observer riding the collapsing surface, however the whole mass will shrink to a point at the center in finite time. No message or object sent by him, even via electromagnetic waves, is capable of ever reaching *outside* of the sphere $r = R_S$, if he is already *inside* that sphere when sending it [such a sphere in GTR is known as an *event horizon*].

---

933 Two months before Oppenheimer and Snyder submitted their paper on stellar collapse (*Phys. Rev.* **56**, 455, 1939), Einstein submitted a paper (translated) "On a stationary system with spherical symmetry consisting of many gravitating masses" (*Ann. Math.* **40**, 922, 1939), in which he sought to prove, using his own GTR, that black holes were impossible.

His belief in the inadmissibility of singularities was so deeply rooted that it drove him to show that "*the Schwarzschild singularity at* $r = \frac{2GM}{c^2}$ *does not appear* [*in nature*] *for the reason that matter cannot be concentrated arbitrarily... because otherwise, the constituting particles would reach the velocity of light*". Ironically, the modern study of black holes, and more generally, that of collapsing stars, builds on a completely different aspect of Einstein's legacy-namely, his invention of quantum-statistical mechanics.

Without the effects predicted by Fermi–Dirac *quantum statistics*, every astronomical object would eventually collapse into a black hole, yielding a universe that would bear no resemblance to the one we actually live in.

After 1939, Oppenheimer never worked on the subject of black holes again. In 1947 Oppenheimer became the director of the Institute for Advanced Study in Princeton, NJ, where Einstein was still a professor. There is no record of their ever having discussed black holes. Further progress would have to await the 1960s, when discoveries of quasars, pulsars and compact X-ray sources reinvigorated thinking about the mysterious fate of stars.

934 As always in GTR, care must be taken to identify which coordinate system is meant, when coordinate values are specified.

As perceived by an external observer $(r > R_S)$, the comoving observer's fall is infinitely slowed down as he approaches the Schwarzschild radius. Any matter or radiation that becomes trapped inside $r = R_S$, simply increases the mass of the resulting *black hole*[935].

Oppenheimer was born in New York, the son of a Jewish emigrant from Germany, who had made his fortune by importing textiles. His mother, a painter and teacher, died when he was 9 years old. He was a child prodigy. After graduating from Harvard University (where he excelled in Latin, Greek, physics, chemistry and oriental philosophy) in 1925, he continued his studies at Cambridge and Göttingen.

In 1927 he received his doctorate at Göttingen, where he met **Niels Bohr** and **Paul Dirac**. He then accepted professorial positions at the University of California at Berkeley and the California Institute of Technology at Pasadena. Oppenheimer was a brilliant teacher, intense and dedicated — reading no newspapers, owning no radio, and learning Sanskrit as a diversion. In 1939 he began to seek a process for the separation of the isotope uranium-235 from natural uranium and the determination of the critical uranium mass required to make a nuclear bomb.

He became director at Los Alamos in 1943. There, a joint effort of outstanding scientists culminated in the first nuclear explosion on July 16, 1945. It was detonated at Alamogordo, NM, when Germany had already surrendered. In October 1945 he resigned as director of Los Alamos, and in 1947 became director of the Institute of Advanced Study at Princeton (1947–1966). He also served (1947–1952) as chairman of the General Advisory Committee of the Atomic Energy Commission (AEC), and in October 1949 *opposed* development of the hydrogen, thermonuclear, bomb.

After a heated debate with physicist **Edward Teller** and the AEC chairman Lewis Strauss, his security clearance was canceled in 1954 because of his early association with communists in the late 30's and delaying the naming of Soviet agents. A security hearing declared him not guilty of treason, but ruled that he should not have access to military secrets. He retired from Princeton in 1966 and died the following year of throat cancer.

Isadore Rabi said of him:

> "If he had studied the Talmud and Hebrew, rather than Sanskrit, he would have been a much greater physicist. I never ran into anyone who was brighter than he was. But to be more original and profound, I think, you have to be more focused."

---

[935] The term 'black hole' was coined in 1967 by **John Archibald Wheeler** (b. 1911, U.S.A.).

1938–1939 CE **Otto Hahn** (1879–1968, Germany), **Lise Meitner** (1878–1968) and **Fritz Strassmann**[936] (1902–1980, Germany), using chemical techniques, collaborated in the discovery of '*nuclear fission*'.

The history of fission reads like a first-class adventure story:
Soon after the discovery of the neutron (1932), **Fermi** began systematic studies of reactions induced by the bombardments of heavy nuclei with neutrons (1934). However, these experiments, especially those where uranium was used, gave puzzling results. Thus, when bombarding uranium atoms with neutrons, isotopes of lighter elements, such as barium and krypton, were detected in the products of the reaction.

In the experiment of Hahn and Strassmann at the Kaiser Wilhelm Institute for Chemistry in Berlin, uranium was bombarded with neutrons, and it broke into two parts, or "fissioned". In the process it released extra neutrons, but the experimenters did not understand the mechanism of the process.

In 1939, **Lise Meitner**[937] and **Otto Frisch**, working in Sweden, explained the results of Hahn and Strassmann as being due a splitting of the heavy uranium atom into two roughly equal parts[938]. They predicted that the fission

---

[936] **Fritz Strassmann**, physical chemist. His mastery of analytical chemistry contributed to the team's recognition of the lighter elements that resulted from uranium splitting. From 1945 to 1953 he was the director of the chemistry department at the Max Planck Institute for Chemistry.

[937] In November 1945, three months after the end of WWII, a narrow margin of the members of the Swedish Academy of Sciences decided to award the 1944 Nobel Prize in *Chemistry* to Otto Hahn for the discovery of nuclear fission. Hahn's Berlin colleagues, the chemist Fritz Strassmann and the physicist Lise Meitner, were excluded. Probably Strassman was ignored because he was not a senior scientist. Meitner's exclusion, however, points to other flaws in the decision process, and to four factors in particular:

- difficulty of evaluating an interdisciplinary discovery;
- a lack of expertise in theoretical physics;
- Sweden's scientific and political isolation during the war;
- a general failure of the evaluation committees to appreciate the extent to which German persecution of Jews skewed the published scientific record.

The subsequent effort by prominent physicists to reward Meitner and Frisch with the Nobel Prize in *Physics*, failed.

[938] One of the possible reactions is:

$$n + {}^{235}\mathrm{U} \rightarrow {}^{236}\mathrm{U} \rightarrow {}^{139}\mathrm{La} + {}^{95}\mathrm{Mo} + 2n$$

would release large amounts of *binding energy*. [A heavy nucleus is held together by nuclear forces and its stability against deformation is a result of its tendency to keep its surface area to a minimum. However, the electric charges carried by the protons repel one another, and thus tend to magnify any distortion of the nucleus that may occur. In a sufficiently heavy nucleus, the disruptive effects of the Coulomb repulsion may overcome the surface tension, and the nucleus then *spontaneously splits* into smaller fragments. In a nucleus that is somewhat less heavy than this critical value, splitting may be induced *artificially* by letting it absorb a slow neutron.]

Hypothetically, when free nucleons are brought from infinity (fiducial level of zero energy) to form a nucleus, the total energy of the system must *decrease* by a positive amount ΔE, which is radiated away as photons and/or nuclear fragments. This energy deficit, known as the binding energy of the nucleus, is equivalent, by STR, to a *mass deficit* $\Delta E/c^2$. Upon fission, a similar process takes place: the sum of the rest energies of the two fragments is less than that of the original nucleus. This energy deficiency ΔE, about 200 MeV, is of such size that 1 kg of ordinary uranium is equivalent in its heating effect to 2.5 *million* kg of coal, and the cost of fuel is about 400:1 in favor of uranium.

Another important property of fission is that the resulting fragments are relatively rich in free neutrons. On the average, 2 or 3 neutrons are actually emitted, which makes possible a *chain reaction* involving fissionable materials. The neutrons emitted in the fission of U^{235} have an average energy of 2 MeV, which corresponds to a velocity of $\sim 2 \times 10^9$ cm/s. Therefore, the time that elapses between the emission of a neutron and its capture by a new fissionable nucleus is very small, and the process of multiplication of neutrons in a fissionable substance is quite rapid.

The theoretical understanding of the fission process was advanced by **N. Bohr** and **J.A. Wheeler** in their '*liquid-drop model*' (1939). On his visit to the US (1939), Bohr bore the momentous news that fission of uranium had been demonstrated in Berlin and confirmed in Sweden. The news also reached **Leo Szilard**, who already in 1933 developed the idea of a nuclear '*chain reaction*' and the concept of a '*critical mass*' to create it. (He even

---

The ^{235}U captures a neutron, and the compound nucleus ^{236}U is formed. *In the ground state* ^{236}U is essentially stable; it has a half-life of 2.4×10^7 yr. Such a nucleus can perform vibrations about its equilibrium state without fissioning. However, when ^{235}U captures a neutron, the compound nucleus ^{236}U is *excited*, and the amplitude of the vibration can became so large that the nucleus separates into two. The Coulomb force between the two fission products then drives them apart with considerable energy; part of it contributes to the fragment nuclei's own kinetic energy and part goes to evaporate some neutrons.

patented these concepts in 1934, without specifying the element capable of effecting such a reaction!) Szilard immediately realized the military potential of fission for the creation of a nuclear bomb, and from that moment on started feverish activities to convince both scientists and politicians to develop the bomb ahead of the Germans.

This eventually led to the Manhattan Project. In the summer of 1939 Szilard collaborated with Fermi to design the first nuclear reactor and in Dec 2, 1942 he put into operation, with Fermi, the world's first chain-reaction atomic "pile" (reactor) of their design.

Indeed, already in 1939, **Leo Szilard** (1898–1964, U.S.A.) and **Walter Zinn** (1907–2000, U.S.A.) had confirmed that fission reactions can be self-sustaining.

Table 5.18: Timeline of Nuclear Reactors and Weapons

1934	**Leo Szilard** patented in London the idea of an *atomic bomb*.
1934	**Ida Noddack** suggested the idea of *nuclear fission* (which attracted scant attention).
1934	**Enrico Fermi** discovered *induced radioactivity* by slow neutrons.
1936	**Niels Bohr** proposed the *liquid-drop model* of the atomic nucleus.
1936	**Aston** proposed energy production by conversion of hydrogen to *helium*.
1938–1939	*Uranium nuclear fission* after irradiation of uranium 235 by slow neutrons: **Otto Hahn**, **Lise Meitner**, **Fritz Strassmann** and **Otto Frisch**; Idea of *nuclear reactor*(Pile) by **Enrico Fermi** and **Leo Szilard** (1939).
1939	**Hans Bethe**'s theory of energy production in stars.
1942	First self-sustaining nuclear chain reaction in Chicago, headed by **E. Fermi**.
1945	• July 16, 05:29:45 GMT : First *atomic bomb explosion* test at Alamogordo New Mexico, USA ("TRINITY"). Yield = 18.6 kilotons of TNT. • Aug 06 08:16:45 : bombing of Hiroshima; Yield = 12.5 kilotons of TNT, from 60 kg of uranium 235. Bomb's gross weight = 4 tons; 140,000 civilian citizens were killed. • Aug 09 11:02:00 : bombing of Nagasaki; Yield = 22 kilotons of TNT, using 8 kg of plutonium; Bomb's gross weight = 4.5 tons; 70,000 civilian citizens were killed.
1949, Aug 29	The *Soviet Union* explodes an atomic bomb – (an implosion type plutonium bomb) at Semipalatinsk.

1950	USA explodes a *megaton atomic bomb* at Eniwetok atoll.
1952 Nov 01	USA explodes first H-bomb; Yield = 10.4 MT. Gross weight 65 tons. Elugelop island at Eniwetok disappeared.
1954, Jan 21	USA launched *Nautilus*, a nuclear-powered submarine.
1964, Oct	China exploded an atomic bomb at Lop Nor.
1973	USA developed miniature nuclear warhead; Yield 50 tons TNT.
1977	USA decided to develop *neutron bomb*. It differs from standard nuclear weapons insofar as its primary lethal effect come from the radiation damage caused by neutrons it emits.
1983	USA exploded to date 1051 nuclear bombs including 204 secret small scale (below 20 kT) underground tests.
1986, Mar 26	Chernobyl nuclear power-plant disaster.
1995	Nuclear warhead stockpile totaled 9000: 7000 in USA; 480 in Europe; 1500 with submarines.
1996	Nuclear explosion tests on earth have totaled 1452.

Nuclear Power (1932–1945)

Soon after the discovery of the neutron (1932), ***E. Fermi****,* ***E. Segré****, and others began systematic studies of reactions induced by the bombardment of heavy nuclei with neutrons (1934). Since experiments with uranium showed the presence of β particles, researchers thought that they have produced elements with Z (number of protons) > 92. However, In 1938,* ***O. Hahn*** *and*

***F. Strassmann** detected barium after the reaction, indicating that elements with far smaller atomic number than uranium are produced. **L. Meitner** and **O.R. Frisch** suggested (1939) that the uranium nucleus, after neutron capture, must divide itself into two nuclei of roughly equal size, and borrowed the name* fission *from biology. They also pointed out the analogy between the fission process and the division of a small liquid drop into droplets. Further theoretical understanding of the fission process was provided by **N. Bohr**[939] and **J.A. Wheeler** (1939).*

The discovery of fission was missed, for various reasons[940], by quite a few scientists. When it was finally confirmed, the news was carried to the United States by Niels Bohr, and it sparked feverish activity in many laboratories.

When the proton and neutron are well separated from each other, they are completely unbound. However, when they are together in a single nucleus, they are both parts of a bound system; *in the case of the* deuteron *(nucleus of the hydrogen isotope $^2H = D$), the nucleus comprises just one proton and one neutron. The sum of the potential and kinetic energies (w.r.t. infinite separation at rest) of any bound system is negative. Therefore the energy of the deuteron is* less *than the energy of the separated proton and neutron. Because of the relativistic mass-energy equivalence $E = mc^2$, less energy means less mass.*

The binding energy, *B is defined as the minimum energy* released *when a system becomes bound. It is also the minimum energy needed to break a bound system into its constituent parts.*

The parts of a nucleus are its Z protons and N neutrons. Therefore, conservation of mass-energy tells us that

$$M_N c^2 + B = Z m_p c^2 + N m_n c^2. \tag{1}$$

Here, M_N is the mass of the nucleus, m_p is the rest mass of the proton, and m_n is the mass of the neutron. For practical reasons it is customary to recast (1) in terms of atomic[941] *and not nuclear masses, where the atomic mass includes*

939 Previously, **C.F. von Weizsäcker** (1935) and **N. Bohr** (1936) patterned one of the early nuclear models after *liquid drops* which led to an understanding of the dependence of *binding energies* on atomic number, and consequently gave a physical picture of the fission process.

940 **L. Fermi** "Atoms in the Family", University of Chicago Press, Chicago, 1954.

941 The unit of atomic mass has been defined to be 1/12 of the mass of the atom ^{12}C; it is called atomic *mass unit* and abbreviated a.m.u.
In terms of MeV and gram (g), u is given by

$$1\ amu = 931.5\ MeV/c^2 = 1.66043 \times 10^{-24}\ g.$$

the mass of all electrons. So we can add the Z electron masses to Z proton masses to obtain $Z\,{}^1_1H$ atomic masses (ignoring the relatively small electron binding energy). Thus we arrive at the binding energy equation

$$B = [(ZM_H + Nm_n) - M_A(Z, N)]c^2 \tag{2}$$

where B is now the total binding energy of the entire nucleus; M_H is the mass of a neutral ${}^1_1H$ atom (1.007825 u); m_n is the mass of the neutron (1.008665 u); M_A is the mass of the neutral ${}^A_ZE$ atom[942]*, where $A = Z + N$ and $c^2 = 931.5$ Mev/u in the units used. Eq. (2) then states:*

"The binding energy equals the sum of the mass of the parts minus the mass of the whole, all times c^2".

The binding energy per nucleon, B/A, is an important quantity in the theory of fission.

To describe the fission process in a simplified model, we consider one possible fission reaction[943]

$${}^1_0n + {}^{235}_{92}U_{143} \to {}^{236}_{92}U_{144} \to {}^{144}_{56}Ba_{88} + {}^{89}_{36}Kr_{53} + 3\,{}^1_0n. \tag{3}$$

Here the ${}^{235}U$ nucleus captures a low-energy neutron, and the composite nucleus ${}^{236}U$ is formed. In the ground state, ${}^{236}U$ is essentially stable; it has a half-life of 2.4×10^7 y. Such a nucleus can perform vibrations about its equilibrium state without fissioning.

However, when ${}^{235}U$ captures a neutron, the compound nucleus ${}^{236}U$ is highly excited (not at ground state), and the amplitude of vibrations can

942 A semi-empirical formula for the *calculation* of M_A in terms of A, m_n, m_H, and Z was given by **von Weizsäcker** (1935) and **H. Bethe** (1936), and known as the *Bethe-Weizsäcker relation*.

943 A *nuclide* is a particular nuclear species with a given number of protons and neutrons; *Isotopes* are nuclides with the same number of protons (Z); *isotones* are nuclides with the same neutron number (N); and *isobars* are nuclides with the same total number of nucleons (nucleon = neutron or proton). Atoms built around *isotopes* behave the same way chemically, since chemical reactions are determined by the numbers of electrons filling the electron shells, which in turn are determined by the number of protons.
We use the notation ${}^A_ZE_N$ (E for 'element') where $A = Z + N$ (atomic mass number) is the *nucleon number*, Z is the *proton number* and N is the *neutron number*. Z, which is also the number of electrons in a neutral normal atom (atomic number), identifies the chemical element in the periodic table of elements.

become so large that the nucleus separates into two parts. The Coulomb force between the two fragments drives them apart with considerable energy. Not all the available energy goes into kinetic energy; some is stored as internal (excitation) energy of the two fragments. This energy is released primarily by evaporation of neutrons. The main products of the fission process are therefore two roughly equal nuclei and a few neutrons.

An estimate of the energy Q released in fission is made through eq. (2), with M_A for each nucleus calculated via the Bethe-Weizsäcker semi-empirical relation, yielding[944]

$$Q \ (in \ MeV) \approx -4.5A^{2/3} + 0.26Z^2A^{-1/3}. \tag{4}$$

For ^{235}U, $Q \approx 180$ *MeV.*

One can get the same result also by considering the binding energy per nucleon (B/A) which is about 7.8 MeV/nucleon for the heavy elements such as uranium. It increases to about 8.5 MeV/nucleon for the medium-mass fission fragments. Therefore, with 236 nucleons involved, the reaction (3) increases the total binding energy by about

$$(236 \ nucleons) \times (8.5 - 7.6)\frac{MeV}{nucleon} \approx 200 \ MeV \ .$$

But an increase in the binding energy means that the total potential energy of the system has decreased. Thus, the internal energy of the nuclides has decreased by about 200 MeV per fission, thereby releasing 200 MeV of kinetic energy for each fission. About 85 percent of this energy goes to the kinetic energy of the fission fragments. The remaining 15 percent is divided among the neutrons and the electrons, antineutrinos, and γ rays of the radioactive decays of the two heavy fission fragments.

A chemical reaction (e.g. a combustion: hydrocarbon $+O_2 \rightarrow CO_2 + H_2O$*) involves the valence electrons of the atoms, and cannot release more than the energy changes of the valence electrons, so a release of 20 eV per molecular*

---

944 The *first* term in (4) is the *surface tension* term in the liquid-drop model, proportional to the nucleus' *area* ($r_{\text{nucleus}} \propto A^{1/3}$ is roughly true empirically, as determined by nuclear scattering cross-sections). This term is negative since surface tension helps to hold a nucleus together.
The *second* term in (4) is due to the Coulomb repulsion between protons, and is proportional to $(Ze)^2/r_{\text{nucleus}}$. This repulsion helps to *destabilize* a nucleus, which is why this term is *positive*. The liquid-drop model is a reasonable approximation because inter-nucleon forces are short-range, fairly non-directional and allow a nucleon freedom of movement — quite similar to inter-molecular forces in a liquid.

reaction would be considerable. However, about 200×10^6 eV per fission yields 10^7 times the energy output per reaction! This explains the immense energy output of fission processes from a relatively small amount of material.

On average, 2.5 neutrons are produced in every slow neutron-induced fission of ^{235}U. The neutrons in one fission process may go on to be absorbed, causing more fissions in what is called a chain reaction. *The average number of neutrons from one fission that actually cause another fission is called the* multiplication factor. *For example, if on average, less than 1 of the 2.5 neutrons produces another fission, the chain reaction will eventually die out. If so, we call the system* subcritical.

If the multiplication factor is exactly 1, the reaction will continue at a constant rate. We then call the system critical. *Finally, if the multiplication factor is greater than 1, the reaction rate increases and we call the system* supercritical. *A nuclear fission bomb (the "atom bomb") is a terrifying example of a deliberately caused supercritical reaction.*

A self-sustaining critical reaction requires that 1.5 of the 2.5 neutrons be removed from the reactions for ^{235}U fission. Some neutrons will simply leak out of the boundary surface of the bulk fissile material. Because of this loss, a certain minimum mass, called the critical mass, *must be present for a self-sustaining critical reaction. The critical mass depends on the fissible material mix and its geometry. Other neutrons will be absorbed within the system in nonfission reactions.*

A nuclear reactor *is a system in which chain reactions can be initiated and controlled. Most present-day reactors in the United States utilize fission of ^{235}U. The fission cross-section of ^{235}U increases as the speed and kinetic energy of the bombarding neutrons decrease. Slow-moving neutrons therefore have the best chance of causing fission before they escape or cause nonfission reactions.*

Let us consider a sphere composed of a pure fissile (fissionable) material ^{235}U, ^{233}U, or ^{239}Pu, unstable with respect to the capture of neutrons. If the diameter of this sphere is larger than the mean free path of the neutrons set free by nuclear fission, a single slow neutron or one spontaneous fission process will initiate an explosion. Namely, two or three neutrons are released on average by each fission process of a ^{235}U nucleus, and each of these neutrons may activate another nucleus to fission, which again releases two or more neutrons, and so on. Such a sequence of reactions is called a chain reaction. The product neutrons initiate further reactions so that the fission reaction spreads through the total fissionable mass by an avalanche-like multiplication. We emphasize that fission in the uranium bomb occurs by fast neutrons in contrast to reactors, where controlled nuclear fission in general is caused by thermal neutrons.

Now the fission of one ^{235}U *nucleus liberates*

$$200 \times 1.6 \times 10^{-6}\ erg = 3.2 \times 10^{-4}\ erg.$$

When this quantity is multiplied by the Avogadro number, the product gives the energy released in the fission of all nuclei in one gram-atom (235 grams *of* ^{235}U*), and is equal to* 1.93×10^{20} *ergs. The energy liberated by a complete fission of* 1 *kg of* ^{235}U *would therefore be* 8.21×10^{20} *ergs, which is roughly equivalent to the energy released in the explosion of 20,000 tons of TNT.*

The first task in developing the nuclear bomb was computation of the important nuclear data and the mean free path of the neutrons in the "bomb material" in order to obtain the correct dimensions for a bomb made from uranium 235 or plutonium. The bomb material, of course, is not actually pure at all, and the computations were based on experimental data which were sparse and obtained from very small quantities of material. ***Heisenberg*** *estimated the critical radius in* ^{235}U *to be 8.4 cm in his "Theorie des Atomkerns" (1949). Without the application of neutron reflectors, this value would require a minimal mass of about 50 kg* ^{235}U *for a nuclear bomb. The critical mass actually seems to be considerably smaller.*

The second condition for the production of an uranium bomb was the isolation of the fissionable ^{235}U*, previously achieved only in microscopic quantities. This* ^{235}U*, which represents only 0.72% of natural uranium, had to be separated from the dominant* ^{238}U *isotope. The expenditures in equipment, development work electric energy, and money necessary for this task were enormous. The official reports*[945] *give an idea of the problems and their actual solution in the USA, where the first bomb was exploded by* ***Robert Oppenheimer*** *and co-workers on July 16, 1945 near Alamogordo in the desert of New Mexico.*

A further problem was how to prevent with certainty the self-ignition of the bomb before the planned moment. For an explosion of the total fission mass must occur automatically as soon as the critical mass necessary for an explosion is united at any spot, since uranium nuclei can split spontaneously and a sufficient number of neutrons is always present, for instance from cosmic radiation.

Thus, self-ignition can only be prevented if the fissionable material in the bomb before its ignition is kept spatially separated in the form of several parts

---

Smyth, H.D. *Atomic Energy for Military Purposes*, Princeton University Press, 1946.

of subcritical size. The ignition is then initiated by the sudden mechanical union of the subcritical parts to one piece of supercritical size.

This mechanical union must be done so rapidly and completely that as many nuclear fissions occur as possible before the bomb explodes mechanically due to its large internal energy production – a process that would interrupt the chain reaction.

To this end bombs consist[946] *of a relatively large number of subcritical masses, which are brought together in the ignition process by the explosion (actually implosion) of appropriately shaped explosive "lenses" acting concentrically toward the center. Since the continuously multiplying number of fission processes in the bomb material is stopped by the mechanical explosion of the bomb, its effect is the greater the faster the fission processes follow one another.*

In order to avoid the capture of neutrons by non-fissionable nuclei, extremely pure material is used and the bomb proper is surrounded by a shield of a suitable material of high density. This reflector is made to scatter back at least part of the neutrons that would normally leave the fissionable material toward the outside.

According to official reports, during the explosion proper about 3% of the total energy released by a bomb is emitted as γ-radiation and another 3% as fast neutrons. This nuclear radiation emitted by the nominal bomb would kill the majority of people exposed to it at any distance less than 1 km. But its effect declines rapidly with increasing distance from the center of the explosion (assumed to occur in free atmosphere) so that the primary nuclear radiation would not be an essential danger at a distance of more than 2 km.

An additional 85% of the total energy of the bomb appear as kinetic energy of the fission products and thus serve to heat up the central vapor mass that originally comprised the bomb. The temperature obtained in this way is said to be of the order of $10^7\,{}^\circ K$. This means that nuclear physicists actually have manufactured a real although short-lived small "star" as far as characteristic core temperatures are concerned. After the end of the explosion proper, this fireball, very small in the beginning, expands very rapidly so that the radiating surface increases quickly and at the same time cools off. The maximum of the bomb's heat radiation will therefore be reached after a few tenths of a second, when the surface temperature of the fireball, now having a diameter of over 100 m, has decreased to $7000\,{}^\circ K$, comparable to the surface temperature of the sun.

[946] Rhodes, R. *The Making of the Atomic Bomb*, Simon and Schuster Inc., New York, 1986.

Depending on the transmittance of the atmosphere, this radiation may cause extremely dangerous burns at distances up to several kilometers, i.e., far beyond the range of the direct nuclear radiation. The absorption of γ-radiation and neutrons as well as that of the short-wavelength part of the heat radiation spectrum may initiate in the surrounding atmosphere a large number of photochemical effects such as dissociation of molecules and ionization of gases.

The remaining 9% of the energy released by the explosion of a typical fission bomb becomes liberated some time after the explosion proper in the form of β-radiation and γ-radiation of radioactive fission products. Together with the radioactive decay of the radionuclides produced by (n, γ)-processes in the immediate vicinity of the explosion center, this radiation causes the dangerous after-effects of a nuclear bomb explosion that are rightly dreaded by mankind.

1938–1949 CE **Claude Elwood Shannon** (1916–2001). Pioneer of the mathematical theory of communication and of modern digital technology. He was born in Gaylord, MI, educated at the University of Michigan and at the Massachusetts Institute of Technology, and then joined the Bell Telephone Laboratories (1941–1972).

His work, *A symbolic analysis of relay and switching circuits* (1938) is a founding document of the mathematical theory of *information*. In it he applied symbolic logic to relay circuits, helping transform circuit design from an art into science. In 1948 he published a classic paper: *The mathematical theory of communication*, seeking therein to render a coherent treatment of all forms of information transmission systems[947], whatever their physical nature.

---

947 *Shannon's Sampling Theorem* (1949) is an important theorem on transmission of information. It states that if the Fourier transform of a function $f(t)$ is zero above a certain frequency ω_c, $F(\omega) = 0$ for $|\omega| > \omega_c$, then $f(t)$ can be uniquely determined from its sampled values $f_n = f\left(n\frac{\pi}{\omega_c}\right)$ at a sequence of equidistant time points. In fact, $f(t)$ is then given by $f(t) = \sum_{n=-\infty}^{\infty} f_n \frac{\sin(\omega_c t - n\pi)}{\omega_c t - n\pi}$. The corresponding *sampling theorem in the frequency domain* is as follows: if a function $f(t)$ is time-limited, $f(t) = 0$ for $|t| > T$, then its Fourier transform $F(\omega)$ can be uniquely determined from its values $F\left(n\frac{\pi}{T}\right)$ at a sequence of equidistant points, $F(\omega) = \sum_{n=-\infty}^{\infty} F\left(n\frac{\pi}{T}\right) \frac{\sin(\omega T - n\pi)}{\omega T - n\pi}$.

Developed further in a series of papers, Shannon's work is fundamental to all modern communication systems.

Shannon's theorem was first proved by the mathematician **J. Whittaker** (1935), before being applied to communication theory by Shannon in 1948. The theorem asserts that if the range of frequencies of a signal is zero through f, then the signal can be represented with *complete accuracy* by measuring its amplitudes $2f$ times a second. This is really a remarkable theorem considering that ordinarily a continuous curve can be only *approximately* characterized by stating any finite number of points through which it passes, and an infinite number would in general be required for complete information about the curve. But if the curve is *band-limited* (composed of a limited range of frequencies) — it can be reproduced *exactly* from a finite number of samples.

The result, which follows directly from Fourier analysis, has enormous consequences for the transmission and processing of information. It was no longer necessary to reproduce an entire analog signal — a limited number of samples suffices. E.g. the range of frequencies transmitted by a telephone is about zero to 4000 cycles per second. In a digital system, at least one voice sampling is thus performed 8000 times a second. Reproducing music with fidelity on a compact discs requires about $44,000$ samples a second. Measuring the signal more often,, or reproducing it continuously (as with old-fashioned records) does not gain anything.

Another important consequence is that high frequencies must be samples more often than low frequencies (audio frequency doubles every time one goes up an octave). The sampling theorem opened the door to *digital technology*: a sampled signal could be expressed as a series of digits.

Although communication theory grew out of the study of electrical communication, it attacks problem in a very abstract and general way. It provides, in the *bit*[948], a universal measure of *amount of information* in terms of choice or uncertainty. Specifying or leaving the choice between two equally probable alternatives, for a portion of a data stream to be transmitted, involves one *bit of information*. Communication theory tells us how many bits of information

---

Shannon acknowledged that **Leo Szilard's** paper (1929) had proposed the basis for his new field of study. Indeed, the key elements of information theory, which Szilard first wrote about in 1922, were even transmitted to John von Neumann during his interaction with Szilard in Berlin in the late 1920s. Physicist Leon Brillouin, in turn, learned of Szilard's 1929 paper only in 1951, hearing about it from Warren Weaver at the Rockefeller Foundation.

948 A contraction of *binary digit*. One "bit" refers to a choice between two alternatives (for a computer, $0/1$, or a circuit that is off or on). The word was coined by **John Tukey**. Eight "bits" make a "*byte*".

can be sent per second over perfect and imperfect communication channels in terms of a rather abstract description of the properties of these channels.

In 1949, Shannon built the first chess-playing machine at the Massachusetts Institute of Technology.

Communication and Information[949] *(1894–1948)*

The range of problems involving the concepts of message and information is very broad. They have long been drawing close attention from physicists, engineers, mathematicians, linguists, and philosophers.

Communication, in the human sense, includes all the procedures by which one mind may affect another. This encompasses not only written and oral speech, but also music, the pictorial arts, the theater, the ballet, and in fact all human behavior. In the 20th century the concept has been broadened to include the procedures by means of which several mechanisms may exchange state-modifying instructions.

Shannon's work harks back to an observation of ***Ludwig Boltzmann*** *in some of his works on statistical physics (1894) that entropy is related to missing information, inasmuch as it is related to the number of alternatives which remain possible to a physical system after all the macroscopically observable information concerning it has been recorded. Shannon's work connects more directly with certain ideas developed by* ***H. Nyquist*** *and* ***R.V.L. Hartley*** *in the late* 1920*'s.*

Communication theory is also indebted to ***Norbert Wiener*** *for much of its basic philosophy, but while Shannon has been especially concerned with applications to engineering communication, Wiener has been more concerned with applications related to or inspired by biology (central nervous system phenomena, cybernetics, etc.).*

---

[949] To dig deeper, see:

- Pierce, J.R., *An Introduction to Information Theory*, Dover, 1980, 305 pp.
- Woodward, P.M., *Probability and Information Theory*, McGraw-Hill, 1957, 128 pp.

Communication problems can be viewed on three levels. Thus it seems reasonable to ask:

- *How accurately*[950] *can the symbols of communication be transmitted? This is the* technical *problem, involving only the engineering details of good design.*
- *How well do the transmitted symbols convey the desired meaning? This is a* semantic *problem, concerned with the faithfulness of the interpretation of meaning by the receiver, as compared with the intended meaning of the sender.*
- *How* effectively *does the received meaning affect conduct in the desired way? This is an* effectiveness *problem, concerned with the success with which the meaning conveyed to the receiver leads to the desired conduct on its part. In the human sphere, this aspect involves aesthetic considerations in the case of the fine arts. In the case of speech, written or oral, it involves considerations which range all the way from the mere mechanics of style, through all the psychological and emotional aspects of propaganda theory, to those value judgments which are necessary to give useful meaning to the words* success *and* desired *mentioned earlier.*

There is overlap between all of the suggested categories of the problem. Shannon's mathematical theory of the engineering aspects of communication applies only to the first level. But any limitations discovered in the theory at the first level necessarily apply to the other two levels, and in this sense Shannon's theory affects the other levels as well.

The overall operation of a communication system on the first level is as follows: The information source *selects a desired* message *out of a set of possible messages. The selected message may consists of written or spoken words, or of pictures, music, etc.*

---

[950] In the exact sciences, a measurement has a high *accuracy* if it has small *systematic* errors. If a measurement has small *random* errors we say that it has *high precision*. Systematic errors are errors associated with the particular instrument or technique of measurement, and are usually caused by biased or improperly calibrated instruments.

Random errors are produced by a large number of unpredictable and unknown variations in the experimental situation. They can result from small errors of judgment on part of the observer, unpredictable fluctuations in temperature, line voltage, etc.; or indeed from any kind of parametric fluctuation in the equipment. Since such random errors are frequently distributed according to a known *statistical* law, they can be dealt using statistical methods.

The transmitter changes this message into a signal *which is actually sent over the* communication channel *from* transmitter *to* receiver *[e.g.: in oral speech, the information source is the brain, while the transmitter is the voice mechanism producing the varying sound pressure (the signal) which is transmitted through the air (the channel). In radio, the channel is simply the air or vacuum, and the signal is the electromagnetic wave which is transmitted].*

The receiver is a sort of inverse transmitter, changing the transmitted signal back into a message, and handing this message on to its destination [e.g.: the ear and the auditory nerve in vocal communication]. During transmission, unwanted additional signals, known as noise*, distort the signal. The kinds of questions which one seeks to quantify and answer concerning such a communication system are:*

(1) How does one measure amounts of information*;*

(2) How does one measure the capacity *of a communication channel*[951]*;*

(3) What are the characteristics of an efficient coding process *(the action of the transmitter in changing the message into the signal according to a specific pattern known only to the transmitter and the receiver);*

(4) What are the general characteristics of noise*? How does noise affect the accuracy of the message finally received at the destination? How can one minimize the undesirable effects of noise?*

(5) If the signal being transmitted is continuous *(as in oral speech or music) rather than formed of* discrete *symbols (as in written speech, telegraphy, binary bits, etc.), how does this affect the problem?*

The word information *in this context must not be confused with meaning, and the semantic aspects of communication are irrelevant to the engineering*

---

951 Let N_t denote the number of possible message sequences of duration t. Shannon defined the *capacity* C of the channel as

$$C = \lim_{t\to\infty}\left[\frac{\log_2 N_t}{t}\right],$$

where $\log_2$ denotes the logarithm to base 2. The rationale behind the definition is this: if a single selection is to be made from a number of equally probable alternatives, and if information is transmitted which reduces the number of alternatives by a factor of 2, then this amount of information is 1 *bit*, the unit of information. Thus, the logarithm to base 2 of the number of alternatives N_t varies in steps equal to the amount of information transmitted; division by time elapsed yields the *rate* of information transmittal (bits/second).

aspects (two messages, one of which is heavily loaded with meaning and the other of which is pure nonsense, can be exactly equivalent, from the present viewpoint, as regards information). But this does not mean that the engineering aspects are necessarily irrelevant to the semantic aspects.

The word information *in communication theory relates not so much to what you* do *say, as to what you* could *say, i.e., information is a measure of one's freedom of choice when one selects a message.*

In 1949, just one year after Shannon published his work establishing the field of information theory, linguist ***Georg Zipf*** *published the book* Human Behavior and the Principle of Least Effort. *In this volume, Zipf announced an empirical rule specifying how the frequency of occurrences of a word in a long stretch of text varies with the word's* ranking *(suitably defined) for given total vocabulary used. This relationship, now termed* Zipf law, *is very closely related to the principles laid down by Shannon.*

Mathematically

$$f(r) \approx \frac{1}{r \log_2[1.78R]}$$

where r *is the word rank and* $(1.78R)$ *is the vocabulary size*[952].

1938–1972 CE **Robert King Merton** (1910–2003, U.S.A.). Historian and sociologist of science. His work suggested important innovations, both theoretical and empirical, in the study of science as a *social process*. In his doctoral dissertation (1938): "*Science, Technology and Society in Seventeenth*

---

952 *Example*: Conan Doyle's *The Hound of the Baskervilles* contains a total word vocabulary of $\sum_k t_k = 59,498$ words of which $R = 6307$ are different, yielding a vocabulary size of $1.78R \cong 10,000$ words. The breakdown according to rank is

$r =$ rank	word	t_k (times of occurrence)
1	the	3328
2	and	1628

Century England" he has shown the need for a marriage between history of science and sociology, and has established the sociology of science as a discipline in its own right.

Merton's work took up the thesis of the sociologist Max Weber (1846–1920, Germany), on the relationship between Protestantism and Capitalism, by examining the explosion of scientific activity in 17^{th}-century England as a central part of social and cultural change. He showed that those sciences justifiable in terms of their utility in mining, navigation and warfare were more vigorously supported and pursued than others. For instance, technical problems relating to the drainage and ventilation of mines required for their solution extensive improvements in the knowledge of aerostatics and hydrostatics. The preoccupations and rhetoric of men of science reflected the high values placed upon useful application. Merton quantitatively analyzed papers offered to the Royal Society of London during the 17^{th} century, claiming to confirm the preponderance of scientific topics directly or indirectly related to capitalist and military technical requirements.

Secondly, Merton argued for significant positive links between Puritan forms of English Protestantism and the institutionalization of science. Rejecting the Victorian tradition of seeing science and religion in 'conflict', Merton showed that men of science justified their activities in terms of accepted Puritan values, such as their demonstration of God's existence and attributes from the study of nature, and their suggestion that natural knowledge was ultimately useful. The Puritanism-science link was supported by the correlation found between membership in the Society and Puritan sentiments. Merton concluded that Puritan values were congenial to scientific culture and that religion provided resources by which the pursuit of 17^{th}-century England science was 'positively sanctioned'.

In other national settings, the 'functional role' of providing social legitimacy for science may have been performed by different cultural constellations, or not performed at all.

Merton was born in Philadelphia, Pennsylvania to poor Jewish parents as Mayer Schkolnick. In 1924, he changed his name to Robert King Merton to enhance his chances to acquire higher education. After finishing high school he studied at the Temple University, founded for poor boys and girls of Philadelphia. Then he went to Harvard University in Cambridge, MA, obtaining his Ph.D. in 1936.

1938–1985 CE **Menahem Max Schiffer** (1911–1997; Israel and USA). Mathematician. His work opened up the possibility of applying variational methods in a systematic way to geometric problems in complex analysis. The 'Schiffer variation' is named after him. Made important contributions to the study of eigenvalue problems, to PDE, and to the variational theory of 'domain functionals' that arise in many classical boundary value problems.

Schiffer was born in Berlin to Jewish parents. He entered (1930) the Friedrich-Wilhelm University with the intention of becoming a physicist and studied physics under **Max von Laue**, **Walther Nernst** and **Erwin Schrödinger** and mathematics under **Issai Schur**. Schrödinger finally pushed him to become a mathematician. As a result of Nazi Persecutions, the Schiffer family emigrated to Israel and Menahem continued his studies at the Hebrew University in Jerusalem (MA, 1934; Ph.D. 1938). In 1952 he settled as a professor of mathematics at Stanford University and remained there thereafter. He was famous worldwide for his remarkable lectures in applied mathematics and mathematical physics: each lecture was a perfect set piece – no pauses, no slips, and no notes.

1938–1988 CE **Barbara Wertheim Tuchman** (1911–1989, The United States). Historian and author. Wrote eleven books about men of war and on brink of war. Of these, the most influential are:

- *Bible and Sword* (1956), about English involvement in the Middle East over the centuries.
- *The Guns of August* (1962), covering the outbreak of WWI and the events leading to that war.
- *A Distant Mirror* (1978), on the calamitous 14^{th} century: a time of ferocity, plague and spiritual agony when a world plunged into chaos.
- *The March of Folly* (1984), a meditation on un-wisdom as a force in history (wisdom = "the exercise of judgment acting on experience, common sense, and available information").

Her central themes are:

- Meaning in history emerges *not* from preconceived design, but from the aggregation of details and events that fall into a pattern; In this process, good is often crushed or subverted.
- The psychology of governing classes is often fatally flawed and the power to command frequently causes failure to think.
- Holders of high office act contrary to the way reason points and enlightened self-interest suggests. Consequently, intelligent mental processes seem often not to function.

Barbara Tuchman was born in New York to an illustrious Jewish family; her uncle, Henry Morgenthau Jr. was secretary of the Treasury under President Franklin D. Roosevelt.

She received a B.A degree from Radcliff College (1933) and in 1937 went to Madrid to report on the Spanish Civil War (which she saw as the end of the liberal world). In 1939 she married Dr. Lester R. Tuchman, a New York Internist, and they had three daughters. In her later years she was a lecturer at Harvard University and the U.S. Naval War College. In 1979 she was appointed the chairperson of the American Academy of Arts and Letters.

1939 CE *Elements de Mathematique*, by Nicholas Bourbaki, pseudonym for a group of young mathematicians at the Ecole Normale in Paris, is begun. This extended set of works aims to set down in writing, on a formal, abstract and rigorous footing, the established branches of modern mathematics.

1939 CE FM radios are sold commercially for the first time.

1939–1940 CE Bitterly cold weather killed 500,000 Russian soldiers invading Finland.

1939 CE **Lise Meitner**[953] (1878–1968, Austria and Sweden). Physicist. Born in Vienna as one of the eight children of a Jewish Viennese lawyer. She studied at Vienna University under **L. Boltzmann** and was one of the first women in Austria to earn a doctorate degree at that University (1906). In 1907 she moved to Berlin University and worked for some time with **Max Planck**. In 1913, she began research into radioactive substances with **Otto Hahn** (1879–1968) and in 1918 they discovered the element *protactinium*. Her major achievement at that time was the determination of the relationship between β and γ radiation of radioactive materials.

Lise Meitner was one of the first women to become a professor at the University of Berlin (1926). From 1917 on, she served for over 20 years as head of the physics department in the Kaiser Wilhelm Institute for chemistry in Berlin.

---

[953] For further reading, see:

- Sime, R.Lewin, *Lisa Meitner: A Life in Physics*, University of California Press, Berkeley, 1996.
- Rife, P., *Lise Meitner and the Dawn of the Nuclear Age*, Birkhäuser, 1999.

After the *Anschluss* in 1938, she escaped[954] from Germany and settled in Stockholm, working on the staff of the Nobel Institute. There she received a letter from Hahn describing his discovery with Fritz Strassmann that, when an uranium atom absorbed a neutron, an atom of barium was sometimes produced thereby.

While vacationing near Gothenburg in December 1938, she discussed this with her nephew, **Otto Frisch** (b. 1904) who was working in Denmark with **Niels Bohr**. The two physicists immediately realized the significance of the discovery, which meant that the *uranium atom was split* into roughly equal parts, accompanied by a tremendous release of energy[955]. Frisch called this "fission", a term borrowed from biology. Lise Meitner visited the United States after 1945, but returned to Sweden and became a citizen there in 1949. Both before and after WWII she received many honors. She eventually retired to Cambridge, England, where she died.

1939 CE, March **Frederick Joliot Curie** (Paris, France) and **Enrico Fermi** (New York) discover the *nuclear chain-reaction*[956]: An uranium nucleus (U^{235} isotope), when split by a neutron, releases (as a rule) two or more neutrons.

Joliot-Curie's second paper in *Nature* (April 22, 1939) triggered two initiatives in Germany. A physicist at Göttingen alerted the Reich Ministry of Education. That led to a secret conference in Berlin on April 29, which led in turn to a research program, a ban on uranium exports and provisions

[954] On June 16, 1938 she was forbidden to leave. With the aid of Bohr, Dirk Coster, Adriaan Fokker, Hahn, Max von Laue and Paul Rosbaud (a scientific publisher) she escaped by train, on July 12, 1938 across the Dutch border to freedom.

[955] Hahn won the 1944 Nobel prize in chemistry for splitting the atom (nuclear fission). Meitner's share in this discovery was at least as great as his, but her contribution was discredited because she was a woman and a Jew. The two were working together on the fission experiment when Lise had to flee Nazi Germany. The fission occurred while she was away, but even so she gave the correct physical explanation of the result.

Hahn, however, dissociated himself from their partnership, and took all the credit for himself.

[956] The theory of *chemical* chain-reactions was established by the physical chemist **Max Bodenstein** (1871–1942, Germany) in 1913. Bodenstein was born in Magdeburg to a Jewish family and perished in the Nazi Holocaust.

for supplies of radium from the Czechoslovakian mines at Joachimsthal. The same week, a young physicist working at Hamburg, **Paul Harteck**, and his assistant **Wilhelm Groth** jointly wrote a letter to the German War Office:

> "We take the liberty of calling your attention to the newest development in nuclear physics, which, in our opinion, will probably make it possible to produce an explosive many orders of magnitude more powerful than the conventional ones... That country which makes use of it has an unsurpassable advantage over the others."

The letter was delivered to **Hans Geiger**. Geiger recommended pursuing the research and the War Office agreed. In June 1940, Paul Harteck in Hamburg tried to measure neutron multiplication in an arrangement of uranium oxide and dry ice (frozen CO_2), but was unable to convince **Heisenberg** to lend him enough uranium to guarantee unambiguous results.

1939 CE **John Vincent Atanasoff** (1903–1995, USA). Father of the electronic digital computer. Inventor, electrical engineer and mathematical physicist. Invented and built the world's first operational prototype electronic digital computer, known as the ABC (Atanasoff Berry Computer). It used vacuum tubes[957] to perform mathematical and logical operations and employed binary numbers that were stored in capacitors mounted on a rotating drum. Data were entered via punched cards. The cost of the entire project was about 1000 dollars. He was assisted by his graduate student Clifford Berry.

Atanasoff saw others take credit for his discovery: many of his ideas were used in the design of the ENIAC which is falsely considered by most people as the world's first electronic digital computer. A long trial ensued and it was not until 1973 that Dr. Atanasoff was given the recognition he deserved.

When Atanasoff invented the computer, he could not imagine the impact it would have on people's lives; the electronic age is a direct result of the invention of the computer. Never before has an invention mushroomed so quickly as the computer. Within the last 60 years, its speed and power has grown at an exponential rate.

John Vincent Atanasoff was born in Hamilton, New York to a family of Bulgarian immigrants. He graduated from the University of Florida (1925),

---

[957] He recognized the usefulness of the fact that a vacuum tube could be turned on and off in about a millionth of a second — thousands of times faster than the sluggish relay.

and received his Ph.D. in theoretical physics at the University of Wisconsin (1930). He became an associate professor of mathematical physics at Iowa State College (1936–1942), and it is there that he built the ABC computer. During 1942–1952 Atanasoff worked in the U.S. Naval Ordnance Lab. He never made money off his invention.

1939 CE **Charles Stark Draper** (1901–1987, USA). Aeronautical engineer and inventor. Developed the first inertial guidance system for launching long-range missiles based on his earlier gyroscopic systems that stabilized and balanced gunsights and bombsights (1939). Draper subsequently developed the SPatial Inertial Reference Equipment (SPIRE) system for automatic aeronautical navigation — a system. He later refined and miniaturized it for use in the Polaris submarine missile system.

Draper was born in Windsor, Missouri. He obtained a D.Sc. from M.I.T. (1938), becoming a professor there. He continued to be a pace-setter in the space age as head of MIT's Department of Aeronautical and Astronautical engineering. His Instrumentation Lab was awarded the Apollo project contract for guiding spacecraft to the moon.

1939–1957 CE **Carl Gustav Rossby** (1898–1957, Sweden). Oceanographer and meteorologist. Provided the ideas and leadership necessary for the progress of synoptic and dynamic meteorology in the 40's and 50's.

After early work on the dynamics of ocean currents, he began to make fundamental contributions to meteorology, notably in studies of long circumpolar waves and the *jet stream*[958], on the application of the vorticity equation of cyclonic development, and on the barotropic model atmosphere for use in numerical forecasting. His name is perpetuated in meteorology by means of the *Rossby diagram* in thermodynamics, *Rossby waves*[959], and the *Rossby number*.

---

958 The atmospheric layer between 8–13 km in altitude, with temperature between $-45\,^{\circ}$C and $-65\,^{\circ}$C and pressures of about 100 mb, accommodates the *jet stream*. These winds move with velocities above 100 km/hr, reaching in extreme cases even 500 km/hr. Commercial jet aircraft today fly in this layer, and even when they travel at an average speed of 800–900 km/hr, jet streams play a decisive role as far as navigation, flying time, and convenience are concerned.

959 Near-barotropic wavy nature of the upper troposphere flow: the upper *westerlies* propagate around both hemispheres in a series of long waves (4000–6000 km). These waves change only slowly in number and amplitude compared with surface systems, and they travel more slowly than the winds blowing through them. There are normally some 3 to 6 long waves around the northern hemisphere on any given day.

Rossby waves were determined by the trajectory of a balloon launched from

Rossby was born in Stockholm. He developed three outstanding university departments of meteorology — at M.I.T. in the 1930's, at Chicago (1941–1947), and at Stockholm from 1947.

New Zealand on 30 March 1966. It drifted at an altitude of 12 km, with mean speed of over 110 km/hr and for 49 days, in the upper westerlies. The movement of the balloon (tracked by satellite) traced out the shape of Rossby waves at a latitude range 30°–50°S during this 7-week period. On average, there were about 4 long waves per revolution, although the trough positions changed with time.

The existence of Rossby waves follows directly from the basic equations of inviscid atmospheric fluid dynamics in an earth–co–rotating frame:

$$\frac{Du}{Dt} - fv + \frac{1}{\rho}\frac{\partial p}{\partial x} = 0;$$

$$\frac{Dv}{Dt} + fu + \frac{1}{\rho}\frac{\partial p}{\partial y} = 0,$$

which arise from approximation in which gravity, sound waves, and vertical motion are excluded. One then makes the additional assumptions:

- Regarding the atmosphere as an incompressible and horizontally homogeneous fluid $\left(\frac{\partial \rho}{\partial x} = \frac{\partial \rho}{\partial y} = 0\right)$.
- Waves travel in the x direction, v is y-independent and u is constant ($u = \overline{u}$; $\frac{\partial f}{\partial y} = \beta =$ constant = Rossby parameter).

Here $f = 2\Omega \sin\theta$ where $\Omega = 7.29 \times 10^{-5}$ rad/sec is the angular frequency of the earth's rotation, and $\theta =$ latitude. Under these conditions, the equations of motion reduce to

$$\frac{\partial^2 v}{\partial x \partial t} + \overline{u}\frac{\partial^2 v}{\partial x^2} + \beta v = 0,$$

with the harmonic wave solution

$$v = Ae^{ik(x-ct)}, \qquad c = \overline{u} - \frac{\beta}{k^2}, \qquad k = 2\pi/\text{wavelength} = \frac{\omega}{c}.$$

The waves are dispersed, since their phase velocity c depends on their wavelength. The transverse-horizontal motion of the Rossby waves is thus established. Such solutions were contained implicitly in the *theory of tides* of **Laplace** (1774), but Rossby was first to recognize their meteorological importance and to isolate them in pure form.

In contrast to sound and gravity waves, Rossby waves are always propagated westward *relative to the medium*, and travel at speeds that depend on their wavelength. They also travel relatively slowly: for wavelengths of 4500 km, their speed relative to the medium is of order 15 km/hr. In addition, their associated horizontal speeds are at least 100 times greater than their vertical speeds.

1939–1968 CE **Max Ferdinand Perutz** (1914–2002, Austria and England). Biochemist. Determined the atom-by-atom structure of *hemoglobin*. Introduced (1939) a technique of adding an atom of heavy element (such as gold) to an organic molecule to improve the X-ray diffraction pattern of the molecule and this method was used by him to obtain the hemoglobin structure (1960). Perutz predicted the presence of the alpha helix in hemoglobin (1951).

Perutz was born in Vienna to a Jewish family. After graduating at Vienna University, he emigrated to Cambridge, England. He became Director of the Medical Research Council (MRC) Unit for Molecular Biology (1947–1962) and after 1962 was Director of the MRC Laboratory for Molecular Biology.

Shared the 1962 Nobel Prize for Chemistry with **John Cowdery Kendrew** (1917–1997, England) who determined, by X-ray crystallography, the structure of the muscle protein *myoglobin*.

The shape of Hemoglobin (1960)

Hemoglobin is the protein in red blood cells that carries oxygen from the lungs to the tissues, and also helps transport carbon dioxide on its return trip. Obviously, it plays an extremely important role in the body. Abnormalities in its structure can lead to such life-threatening diseases as sickle cell anemia or thalassemia.

Besides being important, hemoglobin is also one of the most plentiful proteins in vertebrates. In the human bloodstream some 5 billion red blood cells, each containing 280 million molecules of hemoglobin, can be found in each milliliter of blood.

To decipher the structure of this enormous molecule, ***Max Perutz*** *had to determine the positions of 10,000 atoms, each one located in space by three coordinates. The 574 amino acids formed by these atoms were strung together in four separate, but connected, polypeptide chains. Perutz grew his own crystals of hemoglobin, took his own X-ray pictures, and did millions of computations without the help of a computer, looking for some regular underlying features that would simplify his problem. He thought the molecule* *might have four straight layers, each layer being a polypeptide chain. But he never found anything that clear-cut.*

*His first break came in 1953 when he and his colleagues invented a method that has been called the "*Rosetta Stone*" for interpreting X-ray diffraction patterns of large proteins: the use of certain "heavy" metal atoms, which are added to the hemoglobin crystals to serve as atomic markers. These metal atoms are called heavy because they have an extremely large number of proteins, neutrons, and electrons, and the advantage of using them is that they scatter X-ray beams very strongly.*

Perutz realized that if atoms of mercury or other heavy metals were added to the protein before it was crystallized, they would attach themselves to specific sites in the hemoglobin molecule and produce measurable differences in the intensities of the spots in the X-ray diffraction pattern. By comparing the X-ray patterns of hemoglobin with and without these heavy atoms, he could more precisely determine the intensity and angle of the X-ray reflections. This would allow him to analyze the molecule in three dimensions for the first time.

Six more years of effort were required to make the method work. Finally, all the pieces came together and Perutz stood before the completed structure of the hemoglobin molecule — a bizarre mass of twisted chains with four separate pockets, each one containing the dark red, iron-bearing component called heme *that is essential for the binding of oxygen and gives blood its color.*

Shocked by the result of his labors, Perutz puzzled about its meaning. "Could the search for ultimate truth really have revealed so hideous and visceral-looking an object?" he wondered.

John Kendrew*, who had joined Perutz in Cambridge in the 1940's, had a similar reaction after deciphering the structure of a smaller protein, myoglobin, 2 years earlier. Kendrew had chosen to study myoglobin in the hope that it would have a fairly simple structure, but to his surprise the molecule turned out to have a complex, asymmetrical shape.*

Myoglobin's job is to take oxygen from the red cells in the bloodstream and store it in muscle tissue until needed. This storage occurs by the binding of an oxygen molecule to the iron atom at the center of myoglobin's heme group. Since diving birds and mammals that spend much time underwater have abundant supplies of myoglobin in their muscles, Kendrew worked with myoglobin from sperm whales. After Perutz devised the heavy-metal method *of X-ray crystallography, Kendrew succeeded in solving myoglobin's structure. This was the first three-dimensional model that showed the full complexity of a protein molecule.*

At first there seemed to be neither rhyme nor reason to myoglobin's shape, but when Perutz determined the structure of hemoglobin the obvious similarities between the two models began to offer some clues to the significance of their design. Myoglobin has one pocket for a heme group; hemoglobin, four times its size, has four. Each of hemoglobin's four subunits looks like one molecule of myoglobin. And the interior of all these units consists almost entirely of hydrophobic (water-avoiding) amino acids. This allows the iron atoms in the buried heme group to bind with oxygen without becoming oxidized (rusted).

In 1962, Perutz and Kendrew won the Nobel Prize in chemistry for developing the heavy-metal method of X-ray diffraction and for solving the structures of hemoglobin and myoglobin.

Since this achievement, scientists have deciphered the three-dimensional atomic structure of well over 500 additional proteins. In fact, the structures of most of the proteins that scientists have succeeded in growing into crystals for study by X-ray diffraction are now known. But only a fraction of proteins, which normally exist in solution, crystallize like sugar or salt when the surrounding water is removed. The others either form an amorphous gel, with their molecules pointing in different directions, or turn into a powder. Little is known about the shapes of these tens of thousands of proteins that do not crystallize, although a new technique called 2-D NMR may soon come to the rescue.

Although the amount of data on protein sequences is increasing at an astounding rate because of advances in molecular biology, the folding problem remains a major challenge to scientists. Being able to predict the detailed three-dimensional structure of a protein from a given sequence of amino acids is "the most fundamental problem at the chemistry-biology interface," according to a report by the National Academy of Sciences, "and its solution has the highest long-range priority."

Science Progress Report No. 17

Martyr of Genetics

"We shall go to the pyre, we shall burn, but we shall not renounce our conviction."

(Nikolai Ivanovich Vavilov, 1940)

Joseph Stalin hated the idea that fate (even the fate of a fruit-fly eye) was determined by biology. It behooved his political system to claim that by changing the environment it is possible to do anything. He thus declared total war on "The capitalistic plot of bourgeois Mendelism–Morganism". Under his direct orders, his Director of Agriculture, T.D. Lysenko, started (1939) a hate campaign against genes and chromosomes.

It went a long way; the entire Soviet agriculture was planned on the false theory that exposing parents to a new environment (e.g. a cold spring in Siberia) meant that the offspring would inherit the ability to cope with icy water. This was an expensive disaster for both farming and genetics. Soviet biology thus fell into the hands of the fanatical eccentric Lysenko, who preached a theory of inherited acquired characteristics and what he called 'vernalization' (the transformation of wheat into rye, pines into firs, and so on) — essentially medieval stuff.

All in all, Soviet science went back to the Middle Ages; thousands of intellectuals lost their jobs. Thousands more went to the notorious Siberian slave camps. Their places were taken by creatures still more pliable, cranks and frauds[960]*. Stalin in person edited in advance Lysenko's presidential address of 31 July 1948 to the Academy of Agricultural Science, which launched the witch-hunt in biology. Scientific genetics was savaged as a 'bourgeois pseudo-science', 'anti-Marxist', leading to 'sabotage' of the Soviet economy: those who practiced it had their laboratories closed down. But all this was not enough; the Communist party needed a public show to terrorize the masses and close the lid on all potential dissidents. They needed a 'traitor'.*

He soon materialized in the form of ***Nikolai Ivanovich Vavilov*** *(1887–1943), a Soviet plant geneticist whose research into the origins of cultivated plants (1916–1933) won him a world acclaim.*

---

[960] In medicine, a woman called O.B. Lepeshinskaya preached that old age could be postponed by bicarbonate of soda enemas — an idea that appealed to Stalin.

Vavilov was born in Moscow and graduated at the Agricultural Academy at Petrovsko-Razumovskoe, and later studied under W. Bateson at Cambridge University and at the John Innes Horticultural Institution in London (1913–1914). Returning to Russia, he became professor of botany at the University of Saratov (1917–21), and then head of what was finally called the Lenin All-Union Academy of Agricultural Sciences.

Vavilov made a comprehensive study of the origin of cultivated plants and proposed that there were several world centers of origin at which the greatest concentration of diversity in cultivated plant species occurred. He made expeditions to many parts of the world, including Iran, Afghanistan, Ethiopia, China, and Central and South America, amassing an immense collection of cultivated plants intended to be used for further study and the breeding of new varieties. He brought to the Soviet Union, for further study and breeding, samples of 50,000 varieties of wild plants and 31,000 wheat specimens[961].

Observations made during Vavilov's world-wide studies led him to postulate that a cultivated plant's center of origin would be found in the region in which wild relatives of the plant showed maximum adaptiveness. These conclusions were summarized in The Origin, Variation, Immunity and Breeding of Cultivated Plants *(Eng. trans. by K.S. Chester, 1951). In 1920 he expanded the theory, stating that the region of greatest diversity of a species of plant represents its center of origin. He eventually proposed 12 world centers of plant origin.*

From this prodigious labor emerged a new synthesis of the origin of cultivated plants, the first great advance since de Candolle[962].

Vavilov was arrested (1940) for opposing the views of Lysenko. After hours of interrogation Vavilov was found guilty in a five-minute trial of "belonging to a rightist conspiracy, spying for England, and sabotage of agriculture". He was sentenced to death and died in the Magadan labor-camp, Siberia, on Jan 26, 1943 of starvation and maltreatment by prison guards. The man who had done more than any other to feed Russia, died of starvation. He may have never known of his election as a foreign member of the Royal Society in 1942.

1939–1968 CE **Hannes (Olof Gösta) Alfvén** (1908–1995, Sweden). Astrophysicist. First to bring plasma physics into astronomy, and a pioneer

[961] Sadly, all those collections were *eaten* during the siege of Leningrad in WWII.

[962] **Augustin-Pyrame de Candolle** (1778–1841, Switzerland).

in the study of plasmas in magnetic fields, known as magnetohydrodynamics (MHD)[963]. Won the 1970 Nobel prize in physics for his work on the behavior of ionized gas in the solar magnetic field, through which he explained the puzzling phenomenon that the sun's photosphere is cooler than its chromosphere and corona. Explained the origin of the *cosmic rays* and introduced the new concepts of *Alfvén velocity* and *Alfvén waves*.

Alfvén suggested that *antimatter* may power the *quasars* and the violent explosions in the cores of galaxies [matter and antimatter collide and annihilate each other, thus releasing all of their rest-mass energy content].

Cosmic Rays (1899–1945)

Cosmic rays were first detected by **Elster** *and* **Geitel** *(1899) and* **C.T.R. Wilson** *(1900). In measuring the rate of discharge of a carefully shielded electroscope, they found that pure, dry air possesses a small conductivity, which presumably resulted from the presence of ionizing radiation in the laboratory or in the air (assumed to be caused by small amounts of radioactive substances).*

However, in 1911 **Hess** *showed that the ionizing radiation is entering the earth's atmosphere from above, and these rays must have great penetrating power, since their effects have been detected underground and in deep lakes. It is possible to arrange Geiger counters in coincidence arrays and to show that the detected rays travel predominantly in the vertical direction. Similar techniques reveal the occurrence of cosmic-ray showers, that is, groups of particle trajectories covering a large horizontal area within a short period of time.*

It is also found that the numbers of rays reaching ground level depends on the magnetic latitude; hence the earth's magnetic field must affect the trajectories of the original or "primary" particles entering the upper atmosphere. It is believed that most of the primary particles are protons, but there are also heavier particles in the primary rays, as shown by the heavy-ion tracks

[963] Energy is transferred via hydromagnetic waves from the magnetic field (lines of force) to electrons and ions that spiral along them.

produced in photographic emulsions flown to a great height. Measurements have proved that primary cosmic-ray particles with a kinetic energy up to 10^{20} *eV (corresponding to* 10^{11} *times the rest mass of the nucleon) occur, far greater than the energies achievable in any man-made accelerator.*

The cosmic rays observed at sea level are produced almost entirely by collisions and disintegrations occurring in the atmosphere following the entry of primary particles; most of these primary particles possess high energy, spread subsequently over a large number of particles. Most of the particles produced by the complex high-energy reactions are either intrinsically unstable, or are capable of producing new particles in "cascade" processes.

One important component of cosmic rays is called the "soft" component, because it is easily absorbed in lead, and this consists of electrons of both signs (electrons an positrons) as well as high-energy protons. A single, high-energy electron can generate photons in the presence of matter by the Bremsstrahlung process, and high-energy photons impinging upon nuclei may in turn produce electron-positron pairs, which may then cause further emission of photons.

Thus the soft component forms showers of the cascade type, and a single shower may spread over a wide area at sea level. The total energy found in some showers is of the order 10^{17} *eV, all of which must have come from a single primary particle entering the atmosphere.*

In addition to the soft component, cosmic rays contain a component which can penetrate several feet of lead and which consists of charged particles of both signs. These particles do not lose appreciable amounts of energy by the Bremsstrahlung process, but, at the same time, they are much more penetrating than massive particles like the proton.

Calculations of the energy losses by fast particles in matter suggest that moat of the penetrating particles must be intermediate in mass between the electron and the proton. In 1938 ***C.D. Anderson*** *and* ***S.H. Neddermeyer*** *published evidence strongly suggesting the existence of such* mesons*, with rest mass about* 200 *times that of the electron.*

During the years 1939–1945*, theoretical physicists tried to reconcile the cosmic-ray data with the meson theory of nuclear forces, despite the many difficulties which attend a rigorous theory of strong interactions. Slowly it became clear that the mesons observed in cosmic rays could* not *be responsible for nucleon-nucleon forces, since their interaction with nucleons is too weak. Today, the penetrating meson of Anderson and Neddermeyer are known to be the muon — a heavier analog of the electron, which has its own species of neutrino.*

The mesons thought to mediate the strong nuclear force, on the other hand, are known as pions *or pi-mesons. These latter were predicted by*

***H. Yukawa** (1935), and the confusion arose because pions and muons have similar masses.*

Later in the 20^{th} century, it became clear that pions, like nucleons, are composed of quarks, and that a more accurate description of strong nuclear forces – of both nucleon and pions, as well as their heavier "cousins" – is via exchange of "gluons" between quarks and anti-quarks.

1939–1987 CE **Walter Maurice Elsasser** (1904–1991), Germany and USA). Physicist and 'biological philosopher'. Produced the '*dynamo model*' to account for the earth's magnetic field (1939), and pioneered analysis of the earth's past magnetic fields patterns, now 'frozen' in rocks. He also foresaw the fact that the *genome* does not encode all the information that goes into the biology and functionality of an organism ('*Physical Foundation of Biology*', 1958).

Elsasser was born to a Jewish family in Manheim and educated at Göttingen. He left Nazi Germany (1933) for the Paris Sorbonne and then emigrated to the USA (1936). He worked at Caltech (1936–1941) and for the US Signal Corps in war research on radar (1941–1946). He subsequently held professorships at the Universities of Pennsylvania, Utah, Princeton and Maryland until 1974.

Considering the earth as a having a core of molten iron above the Curie temperature (and therefore no longer able to retain any permanent magnetism), Elsasser suggested that the earth's rotation sets up eddy currents in the liquid core, causing it to behave as an electromagnet. This theory provides an explanation of the terrestrial permanent magnetic field and the presence of secular variations.

In a series of books: *Atom and Organism* (1965), *The Chief Abstractions of Biology* (1975) and *Reflection on a theory of Organisms* (1987), Elsasser expounded his biological thoughts and general philosophy.

All of his biological writings refer to the immense complexity of the organism based on the number and types of atoms in a cell and the number of possible bonds connecting the atoms in organic molecules. *Complexity* is taken as an intrinsic aspect of the living state. Another important consideration is the near *reversibility* of most biochemical reactions with their *relatively small energy changes*.

Furthermore, the closeness of energy exchange in biochemical reactions to *thermal noise* is necessary for the *decision-making ability* of the organism, allowing it to choose between available states without need for more than a *minimal supply of energy.* This condition enables the system to respond with large-amplitude changes to small perturbations, and is also characteristic of the processes involved in the development and differentiation of the organism. These thoughts led Elsasser to formulate a set of principles to represent the living state:

- *The principle of ordered heterogeneity*: Combinatorial analysis shows that the number of structural arrangements of atoms in a cell is immense; that is, much greater than 10^{100}, a number that is itself much larger than the number of elementary particles in the observable universe (10^{80}). But biology also manifests regularity in the large, in addition to heterogeneity in the small.

- *The principle of creative selection*: Nature, through processes compatible with the laws of physics (but not uniquely determined by them!) makes a choice among the immense number of possible patterns inferred from the first principle. However, no mechanism can be specified by the operations of which the selected patterns differ from those not selected. The selection of a relatively small number of organisms from the immerse number[964] of possibilities allowed by quantum mechanics, physics and chemistry is a primary expression of *biological order.*

- *The principle of holistic memory*: It provides the *criterion of choice* not expressed in the second principle. The organism chooses patterns that resemble earlier patterns. This holistic "memory" secures the *stability of information* in time. It is dynamic memory without stable storage which secures transmission of morphological features through time without a dedicated material memory device.

- *The principle of operative symbolism*: a material carrier of information (namely DNA) acts as a releaser for the capacity of the whole organism to

[964] The number of different patterns is also immense in the physical science of *statistical mechanics*, but in that case the variation of structure from pattern to pattern averages out. The patterns of inorganic systems are either fully random or else repeat themselves over and over again ad infinitum, while those of each organism are unique and evolving.

reconstruct a complete message that characterizes the adult of the next generation.

These principles are not scientific laws in the usual sense since they are not derivable from the fundamental laws of physics, and therefore not determined directly by atomic and molecular physics. The basic assumption in this holistic interpretation is that an organism (or a cell) is a source of causal chains which cannot be traced beyond a terminal point because they are lost in the complexity of the organism.

1940 CE, Nov. 07, ca 10 am *The catastrophic collapse of the Tacoma Narrows suspension bridge* (near Seattle, State of Washington, U.S.A.) due to twisting motion induced by gusting winds. The bridge, with the third longest span in the world (853 m), collapsed only four months after its inauguration. One of the surprising facts of the accident was the relatively low speeds of the winds causing it, only $67\,\frac{\text{km}}{\text{hr}}$ $(19\,\frac{\text{m}}{\text{sec}})$ at the moment of collapse. Excluding tornadoes, the worst storms on land may reach $160\,\frac{\text{km}}{\text{hr}}$, but $120\,\frac{\text{km}}{\text{hr}}$ winds are observed frequently enough even in Europe).

Startling scenes of rippling pavements, featured in a classic film that captures this event, rank among the most dramatic and widely known images in science and engineering. This staple of most elementary physics courses, has left an indelible impression on countless students over the years.

The technique of suspension bridges started with the development of metallurgy at the turn of the 19^{th} century. Trial and error taught the method of calculation and indicated possible modes of construction, but several accidents restrained the builders. To begin with, there was the collapse of bridges induced simply by excessive amplitudes of vibration under an imposed alternating load in *resonance* with one of the natural frequencies. For instance, a small bridge erected in 1829 at Broughton near Manchester (England) collapsed due to troops marching in step (1831); a French bridge over the Loire also broke down under a battalion of infantry marching in step; several decades later (1886), an Austrian bridge over the river Ostrawitza collapsed under charging cavalry although the static load (26 soldiers, 16 horses, 2 carts) was very light.

Orders to break step prevented recurrence of these accidents and bridge engineers were led to think that only the properties of the steel used for the suspension cables would limit the possibilities of suspension bridges: Evidently, if the length of the span increases indefinitely, the weight of the cable grows more rapidly than the weight of the roadway it supports, and finally even without a roadway the cable becomes unable to support itself. Between 1900 and 1910 the mechanical properties of the available metals seemed to permit a maximum span of 3 km under these conditions; in 1953 a much greater length appeared admissible.

Nevertheless, experience has shown that the *wind* imposes other limitations: the 10 suspension bridges that have failed in gales[965] during the 19^{th} century illustrate the relentless regularity of these accidents and their apparent independence of technical progress.

Textbooks usually attribute the above events to the phenomenon of resonance. In the case of the Tacoma Narrows bridge, so the explanation goes, the wind blowing past the bridge generated a train of vortices that produced a fluctuating force in tune with the bridge's natural frequency, steadily increasing the amplitude of its oscillation until the bridge finally failed.

Recently[966], however, a new analysis challenged this common explanation. According to the new theory, large scale oscillations are caused by the inherent *nonlinearity* of suspension bridges, through which a bridge could go into large oscillations as a result of a single gust and at other times remain motionless even at high winds. The new theory also explains how large *vertical oscillations* could rapidly change into *twisting motion*.

---

965 Dryburgh Abbey (Scotland, 1818); Union (England, 1821); Nassau (Germany, 1834); Brighton Chain Pier (England, 1836); Montrose (Scotland, 1838); Menai Straits (Wales, 1839); La Roche-Bernard (France, 1852); Wheeling (U.S.A., 1854), Niagara-Lewiston (U.S.A., 1869); Niagara-Clifton (U.S.A., 1869).

966 Linear theory predicts that if you stay away from resonance, then in order to create a large motion, you need a large exciting force. Nonlinear theory says that for a wide range of initial conditions, a given push can produce either small or large oscillations. Nonlinear theory predicts that a suspension bridge can respond to a whole range of forcing frequencies. Also, the nonlinear equations yield mathematical solutions of *waves traveling up and down a bridge's roadbed*. Such waves were indeed observed on windy days on roadbeds of a number of large suspension bridges.

According to the model of **Alan C. Lazer** and **P. Joseph McKenna** (*Science News* **137**, 344–346), gusts of winds initially act as a random buffeting force on a suspension bridge, causing the towers and main cable to go into a high-frequency periodic motion. That motion initiates low-frequency, vertical oscillations that ripple the roadbed. This may be followed by sudden transition to a twisting mode.

Thus an impact, due either to an unusually strong gust of wind or a minor structural failure, may provide sufficient energy to send the bridge from one-dimensional to torsional modes of oscillation. The resulting twisting destroys the bridge.

Suspension bridges built or remodeled after 1940, including the Golden Gate bridge, are unlikely to suffer the same fate as the Tacoma Narrows bridge. Civil engineers responded to the Tacoma disaster by *stiffening* existing bridges and building new bridges heavy and rigid enough to resist wind-induced motion. Because such bridges naturally flex very little, a linear analysis suffices. Only when flexibility becomes an issue and a bridge moves so much that it start loosening does the nonlinear theory come into play.

An *earthquake*, however, is precisely the sort of energy source that may push a suspension bridge into the nonlinear mode. (Indeed, during the 7.1 magnitude *Loma Prieta earthquake*, the Golden Gate bridge oscillated for about a minute. The stays connecting the roadbed to the main cables were alternatively slackening and tightening — a sign that the bridge was in a nonlinear stage. Fortunately, the bridge did not start twisting, because the earthquake wave hit it head-on rather than obliquely.)

1940 CE **Howard Walter Florey** (1898–1968, England), pathologist, and **Ernst Boris Chain**, biochemist (1906–1979, England) isolated and purified *penicillin*[967] as the first powerful antibiotic.

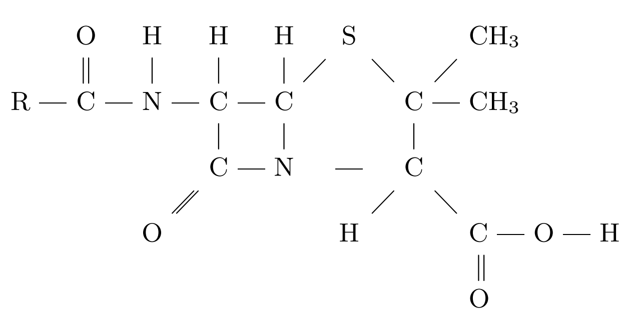
Florey was born in Australia. Professor at Sheffield University (1931–1935), Oxford (1935–1962).

Chain was born in Germany. Researcher at Charité Hospital, Berlin (1930–1933). Fled to England (1933) on account of Nazi persecution of the Jews; Cambridge University (1933–1935), Oxford University (1935–1948), Imperial college, London (1961–1973).

Both were awarded the Nobel prize for physiology or medicine (1945).

Louis Pasteur noted (1877) that some bacteria give off substances that kill other bacteria. It was not until 1939 that this observation was put to use

967 *Penicillin*:



R may be any of a number of hydrocarbon groups, as there are different types of penicillin.

when **René Jules Dubos** (1901–1982, U.S.A.) discovered two antibiotics in a substance produced by soil bacterium.

The details of antibiotic action are poorly understood; it is presumed that in general they block some vital metabolic process of the bacterial organism.

Certain phenomena make the use of antibiotics something less than a panacea for bacterial diseases:

- All antibiotic drugs are capable of producing a wide variety of allergic reactions.
- All antibiotics upset the ecological balance existing among microorganisms present in the human body, which can result in overproduction of particularly resistant bacteria and fungi. These secondary infections can on occasion be worse than the original one.

Bacteria may adjust to the presence of the antibiotic by devising an alternative metabolic pathway, where there is less interference from the antibiotic. In other cases a mutant strain of bacteria develops, which has greater resistance to the drug.

Advent of Modern Pharmacology[968] *(1800–1940)*

1805 ***Friedrich Sertürner*** *isolated the first alkaloid from opium.*

1821 ***Francois Magendie*** *(1783–1855) isolated alkaloids such as emetine and strychnine.*

[968] From the Greek pharmakos=medicine or drug. *Pharmacology* studies the effects of drugs and *how* they exert their effects. In actual use, however, its meaning is limited to the study of action of drugs (how they operate).

1847 *Pharmacology emerged as a separate science when the first university chair was established. This occurred when* ***Rudolf Buchheim*** *(1820–1879) was appointed professor of pharmacology at the University of Dorpat in Estonia (then a part of Russia). Buchheim is credited with turning the purely descriptive and empirical study of medicines into an experimental science.*

1869–1912 ***Oswald Schmiedenberg*** *(1838–1921,* Germany*), a student of Buchheim, is recognized as the founder of modern pharmacology. Introduced urethane as a hypnotic (1885). He was largely responsible for the preeminence of the German pharmaceutical industry up to WWII.*

1897–1926 ***John Jacob Abel*** *(USA). Trained under Schmiedenberg and went to John Hopkins University. Isolated epinephrine from adrenal gland extracts (1897) and histamine from pituitary extract (1919). Also prepared pure crystalline insulin (1926).*

1897–1912 ***Paul Eherlich****'s (1854–1915) chemotherapy, immunotherapy and 'side-chain theory' have influenced 20th century pharmacology.*

1899–1941 *The discoveries of* aspirin *(1899),* vitamins *(1912–1922),* hormones *(1902–1931) and* antibiotics *(1941) have revolutionized the pharmaceutical industry.*

1932 ***Gerhard Domagk*** *(1895–1964) discovered the first of the* sulfanilamide *drugs (1899).*

1940 First color television broadcast in the United States using a system developed by **Peter Goldmark** (1906–1977).

1940 **Igor I. Sikorsky** flew the first practical single-rotor *helicopter* at Stratford, CT.

1940–1947 **William (Wolfe) Frederick Friedman** (1891–1969; USA). Cryptography pioneer. U.S. Army Intelligence Colonel and Chief Cryptoanalyst of the War Department in Washington D.C. (1941–1947). Led the U.S. Army team (Special Intelligence Service) which broke the Japanese code in 1940 (*Purple* Code) and subsequently remained a key member of the Operation Magic teams which decoded Japanese ciphers and enabled U.S. military commanders to read Japanese intercepts on Japanese military movements.

Magic was the code name for the joint Army and Navy operation, first set up in 1939, to break Japanese diplomatic and military codes. Magic provided the U.S. military and political chiefs with much important intelligence throughout the war and its contribution to major Allied operational successes has until recently been largely underestimated. The Navy Special Intelligence Unit, Communications Security Unit, with a staff by 1942 of about 300, worked with Army Signals Intelligence Section (SIS), deciphering and relaying enormous amounts of traffic in coded messages sent by the Japanese government to their agencies worldwide and by Imperial Headquarters to their commanders at sea and in the field.

Probably the most important contribution made by Magic to the U.S. victory in the Pacific was the decoding of ciphers that revealed the Japanese attack plan for the Battle of Midway in mid-1942. Informed in advance of the Japanese objectives, Admiral Nimitz was able to preempt Japanese strategy and fight off a superior Japanese force, decisively halting the thrust of the Japanese offensive in the Pacific.

Friedman was born in Kishinev (now Chisinau, capital of Moldova). The following year, the family emigrated to the United States to escape increasing persecution of the Jews in Russia. The family settled in Pittsburgh (1893). After graduating from Cornell University, Friedman became interested in the study of codes and ciphers and during WWI became a cryptographic officer with the U.S. War Department in Washington.

Friedman introduced mathematical methods into cryptology and produced training material used by several generations of pupils. His work affected for the better both signals intelligence and information systems security, and much of what is done today at NSA may be traced to Friedman's pioneering efforts.

He was buried in Arlington National Cemetery, and his wife, Elisabeth Smith Friedman (1892–1980), a gifted codebreaker in her own right, is buried with him.

Friedman coined the term "cryptoanalysis".

1940–1948 **Martin David Kamen** (1913–2002, USA). Discovered carbon-14, a radioactive isotope of carbon with half-life of about 5700 years, and used it to study primary processes in *photosynthesis*.

Kamen was born in Toronto, Canada and studied in Chicago. In 1960 he was appointed Professor of Biochemistry at the University of California, San Diego. He pioneered the application of several radio-isotopes in a diversity of biochemical, particularly bacterial, systems. Confirmed the hypothesis that all the oxygen released in photosynthesis comes from water and not from CO_2.

He determined (1945) the initial state of 'fixed' CO_2 in photosynthesis; showed that bacteria, which carry out the photosynthetic conversion of CO_2 to carbohydrate (without oxygen release) require the presence of reducing substances (such as hydrogen sulfide); and that illumination increases phosphorus turnover in photosynthesis (1948).

1940–1942 **Hedy Lamarr** (1913–2000, Austria and USA). Movie star and inventor. Incepted the revolutionary idea of *frequency-hopping*, namely of sending radio signals without being detected, deciphered or jammed by simply modifying the carrier frequency according to random preassigned scheme (code) of frequencies, synchronized at both the sending and receiving ends. This she first suggested to apply to submarine torpedoes controlled by radio signals[969].

Hedy Lamarr's invention eventually influenced, impacted, and changed the field of communications. Originally intended to protect U.S. radio-guided torpedoes from interception, jamming, and miscalculated ocean drift, it ended up catalyzing a world-wide wireless revolution utilizing radio frequencies. Used in such devices as traffic signals, cellular phones, pagers, wireless Internet, and the Milstar Defense Satellite, it allows communications to be more secure,

---

969 In order to reconstruct the original message, there is a need for a frequency-synthesizer, able to perform fast-hopping over the carrier frequencies. The faster the "hopping-rate", the higher the processing gain.

quicker, and cheaper than ever before. Radio frequencies were once thought to be a limited resource, but spread spectrum technology effectively allows simultaneous use by multiple users sharing several frequencies.

One of the most fascinating chapters in Lamarr's life and career had nothing to do with her film career and everything to do with her brain power. How many movie stars can you name, who hold the patent on a significant technological breakthrough? It's a story even Hollywood couldn't have invented.

At the age of 84, Hedy Lamarr was finally honored for her invention from the 1940's. She received an award for her and George Antheil's invention.

In 1997 Hedy received an award at the Computers, Freedom, and Privacy conference for "blazing new trails on the electronic frontier."

All that and brains too — the birth of spread-spectrum technology

Silver Screen actress **Hedy Lamarr** *(1914–2000) enjoyed one of the more memorable careers in Hollywood. Her name still ranks among the brightest lights in the history of the movies. But what many people do not know is that in 1941, as a 27 year-old this glamorous Hollywood star created an idea that revolutionized communication technology into the 21st century.*

She was born as Hedwig Eva Maria Kiesler in Vienna, Austria on November 9, 1914. The daughter of a bank director and a concert pianist, she had been well groomed in her native Vienna: Instructed by private tutors, who taught her three languages as well as ballet and piano. She then received her finishing touches at a private boarding school in Switzerland.

She made her first film in 1931 as an extra. In the 1932 Austrian production, Ecstasy, her teenage nudity made her world-famous and set standards for erotic pictures for decades to come. The film was extremely daring for its time and won her the Grand Prize in the 1934 Vienna Film Festival. The part also won her a millionaire husband, Fritz Mandl (1933), one of Europe's *largest armament manufacturers, who supplied Benito Mussolini with arms for his invasion of Abyssinia (1936), and later sold bombs, bullets and airplanes to Hitler. Mandl was also conducting research in weapons control systems, being especially interested in radio-controlled torpedoes. Radio signals, however, had a serious flaw: enemies could access the same radio-wave frequency and jam it. As Mandl's wife, Lamarr was exposed to military technology ideas, being at his side during business meetings. Although she had no formal technical education, she possessed a mind capable of understanding what she heard.*

In 1937, Lamarr fled her husband to London, where she came in contact with Louis B. Mayer of MGM, who arranged for her to come to the U.S. On the voyage across the Atlantic, Mayer gave her the name "Hedy Lamarr", in part inspired by the sea! In Hollywood, the beautiful actress found success, and had the world at her feet[970]*. But she anticipated the perils of Nazism, and as WWII was brewing in Europe she was determined to do something to help the war effort; recalling the 'Torpedo Problem', it occurred to her that jamming could be avoided if the frequency of the radio carrier wave could be quickly changed, taking on values in a prearranged discrete random sequence,* synchronized *at both the sending and receiving ends. Thus, the simple but revolutionary idea of* frequency-hopping *was born.*

To realize this idea technically, Lamarr had to solve the synchronization problem. To this end she engaged (1941) the ultramodern experimental Hollywood composer ***George Antheil*** *(1900–1959) who had a good deal of expertise with sound synchronization. Antheil proposed controlling the frequencies for the transmitter and receiver with paper rolls, perforated with a pseudo-random pattern to delineate the frequency path: two rolls with the same pattern would be installed in the transmitter and receiver; if the two rolls were started at the same time, and one stayed at the launch point while the other launched with the torpedo, and if there existed good rotary stability in the motors driving the paper rolls, one could maintain the synchronization right on down to where the torpedo hit the ship. The two inventors designed their system to use* 88 *frequencies — exactly the number of keys on a piano.*

[970] Hailed as the "Modern Eve", she looked stunning in all of her 26 films (1929–1958), most notably in *Algiers* (1938), in which she became the most alluring lady in American films; *Tortilla flat* (1942), as a Mexican beauty; and *Samson and Delilah* (1950), in which Cecil B. De Mille had the inspired idea of using her sex-appeal straight, and the public loved her as an elegant, cool and adventurous woman — the world's most renowned seductress. Unfortunately, she turned down many good film roles (Ingrid Bergman got most of them) and had little understanding of how best to advance her own career.

On June 10, 1941 Lamarr and Antheil received Patent No. $2,292,387$ *for their invention of a classified communication system that was especially useful for submarines. It was based on radio frequencies changed at irregular periods that were synchronized between transmitter and receiver: signals could be transmitted without being detected, deciphered or jammed — an unbreakable code!*

Rather than develop the patent commercially, they gave it away to the government for the war effort. Despite the fact that they stood to gain financially by holding onto the patent, they were both committed to helping defeat the Nazis.

The Navy, however, refused to take the Secret Communication System *seriously. Technologists questioned whether the paper rolls would hold without breaking, whether the rotary motor that synchronized the rolls would be accurate enough, and whether the paper rolls could be made small enough to fit inside a torpedo. Despite the inventors' active lobbying and insistence that the US Navy needed the invention to compete with Germany's sophisticated military technology, the Secret Communication System was never used during WWII*[971]*. Not only was the invention rebuffed, but so were Lamarr's efforts to contribute her considerable technical abilities to the task of defeating Hitler. When she offered to come to Washington, D.C. and work at the National Inventors Council, she was told she'd be of greater service to the war effort by remaining in Hollywood and using her star status to raise war bonds. She obeyed, selling $7 million worth of bonds in a single day by offering kisses, at $50,000 a kiss. After the patent expired (1958), the government began to use it*[972]*, but Hedy Lamarr received neither money nor recognition for her accomplishments. In the Cold War era, the military expanded its use of frequency hopping technology, relying on it to secure communications during the Cuban missile crisis (1962), but the idea was not yet widely known in the civilian world. In the mid 1980s, the US military declassified the use of frequency-hopping, also known as spread-spectrum technology, and the commercial sector began to develop it for consumer electronics.*

By the 1990s, as telecommunications became a bigger part of everyday life, interest in frequency-hopping grew as it became one way to enable multiple users to share a single radio frequency — an important spectral-efficiency measure as more and more pagers, cellular phones and other devices crowd into limited airwave spectra.

Hedy Lamarr's life is a remarkable story of survival, adventure[973] *and achievement. Her invention was 50 years ahead of its time.*

---

[971] The Navy's reticence was due to an anti-cultural bias: In their patent Lamarr and Antheil attempted to better elucidate their mechanism by explaining that certain parts of it worked like the fundamental mechanism of a player piano. The top military brass in Washington who examined the invention read no further than the words 'player piano'. "My God," they said, "we shall have to put a piano in a torpedo..."

[972] E.g. the *Sonubuoy* was designed for the US Navy (1955); it is a device which had a two-way radio and antenna and was dropped from an airplane and floated on the surface of the ocean. It allowed airplanes to communicate with each other. With the use of Hedy Lamarr's invention of frequency hopping, the planes were able to communicate without interference and in complete security.

[973] She became famous for other things besides films, including a sizzling autobiography (*Ecstasy and Me: Life as a Woman*), over which she sued her collaborators for $21 million; six husbands, most of them millionaires; and a widely-publicized shoplifting incident. She had been short of money through-

The next time you pick up a cellular phone, give a brief thought to the improbable woman who first patented some of its underlying technology — "the most beautiful girl in the world", actress Hedy Lamarr.

1940–1951 CE **Edwin Mattison McMillan** (1907–1991, U.S.A.). With **Philip Hauge Abelson** (b. 1913) discovered *neptunium* (June 08, 1940), element 93, the first known transuranium element; exposed uranium to accelerated neutrons; some of the neutrons stuck to the uranium nucleus and then underwent beta-decay (changing from neutrons to protons by emitting an electron and an anti-neutrino).

Later that year they showed that a similar process also produced element 94, *plutonium*. Exhausting the supply of planets beyond Uranus as names, later elements would be named for places and persons [americium, curium, berkelium, californium, einsteinium and fermium — elements 95 to 100; all of those were created by adding protons to the nuclei of previously existing elements]. Off all these, only plutonium was found to be a fissible (fissionable) element and suitable for making nuclear weapons.

In 1945 McMillan [and independently, Soviet physicist **Vladimir I. Veksler** (1907–1966) invented the *synchrocyclotron*, an accelerator that produces particle energies in excess of 20 million electron volts. Overcoming the limitations of the *cyclotron* (1932), they worked out the theory of *phase stability* which guided the design of all future high-energy accelerators.

Awarded (1951) the Nobel prize for Chemistry, with **Glenn T. Seaborg** (1912–1999) for their discovery of plutonium and research on transuranium elements.

1940–1958 CE **Abraham Selman Waksman** (1888–1973, USA). Microbiologist. Awarded the Nobel Prize in physiology or medicine, 1952, for his discovery of *streptomycin*, the first antibiotic effective against tuberculosis.

Waksman was born in Priluka, Ukraine (near Kiev) to Jewish parents. He received his early education primarily from private tutors, obtained his high-school diploma as an extern in Odessa (1910) and left for the US immediately afterwards. There he studied at Rutgers (B.Sc. 1915; M.Sc. 1916) and at the University of California (Ph.D. in Biochemistry 1918). He returned to

---

out the years: she told police she had jewels stolen but they were found; she filed false rape charges to gain money.

Rutgers University, where he became Professor of microbiology (1930), Head of the Department (1940) and Director of the Institute of Microbiology (1949).

He had isolated, together with his students and associates, a number of new antibiotics, including *actinomycin* (1940), *streptothricin* (1942), *streptomycin* (1943), *neomycin* (1948) and others. Of these, the last two have found extensive application in the treatment of numerous infectious diseases of men, animals and plants.

He has published more than 400 scientific papers and has written, alone or with others, 18 books.

1940–1962 CE **Pierre-Michel Duffieux** (1891–1976, France). Physicist. Originator of the field of *Fourier optics* (1940). Concepts such as "frequency response function", "transmission function" and "transfer function" of an optical system are associated with his name. Those concepts put on a broader foundation some ideas which **J.C. Maxwell** (1856), **Ernst Abbe** (1873) and **Lord Rayleigh** (1879) had conceived much earlier in connection with the resolving power of optical systems and the theory of optical imaging.

Duffieux showed, however, that the role of the Fourier transform is not confined to image formation, but that it is also an indispensable tool in image post-processing, whether the technique employed be analogue or digital.

With the aid of the Fourier transform one tries to simulate a kind of "reverse path", canceling some of the unwelcome features of the image forming process along the way, with a view to restoring the original image function. His theory was of major importance in the development of optical communication in the last third of the 20th century.

Duffieux was born in Saint-Macaire (Gironde), studied at Bordeaux and received a D.Sc. from the Ecole Normale Superieure (1915). He then held academic positions at Marseilles (1916–1927), Rennes (1927–1929), Grignon (1941) and became a professor of physics at the University of Besancon (1945–1962).

1940–1965 CE **Giulio Yoel Racah** (1909–1965; Italy and Israel). Physicist and mathematician. Made important contribution in the fields *atomic spectroscopy*. Named after him are: *Racah's symbol*, *Racah's V-coefficient*, *Racah's W-coefficient*, *Racah-Wigner calculus*. A crater on the moon was named after him. Wrote (with **U. Fano**)[974]: "*Irreducible Tensorial Sets*" (1959).

[974] **Ugo Fano** (1912–2001, Italy and USA). Atomic physicist. Since 1937 – at the University of Chicago with **E. Fermi**. Son of the mathematician **Gino Fano** (1871–1952).

Born in Florence, Italy, he took his Ph.D. from the University there (1930), and later studied under **E. Fermi** in Rome. Emigrated to Israel (1939) and appointed professor of Theoretical physics at the Hebrew University, Jerusalem. Published (1941–1949) three seminal papers on energy levels in many-electron atoms.

Died in Florence, on a way to the Zeeman centennial celebration in Amsterdam, as a result of a gas leak in an old heating installation.

1940–1969 CE **Alfred Day Hershey** (1908–1997, USA). Bacteriologist. Confirmed through experiments that DNA, not protein was the genetic material.

In one of the most famous experiments in 20^{th} century biology, Hershey and his assistant, **Martha Cowels Chase**[975] (1927–2003) marked bacteriophages with radioactive isotopes and then were able to trace protein and DNA to determine which is the molecule of heredity.

He was born in Owosso, Michigan and received his B.S. in chemistry at Michigan State University in 1930 and his Ph.D. in bacteriology in 1934, taking a position shortly thereafter at the Department of Bacteriology at Washington University in St. Louis.

He began performing experiments with *bacteriophages* with Italian-American **Salvador Luria** and German **Max Delbrück** in 1940, and observed that when two different strains of bacteriophage have infected the same bacteria, the two viruses may exchange genetic information.

---

[975] Hershey and Chase announced their results in a paper: A.D. Hershey and M. Chase, 1952. *Independent functions of viral protein and nucleic acid in growth of bacteriophage*. Journal of General Physiology **36**: 39–56.

The experiment inspired American researcher **James D. Watson**, who along with England's **Francis Crick** figured out the structure of DNA at the Cavendish Laboratory of the University of Cambridge the following year.

Hershey shared the 1969 Nobel Prize in Physiology or Medicine with **Salvador Luria** and **Max Delbrück**. Chase, however, did not reap such rewards for her role. A graduate of The College of Wooster in Ohio (she had grown up in Shaker Heights, Ohio), she continued working as a laboratory assistant, first at the Oak Ridge National Laboratory in Tennessee and then at the University of Rochester before moving to Los Angeles in the late 1950s. There she married and earned her Ph.D. in 1964 from the University of Southern California. A series of personal setbacks through the 1960s ended her career in science. She spent decades suffering from a form of dementia that robbed her of short-term memory. She died in 2003.

He moved to Cold Spring Harbor, New York, in 1950 to join the Carnegie Institution of Washington's Department of Genetics, where he performed the famous Hershey-Chase blender experiment with **Martha Chase** in 1952. This experiment provided additional evidence that DNA, not protein, was the genetic material.

He became director of the Carnegie Institution in 1962 and was awarded the Nobel Prize in Physiology or Medicine in 1969, shared with Luria and Delbrück for their discovery on the replication of viruses and their genetic structure.

The Helicopter

In the helicopter [from the Greek: $\epsilon\lambda i\xi$ (helix) = screw, $\pi\tau\epsilon\rho o\nu$ (pteron) = wing], a large propeller (rotor), rotating horizontally, provides the lift that holds up the craft.

When the lift is exactly equal to its weight, the helicopter hovers motionless. If the pilot wants to go forward, he causes the blades to tilt forward at an angle. Then, the reaction of the air on the blades has a vertical component to counterbalance the weight, and a horizontal component to provide a forward motion.

The power-driven rotors serve the helicopter in lieu of fixed wings and a propeller. The helicopter is able to take off and land vertically, to move in any direction, or to remain stationary in the air. The lift is determined both by the rotary speed and angle of attack *(pitch) of the blades. For a certain speed, the generated lift will counterbalance the weight of the craft.*

The rotation of the rotors causes the fuselage of the aircraft to rotate in the opposite direction. To prevent this, a single-rotor helicopter is provided at its tail with a small vertical propeller that produces a counteracting sideways thrust. Alternatively, the helicopter may have two rotors which revolve in opposite directions and thus counterbalance each other[976].

---

[976] The shape of the blade is such that the air streaming above it moves faster than the air below it. This difference creates a pressure gradient that lifts the wing. The helicopter has three controls:

Collective Pitch Stick: controls the main rotor blades to make the helicopter hover and fly straight up or down. To fly *upward*, the pilot pulls the stick up to increase the pitch of all the blades. To fly *downward*, he pushes the stick down to decrease the pitch of the blades. To *hover*, he sets the blades at a medium pitch. The collective pitch stick also increases the power sent to the rotor for upward flight, and decreases power for downward flight.

Cyclic Pitch Stick: controls the main rotor blades to make the helicopter fly *forward*, *backward*, or *sideways*. The pilot pushes the stick in the direction he wants to fly. The stick continuously and periodically changes the pitch of each blade to make it rise highest at a spot directly opposite the direction of flight. For example, to drive the helicopter forward, the blades rise highest at the rear. The blades get their greatest pitch one-fourth of a revolution ahead of the spot where they rise highest.

Tail Rotor Pedals: control the pitch of the tail rotor blades to turn the helicopter

The idea of the helicopter first appeared in the notebooks of ***Leonardo da Vinci*** *(ca 1500), who drew sketches of a flying machine of this type. At about the same time the Chinese made toys that flew like helicopters.*

The earliest attempts to build model helicopters that flew were made by two Frenchmen, ***M. Launoy*** *and* ***M. Bienvenu****, in* 1784. *The British inventor* ***George Cayley*** *designed a steam-powered model in* 1843. *Another British inventor,* ***W.H. Phillips****, built in* 1842 *a steam-powered model helicopter, the rotor of which was driven by jets of steam coming from the tips of the rotor blades.*

In 1878, ***Enrico Forlanini*** *(1848–1930,* Italy*) built a steam-driven helicopter model which hoisted to about* 12 *m above the ground, and stayed up for* 20 *sec.*

The first manned helicopter flight was achieved (1907) by ***Paul Cornu*** *(1881–1944,* France*) and* ***Louis Bréguet*** *(1880–1955,* France*). Both of these machines made short flights, but neither was practical. They were* unstable *(wobbly) and their flights could not be controlled.*

During and after WWI, helicopter designers gradually began to solve the problems of stability and control. In 1937, *a two-rotor helicopter built by* ***Heinrich Focke*** *(1890–1979,* Germany*) flew for more than an hour at an altitude of* 2400 *meters.* ***Sikorsky*** *promoted the development of a big helicopter industry in the United States, which proved its value in WWII and the Korean War. Helicopters rescued countless wounded and trapped troops and brought water, food, ammunition and medical equipment to the fighting men.*

right or *left*. For straight flight, the pitch of the tail rotor is set to prevent the helicopter's body from turning to the right as the main rotor turns to the left. The pilot pushes the left pedal to increase the pitch of the tail rotor and turn the body to the left. He pushes the right pedal to decrease the pitch of the tail rotor and turn the body to the right.

Science Progress Report No. 18
World-War II (Sep 01, 1939 – Sep 02, 1945)

"In the arts of life man invents nothing; but in the art of death he outdoes Nature itself"

George Bernard Shaw, the Devil's words to Don Juan, 1903 (1856–1960)

"There occur from time to time in the course of history, men who have a special genius for conquest and destruction. Think of Alexander the Great, Attila (properly named flagellum Die = "the scourge of God"), Ghingiz Khan, Hulagu (who sacked Baghdad in 1258). The methods of these men were very much the same "Blitzkrieg" accompanied by ruthlessness. Of course, these monsters did not think of themselves as 'destroyers' but of builders of a "new order". They did establish a kind of order, for when their work was done, there ruled in their dominion the order of exhaustion and death. We may apply to them the incisive words which the British chieftain Calagus applied to the Romans: 'To plunder, butcher, steal — these things they misname empire; they make a desolation, and they call it peace"'.

George Alfred Léon Sarton, 1948 (1884–1956)

"Science in the 20^{th} century was doubly warned by history: the First World War and the coup de grace of the second World War with its associates, genocide and vile totalitarianism".

Anon

A. Forerunner — the decline of science in Germany

*The main trend in German science at the turn of the century became one of ever-increasing nationalism. In 1914 a manifesto was issued, signed by 93 eminent German scientists and scholars, including such men as **Ehrlich**, **Haber**, **Ostwald** and **Planck**, which accused the contemporary British and French scientists of plagiarism, and claimed that the priority of German scientists* *to a number of discoveries had not been acknowledge outside Germany. A number of eminent German-speaking scientists did not associate themselves with the manifesto, notably* ***Einstein****, but they were in the minority.*

From 1930 *on, German nationalism began to weaken German science, and the decay in the quality of German science was an inevitable consequence of the degeneration of German culture under the Nazi regime. First, there was the "brain-drain" of Jewish and anti-Nazi scientists who left Germany for Britain, the United States and other countries. No less serious was the infusion of national-socialism into German science. Nevertheless, the theories of science kept contradicting the tenants of national socialism: In physics there was a postulate of the equivalence of all observers of nature (no privileged race!) whilst the findings of biologists and anthropologists did not agree with the racial pseudoscience.*

The spirit of national socialism gradually infected German scientists, and there appeared a tendency toward self-glorification both on the national and personal levels. With the rise of Germany's military power came the decline of fundamental research and its applications.

From 1933 *on, Germany and with it all of central Europe was gradually emptied of its best mathematicians, physicists, biologists and chemists (****Einstein****,* ***Bohr****,* ***Franck****,* ***Stern****,* ***Schrödinger****,* ***Born****,* ***Wigner****,* ***Teller****,* ***Noether****,* ***Weyl****,* ***Courant****,* ***Gödel****,* ***von Neumann****,* ***Bloch****,* ***Brauer****,* ***Artin****,* ***Ulam****,* ***Neugebauer****,* ***Wald****,* ***Neyman****,* ***Eilenberg****,* ***Chain****,* ***Krebs****,* ***Haber****,* ***Delbrück****,* ***Hertzberg****,* ***Lipmann****,* ***Meyerhof*** *and others).*

In toto, about 1150 Jewish scientists, many of them of great brilliance and in high positions, left Germany between 1933 and 1935 — a clear indication of the major role played by the Jews in German science before the rise of Hitler.

This exodus of intellectuals from Europe was mostly directed towards the U.S., which was very fortunate to be able to integrate the European scientific heritage into the ranks of its growing young sciences[977]*. Most of the refugees*

[977] The growth of the number of Jewish students in the American Ivy League universities during the 1920's was viewed with alarm by the WASP leadership of these institutions. At Harvard, for example, president A.L. Lowell struggled with his faculty to institute formal quotas for entering undergraduates. His policies resulted in a sizable reduction of the proportion of Jewish students, from 25–27% in the 1920's to 10–16% in the 1930's. Thus, for example, **Norbert Wiener** was black-listed by **George Birkhoff**. Harvard's concern over what Lowell termed "the Jewish problem" was not unique. When M.I.T. made trouble over the appointment of Norman Levinson to an assistant professorship, **G.H. Hardy**, who was visiting M.I.T. that year (1932), threatened Vannevar Bush, then M.I.T. president, to spread the news that M.I.T. stood for the

were Jews. They belonged to that part of the population that contributed about 30 *percent to overall German achievements in the sciences during* 1800–1933.

The physics brain-drain was accompanied by the rise to power of two strongly antisemitic physicists[978], *Johannes Stark (1874–1957) and Philipp Lenard (1862–1947). They considered the whole field of atomic physics as a Jewish fraud*[979]. *Quantum theory and relativity were for them "Jewish" physics, in contrast to "German" (or "Aryan") physics. German physicists who accepted and taught Jewish physics were called "white Jews". The detrimental effects on physics in Germany were obvious.*

In the biological sciences, those who had inspired the greatest developments in the field had left Germany and were to die in exile: ***Fritz Haber***, ***Richard Willstätter***, ***Otto Meyerhof***, ***Carl Neuberg***, ***Max Bergmann*** *and* ***Rudolf Schoenheimer***.

During the 1933 *business meeting of the Mathematische Reichsverband (MR) [Reich Mathematical Association], the 'leader' principle was accepted, and the former chair and now 'leader' of the group, Georg Hamel, made the*

Massachusetts Institute of Theology.

The influx of European scholars during the 1930's boosted the xenophobia in academic circles to unprecedented levels; in his address to the AMS in 1938, on the occasion of its 50^{th} anniversary celebration, G.D. Birkhoff warned his audience that eminent researchers from abroad were reducing the number of available positions for young Americans with "the attendant probability that some of them will be forced to become 'hewers of wood and drawers of water'."

Four years earlier, on 18 May 1934, the same Birkhoff had written a letter to R.G.D. Richardson to discourage the candidacy of Solomon Lefschetz for president of AMS: "*I have a feeling that Lefschetz will try to work strongly for his own race. They are exceedingly confident of their own power and influence in the good old U.S.A.... He will get very racial and use the Annals as a good deal of racial perquisite. The racial interests will get deeper as Einstein's and all of them do*". In spite of Birkhoff's antisemitic opposition, however, Lefschetz became the first Jewish president of the AMS in 1934.
Eventually, the great influx of European talent had transformed academic and *artistic* life in America.

978 On Lenard's office door in Heidelberg was a note: "Entrance to Jews not permitted".

979 In 1945, Stark and Lenard must have considered themselves very lucky that the *fraudulent Jewish device* was dropped on Hiroshima in lieu of Berlin.

following statement: "We want to cooperate sincerely and loyally in accordance with the total state. Like all Germans, we place ourselves unconditionally and happily in the service of the National Socialist movements, behind the Führer".

The expulsion of mathematicians from their positions began with the "Law for the Restoration of Civil Service" of 7 April 1933. Richard Courant, Edmund Landau, Felix Hausdorff, and Otto Toeplitz were among the victims[980]*. In 1937, the "New Official's Law" affected even those who were "related to Jews by marriage" like Erich Kamke or Emil Artin. By 1938 more than one-fourth of the 227 mathematics instructors in German universities were expelled*[981]*. These loses could hardly be replaced. Of the 7319 students of physics and mathematics in 1931, only 1270 remained by 1939.*

In 1934, the secretary of the Deutsche Mathematiker-Vereinigung (DMV) [German Mathematicians Union], Ludwig Bieberbach, who became the Nazi ideologue of mathematics, extended the Nazi racial theory into the realm of mathematics. Justifying the student boycott against Landau he divided mathematics into Jewish and Aryan mathematics. The former he characterized as "mental arrogance", devilish cleverness, "juggling with concepts" and the "cunning of Jewish mathematicians like Jacobi".

In 1934, ***David Hilbert*** *was sitting next to the Nazis' newly appointed minister of education, at a banquet. When asked: "And how is mathematics in Göttingen, now that it has been freed of the Jewish influence?" Hilbert replied: "Mathematics in Göttingen, there is really no such thing any more".*

Most German scientists considered public expression of any political allegiance to be inconsistent with the dignity of their profession. Einstein was exceptional in his open avowal of socialism and pacifism, as were Lenard and Stark in their vociferous devotion to the 'Führer'. The German universities, however, both staff and students, had been the strongest supporters of antisemitism, and the Weimar Republic had few friends among the professors.

980 After the purge of the Göttingen Mathematical Institute from all of its eminent Jewish mathematicians, the Nazis appointed in 1934 one of their devoted members, **Helmut Hasse** (1898–1979) to succeed Richard Courant as head of the institute. By irony of fate, the spirit of what the Nazis called *Jewish mathematics* continued to live in the works of Hasse, who learned all he knew from his Jewish teachers **Kurt Hensel**, **Edmund Landau** and **Emmy Noether** and propagated their ideas in his own papers during the pre-Nazi period 1923–1931. After the exodus, his contributions to mathematics became rather mediocre and some of his conjectures in number theory have now even proven wrong.

981 This program was overseen by the virulent Nazi mathematician **Oswald Teichmüller** (1913–1943) who perished on the eastern front.

As early as 1930, *the University of Jena appointed the virulently antisemitic Hans Gunther as Professor of Racial Science (Rassenkunde) and his inaugural address was wildly cheered by the students.*

Several efforts were made to persuade Max Planck to make a public protest against the Nazi dismissals of Jewish and socialist professors. Otto Hahn asked him to support a statement by a dozen eminent physicists, but Planck refused. Marie-Elisabeth Lüders, a former member of the Reichstag and old family friend, twice visited Planck in January, 1933, *and asked him to support a protest in which scientists would withdraw from all teaching and research. In later years (1963) she recalled their last meeting:*

"I hoped that this general strike of the intellect would tear from the eyes of millions half-blinded the veil behind which the Nazis concealed their dangerous abyss toward which they were leading Germany. I left Planck with the dreadful knowledge that there was no way to stop the coming downfall of German Science, and no remedy against the disgraceful readiness of so many to sell out teaching and research. Planck himself felt that what was to come, must come. After a long silence, he went to his grand piano and played a Bach chorale, then he offered me his hand, and I left".

In fact, Planck, in a way, cooperated with the Nazi regime: he uttered "Heil Hitler" and raised his arm in the Nazi salute whenever required of him. He even signed his letters to the minister of education with a "Heil Hitler". In his lectures and seminars he refrained from mentioning Einstein's name[982,983]

Planck's personal situation was so prestigious that he could have spoken against some of the excesses of the regime without fear of reprisals, but he chose to remain silent.

Years after the Second World War Einstein told a friend who was going to visit Germany: "Give my regards to Laue"; "And Planck?", the friend asked. Einstein shook his head sadly.

There is no known instance in which a professor of physics or chemistry without any Jewish family ties ever made an open protest against Nazi activities. During 1933 *and* 1934, *the scientific establishment, led by Max Planck and Walther Nernst, washed its hands of the growing terror and concentrated on defending its own special privileges.*

---

[982] In contradistinction, **Laue** was teaching relativity theory in his seminars, always assuring his students that it had originally written in Hebrew!

[983] Yet, the Nazis reciprocated in their own satanic way: On July 23, 1944, three days after the failure of the plot to assassinate Hitler, Planck's son Erwin was arrested on charges of friendship with some of the conspirators. He was then executed on January 23, 1945.

On the 25^{th} *anniversary of Kaiser Wilhelm Gesellschaft, in* 1936*, Planck was able to send a telegram to Hitler thanking him for his "benevolent protection of German science".*

The only notable German scientist who was conspicuous in his disapproval of the Nazis was **Max von Laue***, and even his actions were taken within the physics establishment and not in open criticism of the regime. Laue tried without success to persuade Heisenberg to help resist the worst Nazi excesses.*

This unbroken record of collaboration had its hues and shades: Many were merely opportunists who welcomed the chance to advance their careers by taking the positions of dismissed Jews, while the more eminent were either mildly anti-Nazi like Planck and Hahn, or moderately pro-Nazi like Heisenberg.

During the war (1939–1945) the Nazis have systematically and scientifically exterminated in Poland 6×10^6 *Jews from all over Europe. Among them were many thousands of talented potential scientists, most of which vanished anonymously into oblivion. The ashes of the Auschwitz ovens must have been permeated with the remnants of the brains of future geniuses*[984].

Unpardonable were also the crimes of omission*: The allies and most of the democratic world did very little to offer refuge and save those who could be saved; thus, the allies refused to bomb the gas chambers at Auschwitz and the railroads leading to it during the war.*[985] *During the years between 1933 and*

984 *Example*: Ela Chaim Cunzer (pronounced *Tsunzer*) was born on June 6, 1914 in Lubcz, a small town near Wilno (present day Vilnius, capital of Lithuania). During 1932–1937 he studied for his master degree in mathematics under Antoni Zygmund (1900–1992) at the Stefan Batory University, Wilno, Poland. His master's thesis was *On convex and subharmonic functions* (1937).

After the Nazi occupation of Wilno (June 1941), many Jews were murdered in Ponar, peaceful woods outside Wilno. Cunzer, then working on his Ph.D. thesis, was herded, with others, into the Wilno ghetto. There, in the face of day-to-day treat of death by starvation, disease and violence, he continued in unimaginably crowded and squalid quarters to work on his doctoral thesis. When asked by his cousin whether studying mathematics under such horrifying conditions did not make him feel crazy, he replied: "I would go insane if I did not do it".

Cunzer was deported from the Wilno ghetto to a concentration camp where he perished during the winter of 1943–1944.

His thesis was found intact in 1993 in the archives of the Vilnius University.

985 The American President **Franklin Delano Roosevelt** (1882–1945) and the British Premier **Winston S. Churchill** (1874–1965) refused to do it, despite the fact that Allied bombers were regularly dropping bombs in military targets in the vicinity of the death camps. It is incomprehensible how such an enormous

1948, of all the nations in the Western world, Canada had the worst record in providing sanctuary to European Jewry. In fact, Canada was hermetically closed to the Jews of Europe. After 1945, however, Canada opened its gates to... Nazi war criminals (!) who settled there by the thousands.

It is a story summed up best in the words of a Canadian official who when asked how many Jews would be allowed into Canada after the war, replied: "None is too many"[986]*. Had Canada been admitting European Jews, her cultural record could have looked better. But it is a matter of record that no Canadian won the Nobel prize for Physics, Economics, Chemistry or Literature during the entire 20th century until 1971, and very few afterwards.*

The behavior of the 'neutral' countries in Western Europe did not fare better: they were willing to accept blood money for economic advantages. This was particularly true of Switzerland[987]*.*

---

moral crime could have been perpetrated by Christian men deeply versed in the ancient Biblical tenet: "*Thou shalt not stand against the blood of thy neighbor: I am the Lord.*" (Leviticus **19**, 16).

Ironically, Roosevelt's mother, **Sara Delano** (1855–1941) was of Jewish origin (de-Leone) and his ancestors (who arrived from Holland in 1649) were also Jewish (Rosenfeld).

986 *"NONE IS TOO MANY": Canada and the Jews of Europe 1933–1948*, by Irving Abella and Harold Troper, Lester and Orpen Dennys, Publishers Toronto, 1983, 285 pp.

From 1933 to 1945, the United Kingdom opened its doors only to 70,000, and allowed another 125,000 into British-administered Palestine. Argentina took 50,000, Brazil 27,000 and Australia 15,000, The United States took only 200,000 Jews, including the select of European intellectual, cultural and scientific life.

987 The majority of Americans, when referring to Switzerland, think of exquisite chocolates, fine timepieces and visions of Heidi chasing goats across alpine meadows. Nonetheless, Switzerland was a much different nation during the 1940's despite that idyllic view. While the legend of the fierce Swiss neutrality lives on, it is more of myth considering Swiss policy during WWII was balanced heavily in favor of the Nazis. Much of Switzerland's complicity with the Nazis has only recently (1997) come to the forefront from the efforts of President's **Clinton** action regarding the return of the gold of the holocaust victims, allegedly held in the cellars of the Union Bank of Switzerland.

In Aug 1938, The Federal Council of Switzerland petitioned the Nazi government in Berlin to affix a "J" stamp on all passports for Jews in order to make it easier for their border guards to turn away Jews. Over 30,000 Jewish refugees were thus turned away. In August 1942, the Federal Council passed an additional law to seal the border to Jewish refugees. At the same time Switzerland made fortunes in dealing with the Nazis: Swiss manufacturers provided the

A fact that transcends all others is that the Jews of Europe were not so much trapped in a whirlwind of systematic mass murder as they were abandoned to it. The Nazis planned and executed the Holocaust, but it was made possible by an indifference to the suffering of the victims which sometimes bordered on contempt. The Nazis read rejection of the Jews by the democracies and the Catholic Church[988] *as tacit approval of their policies. If no one wanted them, then the Nazis felt free to offer their own solution. The Holocaust followed.*

B. The military conflict*: Sept. 1, 1939–Sept. 2, 1945*

More than 50 countries, representing the majority of world population took part in the war, which caused previously unheard of human misery. It killed more persons, cost more money, damaged more property, affected more people than any other war in history. It heralded the atomic age and brought about

---

Nazis with ball-bearings, timers, locomotives, arms, ammunition, aluminum, electric power and other manufactured goods used in the production of war equipment. Credit Suisse and Union Bank supplied the Nazis with foreign currency. In return the Nazis deposited in Swiss Banks large amounts of looted gold, gems and art objects.

988 Neither the Vatican nor its German prelates even condemned the foul principles and practices of the Nazi Government. On the contrary, both Pius XI and Pius XII helped Hitler to attain power and made repeated and increasing efforts to contact an alliance with him. In fact, Pius XII was the ideal Pope for Hitler's unspeakable plan. In his book: '*Hitler's Pope*' (Viking, 1999), **John Cornwell** (a practicing Catholic) asserted that Eugenio Pacelli, alias Pope Pius XII (1876–1958), the Pope during World War II, brought lasting shame on the Catholic Church by failing to denounce the *Final Solution*. According to Cornwell, Pacelli was "a ruthless cynic and a secret anti-semite who was more interested in the Vatican's stockholdings, than the fate of the Jews." Cornwell charges that the pope was so intent on signing the Reich Concordant that he facilitated Hitler's rise to power, suppressed the Catholic Center Party in Germany, gulled Catholic resistance to Nazism, refused to support the Allies against Hitler, kept silent when by speaking out he could have saved European Jews, allowed Nazis to send Roman Jews to concentration camps and supported the Nazi puppet regime in Croatia.

Similar accusations were made by **Rolf Hochhuth**'s drama 'Der Stellvertreter' (*The Deputy*, 1963).

sweeping changes in warfare and geopolitics, as well as science, technology and their relation to society.

The cost of the war and its damages totaled 1600 *billion dollars. Ca.* 75 *million servicemen fought on either side, of which* 16 *million were killed*[989], 10 *million were wounded and* 3 *million were missing. In addition, about* 20 *million civilians were killed*[990].

Scientific inventions and discoveries helped shorten the war. Among them: radar[991]*, guided missiles, jet engines, early computers, and the atomic bomb.*

Germany surrendered on May 7, 1945. *It took two atom bombs (Hiroshima, Aug.* 6, 1945*; Nagasaki, Aug. 9, 1945) to bring about Japan's surrender on Sept. 2, 1945.*

C. German Secret Weapons

Between 1936 and 1944, Germans mere achieving a quite revolutionary level of design and development in aeronautical science. Although both Britain and the United States achieved great success during pre-war and war years in designing and developing fighters and bombers of an entirely conventional type (the Spitfire, Flying Fortress, Lancaster, Mosquito and P-51 Mustang), equal or superior of their German equivalents — Germans built and flew the first practical helicopter (the Focke-Achgelis FW-61), the first turbo-jet aircraft (the Heinkel He 179), the first cruise missile (the FZG-76 or V-1) and the first extra-atmospheric rocket (the A-4 or V-2).

It was an astonishing achievement, largely conducted in complete secrecy. Only the small size of Germany's industrial base, compared to that of the United States, prevented it from dominating the skies during WWII. Of all four achievements: helicopter, jet aircraft, cruise missile, rocket, the development of the V-2 was by far the most impressive.

---

[989] Weather vicissitudes also played an important role in WWII: In 1941, a million German soldiers invading Russia succumbed to the winter, thus changing the course of the war. On Dec 13, 1944, the U.S. Pacific 3rd fleet under Admiral Halsey lost 3 destroyers with 7 more damaged, 100 aircraft and 800 men during a typhoon — one of the worst losses of the U.S. Pacific fleet during the war.

[990] Russia claimed to have lost 27 million of its citizens. Of these 300,000 soldiers were killed during the battle of Berlin.

[991] British historians maintain that "The atomic bomb ended the war but radar won it." This reflects the opinion that radar decided the 1940–1941 'Battle of Britain'.

Honors in the V-weapons campaign, if that word can be used about a method of making war on civilians, go to the Germans. Both the V-1, the first cruise missile, and the V-2, the direct technical ancestor of all extra-atmospheric missiles and of the space rockets, were far in advance of any aeronautical weapon produced by their enemies in 1939–45. ***Wernher von Braun****, who was to become an American citizen and to be celebrated as "the father of the space programme," was a scientific genius. The men who produced the V-1 were aeronautical technicians of the first class. Had Hitler had the vision to devote a proportion of Germany's scientific effort similar to that given to other weapon programmes to nuclear weapons, it is possible that, with the V-weapons, he could have won the war.*

Let us go in some more technical detail into the V-weapons: up to 1940, the Germans made good progress in the fields of aerial radio navigation, radar, tank technology and underwater warfare. These developments were manifested in the following weapon-systems, graded in ascending order of importance:

- *The anti-ship glider bomb (the HS 293)*
- *The acoustic torpedo ("Zaunkönig")*
- *The rocket-propelled shell (V-2, father of the ballistic missile; developed by the German Army)*
- *The Flying bomb (FZG-76 or V-1; father of the modern cruise missile, known as Flakzielgerät; developed by the German Airforce)*

The V-1 had the shape of cylinder, pointed at the nose, containing a ton of high explosives and was detonated by an impact fuse. Two short wings were attached at the point of launch. At the rear, mounted above the tail assembly, was the tube for a pulse-jet, fueled by low-grade petrol fed from an on-board tank. A shutter system caused the injected fuel to burn in regular bursts, giving the missile a speed over $640\ \frac{\text{km}}{\text{hr}}$, *its characteristic drone and a range of* $240-320$ km. *A single cut-out device shut off the fuel at a selected point, leaving it to dive vertically to earth.*

It was either launched from a mother aircraft or from a ramp. It was reliable and cheap, costing about 150 sterlings in 1944 values.

Had it been given priority, and been mass-produced in large numbers during 1943, it would have caused terrible damage to London and other southern British cities; it might have disrupted shipping in British southern ports as to have set back the June 1944 invasion.

But its production schedule (16,000 units during Jan-Sept. 1944) was not met because the V-2 programme diverted most of the secret weapons efforts.

The V-2 was expensive (12,000 sterling in 1944 values), complex (65,000 separate modifications had to be carried out before reliable performance was achieved), too difficult to mass-produce, and delivered too small a warhead to achieve decisive results. Its development was plagued by guidance system failures, disintegration of rocket body and explosion of the fuel.

However, it needed no elaborate launching system, it achieved stability without rotation, it had on board an autonomous guidance system, it was liquid-fueled and was single-stage — a truly revolutionary weapon.

D. The Breaking of the German and Japanese Codes

* * *

"Amid the torrent of violent events one anxiety reigned supreme. Battles might be won or lost, enterprises might succeed or miscarry, territories might be gained or quited, but dominating all our power to carry on war, or even keep ourselves alive, lay our mastery of the ocean routes and the free approach and entry to our ports."

Winston Churchill

* * *

Two words describe the German WWII fighting machine successes: organization, and communication. Their lightning "blitzkrieg," which allowed them to roll over Europe almost unopposed, was a well-coordinated operation employing panzers (tanks) and Stukas (dive bombers). At sea, their efforts were aimed at cutting England's supply line from North America by well-directed submarine "wolf pack" attacks on convoys. For communications, the Germans relied almost entirely on messages sent by radio. These messages could be heard, of course, by anyone equipped with a receiver.

To ensure that the enemy would not intercept vital information, they used an electro-mechanical device called Enigma to encode the data. They believed that even if the enemy were to capture a machine, it would be useless unless both sender and receiver were also in possession of the same "key" which described how the message was encoded.

The Germans used different radio frequencies and keys for messages sent to their various units. This ensured that messages meant for the Luftwaffe (Air Force) were not readable by the Kriegsmarine (Navy). By assigning different keys to different units, communication could be directed to the appropriate unit. Not only would there be no point in a submarine decoding a message meant for a panzer unit, but some ultra-secret messages (for example to the SS) were confidential.

Scherbius' *Enigma, in a modified and improved form, was later used widely throughout the German armed forces as the standard method of encrypting messages prior to radio transmission.*

The British ULTRA and the American MAGIC are names applied to Allied Intelligence obtained from cryptoanalysis. It played a decisive role in many of the major battles in the European, Mediterranean, Atlantic and Pacific theaters. Most of ULTRA was derived from German traffic, after the Poles (1933) and the British (1940) have broken the Enigma Code. Likewise, most of MAGIC came after American cryptoanalysts breached the Japanese 'RED' and 'PURPLE' codes in 1940.

Had the Enigma Code not been broken, the Battle of Britain and the Battle of the Atlantic might have been lost, and England forced to capitulate[992].

---

992 Prior to the outbreak of hostilities, England had established a balance of trade with the Western hemisphere. Manufactured goods were traded for raw materials such as oil, iron and grain. With the outbreak of war, this balance shifted. Imports increased while exports decreased as manufacture moved to the production of weapons. This excess of imports over exports was paid for by transferring England's gold reserves to the West. But those reserves, not unlimited, were rapidly becoming exhausted. German submarines were taking a fearful toll of merchant shipping. Prime Minister Winston Churchill realized that England's only salvation was to involve the United States in the conflict. Franklin D. Roosevelt, President of the United States, was sympathetic to the British cause, but his hands were tied by the complexities of American politics. It was a delicate situation — how could America supply vital war materiel to Great Britain and, at the same time, maintain its neutrality?

Roosevelt knew that America's involvement in the global conflict was inevitable, but the country was in no mood for another war. Furthermore, there was no guarantee that England would not be defeated. Roosevelt not only had to face an isolationist Congress, but worried that he would not be elected to a third term, realizing that switching national leaders on the eve of war would be most unwise.

The Irish Free State (Republic of Ireland, or Eire) had been established in 1921, leaving Northern Ireland still closely tied to Great Britain. As part of the settlement, some naval bases in the Irish Republic were occupied by the British. At

The Americans would have been denied a staging ground for the invasion of Europe. The War might have been dragged on for another two years, with many more millions of lives lost. Far worse, given this respite, Hitler might have developed the atomic bomb, and, most unthinkably, mated it to a 3-stage intercontinental ballistic missile capable of crossing the Atlantic.

So, already by 1940, the Allies were reading their enemy's mail on a regular basis and by the end of the War, some 10,000 people with sophisticated computers were decoding Axis messages, which they never could without the pioneering work of the master-codebreakers ***Marian Rejewski*** *(1906–1980, Poland),* ***Alan Turing*** *(1912–1954, UK) and* ***William F. Friedman*** *(1891–1969, USA).*

Cryptology, the science of ciphers, has applied since the very beginning some mathematical methods, mainly the elements of probability theory and statistics.

---

the start of World War II, the Irish Republic flatly refused to become involved unless the whole island was united under their rule. The British declined, and relinquished their bases. However, they still maintained facilities in Northern Ireland, which guarded the vital Atlantic approaches. (The Republic of Ireland managed to stay neutral throughout World War II.)

In view of this, it was not surprising that Irish-Americans resisted the United States siding with the British. Irishman Joseph Kennedy, America Ambassador to Great Britain, was convinced that England could not hold out much longer. Some industrialists were looking forward to lucrative sales to a Nazi dominated Europe. Other Americans holding anti-British sentiments were German-Americans and American Communists (in view of Germany's non-aggression pact with Russia). Irishman John L. Lewis of the powerful United Mine Workers Union, controlled 5 million anti-Roosevelt votes. Besides, if England's fall was a foregone conclusion, why send military aid that would only fall into German hands?

Finally the U.S. arms embargo was modified to allow a "Cash and Carry" policy, declaring certain arms "surplus," which Britain could purchase for cash. There were other ways to get around the arms embargo; in September, 1940, fifty American four-stacker destroyers were traded for the U.S. use of British bases.

As British supplies of U.S. dollars and gold reserves were rapidly depleted, technology was traded for credit. The magnetron, an essential radar component, had been invented by the British, but was traded to the U.S. for arms.

Nov. 5, 1940, Roosevelt was elected to a third term, the first ever for a U.S. President, his hands now free to send vitally needed aid to Great Britain. On Jan. 10, 1941, the "Lend Lease" program was instituted. By War's end 30 billion dollars had been lent to Great Britain.

Mechanical and electromechanical ciphering devices, introduced to practice in the 1920s, broadened considerably the field of applications of mathematics in cryptology. This is particularly true for the theory of permutations (substitutions), developed in the second half of the 19^{th} *century. Its application by Polish cryptologists enabled, during 1932–1933, to break the German Enigma cipher, which subsequently exerted a considerable influence on the course of WWII (1939–1945).*

In the period between the World Wars, all the major powers and some of the minor ones were routinely decoding each other's messages. The Polish Cipher Bureau was among the best, and in 1932 embarked on a determined mission to break Enigma.

They were assisted by documents passed to them by the French stolen by Hans-Thilo Schmidt, an avaricious German cipher clerk with the chilling codename ASCHE (Ashes). Schmidt was arrested, interrogated and shot for his treachery in 1943.

At the Cipher Bureau, three university mathematics students, ***Marian Rejewski*** *(1906–1980),* ***Henryk Zygalski*** *(1906–1978)* and ***Jerzy W. Rozycki*** *(1909–1942), succeeded in breaking the Enigma in 1933. In one of the greatest-ever feats of cryptoanalysis, Rejewski deduced the internal wiring of the Enigma's rotors and Umkehrwalze. Zygalski invented a cryptanalytical method using perforated sheets which exploited the German procedural error of repeating the encipherment of the message-setting. Rózycki devised the clock method which was sometimes able to determine which of the Enigma's rotors was in the fast position. The Poles invented two rotary electro-mechanical machines, the cyclometer and the bomba, to assist in their work.*

Prior of the invasion of Poland by the Nazis, the Poles handed to the British cryptoanalysts the gear they developed for cracking the Enigma messages, and during the autumn of 1939, the scientists and mathematicians at Bletchley learned the intricacies of the Enigma cipher and rapidly mastered the Polish techniques. The Bletchley group was a bizarre combination of mathematicians, scientists, linguists, classicists, chess grandmasters and crossword addicts. A figure, who deserves to be singled out of this group was ***Alan Turing****, who identified Enigma's greatest weakness and ruthlessly exploited it*[993].

993 Turing focused on what would happen if the German military changed their system of exchanging message keys. Bletchley's early successes relied on Rejewski's work, which exploited the fact that Enigma operators encrypted each message key twice (for example, if the message key was YGB, the operator would encipher YGBYGB). This repetition was supposed to ensure that the receiver did

Yet, Bletchley still failed to crack the Naval Enigma and the Allies had no idea of the location of the German U-boats. Between June 1940 and June 1941 the Allies lost an average of 50 ships each month, and there was also a terrible human cost. (50,000 Allied seamen died during the War.) Britain was in danger of losing the Battle of the Atlantic, which would have meant losing the war.

Thus, an alternative strategy for cracking the Naval Enigma depended on stealing keys. Combined with the Rejewski-Turing techniques, the German Naval Code was finally breached.

The most valuable intelligence produced by the British intelligence services during WWII was derived from the interception and decryption of enciphered enemy signals.

By December 1940, with the help of recently acquired IBM card-sorting machines, Friedman's group at the SIS broke the Japanese diplomatic traffic enciphered on the "Purple machine." This machine was designed to achieve the same effect as Enigma. It was less mechanical, having no rotors, but instead a set of telephonic switches, connected to two typewriters. The first was used to input the text, the second to print out the encipherment for transmission. In between, the switches moved the incoming electrical current to achieve alphabetic substitutions.

---

not make a mistake, but it created a chink in the security of Enigma. British cryptanalysts guessed it would not be long before the Germans noticed that the repeated key was compromising the Enigma cipher, at which point the Enigma operators would be told to abandon the repetition, thus confounding Bletchley's current codebreaking techniques. It was Turing's job to find an alternative way to attack Enigma, one that did not rely on a repeated message key.

As the weeks passed, Turing realized that Bletchley was accumulating a vast library of decrypted messages, and he noticed that many of them conformed to a rigid structure. By studying old decrypted messages, he believed he could sometimes predict part of the contents of an undeciphered message, based on when it was sent and its source. For example, experience showed that the Germans sent a regular enciphered weather report shortly after 6 a.m. each day. So, an encrypted message intercepted at 6:05 a.m. would be almost certain to contain **wetter**, the German word for "weather." The rigorous protocol used by any military organization meant that such messages were highly regimented in style, so Turing could even be confident about the location of **wetter** within the encrypted message. For example, experience might tell him that the first six letters of a particular ciphertext corresponded to the plaintext letters **wetter**. When a piece of plaintext can be associated with a piece of ciphertext, this combination is known as a *crib*.

E. The Manhattan project *(1942–1945)*

The magnitude of the potential technical revolution introduced by the discovery of nuclear fission, (especially its potentialities as a weapon in the face of the imminence of WWII), drove ***Eugene Paul Wigner*** *(1902–1995) and* ***Leo Szilard*** *(1898–1964, U.S.A.) to seek the help of* ***Albert Einstein****, then at the Princeton Institute for Advanced Study.*

The events that followed heralded the nuclear age: Einstein agreed to write a letter to U.S. President Franklin D. Roosevelt (1882–1945), in which he suggested that the fission of uranium could be used to produce an atomic bomb (Aug. 2, 1939).

The result of this letter was the establishment of the Manhattan project by the U.S. Government for the production of an atomic bomb. The work started in 1942*. It was the largest single enterprise in the history of science and technology, and also the costliest single weapons project.*

It comprised 37 *installations in* 19 *states and Canada, and employed* 43,000 *people with an overall budget of* 2.2 *billion dollars. A large number of physicists, among them famous scientists who had fled totalitarian Europe, such as* ***Niels Bohr****,* ***Enrico Fermi*** *and* ***Leo Szilard****, joined the project. New cities sprouted in the wake of the project: Oak Ridge, TN, for the gaseous diffusion plant for the separation of* U^{235} *from* U^{238} *(p. 79,000), and Hanford, WA, for the nuclear reactors that transformed* U^{238} *to* Pu^{239} *(p. 60,000). The fissionable material was shipped to Los Alamos, NM where* ***Robert J. Oppenheimer*** *directed the design and assembly of the bomb itself.*

At 3 : 20 *pm on Dec.* 2, 1942*,* ***Fermi*** *and his co-workers at the University of Chicago succeeded in producing the first man-made chain reaction, in an uranium and graphite pile set on the floor of a squash court. As soon as this happened,* ***Arthur Compton*** *sent the cryptic message, "The Italian navigator has landed in the new world", to other American scientists working on nuclear research.*

The bomb was finally tested on July 16, 1945*, at a secret site near Alamogordo, NM. A later War Department news release described the resulting phenomenon in those words: … "the whole country was lighted by a searing light with an intensity that of the midday sun. It was golden, purple, violet, grey, and blue. It lighted every peak, crevasse, and ridge of the nearby mountain range with a clarity and beauty that cannot be described … The explosion was followed by the strong, sustained, awesome roar which warned* *of doomsday, and made us feel that we, puny things, were blasphemous to dare tamper with the forces reserved for the Almighty"*[994].

The Germans underrated the value of science in general during World War II, and drafted many of their young scientists into the armed forces.

They did not appreciate the value of 'operational research', the use of scientific methods for ascertaining the most effective way of deploying limited military resources, a development which brought about a great saving of men and materials on the allied side.

No one in Germany (apart from a few individuals who were ignored) appears to have thought of an atomic bomb composed of an element heavier than uranium, until very near the end of the war. The possibility of developing a bomb composed of the light uranium isotope of mass 235 *was suggested, but the idea was dropped, as the German scientists thought that the separation of the uranium isotopes was impossible. However, the separation was carried out in America, and so too was the preparation of elements heavier than uranium, by means of the uranium pile. The German scientists conceived only of an uranium pile for use as a source of energy. By mid-*1945 *they had not yet constructed such a pile, that is, they had not reached the stage attained in America by the end of* 1942.

In addition, the Nazi nuclear research programme was dissipated between too many research organizations. There was no von Braun, no Peenemmünde and never enough money. The world, nevertheless, had a very narrow escape.

It is remarkable that the atomic bomb was mainly created (both theoretically and experimentally) by Jewish scientists from Europe and the USA, who were motivated by their desire to win the nuclear race with Nazi Germany. Many of them were deeply disappointed when the allies decided to drop it instead on Japan and later use it as a threat in the Cold War against the Soviets.

In the field of radar, the German did not go beyond the generation of radio waves of the order of a meter[995]*. In Britain, the development of the magnetron rendered waves of few centimeters or so in wavelength, affording*

---

[994] Incidentally, **Robert Andrews Millikan** (1868–1953) along with the scientific advisers of Harry S Truman and Winston S. Churchill did not believe that the bomb would explode. Even **Albert Einstein** had his doubts; to a question of a reporter of the Pittsburgh Gazette (Dec 29, 1934) whether the huge amounts of energy corresponding to his formula $(E = mc^2)$ might be released by bombarding an atom, he replied: "It is as unpromising as firing at birds in the dark, in a neighborhood that has few birds." **Leo Szilard** knew better.

[995] The Germans had set up their own radar stations, but employed them in anti-shipping operations. German radar operated on a much shorter wavelength

much greater precession in the location of objects and less interference from extraneous sources.

F. Aftermath

WWII boosted the development of American applied science much more than WWI. Out of WWII came not only atomic energy, computers and radar, but many other advances:

WWII brought an end to the development of the airplane as had been conceived by Orville and Wilbur Wright. War-stimulated propulsion advances in the form of turbojet and rocket engines, brought manned flight *beyond the speed of sound within man's reach. Continued development of rocket-powered airplanes for aerodynamic research led the technology of manned flight to the threshold of space, at altitudes above atmospheric densities which allow sufficient lift to airfoils.*

Because of wartime shortages, American chemists worked to produce various substitute materials, such as plastics and synthetic rubber[996]*. Many of*

($1\frac{1}{2}$ meters to 50 cm) than the British (an unbelievable 10 meters!) and was transmitted from bowl-shaped parabolic antennas. To determine if the British had radar, the *Graf Zeppelin* (a large dirigible) made several flights up the coastline, listening for signals. The British were tracking the largest blip they had ever seen on their radar scopes. The Germans found nothing and concluded there was no British radar, which would cost them dearly once they started their attacks. They had been searching for the wrong wavelength! They had observed British coastal installations sporting some rather old-looking antennas, none of which were bowl-shaped, and decided they couldn't possibly be connected with radar. Besides, they were difficult to attack. This was to be their downfall in the Battle of Britain.

996 The importance of rubber in warfare had been demonstrated by the Germans in World War I. The Germans had been cut off from their foreign rubber supply by the British blockade. Without rubber their trucks ran out of tires while the troops did not have enough boots. In an effort to salvage the situation Germany began experimenting with synthetic rubber. However they could never find a formulation that worked well enough or could be produced in large enough quantities.

In World War II, Japan rapidly captured rubber producing lands in the far east, depriving America of 90% of its natural rubber sources. Suddenly America found itself in the same undesirable position that had confronted the Germans a generation before.

these proved superior to the material they replaced. In metallurgy, when imports of tungsten from China had been cut off during the war, molybdenum was successfully substituted for hardening steel. Because of its enormous contributions, American science seemed finally to have overcome the Government's established reluctance to support basic research. In 1950 *Congress established the National Science Foundation (NSF), the first U.S. Government-supported body created to sponsor basic research. It was small compared to such giants as the Atomic Energy Commission (AEC) and the Defense Development, which together accounted for* 3/4 *of the Research and Devel-*

However, due to their new educational emphasis, American chemical engineers were in a position to make great contributions to the synthetic rubber effort.

The unit operations concept, combined with mass and energy balances and thermodynamics (which had been stressed in the 30's), allowed the rapid design, construction, and operation of synthetic rubber plants. Chemical engineers now had the training to build industries from the ground up. With funds from the government, the chemical industry was able to increase synthetic rubber production over a hundred fold. This synthetic rubber found uses in tires, gaskets, hoses, and boots, all of which contributed to the war effort.

As German tanks and bombers swept across Europe using *Blitzkrieg* tactics, it became evident that World War II would be a highly mechanized conflict. The Allies needed tanks, fighters, and bombers, all supplied with *large quantities of high quality gasoline*. In supplying this fuel the American petroleum industry was stretched to its limit.

However, the development of Catalytic Reforming in 1940 by the Standard Oil Company had given the Allies an advantage. The reforming process produced high octane fuel from lower grades of petroleum (and it also made *Toluene* for TNT). Because of the performance edge given by better fuel, Allied planes could compete with better designed German fighters.

During World War II, American chemical engineers where called on to build and operate many new facilities, some never before conceived. After the war, Germany's massive chemical industry lay in ruins while the Americans were still operating at full production. Nevertheless, the United States Government still feared the German chemical complex. They therefore dismantled Hitler's enormous *I.G.Farben* and out of it, three new companies where created: BASF, Bayer, and Hoechst.

With America firmly leading the world in chemical technology, chemical engineering education began to change. Suddenly, the best way to discover the latest events in chemical technology was not to pick up a German technical journal, but instead to make those discoveries for yourself. Chemical engineering was becoming more focused on science than on engineering tradition.

opment (R&D) budget at that time. The R&D budget covered such elements as weapons developments by the AEC and the DOD.

WWII terminated the dominance of European science, and the center of science moved west to the United States.

In February 1950, Washington learned that for seven crucial years (1942–1949) ***Klaus Fuchs****, a Soviet nuclear spy, passed along secret information to the Soviet Union, on the basis of which they could explode their own fission bomb on Sept 22, 1949.*

Military research after 1930 led to inventions which were incorporated into decoding machines, analog computers and eventually stored-programme digital computers. British work took place at Manchester, Cambridge and the Natural Physical Laboratory. German work was done in Berlin, while in the USA work centered at Harvard and Princeton.

1941–1975 CE **Charles Ehresmann** (1905–1979, France). Mathematician. One of the creators of *differential topology*. Participated in the creation and development of current view of *fiber spaces*, *manifolds*, *foliations* and *jets*. After 1957 he became a leader in *category theory* and structures defined by *atlases*, and *germs of categories*.

Ehresmann was a native of Alsace[997]. He studied at the Ecole Normale Supérere (1924–1927), and the universities of Göttingen (1930–1931), Princeton (1932–1934) and Paris where he was awarded his Ph.D. (1934). From there on, his career was associated with the University of Strasbourg (1939–1955) and the University of Paris, where he held the chair of topology (1955–1975).

---

997 *Alsace*, which was originally French, had come under German rule in 1871 but by 1902 had effective self-government. After 1911 it had its own constitution and progress was made toward Germanization in the region. After 1919 it was returned to France. The Germans invaded Alsace in 1940 and occupied it until 1945, whereupon it returned to the French again.

Science Progress Report No. 19

From the Cross to the Swastika

(1543–1943)

* * *

"First, their synagogues should be set on fire[998]*, and this ought to be done for the honor of God and of Christianity... Secondly, their homes should likewise be broken down and destroyed... we ought to drive the rascally bones out of our system: drive them out of the country for all time... so that you may be free of this insufferable devilish burden – the Jews."*

(Martin Luther, 1543)

* * *

"If the international Jewish financiers in and outside Europe should succeed in plunging the nations once more into a world war, then the result will be the annihilation of the Jewish race in Europe!"

Adolf Hitler, Reichstag speech (Jan. 30, 1939)

* * *

"How evil are these Jews? They are responsible not just for the blood of Jesus and the blood of all his messengers but also for the blood of all the righteous men who were ever murdered...

---

[998] On Nov 10, 1938, on Luther's birthday, Jewish synagogues burned throughout Germany ("**Kristallnacht**"). On that very day, from his Church's pulpit, Bishop Martin Sasse of Thuringia, a leading Protestant Churchman, said:
"*The German people ought to heed these words of the greatest antisemite of his time, the warner of his people against the Jews.*"
In the light of the eliminationist antisemitism that pervaded the Protestant churches, it is no great surprise that even many prominent Church leaders threw their moral weight behind anti-Jewish measures that were still more radical than those of *Kristallnacht*.

These people produce idea after idea for the benefit of the World, but whatever it takes up becomes poisoned, and all that it ever reaps is contempt and hatred because ever and anon the world notices the deception and revenges itself in its own way."

(Martin Niemöller[999], "Here Stand I," 1937)

* * *

"The German State would be justified in taking steps to ward off the calamitous influence of one race on the national community. Wherever they were, Jews caused trouble for the host nation. The Jews had harmed Germany and a solution is necessary that would prevent future harm to Germans. . . . In the future perhaps it would be possible to allow Jews back into Germany because the number of Jews surviving and returning to Germany will not be so large that they could still be regarded as a danger to the German Nation."

(Dietrich Bonhoeffer[1000], "Proposals for a Solution to the Jewish Problem in Germany," 1943)

* * *

[999] **Martin Niemöller** (1892–1984) was a Protestant minister and an opponent of Nazism. As did many who were opponents of Nazism, despite his hatred of the regime, he concurred with the Nazi view of the world in one foundational respect: the Jews were eternally evil. However, by the time of his imprisonment in the Sachsenhausen concentration camp in 1939, he had overcome his antisemitism.

[1000] **Dietrich Bonhoeffer** (1906–1945) was a Protestant theologician who joined the unsuccessful wartime conspiracy to assassinate Hitler (hanged on 9 April 1945).

German 'Faustian' Ideology since Luther

There is a continuity in German ideology over a period of four centuries[1001]. ***Luther****, who had sown the seed of hatred that reached its horrible climax in the Third Reich, gave legitimation to the absolute evil. In 1517 he exempted the 'good Christian' from the need to make good deeds which, a-la-Luther, do not lead to redemption. Man's soul, he preached, is not affected by his deeds – it remains pure whatever he does. (No wonder that the Nazi leaders at the Nuremberg trials insisted that their conscious was clear!).*

Goethe *(1808) adopted a character, created in Luther's time, and rendered full legitimation to its crimes – Faust is never punished; on the contrary, it is received into Heaven!*

Faust, the archetype "everyman" figure, was accepted by all; we all identify with him and his unattainable goal. In that, Goethe gave legitimation to absolute evil; the Devil is the legitimate ruler of the real world. While all other European cultures set limitations to absolute freedom by means of laws, Germans since Luther were taught to create their own destiny, irrespective of an external binding law, bowing only to authority.

Kant *(1781) spoke of absolute freedom; man alone determines the laws and his own destiny. There is no external measure for morality. Consequently, the Germans held any external pragmatic morality in total contempt. Kant also introduced the concept of "People's Will", thus granting a philosophical foundation to the will of the people*[1002].

This tradition continued to flow through the teachings of ***Fichte*** *(1762–1814),* ***Hegel*** *(1770–1831),* **Bauer**[1003] and **Daumer**[1004], *in each of whom the anti-Jewish elements became more pronounced and more virulent, until reaching its climax in Nazi Germany.*

[1001] **Rivka Shechter**: "*Cosmic Enemy*", Jerusalem, 1979.
Hyam Maccoby: "*A Pariah People*", Constable: London, 1966, 236 pp.

[1002] In Nazi Germany, the will of Hitler and his cohorts was the will of the German people. The German War Criminals justify claimed that they carried out orders according to the general will.

[1003] **Bruno Bauer** (1809–1882). Leader of the *Hegelian Left*. In his '*Die Juden Frage*' (1843) radically criticized Judaism in the spirit of Voltaire.

[1004] **Georg Friedrich Daumer** (1800–1875). Vitriolic in his most-influential attacks on Judaism and Jews.

Gloom and Doom – Annihilation of the Jews in Western and Central Europe (1939–1945)

Toward the end of the 19^th century we come face to face for the first time with a unique phenomenon which, more than any other single factor, has influenced the course of European history since 1850. This is the phenomenon of anti-Semitism *which together with nationalism and racism created the barbarism of our age: some 9 million people died in Nazi-controlled concentration camps during 1934–1945; six million of them were Jews. To the earnest Nazi, the Jew was a non-man.*

Before it was institutionalized by the Nazis, antisemitism usually figured not as an active treat but as a dull, throbbing annoyance, casual and anonymous – an ugly possibility, rearing its head when least expected.

Already in 1922 Hitler declared that if he gained power "the annihilation of the Jews will be my first and foremost task". In Mein Kampf *(1925–1926) Hitler openly announced his political program: "might is right", racial supremacy of the* Aryans *and specifically the German people as a 'master race' (Herrenfolk) with a natural right to living space (Lebensraum) at the expense of inferior races as the Slavs, and the total elimination of the Jews.*

From the start the racial policies of the Third Reich were applied with equal ferocity to all Jews: orthodox and the assimilated, bankers and beggars, Nobel laureates, department-store clerks and school children; to the president of the Academy and to the German women's fencing champion (who won two Olympic medals for Germany); to the 100,000 Jewish veterans, many of them wounded or crippled, who had fought for Germany during WWI and had earned their 31,500 iron crosses as bravely as the next man.

At the same time, the Nazis proceeded with the willful destruction of everything that had to do with the Weimar Renaissance. During the early years of the regime, the world was treated to the unusual spectacle of a whole nation deliberately committing cultural suicide. *In the prevailing mindless frenzy to follow – the Führer, the mere possession of intellect became grounds for suspicion, and "Aryans" who persisted in trying to exercise it were denounced in the Nazi press as* weisse Juden *(white Jews).*

Nazism from the first had been essentially a revolt of the Know-Nothings: as a cultural revolution *it aimed at nothing less than the annihilation of the German intelligentsia. It was as if the Nazis could hardly wait to get their hands on the machinery of state so that they could begin smashing works of art and burning books.*

Indeed, within months after taking over the central government of the Reich, they had succeeded in paralyzing the literary and scientific life of the *nation. More than 1100 "non-Aryan" faculty members of universities and technical institutes lost their jobs in the initial purge.*

A traveling exhibition that made the rounds of German schools at the same time displayed Einstein's picture in the form of a "wanted" poster that identified him as an exiled subversive who remained at large and "still unhanged". The refugee intellectuals[1005] *constituted the greatest intellectual migration in history.*

During the World-War that followed (1939–1945), Hitler ruthlessly realized his campaign to 'eliminate' the Jews from German life, which led to the deliberate premeditated and methodical extermination of more than six million Jewish people. The pseudobiological ideology behind this holocaust was not new. Hitler's originality lay in the literal mindedness with which he was prepared to put these ideas into effect.

Part of the Jewish mathematicians in Europe were fortunate to reach safe havens in England, the United States, or South America. Many, however, perished in the Holocaust. Notably, ***Alfred Tauber*** *(1866–1942);* ***Felix Hausdorff*** *(1868–1942);* ***Alexander Rajchman*** *(1890–1940);* ***Juliusz P. Schauder*** *(1899–1943);* ***Stanislaw Saks*** *(1897–1942)* and ***Ela Chaim Cunzer*** *(1914–1942).*

[1005] Among them the non-Jews **Heinrich** and **Thomas Mann**, **Robert Musil**, **Erich Maria Remarque**, **Paul Hindmith**, **Walter Gropius**, **Erwin Schrödinger**, **Paul Klee**, **Bela Bartok**, **Max Beckmann**, **Fritz** and **Adolf Busch** and many others.

Contribution of the Jews to Modern Science and Western Culture

During the 165 years that elapsed from their Emancipation (1778) up to the German Holocaust (1943), Jews played a major role in the service of world culture; They helped extend the frontiers of mathematics, logic, physics, chemistry, biology, medicine, economy, psychology, to name just the leading sciences.

They became viceroys, prime ministers, statesmen, generals, explorers, historians, chess-champions, composers, soloists, conductors, painters, sculptures, educators – an avant-garde intellectuals who helped shape the map of Europe and chart the course of world history. All this in spite of the fact that the European non-Jews had a head-start of more than 300 years, in spite of the fact that the Jews in Central and Western Europe constituted about one percent of the total population, and in spite of adverse conditions of growing anti-semitism.

*Indeed, in spite of all that, 22.5 percent of all Nobel prize winners in the Science in the 20th century are of Jewish origin! Among the ten greatest physicists born during 1879–1918 [**Einstein**, **Born**, **Bohr**, **Schrödinger**, **de-Broglie**, **Pauli**, **Fermi**, **Heisenberg**, **Dirac**, **Feynman**], five* are Jews. *Among the ten greatest mathematicians born during 1777–1887 [**Gauss**, **Abel**, **Jacobi**, **Hamilton**, **Galois**, **Riemann**, **Cantor**, **Hilbert**, **Hardy**, **Ramanujan**], two are Jews.*

However, the contribution of the Jews to modern mathematics was much more decisive: During the activity period 1850–1950, 57 percent of the world's leading mathematicians were Jews, while their minuscule percentage in the combined populations of Europe and North America was less than one percent. All this was taking place at a time when Jewish Scholars were severely discriminated in Western Europe, Russia and the United States.

Not less impressive is their contribution to the nascent of the modern life-sciences: Botanist **Ferdinand Julius Cohn** *(1828–1898) became the founder of bacteriology;* **Paul Ehrlich** *(1854–1915) produced the first practical form of chemotherapy;* **Julius Sachs** *(1832–1897) was the creator of modern plant physiology and experimental botany;* **Leopold Auerbach** *(1828–1897) was a pioneer in the domain of cellular biology and histology.* **Eduard Adolf Strassburger** *(1844–1912) was a pioneer of the emerging science of cell biology;* **Robert Remak** *(1815–1865) pioneered neurology, embryology and histology.* **Julius Cohnheim** *(1839–1884) opened the field of modern pathology.*

Apart from the above-mentioned luminaries, the Jews produced during the post-emancipation era, many distinguished contributions in all active domains *of Western culture. We list below the most prominent among them born between 1778 and 1955:*

1. Mathematics and Logic

James Joseph Sylvester	*1804–1851*
Siegfried Aronhold	*1819–1884*
Leopold Kronecker	*1823–1891*
Gothold Max Eisenstein	*1823–1852*
Antonio Cremona	*1830–1903*
Julius Richard Dedekind	*1831–1916*
Rudolph Lipschitz	*1832–1903*
Lazarus Immanuel Fuchs	*1833–1902*
Julius Weingarten	*1836–1910*
Paul A. Gordan	*1837–1912*
Giulio Ascoli	*1843–1896*
Moritz Pasch	*1843–1930*
Amandus K.H. Schwartz	*1843–1921*
Georges-Henri Halphen	*1844–1889*
Georg Cantor	*1845–1918*
Cesare Arzela	*1847–1912*
Alfred Pringsheim	*1850–1941*
Salvatore Pincherle	*1853–1936*
Arthur M. Schönflies	*1853–1928*
Adolf Hurwitz	*1859–1919*
Vito Volterra	*1860–1940*
Kurt Hensel	*1861–1941*
Corrado Segré	*1863–1924*
Hermann Minkowski	*1864–1909*
Guido Castelnuovo	*1865–1952*
Jacque Solomon Hadamard	*1865–1963*
Alfred Tauber [(H)]	*1866–1942*
Felix Hausdorff [(H)]	*1869–1942*
Emanuel Lasker	*1868–1941*
Gino Fano	*1871–1952*
Boris Galerkin	*1871–1945*
Ernst Steinitz	*1871–1928*
Tullio Levi-Civita	*1873–1941*
Issai Schur	*1875–1941*
Edmund Landau	*1877–1938*
Max Dehn	*1878–1952*

[(H)] H = perished in the Holocaust.

Guido Fubini	*1879–1943*	
Sergei Bernstein	*1880–1968*	
Frigyes Riesz	*1880–1956*	
Lipot Fejer	*1880–1959*	
Otto Toeplitz	*1881–1940*	
Emmy Noether	*1882–1935*	
Harry Bateman	*1882–1946*	
Ernst Hellinger	*1883–1950*	
Richard Von Mises	*1883–1953*

Peter Altenberg	*1859–1919*	
Edmund Husserl	*1859–1938*	
Henri Bergson $^{(H)}$	*1859–1941*	*NP*
Italo Svevo	*1861–1928*	
Arthur Schnitzler	*1862–1931*	
Richard Baer-Hoffmann	*1866–1945*	
Felix Salten	*1869–1945*	
Else Lasker-Schüler	*1869–1945*	
Marcel Proust	*1871–1922*	
Jacob Wassermann	*1873–1934*	

Hugo von Hofmansthal	*1874–1928*	
Robert Walser	*1878–1956*	
Otto Weininger	*1880–1903*	
Emil Ludwig	*1881–1948*	
Stefan Zweig	*1881–1942*	
Franz Kafka	*1883–1924*	
Georges Duhamel	*1884–1966*	
Lion Feuchtwanger	*1884–1958*	
André Mauroit	*1885–1967*	
Franz Rosenzweig	*1886–1929*	
Fernando Pessoa	*1888–1935*	
Shmuel Yosef Agnon	*1888–1970*	*NP*
Ludwig Wittgenstein	*1889–1951*	
Franz Werfel	*1890–1941*	
Boris Pasternak	*1890–1960*	*NP*
Nelly Sachs	*1891–1970*	*NP*
Herbert Marcuse	*1898–1979*	
Karl R. Popper	*1902–1994*	
Eric Hoffer	*1902–1983*	
Isaac Bashevis Singer	*1904–1991*	*NP*
Ayn Rand (Alice Rosenbaum)	*1905–1982*	
Simone Weil	*1905–1943*	
Elias Canetti	*1905–1994*	*NP*
Samuel Beckett	*1906–1989*	*NP*
Eugene Ionesco	*1909–1994*	
Alfred Ayer	*1910–1989*	
Saul Bellow	*1915–2006*	*NP*
Nadine Gordimer	*1923–*	*NP*
Imre Kertész	*1929–*	*NP*
Jacques Derrida	*1930–*	*NP*
Joseph Brodsky	*1940–1996*	*NP*

6. Psychology, Sociology, Anthropology

Joseph Popper-Lynkeus	*1838–1921*
Sigmund Freud	*1856–1939*
Emile Durkheim	*1857–1917*
Georg Simmel	*1858–1918*
Franz Boas	*1858–1942*
Alfred Adler	*1870–1937*
Max Wertheimer	*1880–1943*
Otto Selz	*1881–1943*

Edward Sapir	*188?–1939*
Erich Fromm	*1900–1980*
Bruno Bettelheim	*1903–1969*
Theodor Adorno	*1903–1969*
Viktor Frankl	*1905–1997*
Claude Levi-Strauss	*1908–*
Robert King Merton	*1910–2003*

7. World Chess Champions

Wilhelm Steinitz	*1836–1900*	*(1886–1894)*
Emanuel Lasker	*1868–1941*	*(1894–1921)*
Mikhail Botvinnik	*1911–1995*	*(1948–1957; 1958–1960; 1961–1963)*
Vasily Smyslov	*1921–*	*(1957–1958)*
Mikhail Tal	*1936–1992*	*(1960–1961)*
Boris Spassky	*1937–*	*(1969–1972)*
Robert Fisher	*1943–*	*(1972–1975)*
Garry Kasparov	*1963–*	*(1985–2000)*
Vladimir Kramnik	*1975–*	*(2000–)*

8. Prime Ministers (1868–1991)

Benjamin Disraeli	*(1868–1880)*	*1804–1881*	*England*
Julius Vogel	*(1873–1876)*	*1835–1899*	*New Zealand*
Luigi Luzzatti	*(1910–1911)*	*1841–1927*	*Italy*
Sydney Sonnino	*(1906–1910)*	*1847–1922*	*Italy*
Kurt Eisner	*(1918–1919)*	*1867–1919*	*Bavaria*
Leon Blum	*(1936–1938; 1946–1947)*	*1872–1950*	*France*
Bela Kun	*(1919)*	*1886–1937*	*Hungary*
Matyas Rakosi	*(1952–1953)*	*1892–1971*	*Hungary*
René Mayer	*(1953)*	*1895–1972*	*France*
Pierre Mendes-France	*(1954–1955)*	*1907–1982*	*France*
Roy Welensky	*(1958–1963)*	*1907–1991*	*Rhodesia*
Bruno Kreisky	*(1970–1988)*	*1911–1990*	*Austria*
Michel Debre	*(1959–1962)*	*1912–1996*	*France*
Joshua Hassan	*(1964–1987)*	*1915–1997*	*Gibraltar*
Petre Roman	*(1889–1991)*	*1946–*	*Romania*
Laurent Fabius	*(1984–1986)*	*1946–*	*France*

9. Explorers

Herman Vambery	*1832–1913*
Emin Pasha	*1840–1892*
Marc Aurel Stein	*1862–1943*
Sven Hedin	*1865–1952*

10. Painters

Camille Pissarro	*1830–1903*
Lionel Feininger	*1871–1956*
Franz Marc	*1880–1916*
Amadeo Modigliani	*1884–1920*
Jules Pascin	*1885–1930*
Marc Chagall	*1887–1985*
Man Ray (Emmanuel Radnitzky)	*1890–1976*
Moise Kisling	*1891–1953*

The Social and Political Context of Science (1925–1950) – ***or, the road from exceptional prominence to prominent exception***

The 1944 Nobel Prize for chemistry went to the German Otto Hahn for "his discoveries in atomic fission."

The 1946 Nobel Prize for physiology medicine went to the American Hermann Joseph Muller for "his discovering that X-rays can produce mutations."

The 1950 Nobel Prize for physics went to the Briton Cecil Frank Powell for "his photographic method of studying atomic nuclei."

Yet, ***Lise Meitner***[1006] *(1878–1968), mother of nuclear shell physics, played a crucial role in the experiments that led to the fission discovery in December 1938. But she had to escape secretly to Holland on 13 July 1938. She was not included as a coauthor in Hahn and Strassman's publication (politically that would be impossible in Nazi Germany) — and, as a result, her part in the discovery was not recognized.*

Her exclusion from the fission discovery itself damaged her reputation, casting doubt on the work she had done before. Adding to the damage, Hahn was afraid to admit to his ongoing collaboration with a "non-Aryan" in exile and soon began to claim that Meitner and physics had contributed nothing to the discovery. Those who did not understand the science or the political situation concluded that the chemists had discovered fission while the physicists had merely explained it, and in 1945 the Nobel Prize in chemistry for 1944 was awarded to Hahn alone. With that, Meitner largely lost her place in the history of science.

As president of the newly formed Max-Planck-Gesellschaft, Hahn was the spokesman for the postwar rehabilitation of German science. Himself a "pure" scientist, a Nobel laureate, and a non-Nazi, Hahn projected an image of science as inherently excellent and untouched by the Nazi regime. Hahn never set the record straight with respect to Meitner, and for decades a chorus of his associates and other scientists, none of them close to the discovery, echoed his contention that Meitner had done nothing for the fission discovery except, perhaps, to impede it. Their stridency suggests a political motivation. A fair examination of the circumstances of the discovery would have called attention to the racial prosecution, political oppression, and moral compromises that permeated the scientific establishment, including Hahn's own institute, and that was just what Hahn and much of his generation were trying to suppress and forget.

Mariette Blau *(1894–1970) did pioneering work in the photographic method of studying particle tracks. She created emulsions with characteristic and development conditions that allowed for observations and measurement of proton tracks. She was the first physicist to show that proton tracks could*

[1006] For further reading, see:

- *Biographical Memoirs of the Fellows of the Royal Society*, London, 1995 (*Charlotte Auerbach*).

be separated from α-particle tracks in emulsions. She was first to use nuclear emulsions to detect neutrons by observing recoil protons. All this she did during 1925–1942, years ahead of Powell. She must have been deeply frustrated that he was awarded the Nobel Prize for a discovery using her method.

She was nominated several times for the Nobel Prize by Erwin Schrödinger, Born and Einstein, but to no avail.

She was a prominent scientist who had the misfortune to live in a hostile environment, a victim of a sick society.

***Charlotte Auerbach** (1899–1994). Founded the science of mutagenesis — the study of gene mutation by chemicals — ahead of Muller. But, the Nobel committee, blinded by political considerations and social discrimination, did not consider this Jewish refugee woman worthy of the prize she deserved.*

1941–1979 CE **Friedrich August von Hayek** (1899–1992, Austria, England). Economist and political philosopher. *A philosopher of freedom.* Made major contributions to scientific methodology, psychology and the history of ideas. Largely concerned with the problem of individual values in a world of increasing economic controls. Argued the case for an economic system based on free markets and a political system granting individual freedom within the law. The importance of prices in controlling the functioning of the economy has been a constant theme in his works.

Hayek was born in Vienna, where he was a civil servant and a teacher (1921–1931); Professor of economics at London University (1931–1950). Naturalized British citizen (1938); Professor of social and moral sciences at the University of Chicago (1950–1962) and Professor at the Universities of Freiburg (1962–1968) and Salzburg (1968–1977). Nobel Prize for economics (1974). His major works: *The Pure theory of Capital* (1941); *The Road to Serfdom* (1944); *Law, Legislation and Liberty* (3 vols, London 1973–1979).

Hayek's name is virtually synonymous with the cause of *libertarianism*, the modern successor to the political *liberalism* of the 19th century. Through analysis of the relationships between economic and social factors he sought an answer to the question: "Is social justice feasible within the framework of the capitalistic economy?"

1942 CE, Nov 25 A small article appeared on *page 10* of the *New York Times* reporting the first official news that up to then, two million Jews had been killed in Europe.

1942 CE The beginning of the modern development of *radio astronomy*. During WWII, over the period February 26–28, 1942, British radars were being jammed and it was discovered that storms of radio-emission from the sun were responsible. At the time it was considered a top secret project, but in 1946 it was reported by J.S. Hey in *Nature* (*156*, 47–48). **Bracewell** (1956) succeeded in mapping the regions of emitted microwave radiation from the sun's disc by a tomographic method.

1942 CE **Bengt Edlen** (1906–1993, Sweden). Astrophysicist. Resolved the identification of certain lines in spectra of the solar corona[1007] that had misled scientists for the previous 70 years.

During the eclipse of 1869, astronomers recorded unexpected spectral lines in the sun's corona that they ascribed to the presence of a new element which they called 'coronium'. Similar lines were later discovered to originate nearer the earth; these were attributed to 'geocoronium'.

In the early 1940s, Edlen showed that, if iron atoms are deprived of many of their electrons, they can produce spectral lines like those of 'coronium'. Similarly ionized atoms of nickel, calcium, and argon produced even more lines. It was determined that such high stages of ionization would require temperatures of about 1,000,000 °C and when, in the 1950s, it was verified that such high temperatures did indeed exist in the solar corona, it became accepted that 'coronium' did not exist.

The lines thought to be caused by 'geocoronium' were found to be produced by atomic nitrogen emitting radiation in the earth's upper atmosphere.

Edlen was born in Gusum in Ostergotland, south-eastern Sweden. He was educated at Uppsala University. In 1944 he became Professor of Physics at Lund University, a post which he held until 1973.

[1007] During a total eclipse of the sun, when for a few minutes the moon completely covers the sun's face, a glow appears around the darkened sun – the solar corona, the sun's outermost atmosphere.

Structures visible in the corona at such times suggest that they are shaped by magnetic fields, and therefore that the corona consists of plasma. For instance, short "plumes" rising from the polar regions of the sun look very much like field lines coming out of the end of a bar magnet, and they therefore suggest that the sun, in addition to the intense fields of sunspots, also has a global magnetic field like the earth's.

Structures observed in the corona above sunspots often have horseshoe-shaped outlines, again suggesting that they follow magnetic field lines. From the tops of such "arches" long streamers may extend, to distances of the sun's diameter or even more, looking like pulled taffy, as if some process was pulling material away from the tops of the arches into space.

The most remarkable aspect of the corona is its high temperature. Much of that is sunlight scattered by coronal dust, but some light is also produced by the corona itself, in narrowly defined colors ("spectral lines") characteristic of its emitting atoms. In the 19^{th} century, some of the spectral lines of sunlight did not match the lines of any substance on Earth, and it was proposed that they came from a new unknown chemical element, named *helium* (from the Greek *helios* = sun). Later, in 1895, **Norman Ramsey** actually discovered helium on earth.

The source of the corona's heat remains a puzzle. It is almost certain that its energy comes from the sun's internal furnace, which also supplies the rest of the sun's heat. However, as a rule, temperatures are expected to drop the further one gets from the furnace, whereas the million-degree corona lies *outside* the surface layer where sunlight originates, whose temperature is less that 6000 C.

The space station *Sky lab* (1973–1974) observed soft X-rays emitted by the corona. The corona in such pictures appears quite uneven. It is brightest near sunspots, whose arched field lines apparently hamper the outflow of solar wind which carries away energy and helps cool the corona. It is darker in "coronal holes" in between, where field lines apparently extend out to distant space, making it easier for the solar wind to escape.

1942 CE **William Edward Hanford** (1908–1996, USA) and **Donald Fletcher Holmes** (1910–1980, USA). Chemists. Invented a process for making and modifying *polymeric products*. This method is today the basis for manufacture of all *polyurethanes*.

Flexible polyurethane foam is used as an upholstery material, and the rigid foam is commonly used as heat-insulating material in homes and refrigerators. Polyurethane is also used in life-saving *artificial hearts*, as safety padding in modern automobiles, and in carpeting.

Hanford was born in Bristol, Pennsylvania and received his B.S. from the Philadelphia College of Pharmacy (1930). Holmes received his B.S. in Organic Chemistry from Amherst College (1931). Both received their Ph.D. degrees from the University of Illinois and teamed up at the Dupont company.

1942–1952 CE **Norman Earl Steenrod** (1910–1971, USA). Mathematician. One of the leading topologists of the 20th century. Codified and solidified the theories of *homology* and *cohomology* in the framework of algebraic topology and played a crucial role in the development of the theory of *fiber bundles*. Named after him are: '*Steenrod algebra*', '*Steenrod volumes*'.

Steenrod was born in Dayton, Ohio and was educated at the Universities of Michigan (1932), Harvard (1934) and Princeton (Ph.D., 1936). He held positions at the University of Chicago (1939–1942), Michigan (1942–1947) and Princeton (1947–1971). His books: "*Topology of Fiber Bundles*" (1951), "*Foundations of Algebraic Topology*" (1952, together with Samuel Eilenberg).

1942–1969 CE **Salvador Edward Luria** (1912–1991, Italy and USA). Biologist. Pioneer in molecular biology, especially the genetic structure of viruses[1008]. Awarded the Nobel Prize for Physiology or Medicine (jointly with Delbrück and Hershey, 1969) for his discoveries related to the role of DNA in bacterial viruses.

Luria was born in Turin, Italy to a Jewish family. He graduated in medicine at Turin University. He left Fascist Italy (1938), and went to the Radium Institute in Paris to study medical physics, radiation and techniques of working with *bacteriophage*, the bacterial virus. When Italy entered WWII, Luria emigrated to the USA (1940), where he taught at Indiana University. In 1959 he became professor at MIT.

Luria obtained the first good electron photographs of a bacteriophage (1942). He then showed (1945) that the same spontaneous *mutations* occur in bacteriophages and in the bacteria on which the phages prey, suggesting that the genetic material of the phage gets mixed into the genetic material of the bacteria.

1942–1976 CE **Charlotte Auerbach** (1899–1994, Scotland). Geneticist. Founded the science of *mutagenesis* — study of gene mutation by chemicals.

[1008] Viruses that attack bacteria are called *bacteriophages*. This word means: *bacteria eater*. Bacteria, like plants, have tough cell walls. To penetrate these walls, most bacteriophages have a structure that resembles a hypodermic needle and works in a similar manner. This structure consists of a sphere-shaped head that contains *nucleic acid*, and a hollow, rod-shaped tail made of *protein*. When a bacteriophage enters a bacterium, the tail first penetrates the cell wall. Then the nucleic acid in the head moves through the tail and into the cell.

Viruses are such simple organisms that scientists can easily study them to gain more knowledge about life itself. Thus, research on bacteriophages has helped biologists understand *genes*, DNA, and other basic cell structures. In general, studies of the biological properties of bacteriophages contributed greatly to our understanding of the chemical and biological interactions of viruses and living cells.

She was born in Berlin into a learned scientific and artistic Jewish family[1009]. During 1919–1924 she studied biology, chemistry and physics at the Universities of Berlin, Wurtzburg and Freiburg. She fled Nazi Germany (1933) and joined the Institute of Animal Genetics at Edinburgh as a Ph.D. student. In 1942 she discovered (with A.J. Clark and J.M. Robson) that mustard gas (a highly toxic substance that had been used in trench warfare), caused genetic mutation in fruit flies (Drosophila). She was awarded Ph.D. (1935) and D.Sc. (1947) by the University of Edinburgh. Elected FRS (1957) and received the Darwin Medal (1977). Published: *Mutation* (1962), *Mutation Research* (1976).

Her approach was biological rather than chemical in that, while she acknowledged that mutation took place in the chemistry of the gene, she adhered to the idea that it was the biological interaction that gave the process its complexity. She used Drosophila, and later, microorganisms such as Neurospora and yeasts to test the mutagenic properties of other agents (mustard gas had proved too dangerous). From this she pursued several lines of inquiry: the patterns of combinations called mosaics (mutant and non-mutant cells), that increased mutation occurred in delayed or stored genes affected by a mutagen, 'replicating instabilities', i.e., that mosaics produced more mosaics in later generations, and that in 'specificity' — parts of the gene were affected differently by mutagenesis.

In 1947, she published a book of fairy stories titled *Adventures with Rosalind* under the pen-name of Charlotte Austen.

1943 CE **Oswald Theodore Avery** (1877–1955, U.S.A.). Biochemist. Announced the chemical nature of the gene, showing that hereditary characteristic could be induced by pure DNA, without a protein involved. Working at the Rockefeller institute with his colleagues **Colin M. MacLeod** and **Maclyn McCarty**, they were able to show that the gene was nucleic acid — and only nucleic acid. Moreover, they were able to transform one strain of bacteria into another by using a solution of the nucleic acid without any protein at all. They thus proved that the DNA, a hitherto unexplained substance, in the nucleus of living cells, was the very material of the gene, i.e. — that DNA is the hereditary material that carries the genetic information for almost all living organisms.

1943 CE **Willem J. Kolff** (b. 1911, Netherlands and USA). Physician and inventor. Invented the kidney dialysis machine (1943). Headed a team which invented and tested an artificial soft shell mushroom shaped heart.

[1009] She was the grandchild of **Leopold Auerbach** (1828–1897), the neuroanatomist and discoverer of *Auerbach's plexus*, and the daughter of the chemist, **Friedrich Auerbach** (1870–1925).

Kolff was born in the Netherlands and received his M.D. in Leiden (1938) and a Ph.D. degree from the University of Groningen (1946). Since 1967 he has been professor of surgery and head of the Division of Artificial Organs at the School of Medicine of the University of Utah.

1943 CE **Shin-ichiro Tomonaga** (1906–1979, Japan). Physicist. Developed (parallel to **R.P. Feynman** and **J.S. Schwinger**) a renormalizable, covariant quantum electrodynamics (QED), for which he shared with the aforementioned the Nobel prize for physics in 1965. In establishing this theory he had resolved the inconsistencies of the old QED theory of Heinsenberg, Pauli and others, without making any drastic changes and in a manner fully consistent with the special theory of relativity.

Tomonaga was born in Kyoto, Japan. He became professor of physics at Tokyo in 1941. His work, completed in 1943, came to the attention of the West only in 1946, since he was isolated from Western scientists during WWII.

1943–1950 CE **Abraham Wald** (1902–1950, USA). Mathematician. Originated the powerful optimization method of *dynamic programming*[1010], to address an array of questions arising in optimal control theory, game theory, production and scheduling processes.

Developed a new statistical method of *quality control*[1011] known as *sequential analysis* (1947), in response to the demand for more efficient methods of

---

[1010] The extension of *linear programming* to *nonlinear* optimization problems. One class of such problems concerns the passage of people or information rather than commodities – for example, when people move from one part of a network to another at minimal cost — either in time, money, energy, or some other resource (*routing problems* that are reflected in the way airline ticket prices are set nowadays). Optimal control processes, like getting a satellite into orbit with minimal energy, problems with random influences such as investments with risky payoffs, "minimax" methods of game theory — are all within the purview of the theory.

[1011] *Quality control* methods permit us to regulate product quality by testing; A lot of items is sampled according to a scheme guaranteed to reject a good lot with probability α ("*supplier's risk*") and to accept a defective lot with probability β ("*consumer's risk*").

A lot is considered *good* if the parameter that negatively characterizes its quality does not exceed a certain limiting value and *defective* if this parameter has value not smaller than another limiting value. There are different methods of control: *single sampling*, *double sampling* and *sequential analysis*. The sequential Wald analysis for a variable sample size n and a random value of the controlled parameter in the sample, the likelihood coefficient γ, is computed and the control lasts until γ leaves the limits of the interval (B, A) where industrial quality control during WWII. In this connection he also developed the topic of *decision functions*.

Wald was born to a Jewish family in Kolozsvár, Hungary (now Cluj, Romania) and studied at Vienna. After the Nazis occupied Austria (1938) he fled to the USA, the only survivor of his family, who perished in the gas chambers of Auschwitz. Wald and his wife were later both killed in a plane crash in India.

1943–1960 CE **Shiing-Shen Chern** (1911–2004, USA). Mathematician. Made significant contribution to *global differential geometry*.

The now named '*Chern characteristic classes in fiber spaces*' are important not only in pure mathematics but also in mathematical physics.

Introduced the key concepts of *Secondary Invariants*, *Fiber Bundles*, *Sheaves* and *Foliated Leaves*. Gave a new proof to the Gauss-Bonnet formula[1012]. A large share of the credit for transforming differential geometry into a major subject in mathematics belongs to him.

Chern was born in Jiaxing, Zhejiang province, China. Received his D.Sc. from Hamburg University (1936) and studied under **Cartan** in Paris (1936–1937). Worked under **Weyl**, **Veblen** and **Lefschetz** at Princeton, USA (1943–1945). Held the chair of geometry at the University of Chicago (1949–1960) and then went to the University of California, Berkeley (1960–1980).

$B = \frac{\beta}{1-\alpha}$; $A = \frac{1-\beta}{\alpha}$; if $\gamma \leq B$, then the lot is accepted, if $\gamma \geq A$, the lot is rejected, and for $B < \gamma < A$ the test continues.

1012 For a closed orientable surface S of genus g,

$$\text{Integral curvature } = \iint_S K\,dA = 4\pi(1-g),$$

where K is the Gaussian curvature. [E.g. $g = 0$ (sphere), $g = 1$ (torus), $g = 2$ (pretzel).]

The Mathematics of Europe and USA (1850–1950): Fusion of Geometry, Algebra nd Analysis

Moritz Cantor's history of mathematics, which terminates with the end of the eighteenth century, consists of four large volumes averaging almost a thousand pages each.

It has been conservatively estimated that if the history of the mathematics of the nineteenth century should be written with the same detail, it would require at least fourteen more such volumes!

No one has yet hazarded an estimate of the number of such volumes needed for a similar treatment of the history of the mathematics of the twentieth century, which is by far the most active era of all. Little of this additional material could be properly appreciated by the ordinary undergraduate; indeed, an understanding of much of the material would require the deep background of a mathematical expert.

The almost explosive growth of mathematical research in modern times is further illustrated by the fact that prior to 1700 there were only 17 periodicals containing mathematical articles. In the eighteenth century there were 210 such periodicals, in the nineteen century 950 of them, and the number has increased enormously during the first half of the twentieth century.

Furthermore, it was not until the nineteenth century that there appeared journals devoted either primarily or exclusively to mathematics. Very few of the present-day articles can be read by anyone but the specialist.

Table 5.19 lists the leading mathematicians born between 1842 and 1919, 158 in number. The biographies of most them are included in chapters 4 and 5 of our Encyclopedia. The table includes the major contributions, life-span and national affiliation of the individuals.

The ethno-national affiliation of each biography are part and parcel of the person's origin, milieu, background and the grand scheme of the historical evolution of mankind.

In this day and age, where the history of diversity of the human species and its impact on genetics *are the subject of intense research*[1013]*, it is of great interest to weave human history, culture, and language in one grand sweep, and discover the hidden connectivity of scientific creativity and the ethno-cultural background of the individual scientists.*

[1013] e.g. **L.C. Cavalli-Sforza** and **F. Cavalli-Sforza**: "*The Great Human Diasporas*", Addison Wesley, Reading, Mass. USA, 1995; 300 pp.

1943–1962 CE **Benjamin Levich** (1917–1987, Russia and USA). Physicist. Opened the new field of *physicochemical hydrodynamics* which refers to phenomena governed by the interaction of fluid mechanics, heat and mass transfer, and chemical reactions. In particular, he studied *electrochemical kinetics*. An equation describing the current at a *rotating disc electrode*[1014] is named after him.

[1014] During 1945–1960 Levich collaborated with the electrochemist **Alexander Naumovich Frumkin** (1895–1976, Russia). The latter studied the funda-

Levich was born in Kharkov, Russia. He became a pupil of Lev Landau (1937) and worked with him on interfacial phenomena. He emigrated (1979) to the USA, where he established the Institute of Applied Chemical Physics at the New York City College.

1943–1968 CE **Jean-Paul Sartre** (1905–1980, France). Philosopher and political leader. Absorbed and amalgamated the existentialist ideas of the German philosophers **Hegel**, **Marx**, **Nietzsche**, **Husserl**, **Heidegger** and **Jaspers** into a form that fitted the political millieau of post WW2 world. Then, spent much of his literary life attempting to reconcile these existentialist views[1015] about free will with communist principles.

Existentialism tends to focus on the question of human existence – the feeling that there is no purpose at the core of existence. Finding a way to counter this nothingness, by embracing existence, is the fundamental theme of existentialism, and the root of the philosophical name.

Through the wide dissemination of the postwar literary and philosophical output of Sartre and his associates – existentialism became identified with a cultural movement that flourished in Europe during 1945–1970. Among the major philosophers identified as existentialists were Karl Jaspers, Martin Heidegger, **Ortega y Gasset** and **Miguel de Unamuno**. the 19^{th} century philosophers **Soren Kierkegaard** and **Friedrich Nietzsche**, came to be seen as precursers to the movement.

Existentialism was as much a literary phenomenon, and a very diverse coterie of writers and artists linked under the term: **Dostoevsky**[1016], **Ibsen**, **Kafka**[1017], **André Gide**, **Andre Malraux**, **Samuel**, **Albert Camus**,

mental theory of electrode reactions, considering the influence of the structure of the electrode/solution interface on the rate of electron transfer.

1015

- Satre J.-P., *Being and Nothingness (L'Etre at al n'eant)*, 1948
- Satre J.-P., *Existentialist is a Humanism (L'Existentialisme est un Humanisme)*, 1946
- Satre J.-P., *Critique of Dialectical Reason (Critique de la raison dialectique)*, 1960

1016 Kafka created often surreal and alienated characters who struggle with hopelessness and absurdity.

1017 Many of Dostoevsky's novels covered issues pertinent to existential philosophy.

Samuel Beckett, **Knut Hamson**, **Eugene Ionesco**, **Alberto Giacomneti** and **Emil Cioran**.

Sartre himself failed to write a great novel, or remarkable play, but used his novels and plays to transmit his political and social messages.

According to the existential view neither scientific nor moral inquiry can fully capture what it is that makes me *myself*, my ownmost self. Thus, a further set of categories is needed to grasp human existence. These categories are characterized by flight from the iron cage of reason. Thus, existential philosophy cannot be practiced in the disinterested manner of an objective science. Indeed, all themes popularly associated with existentialism – dread, boredom, alienation, the absurd, freedom[1018], commitment, nothingness, and so on – find their philosophical significance in the context of the search for a new categorical framework.

As a culture movement, existentialism belongs to the past. As a philosophical inquiry it has continued to play an important role in contemporary thought[1019], often bringing it into confrontation with more recent movements such as structurism, deconstruction, hermeneutics and feminism.

Sartre was born in Paris. His mother, of Alsatian origin, was the cousin of **Albert Schweitzer**. He graduated from the Ecole Normal Superieur (1929) with a doctorate in philosophy, drafted into the French army (1935) and held by the German as a war prisoner in Nancy and Trier (1940). He was released and given a civilian status (1941) and then settled in Paris and found a position at the Lucée Condorcet, replacing a Jewish teacher who was forbidden to teach by Vichy law.

Sartre's lack of political commitment during the German occupation and his further struggles for liberty was considered by his critiques as an attempt to redeem himself. According to **Camus** Sartre was "a writer who resisted, not a resistor who wrote".

1018 Existentialism generally postulates the absence of a transcendental force (such a God). It means that the individual is entirely free, and, therefore, ultimately responsible. It is up to humans to create an ethos of personal responsibility outside any belief system. Personal articulation of being is the only way to rise above humanity's absurd condition of much suffering and inevitable death. Existentialism is a reaction against traditional philosophies, such as rationalism and empiricism.

1019 To dig deeper, see

- Kaufmann, W., *Existentialism from Dostoevsky to Sartre*, Cleveland Meridian Books, 1968.
- Hayman, R., *Sartre: a life*, Simon and Schuster: New York, 1987.

Until 1944, when Sartre was almost forty, he had to earn his living as a schoolteacher. When the war ended he established a monthly literary and political review, and started writing full-time as well as continuing his political activism.

At that time France was a political quagmire; it was torn, radicalized by war and occupation; the movement of colonial liberation was spreading and the world was soon to split by the Cold War. The time was ripe for a socio–political upheaval in France and history put Sartre in the right place at the right time. He soon found himself famous and existentialism was *the* philosophy to study.

Curiously, as existentialism grew in popularity – to a point of becoming a pop–culture term – Sartre slowly left the philosophy that had brought him to fame and claimed a conversion to Marxism (1953).

As the Cold War developed, Sartre adhered to the Stalinist French Communist Party and became an orthodox Stalinist, ending up as a servant of one of the most oppressive regimes of all time. He accepted, at face value, the claims of the Soviet Union to be a peace–loving, democratic and socially just society. – a philosopher in service of totalitarism.

Jean-Paul Sartre also supported Mao, Castro and Che Guevara. He took prominent role in the struggle against French rule in Algeria and became an ardent supporter of the FLN in the Algerian War.[1020] By the 1970's, Sartre was reduced to being an apologist for tyranny and terror[1021].

The events in Cambodia in the 1970's, in which between $\frac{1}{5}$ and $\frac{1}{3}$ of the nation was starved to death or murdered, were entirely the work of a group of intellectuals who were for the most part pupils and admirers of J–P Sartre.

Paris university students rebelled in 1968, calling for various reforms. Sartre's support of the students caused him problems with both the left and the right in France. The Beat Generation owes a great deal to him.

Sartre political views and activities present, at best, the philosopher's lack of consistency: after making his philosophical debut as an impassioned advocate of individual freedom, denouncing Marxism as deterministic and Communism as undemocratic, he aligned himself with Marxism and relegated Existentialism as being a mere ideology. Marxism, he declared, was the only valid philosophy for our time. But in the seventies he announced that he was no longer a Marxist. Indeed, his Marxism had really shrunk back within the

[1020] He had an Algerian mistress (Arlette Elkayam) who became his adopted daughter (1965).

[1021] He justified the massacre of the Israeli Olympic team by the PLO in Munich (1972) as well as killing of European civilians by FLN in Algeria.

confines of the traditional hatred of the affluent capitalist West. The working–class Marxists still thought about surplus value but French intellectuals were obsessed by culture and found themselves without a proletariat.

1943–1976 CE **Mark Aronovich Naimark** (1909–1978, Russia). Mathematician. Contributed to functional analysis and the theory of group representations. Proved (1943) the Gelfand-Naimark theorem on self-adjoint algebras of operators in Hilbert space and generalized von Neumann's spectral theorem to locally compact Abelian groups. Made a detailed analysis of the infinite-dimensional representation of the *semi-simple Lie groups* and wrote with Gelfand a treatise on irreducible representations of the classical matrix groups (1950). This work formed the basis for later work on representations of semi-simple Lie Groups.

Naimark also contributed to the theory of Banach spaces. He wrote books entitled *Normed Rings* (1956) and *Theory of group representations* (1976).

Naimark was born in Odessa to Jewish parents. He was educated at the Odessa State University (1933) and received his doctorate from the Steklov Mathematical Institute of the USSR Academy of Sciences, Moscow (1941). Appointed professor at the Moscow Physical-Technical Institute (1954).

Life and the Laws of Physics[1022] ***— or, why are we here now? (The Anthropic Principle)***

"Life feeds on negative entropy"[1023].

Erwin Schrödinger, 1943 (1887–1961)

[1023] This statement has a very profound meaning: contrary to popular belief, the essential purpose of eating, drinking and breathing is not merely to provide energy for vital body functions, but also to rid the system of the entropy it cannot avoid producing while being alive.

Since negative entropy may be considered as a measure of order, it is legitimate to say that an organism maintain a steady state by continually extracting order from its surroundings.

* * *

"We exist only in portions of the universe where the energy levels in carbon and oxygen nuclei happen to be correctly placed."

Fred Hoyle, 1965 (1915–2001)

Although the nature of living things has concerned natural philosophers since antiquity, 'life' as a general concept emerged in the early 1800's. Its emergence coincided with the introduction of biology as a new scientific field and with the growing conviction that the essential nature of animals and plants was the same, lying in their organization *rather than in their visible structures.*

18th and 19th century investigators attempted to identify common properties of living beings that distinguished them from inanimate objects.

Scientists divided into two groups: Vitalists *insisted that the phenomena of life cannot be explained adequately without ascribing to living organisms properties neither physical nor chemical. Among them were* ***Francois-Xaviar Bichat*** *(1771–1802),* ***Georges Cuvier*** *(1769–1832) and* ***Justus von Liebig*** *(1803–1873).*

In contrast, mechanists *and* reductionists *believed that the phenomena of life can be potentially explained by ordinary physical and chemical laws and that only physicochemical forces were at work in living organisms.*

Such were e.g. ***Helmholtz*** *(1813–1894) and* ***Karl Ludwig*** *(1816–1895). Others, such as* ***Claude Bernand*** *(1813–1878) and* ***Rudolf Virchow*** *(1821–1902) held intermediate views. Thus Bernard denied that living bodies were distinguished from non-living bodies by their physicochemical properties, however complex these might be. Rather, he held that the distinguishing feature of the living organism was the 'definite idea' directing its development.*

Virchow insisted that the cell was the ultimate locus of life and also disease. Others soon suggested that life might be a property of something less than

---

In the case of human beings and other higher animals it is clear how this process is realized. Food stuffs consisting of highly organized (entropy-poor) organic molecules are taken in by the body, their energy partly utilized, and finally returned to the environment in a highly disorganized, or entropy rich form.

the cell, namely protoplasm [e.g. **T.H. Huxley** *(1868)]. The first physicists to expound influential views of life were* **Niels Bohr** *(1932),* **Max Delbrück** *(1943)* and **Erwin Schrödinger** *(1943).*

In February 1943, *at a bleak moment in the history of mankind, the physicist Schrödinger (then exiled from the Nazi Third Reich) gave a course of lectures at Trinity College, Dublin, Ireland. The lectures were published in a little book with the title What is Life? This book addressed the question: "How can the events in space and time which take place within the spatial boundary of a living organism be accounted for by physics and chemistry"? In short: is life based on the laws of physics? Schrödinger's own conclusion was that from all we know about the structure of living matter, it functions in a manner that cannot be reduced to the ordinary laws of physics. This meant that the laws already discovered in the analysis of matter were not enough in themselves and that new laws had to be found. Schrödinger's own conviction was that living organisms do involve other laws of physics, hitherto unknown. He described heredity in terms of molecular structure, inter-atomic bonds and thermodynamic stability.*

His message was clear — to continue investigation on the structure and function of living matter, biology must change its historical course and cooperate closely with physics and chemistry. Thus, his vision and prophecy opened the floodgates of molecular biology: the quest for these 'new laws' fired the enthusiasm of young physicists and later led (1962) to the breaking of the genetic code by **J.D. Watson**, **F.H. Crick** *and* **M.H.F. Wilkins**.

Consequently, it is now possible to understand something of the mechanism of evolutionary change at the molecular level.

In Darwin's theory, evolution is driven by random mutation and natural selection; mutations occur when genes, which are groups of molecules that can be studied directly, become randomly rearranged within an organism's DNA. Natural selection is the process whereby, in the continual struggle for resources, badly adapted individuals or groups (mutants or not) compete poorly and tend to die out. Thus organisms which are better suited to their environment are more likely to survive and reproduce than their less well-adapted competitors.

Although scientists do not doubt the fact of evolution — the adequacy of the Darwinian mechanism (i.e., random mutation and natural selection) has been questioned.

First, the principle of natural selection is essentially tautological ('Those organisms better suited to survive will survive better'). Also problematic is *the claim that evolutionary change is driven by* random fluctuations[1024]*. Some of the objections raised are:*

- *How can an incredibly complex organism, so harmoniously organized into an integrated functioning unit, perhaps endowed with exceedingly intricate and efficient organs such as eyes and ears, be the product of a series of pure accidents?*
- *How could random events have successfully maintained biological adaptation over millions of years in the face of changing conditions?*
- *How can chance alone be responsible for the emergence of completely new and successful structures, such as nervous system, brain, eye, etc. in response to environmental challenge?*
- *How could life have been started on earth by a series of random chemical reactions when simple minded probabilistic estimates show that* there was not enough time *for random reactions to get life going as fast as the fossil record shows that it did*[1025]*?*

[1024] In spite of the complexity of individual proteins, often containing specific combinations of as many as 300 individual amino acids, there are several proteins that appear in most forms of life in nearly-identical forms. This equivalence is strong evidence for a single source of all life forms.

It is implausible that this similarity arose by chance: There are 20 different types of amino acids used in forming proteins. The probability of *random* duplicating of two identical protein chains, each with 100 amino acids, is one in $20^{100} \sim 10^{130}$.

Since there are of order 10^{18} seconds in the (approximately) 14 billion years that elapsed since the Big Bang, we would need 10^{112} trials each second since the start of time just to reach a condition allowing a single protein to arise by chance with reasonable probability.

With these odds, it is impossible to explain the existence of similar proteins in bacteria and humans as due to mere chance.

[1025] *Metaphor*: Consider the likelihood that a troupe of monkeys, hammering away at typewriters, will eventually reproduce Shakespeare's 18^{th} sonnet, that ends with the lines:

> SO LONG AS MEN CAN BREATH OR EYES CAN SEE,
> SO LONG LIVES THIS, AND THIS GIVES LIFE TO THEE.

There are 488 letters in the sonnet. Neglecting the spacing between the words, the chance of randomly typing the 488 letters to reproduce this one sonnet is one in $26^{488} \sim 10^{690}$. Even with all the monkeys (plus every other animal) on earth typing away on typewriters over a period of time that exceeds that

And how about accidental copying errors during reproduction? The more intricately and delicately a complex system is arranged, the more vulnerable it is to degradation by random changes (even a tiny error in the blueprint of an aircraft or spacecraft might well lead to disaster!)

Thus, one would suppose that random mutations in biology would tend to degrade, rather than enhance, the complex and intricate adaptedness of organisms. Yet, it is still asserted that random 'gene shuffling' is responsible for the emergence of eyes, ears, brains, and all the other marvelous paraphernalia of living things. How can this be?

The above considerations suggest that biological evolution may require additional organizing principles *if the existence of the plethora of complex organisms on earth is to be satisfactorily explained.*

Schrödinger's ideas also impacted the ill-formulated Darwin's principle of evolution by natural selection. During the second half of the 20^{th} century many attempts have been made to prove *evolution by natural selection on the basis of mathematical models and physical laws. Although it has been accomplished in a few idealized cases, these share a common deficiency — scant physical input and lack of control over the range of values of many phenomenological parameters involved in their description.*

---

elapsed since the Big Bang (10^{18} seconds) – still the probability of a sonnet appearing would be vanishingly small.

At one random try per second, with even a simple sentence having only 16 letters, it would take 2 million billion years to exhaust all possible combinations.

This calculation is based on the premise that the monkeys type independently of each other and that typewriters and monkey-groups do not evolve.
Hence the following caveats in the 'typing-monkeys' paradigm:

- Group of monkeys may evolve cooperative strategies.
- Typewriters may themselves evolve and become programmable (*Turing Machine*), thus enabling a monkey to reproduce a whole sensible word (e.g. 'Men') with a *single* key-stroke-like a key of the computer keyboard — having once programmed this key by accident.
- The environment could differentially reward literary outputs of varying quality ('selective pressure'), e.g. one could imagine an editor rewarding a monkey 'best-seller' by copious supplies of bananas or mates.
- Hierarchies could naturally evolve with some monkeys assuming managerial positions. In effect, such monkey-bosses are equivalent to higher order programmers.

Each of these points has its counterpart in molecular biology, where e.g. the sole task of some genes is to supervise complex patterns of activation and deactivation of lower-level genes (and similarly for neurons).

Another approach is based on the assumption that natural selection has led to the optimization of living beings according to various criteria of merit, which one tries to identify based on theoretical and experimental information. Several criteria of optimization have been proposed, such as maximal 'average fitness', maximal efficiency in resource utilization, minimum metabolized energy per unit biomass, etc. Of greater interest are the attempts to characterize fitness in thermodynamic terms. A fundamental tendency of non-equilibrium systems towards stationary states of maximal organization and minimal dissipation constitutes a potentially solid bridge between thermodynamics and Darwin's principle.

This has a direct bearing on the problem of the origin of life, namely: how does non-life beget life. The sort of conditions under which life is believed to have emerged were far from equilibrium and under these circumstances highly non-random behavior is expected. Quite generally, matter and energy in far-from-equilibrium open systems have a propensity to seek out higher and higher levels of organization and complexity. Thus, the primeval soup could have undergone successive leaps of non-random self-organization bifurcations along a very narrow pathway of chemical development. It could perhaps be that there are as yet unknown organizing principles operating in prebiotic chemistry that greatly enhance the formation of complex organic molecules relevant to life.

Is life a rare accident, an irrelevant fluke in a mindless and hostile cosmos?

Stellar lifetimes are a straightforward consequence of the physical laws and constants; biological evolution, on the other hand, is an immensely complex multistage process. There seems no conceivable reason why these times should be closely comparable. In typical cases, even if biological evolution got started on a planet, it might not have proceeded very far before that planet's star died.

Indeed, life as we know it is so special, so complexly organized and so fragile that it can flourish only within the narrowest finely-tuned environmental conditions; The continuation of life on earth and its successful development from the simple forms that we find in 3.3 *billion-year-old fossils to the complex organisms of today — reflect the earth's extraordinarily suitable conditions for life. It is as if the earth were especially made for life's eventual appearance and maintenance*[1026].

[1026] **James E. Lovelock** (1975) has introduced a concept known as '*Gaia* (the Greek earth goddess). Accordingly, planet earth is viewed as a holistic self-regulating system, in which the activities of the biosphere cannot be untangled from the chemical and physical processes that take place in the solid earth, its oceans and its atmosphere.

Carbon, oxygen and hydrogen are required in abundance to form the intricate and varied molecules of life. Yet neither carbon nor oxygen is abundant

---

Moreover, the *Gaia* hypothesis suggests that life acted in such a way as to maintain the conditions needed for its own survival and progress. It provides an illustration of how a highly complex non-linear feedback system can display stable modes of activity in the presence of drastic external perturbation. It seems as if the earth "seeks" an optimal physical and chemical environment for life on this planet.

Example: Over the earth's history the internal structure of the sun changed due to its burn-up of hydrogen fuel. This, in turn, affected its luminosity, which increased by about 30 percent over the earth's history. In spite of this, the temperature of the earth's surface has remained remarkably constant over this time – since we know that the oceans have neither completely frozen, nor boiled [the very fact that life has survived over the greater part of the earth's history is itself testimony to the equability of conditions].

How has the earth's temperature been regulated? The primeval atmosphere contained large quantities of carbon dioxide, which acted as a blanket and kept the earth warm in the relatively weak sunlight of that era. With the appearance of life, however, the CO_2 in the atmosphere began to decline as the carbon was synthesized into living material.

In compensation, oxygen was released. As the sun grew hotter, so the CO_2 was gradually eaten away by life. On the other hand the oxygen produced an *ozone layer* in the upper atmosphere that blocked out the dangerous ultraviolet rays. With this ozone protection life was no longer restricted to the oceans, but could flourish in the exposed conditions on land.

The perturbations mentioned above do *not* necessarily include *man-made* alterations of some of the planet's major chemical cycles due to an ever increasing industrialization: we have increased the *carbon cycle* by 20 percent, the *nitrogen cycle* by 50 percent, and the *sulphur cycle* by 100 percent! We have increased the flow of toxins into air, water, and food chains. We have reduced the planet's green cover, while our factory outpourings reach the upper atmosphere and far into the oceans.

In the words of James Lovelock (1988): "*We shall have to tread warily to avoid the cybernetic disasters of a runaway positive feedback or of sustained oscillation between two or more undesirable states. We could wake one morning to find that we have landed ourselves with a lifelong task of planetary maintenance engineering. Then at last, we should be riding in that strange contraption,* Spaceship Earth.

People sometimes have the attitude that 'Gaia will look after us'. But that's wrong. If the concept means anything at all, Gaia will look after herself. *And the best way for her to do that might well be to get rid of us*".

in the universe, nor were they produced in the Big Bang. To nurture life, the Universe needed the nuclear alchemy that would change the primeval building blocks of hydrogen and helium into the heavier elements employed by life.

Following WWII, a group of physicists at the California Institute of Technology created a new field called Nuclear Astrophysics, which is the study of nuclear processes in stars. It seeks to learn how stars produce their energy, how the stars evolve, and how the stars produce the particular distribution of chemical elements throughout the universe.

*The specific nuclear reaction that is needed to make carbon is a rather improbable one: it requires 3 nuclei of helium to come together to fuse into a single nucleus of carbon. It was soon recognized (**Hoyle**, 1952) that making carbon in stars by this process was difficult: first, it were difficult to get three alpha-particles to meet, and then, even if this was accomplished, the fruits of their liaison might be short-lived, since all carbon could quickly get consumed by interacting with another alpha-particle to create oxygen.*

Hoyle realized (1954) that the only way to explain why there was a significant amount of carbon in the universe was to posit that the production of carbon went much faster and more efficiently than had been envisaged, so that the ensuing burning to oxygen did not have time to destroy it all.

There was only one way to achieve this carbon boost. A nuclear reaction may occasionally experience a special circumstances where its rate is dramatically increased. It is said to be 'resonant' if the sum of the energies of the incoming reacting nuclei is very close to a natural excited energy level of a new heavier nucleus. When this happens the nuclear reaction rate can be greatly enhanced, especially if the resonance is weakly damped (i.e. narrow[1027]).

Hoyle saw that the presence of a significant amount of carbon in the universe would be possible only if the carbon nucleus possessed a natural energy level at about 7.65 MeV above its ground state (i.e. 0.07% heavier). Only if that was the case could the cosmic carbon abundance be explained, Hoyle reasoned. Unfortunately no energy level was known in the carbon nucleus at the required place.

Hoyle decreed, in effect, "Since we exist, then carbon must have an energy level at 7.65 MeV!".

*In 1957, **William Fowler** led a team of nuclear physicists in search of the energy level that Hoyle was proposing, persuading himself that all the past*

[1027] Resonances in classical physics are tuned to particular *frequencies*. Due to Planck's relation $E = h\nu$, *quantum mechanical* resonances are tuned to *both frequency and energy*. And by dint of STR this implies a tuning of *mass* as well $(E = mc^2)$.

experiments could have missed the 7.65 MeV level. The result was dramatic: there was a new energy level in the carbon nucleus at 7.656 MeV, just where Hoyle had predicted it would be.

The whole sequence of events for the production of carbon by stars then looked delicately balanced *(fine tuned): Three helium nuclei (alpha-particles) have to interact at one place*

$$3\,{}^{4}_{2}He \rightarrow {}^{12}_{6}C + 7.656\ MeV. \tag{1}$$

This reaction proceeds in two steps: first, two α-particles fuse for a very short time ($\approx 10^{-16}$ sec) into an unstable beryllium ${}^{8}_{4}Be$ isotope nucleus

$$(99 \pm 6)keV + {}^{4}_{2}He + {}^{4}_{2}He \rightarrow {}^{8}_{4}Be. \tag{2}$$

Fortunately, beryllium has a peculiarly long lifetime, ten thousand times longer than the time required for two helium nuclei to interact; and so it stays around long enough to have a good chance of combining with another helium nucleus to produce a carbon nucleus and two gamma-ray photons:

$${}^{4}_{2}He + {}^{8}_{4}Be \rightarrow {}^{12}_{6}C + 2\gamma. \tag{3}$$

The 7.656 MeV energy level in the carbon nucleus lies just above the energies of the beryllium plus helium (which are equivalent to an excitation of 7.3667 MeV), so that when the thermal energy of the inside of the star is added, the nuclear reaction can become resonant and abundant carbon is produced (in some *stars and in* some *stages of their lives). But that is not the end of the story. The next reaction threatening to burn up all the carbon is*

$${}^{12}_{6}C + {}^{4}_{2}He \rightarrow {}^{16}_{8}O + \gamma. \tag{4}$$

Once reactions (1) and (4) have been completed the core of the star will be made up of carbon (${}^{12}_{6}C$ isotope) and oxygen (${}^{16}_{8}O$ isotope).

Clearly, if reaction (4) should turn out to be resonant as well, then all the rapidly produced carbon would disappear and the carbon resonance level would have been to no avail.

Remarkably, this last reaction just fails to be resonant. The oxygen nucleus has an excited energy level at 7.1187 MeV that lies just below *the total energy of carbon plus helium at 7.1616 MeV. So even when the extra thermal energy in the star is added, the oxygen-producing reaction can never be resonant and the carbon survives.*

Hoyle recognized that his finely balanced sequence of apparent coincidences was what made carbon-based life a possibility in the Universe.

The positioning of the nuclear energy levels in carbon and oxygen is the result of a very complicated interplay between nuclear and electromagnetic forces that could not be calculated easily when the discovery of the carbon resonance level was first made.

Today, it is possible to make very good estimates of the contributions of electromagnetic and nuclear forces to the levels concerned. One can see that their positions are a consequence of the fine structure constant *and strong* nuclear force (QCD) coupling constant *taking the values that they do, and that slight departure from these values would cause a "cosmic carbon bottleneck" and make carbon-based life impossible anywhere in the universe!*

If the fine structure constant, that governs the strength of electromagnetic forces, were changed by more than 4 per cent or the strong-interaction coupling constant by more than 0.4 of one per cent then the production of carbon or oxygen would be reduced by factors of between 30 and 1000.

Geoffrey *and* ***Margaret Burbidge***, ***Fred Hoyle*** *and* ***William Fowler*** *coauthored (1957) the paper: "*Synthesis of the Elements in the Stars*". In it they showed that* all *the elements from carbon to uranium could be produced by nuclear processes in stars, starting only with the hydrogen and helium produced by the Big Bang.*

Yet another fine tuning of the fine-structure and nuclear coupling constant involves the cosmological production of helium itself *during the first three minutes after the Big Bang. Were the strong nuclear force slightly weaker,* deuterium *nuclei would not exist — and the early-universe production of helium from hydrogen depends on deuterium as an intermediate state. And were the strong nuclear force strong enough for a* diproton *(a two-proton nucleus) to exist, again (almost) no deuterium would be produced, and very little helium — and thus no carbon.*

Water in its liquid state is needed as the medium within which the reactions of life are to occur (at least, this is so for terrestrial life). Yet liquid water exists only within a narrow range of temperatures and pressures. A long-term source of energy with constant output for billions of years is necessary to warm the water and to fuel the development of life from the simple to the complex. Such a long-term energy source can probably only originate with a star, but accompanying the warming stellar light is the devastating flux of ultraviolet and cosmic radiation. The potential abode of life required a window that allows light to enter but keeps out the ultraviolet radiation. This same home must have an umbrella that effectively deflects the continual shower of lethal cosmic radiation.

Earth's average distance from the sun is approximately 150 *million kilometers. Venus is only* 30 *percent closer than we are but the difference is crucial; typical surface temperatures on Venus are about* $500\,^{\circ}C$*. At this temperature, zinc and lead melt, wood burns spontaneously and glass is almost soft putty. There is not much chance for life under these conditions.*

The annual variation in distance from earth to the sun is only 4.5 *million kilometers, that is, only* 3 *percent of the total distance. (We are* 3 *percent closer in January.) This small annual variation means that the earth's orbit is almost circular. The orbit of Mars is quite elliptical, causing a variation in the distance to the sun of* 50 *million kilometers during the year. If the earth had such variance, our crust would deep-fry each January.*

In fact, if our distance from the sun were only 10 *million kilometers less (a change of less than* 7 *percent), the increased solar heat would prevent water vapor from condensing. There would be neither rain nor oceans. Ultraviolet radiation is able to penetrate only a few millimeters of water. This gave life a chance to develop within the oceans* prior *to the presence of oxygen (and thus UV-blocking* ozone*) in the atmosphere. Oxygen produced by aquatic algae formed the initial ozone screen. Life could then emerge from its protected berth in water and populate the land.*

The fine balance of the earth's composition is made manifest by another characteristic of the planet we inhabit: its radioactivity. The young earth contained enough radioactivity to have heated and melted it during its early development. Evidence of this internal heating is the increasing temperature experienced as we dig into the earth.

Because of the decrease in radioactivity over time, the earth now has a solid crust, but still a molten core. The motion of the molten iron mass within the earth's core produces the magnetic field with which we are familiar. The Lorentz forces due to this field divert much of the potentially lethal ionizing cosmic radiation that reaches the vicinity of the earth. We live under a literal magnetic umbrella. Were this cosmic radiation not deflected, it would bathe the surface of the earth with a continual shower of life-devastating ionization.

These constraints deal with the macroscopic characteristics of the universe required at life's abode. At the subatomic level, the demands of life are equally rigorous.

The forces that bind protons and neutrons into nuclei of atoms must be sufficiently strong to form the stable units we refer to as the elements, but weak enough to allow the spontaneous fission of some of the nuclei of the heavier among elements. The radioactivity caused by this fission supplied the heat that fueled the volcanoes that released trapped vapors and gases which formed the biosphere, the thin film of water and air in which all of life thrives.

Electromagnetism, which binds electrons to nuclei and repels them from each other and thus defines the properties of atoms — including all of chemistry, material science, optics and molecular biology — is also finely balanced. It must be weak enough to free electrons for occasional passage through and into neighboring atoms, yet strong enough to organize and join these adjacent atoms into ions and molecules, the basis for the solid and liquid structures of matter.

Gravity, the most enigmatic of the four fundamental forces of the universe, is the weakest of the four. Yet on large scales (planets, stars, galaxies and the universe as a whole) it is the most powerful force. As such it shapes the macrostructure of the universe and through gravitational instabilities and collapse, forms galaxies, stars and planets. If gravity were significantly more powerful, the life-times of the stars would be too short to allow life to flourish. Increasing or decreasing gravity, which binds planets, stars and galaxies in their flight through space, would result in unstable orbits, with planets spiraling toward, or away from their star; it also changes planets' sizes and chemical compositions.

To see this, we briefly summarize the, so-called coincidence of large numbers*, first exploited by* ***Arthur Eddington*** *(1921),* ***Paul Dirac*** *(1937) and* ***Robert Dicke*** *(1961).*

Eddington believed that he could create a theory that would weave together the macroscopic world of astronomy and cosmology with the subatomic world of protons and electrons. To this end he used the experimental values of his day to choose four dimensionless numbers:

- *The ratios of the masses of the proton and electron*

$$m_p/m_e \approx 1840. \tag{5}$$

- *The inverse of the* fine-structure constant

$$\frac{2\epsilon_0 hc}{e^2} \approx 137, \tag{6}$$

  (h = Planck's constant; c = velocity of light in vacuum, e = charge of the electron).

- *The ratio of the electromagnetic force to the gravitational force between an electron and a proton*

$$\frac{e^2}{4\pi\epsilon_0 G m_p m_e} \approx 2 \times 10^{39}. \tag{7}$$

- *The number of protons in the visible universe*

$$N_{Edd} \approx 10^{80}. \tag{8}$$

Note that since $e^2 \approx \frac{2\epsilon_0}{137}hc$, *we may use* (5) *to recast* (7) *in the form*

$$\frac{\hbar c}{Gm_p^2} \approx 1.5 \times 10^{38}; \qquad \hbar = \frac{h}{2\pi}. \tag{9}$$

Eddington then concocted a numerological derivation of the quadratic equation

$$10m^2 - 136m + 1 = 0, \tag{10}$$

which has two roots, the ratio of which is 1847.6. This equation thus ties up the first two of his constants (since m *is interpreted as* $\frac{m_p}{m_e}$, *and the coefficient* $136 = 137 - 1$ *is related to the fine-structure constant in his derivation). Then he claimed that* $\sqrt{N_{Edd}} \approx 10^{40} \approx \frac{e^2/4\pi\epsilon_0}{Gm_pm_e}$ *is justified on the premise that the ratio of the electric force to the gravitational force between two protons was a* statistical fluctuation *of a collection of* N *particles, given by the square root of* N.

Eddington's attempt to produce a unified explanation for the constants of nature attracted few adherents. The great physicists of his day, such as **Einstein**, **Dirac**, **Bohr** *and* **Born**, *found it useless and politely confessed that they could not understand it. Yet, his efforts drew the attention of physicists and created a new frontier to strive for.*

Unpersuaded by Eddington's numerological approach to dimensionless constants and the presence of large numbers amongst the constants of nature, **Dirac** *(1937) nonetheless argued that very large dimensionless numbers taking values like* 10^{40} *and* 10^{80} *are most unlikely to be* independent; *He then expounded the new conjecture: 'Any two very large dimensionless numbers occurring in nature are connected by a simple mathematical relation, in which the coefficients are of the order of unity'.*

The large numbers that Dirac marshalled to motivate this daring new hypothesis drew on Eddington's work and were three in number: (t = *present age of universe; modern, 1990's value used)*

$$\begin{aligned} N_1 &= \text{(size of the observable universe)/(classical electron radius)} \\ &= \frac{ct}{e^2/4\pi\epsilon_0 m_e c^2} \approx 5 \times 10^{40} \end{aligned} \tag{11}$$

$$\begin{aligned} N_2 &= \text{electromagnetic-to-gravitational force ratio between proton and electron} \\ &= \frac{e^2}{4\pi\epsilon_0 G m_e m_p} \approx 2 \times 10^{39} \end{aligned} \tag{12}$$

$$\begin{aligned} N &= \textit{number of protons in the observable universe}^{1028} \\ &= c^3 t/G m_p \approx 10^{80}. \end{aligned} \tag{13}$$

It then follows from (11)–(13) and Dirac's hypothesis that

$$N_1 \approx N_2 \approx \sqrt{N} \propto t \tag{14}$$

which implies

$$\frac{e^2}{4\pi\epsilon_0 G m_p^2} \propto t \tag{15}$$

at any *cosmological epoch. Dirac chose to accommodate (15) by abandoning the constancy of Newton's gravitation constant, G. He suggested that it was decreasing in direct proportion to the age of the Universe over cosmic time scales, as*

$$G \propto 1/t \tag{16}$$

Thus in the past G was bigger and in the future it will be smaller than it is measured to be today. One now sees that the huge magnitude of the three Large Numbers is a consequence of the great age of the universe: they all get larger as time wears on.

We define a nuclear time *t_N as the travel time of light across the* Compton wavelength *of the proton*

$$t_N = \frac{1}{c}\left(\frac{h}{m_p c}\right) = \frac{h}{m_p c^2}. \tag{17}$$

Combining (5), (11) and (17) we obtain for $t = t_{now}$

$$\frac{t_{now}}{t_N} \approx 10^{41}, \tag{18}$$

meaning that the age of the universe bears about the same numerical relation to t_N (up to a factor ≈ 50) as the electric force between a proton and electron in the hydrogen atom bears to their gravitational attraction.

One of the earliest specific demonstrations that biology can be used to explain the coincidence of large numbers *is due to* **Robert Henry Dicke** *(1916–1997, USA). In 1961 he declared that both Eddington and Dirac had been misguided in searching for new fundamental principles of physics to explain the apparent coincidences (14).*

Clearly, the present *age of the universe is defined by the recent nascence of the human technological society, occupying a minute fraction of its life-span. Dicke reasoned that t_{now} is not a randomly selected instant of time,*

[1028] Assuming a spatially closed and flat universe with no cosmological constant.

but intimately connected with the timescales of certain physical processes in the universe that are themselves prerequisites for the existence of intelligent life, and hence technology.

One could imagine a variety of such prerequisites, but the one chosen by Dicke concerns the existence of elements heavier than hydrogen. Life on earth is based on the element carbon, while nitrogen and oxygen are also vital. These elements did not exist in the primeval universe. Their presence in reasonable abundance is attributed to the nucleosynthesis which occurs inside stars.

Dicke presented these ideas (1961) in a more quantitative and cogent form specifically geared to explaining (in part) the large-number coincidences: The heavier elements are synthesized in the late stages of stellar evolution and are spread through the universe by supernovae explosions *which follow the* main-sequence *evolution of stars. Only universes of roughly the main-sequence stellar age could produce the heavy elements, like carbon, upon which life is based. Only those universes could evolve '*observers*'.*

Quantitatively, the argument shows that the main-sequence stellar lifetime *is roughly*

$$t_{ms} = \frac{\begin{pmatrix}\text{nuclear energy}\\ \text{available from}\\ \text{hydrogen fusion}\end{pmatrix}}{\begin{pmatrix}\text{nuclear-released energy}\\ \text{trapped within a star}\\ \text{at any given moment}\end{pmatrix}} \cdot \begin{pmatrix}\text{time for radiation}\\ \text{to diffuse out of}\\ \text{the star}\end{pmatrix}.$$

Now, the mean free path for photon diffusion is $\lambda \approx \frac{1}{\sigma n}$, *with* n *the hydrogen atom stellar density and* σ *the Thomson cross section* $\sim e^2/4\pi\epsilon_0 m_e c^2$; *the available fusion energy per hydrogen nucleus is of order of the nuclear self-Coulomb energy* $\sim e^2/4\pi\epsilon_0\lambda_c$, *with* $\lambda_c = h/m_p c$ *the proton Compton wavelength; while the thermal nuclear-derived energy inside the star at any moment is of order of its self-gravity potential energy. Thus*

$$t_{ms} \approx \left(\frac{hc}{Gm_e^2}\right)\left(\frac{h}{m_p c^2}\right)\alpha^3 \approx 4 \text{ billion years},$$

with $\alpha = e^2/4\pi\epsilon_0\hbar c$ *the fine structure constant.*

We could not expect to be observing the universe at times significantly in excess of t_{ms}, *since all stable stars would have expanded, cooled and died (i.e. all stars would be white dwarves, neutron stars and black holes). Nor would we be able to see the universe at times much less than* t_{ms} *because we could not exist! (i.e., no late-life stars, nor heavy elements like carbon).*

Living beings are therefore most likely to exist when the age of the universe is roughly equal to t_{ms}, *with* $t = 0$ *designating the Big Bang. Thus the value of Dirac's Large Number* $N(t)$ *is by no means random. It must have a value close to the value taken by* $N(t)$ *when* $t = t_{ms}$*. At that time we must inevitably observe the Dirac coincidence* $N_1 \approx N_2$ *to hold. It is a prerequisite for our existence, and no hypothesis of varying constants is necessary to explain it.*

Indeed, at time t_{ms} *after the beginning of the expansion of the universe it is inevitable that we observe* N_1 *to have the value*

$$N_1 \approx 4\pi\epsilon_0 \frac{m_e c^3}{e^2} t_{ms} \approx \left(\frac{hc}{Gm_e^2}\right)\left(\frac{m_e}{m_p}\right) 2\pi\alpha^2 \approx (2\pi)^2 \alpha N_2 \approx N_2. \qquad (20)$$

All that Dirac's coincidence is saying is that we live at a time in cosmic history after the stars have formed and before they die. This is not surprising. Dicke is telling us that we could not fail to observe Dirac's coincidence: it is a prerequisite for life of our sort to exist.

Note that since $N_1 N_2 = N$ *identically, Dicke's argument also explains the other Dirac coincidence,* $N_2 \approx \sqrt{N}$.

There is no need to give up Einstein's theory of gravitation by requiring G *to vary, as Dirac implicitly required, nor do we need to deduce some numerological connection between the strength of gravity and the number of particles in the universe as Eddington had thought. The Large Number coincidence is no more surprising than the existence of life itself. Nevertheless, Dicke's argument does* not *explain why gravity is so weak, nor why the universe is so old now that we exist — it only* reflects *the two facts. The separate explanation of either one may lie in grand-unified or string theories of particle physics, through the so-called "running coupling constant" phenomenon. If so, then physics will eventually explain why the timescale* t_{ms} *of stars is so huge in units of molecular interaction times — a fact that allowed life enough time to evolve.*

Dirac's response, his first written remarks about cosmology for more than twenty years, to this unusual perspective upon cosmological observations was rather bland:

'On Dicke's assumption habitable planets could exist only for a limited period of time. With my assumption they could exist indefinitely in the future and life need never end. There is no decisive argument for deciding between these assumptions. I prefer the one that allows the possibility of endless life.'

Although he was willing to admit that life would be unlikely to exist before the stars had formed he was unwilling to concede that it could not continue long after they had burnt out. With Dirac's idea of varying G the coincidences would continue to be seen at all times but on Dicke's hypothesis would only be seen near the present epoch.

Dirac didn't think there was any problem with having habitable planets in the far future on his theory. However, if gravity is getting weaker it is not clear that stars and planets would be able to exist in the far future. At the very least, other constants would need to vary to maintain the balance between gravity and the other forces of Nature that make their existence possible.

Dirac's hypothesis, however, did not survive for long. Other notable cosmologists did not believe that any 'Fundamental Theory' a-la Eddington could possible hope to explain coincidences between large numbers precisely because the large numbers involved the present *age of the universe.*

Since there was nothing special about the present time we were living at (apart from our existence), no theory of physics could predict it or pick it out so it could explain the coincidences. Yet, Dicke's arguments strikingly support the notion that the observable universe must be at least ten billion years old. Since it is expanding, it must be at least *of order ten billion light years in size. We could not exist in a universe that was significantly smaller.*

Thus, modern cosmology provide an illuminating response to the question why we are here at the time and place that we are.

Furthermore, the blend of the natural laws of the universe, along with the relative strength of the fundamental forces that operate among matter and energy, cannot vary by much if the universe is to develop such complicated things as multibillion-year-old stars and *living cells.*

The Anthropic Principle seeks to link aspects of local and global structure of the universe to those conditions necessary for the arousal and existence of *living* observers.

The expulsion of Man from his self-assumed position at the center of nature owes much to the Copernican principle that we do not occupy a privileged position in the universe. Although we do not regard our position in the universe to be central or special in every way, this does not mean that it cannot be special in any *way.*

This led **Brandon Carter** (1974) to limit the Copernican dogma by an *Anthropic Principle*, to the effect that our spacetime location in the universe and perhaps the very laws of nature, are necessarily privileged to the extent of being compatible with our existence as observers.

In other words: the measured values of many cosmological constants and physical quantities that define our universe (and our location and epoch therein) are circumscribed by the necessity that we observe from a site and time where conditions are appropriate for the occurrence of biological evolution and at a cosmic epoch exceeding the astrophysical and biological timescales required for the development of life-supporting environments and biochemistry[1029].

Put another way, the Anthropic Principle states that the structure of the universe is restricted by the fact that we are observing this structure; by the fact that, so to speak, the universe is observing itself. These ideas are phrased in the definition of the Weak Anthropic Principle (WAP):

> *The observed values of all physical and cosmological quantities are not equally probable but they take on values restricted by the requirement that there exist sites where carbon-based life can evolve and by the requirement that the universe be old enough for it to have already done so.*

The existence of a number of a priori unlikely coincidences and fine-tunings between dimensionless numbers (some of them of enormous magnitude) that are, superficially, either completely independent or determined from some life-unrelated mathematical principles, and the further fact that these unlikely relations appear essential to the existence of carbon-based observers in the universe – led some scientists to propose a stronger version of the WAP, namely the strong Anthropic Principle (SAP):

> *The universe must have those properties which allow life to develop within it at some stage in its history.*

This is clearly a more metaphysical and less defensible notion, it implies that the constants and laws of nature must be such that life can exist. This speculative teleological hypothesis admits a number of distinct interpretations of a radical nature:

- *Nature organizes itself in such a was as to make the universe self-aware.*
- *There exists a restricted set of possible universes 'designed' with the goal of generating and sustaining 'observers'.*

[1029] The observer's *scale* is privileged too: the mass of an adult *human* (ca 60 kg) is roughly the geometric mean of a *stellar mass* (ca 10^{30} kg) and an atomic mass (ca 10^{-27} kg). And the *size of a living cell* is about the geometric mean of the size of the observable universe (ca 10^{10} LY $\approx 10^{28}$ cm) and the Planck length ($\approx 10^{-33}$ cm)!

- *Observers are necessary to bring the universe into being.*
- *Intelligent information-processing must come into existence in the universe, and, once it comes into existence, it will never die out (known as the Final Anthropic Principle or FAP).*

While FAP and SAP are quite speculative, WAP is just an extension of the well-established principle of science that it is essential to take into account the limitations of one's measuring apparatus when interpreting one's observations.

Note that the SAP can be regarded as a meta-principle of organization, because it arranges the fundamental laws themselves so as to permit complex emergent organization to arise.

1944 CE **Howard Hathaway Aiken** (1900–1973, U.S.A.). Mathematician. Built one of the first automatic electro-mechanical digital calculating machine (1944) dreamed up by Babbage in 1833.

In 1937, Aiken had the idea of using the techniques and components developed for punched-card machines to produce a fully automatic calculating machine. At that time he was a graduate student at Harvard, and getting fed up with the tedious calculations required for his Ph.D. thesis. To implement his idea he approached the I.B.M. Corporation, one of the largest manufacturers of punched-card machinery. The result of their collaboration was the Automatic Sequence Controlled Calculator (A.S.C.C.), also known as Mark I, which was completed in 1944 and presented to Harvard University in August of that year.

In 1940, Aiken had his attention called to Babbage's pioneering efforts. When he read Babbage's charge to his successors he felt that Babbage was speaking directly to him from the past.

When the Harvard Mark I was in operation, it sounded "like a roomful of ladies knitting". The muted clicking noises were made by thousands of electromechanical relays opening and closing. Unlike most modern computers, the Mark I included electro-mechanical counters, descendants of those designed by Pascal.

1944 CE **Archer John Porter Martin** (1910–2002, England) and **Richard Lawrence Millington Synge** (1914–1994, England). Biochemists.

Developed *paper chromatography*, a new tool in identifying organic compounds using absorbent paper[1030]. They were awarded the Nobel prize for Chemistry (1952).

In this technique, a drop of mixture (amino acids, say) is placed at one end of a piece of very porous paper and is allowed to dry. The amino acid molecules remain firmly bound to a thin and invisible film of water on the paper. Now, an organic liquid such as butyl alcohol is allowed to creep up the paper, by capillary action. As the alcohol passes the dried mixture of amino acids, each amino acid moves at a different rate and is found at a different spot on the paper. In this way the individual components of even a very complex mixture can be separated and analyzed individually.

By this method, the amino acid analysis of a number of different proteins was carried through. For instance, the albumin of human blood plasma was found to be made of 510 proteins, each composed of 19 amino acids. This method is of course incapable of revealing the *order* in which the amino acids appear[1031] in the original protein molecules.

Their technique revolutionized analytical biochemistry and enabled rapid separation of small amounts of complex mixtures of *biochemicals* not possible by ordinary chemical methods.

1944 CE **Rudolf Karl Luneburg** (1902–1949, Germany and USA). Mathematician. Accomplished a systematic and fundamental development of ray and diffraction optics from Maxwell's equations.

Luneburg was born in Volkersheim, Germany. Received his doctorate from Göttingen University (1930) and was a Research Associate in Mathematics there (1930–1933). Emigrated to the United States (1935), holding a series of short term university appointments and worked for the American Optical Company during 1938–1945. His book: *Mathematical Theory of Optics*, pub-

---

[1030] Thus extending the *chromatography* of **Willstäter**. Martin and Synge used *ninhydrin* to reveal the position of the *amino acids*. The developed strip is called a *chromatogram*.

[1031] Nevertheless, **Frederick Sanger** (b. 1918) was able (1953) to determine the order in which amino acids compose the molecule of *insulin*. The number of possible arrangements for these amino acids is greater than 10^{100}. For this he was awarded the Nobel Prize for Chemistry in 1958, and a second one in 1980 for work on the chemical structure of *genes*.

lished posthumously, was based on notes of lectures given in 1941 at Brown University.

He was killed in an automobile accident in Montana.

The chief contribution Luneburg made through his theory lies in having shown how the two main mathematical disciplines of instrumental optics, namely *geometrical optics* and *scalar-diffraction optics*, may be developed in a systematic manner from the basic equations of Maxwell's electromagnetic theory.

Prior to Luneburg's work these two disciplines were treated as self-contained fields, with little or no contact with each other and less with electromagnetic theory. The starting point of Luneburg's investigation was the observation of the formal equivalence of the basic equation of geometrical optics (the eikonal equation) and the equation that governs the propagation of discontinuous solutions of Maxwell's equations (the equation of characteristics).

By identifying the geometrical optics field with the electromagnetic field on a moving discontinuity surface, Luneburg was led to a complete formulation of geometrical optics as a particular class of *exact* solutions of Maxwell's equations. This formulation is by no means based on traditional ideas; for traditionally geometrical optics is regarded as the short wavelength limit of the monochromatic solution of the wave equation.

Luneburg was, of course, aware of this more traditional viewpoint, and he devoted considerable time to the interrelation between the two approaches. Some of his ideas became the nucleus from which a systematic theory of asymptotic series solutions of Maxwell's equations has gradually been developed.

1944–1951 CE **Hendrik Christoffel van de Hulst** (1918–2000, Holland). Astronomer. Suggested that interstellar hydrogen must emit radio waves at wavelength 21.2 cm (the key to mapping the spiral arms of our galaxy).

The ground state of the hydrogen atom is split by the hyperfine magnetic interaction of the electron and proton spins into two quantum states, with separation 0.047 cm^{-1} in inverse wavelength. In one of the states the spins of the electron and the proton are parallel, in the other antiparallel. When a spin reversal occurs in a ground-state atom due to an external disturbance, a photon of wavelength 21.2 cm is eventually emitted[1032], thus relaxing the atom back to its ground state spin configuration.

Even though in any individual excited interstellar atom, such emission (and accompanying spontaneous reversal) occurs, on the average, once in 11 million years, the cumulative effect of the large number of hydrogen atoms in interstellar space might be observable.

Confirmation of van de Hulst's prediction was provided on March 25, 1951, by the first observation of the interstellar hydrogen absorption line by **Harold Ewen** (U.S.A.) and **Edward Mills Purcell** (1912–1997, U.S.A.). An extremely important line of investigation has resulted from this discovery, enabling astronomers for the first time to map with some success the structure of the Milky Way.

1944–1952 CE **Stanislaw Marcin Ulam** (1909–1984, Poland and USA). Mathematician. Solved the problem of how to initiate fusion in the *hydrogen (thermonuclear) bomb*[1033]. Devised the '*Monte-Carlo method*' (1945) which

---

[1032] This is in the radio region, and corresponds to a transition between two levels, 10^{-17} ergs apart in energy. Ewen and Purcell showed, in a laboratory experiment, that it is possible to stimulate the transition in a beam of hydrogen atoms, and thereby to measure the corresponding radio frequency 1420.403 Mc/sec, giving a wavelength of just over 21 cm.

[1033] An important thermonuclear reaction between the hydrogen-isotope nuclei is

$$\text{Deuterium} + \text{Tritium} \quad \rightarrow \quad (\alpha\text{-particle}) + \text{neutron} + 17.4 \text{ MeV}.$$

But tritium is radioactive with a half-life of 12 years and would be a troublesome permanent ingredient of a bomb, generating unwanted heat with the necessity of frequent replenishment.

The use of ^{6}LiD (Lithium deuteride with the isotope lithium-6) solved two crucial problems at once: as a chemical molecule it holds the deuterium in solid form without the need for refrigeration, and at the instant of detonation the ^{6}Li present provides the tritium needed for the $\mathrm{D}+\mathrm{T}$ (i.e., ${}^2_1H_1 + {}^3_1H_2$) reaction through the reaction $^6\mathrm{Li} + n \rightarrow \alpha + T + 5$ MeV.

It is because this reaction has a larger cross-section than the corresponding ^{7}Li reaction, that the separated isotope ^{6}Li is used in the lithium deuteride. So this design produces more tritium to increase the intensity of the thermonuclear reaction. Since lithium is cheap and tritium is expensive, this has economic as well as technical advantages.

We may think of an H-bomb as consisting mainly of an A-bomb (fission nuclear bomb) surrounded by, or close to, a mass of ^{6}LiD. When the A-bomb trigger explodes, and instantaneously before it has a chance to blow the H-bomb ingredients apart, it emits a very intense burst of neutrons that bombard the searches for solutions to mathematical problems using a statistical sampling method with pseudo–random numbers. Invented the concept of *cellular automata* at the Los Alamos laboratory (1948).

Ulam was born in Lemberg, Poland (now Lviv, Ukraine) to Jewish parents. He obtained his Ph.D. from his hometown Polytechnic Institute (1933). A common interest in set theory led to contact with von Neumann, who invited him to the USA (1936) and later involved him in the atomic bomb project at Los Alamos (1944). From 1946 he collaborated with Edward Teller in the design of the hydrogen bomb. His work required massive calculations; Ulam utilized existing calculation machines and applied probabilistic (so-called 'Monte Carlo') methods.

After WWII, Ulam continued to pursue his interest in using machines to solve mathematical and scientific problems, and held several professorships. At the time of his death he was a professor of biomathematics at the University of Colorado (from 1965).

---

^{6}Li to produce the tritium needed, mixed with the deuterium already there, so that the heat produced by the A-bomb can detonate the $D + T$ reaction. This in turn gives off more heat to speed up this and other reactions and at the same time makes more neutrons to hit ^{6}Li nuclei and make more tritium, further speeding up the $D + T$ reaction.

All these interactions amongst the reactions conspire to make the explosion proceed very suddenly and to render a high energy yield, using up a considerable part of the materials present before the explosive expansion proceeds far enough to stop the reaction.

Cellular Automata[1034]

"God has put a secret art into the forces of Nature so as to enable it to fashion itself out of Chaos into a perfect world system."

(Immanuel Kant, 1781)

"If we wish to understand the nature of the universe, we have an inner hidden advantage: we are ourselves little portions of the universe and so carry the answer within us."

(Jacques Boivin, 1988)

The idea of living organisms as machines has proven irresistibly attractive to scientists and philosophers since the time of ***Aristotle***.

The evolution of science up to the middle of the 20th century has taught us that the human mind, when aided by numbers and symbols, is capable of expressing and understanding concepts of great complexity. Yet, expression *of complicated relations and equations is one thing; —* insight *gleaned from these relations is quite another.*

Today, powerful computers with advanced graphics can be used to produce representations of observed, processed and simulated multi-dimensional data from a number of perspectives, and to characterize and elucidate natural phenomena and mechanisms (man-made or naturally occurring) with increasing clarity and usefulness — thus vastly aiding the human mind in generating insights. Indeed, cellular automata *– classes of simple mathematical systems with exotic behavior – are not only at the core of the inner workings of computers, but are also beginning to show promise as models for a variety of physical processes. Though the rules governing the dynamics of these systems are simple, the patterns they produce are complicated and often pseudo-random, like a turbulent flow or the output of a cryptographic system.* Cellular automata

[1034] For further reading, see:

- Shatten, A., *Cellular Automata*, Vienna University of Technology, Vienna, 1997.
- Wolfram, S. (ed), *Theory and Applications of Cellular Automata*, World Scientific Press, Singapore, 1986.

are characterized by the fact that they operate in a discrete state space *(or* grid*) as opposed to a continuum.*

The history of cellular automata *(CA) began in 1947, when the mathematician* ***Stanislaw Ulam*** *was interested in the evolution of graphic constructions generated by simple rules. The basis for his construction was a 2-dimensional space divided into "cells", a sort of grid. Each of these cells has two possible states: ON* and *OFF.*

Starting from a given pattern, the pattern of the following "generation" was determined according to a neighborhood-based majority rule: e.g. if a cell was adjacent to two or more "ON" cells, it would switch to become ON too; otherwise it would switch OFF.

Note that in this scheme, the state transitions are local *in both space and time. This means that the next value of a given cell depends only upon the current value of that cell and the values of cells in an immediately adjacent neighborhood. So there are no fundamental time-lag effects, nor are there any direct nonlocal spatial interactions affecting the state transition.*

Another property is homogeneity*: each cell of the system is the same as any other cell, in the sense that they can each take on exactly the same set of possible values (on and off) at any moment, and each change their state in accordance with the same set of formal (deterministic and/or stochastic) rules.*

Ulam, who used one of the first computers, quickly noticed that this mechanism permitted the generation of complex and graceful figures and that these figures could, in some cases, self-reproduce: *copious and repetitive application of extremely simple rules resulted in the emergence of very complex patterns.*

Let us give here a few examples. Consider first the simplest CA – an infinite string of cells changing values according to a given rule. Let this system be specified by two numbers k and R at each cell, together with a rule determining the next value at each cell. The first number, k, specifies how many values are possible for each cell, while R refers to the range of the neighborhood used to compute the next value of a cell. So, for example if $k = 2$, $R = 1$, there are two possible states per cell (say 0 and 1), and a cell's neighbors are defined as the two cells on either side of it. A cell and its two neighbors form a neighborhood of 3 cells, so there are $2^3 = 8$ possible patterns for any given neighborhood at time t, namely

$$111, 110, 101, 011, 100, 010, 001, 000$$

A possible rule, known as the 'mod 2 rule', determines the central cell value of each neighborhood by adding the values of its two neighbors, dividing that number by 2, and keeping the remainder. The central cell of the above octet *will then have the values* $\{0, 1, 0, 1, 1, 0, 1, 0\}$. *Each time the rule is applied to the whole line, a new generation is produced.*

*The behavior of some one-dimensional CA can be quite complicated. It has been shown (***Wolfram***, 1980) that, depending on the rule chosen, the long-term behaviors of a CA are counterparts in discrete time and space of continuous-time patterns exhibited by dynamical systems exhibiting* fixed points, limit cycles, strange attractors *and patterns exhibited by quasi-periodic orbits.*

These kinds of simple CA have been used to model a bewildering variety of processes — ranging from the sequences of nucleotide bases on a strand of DNA to the dynamics of both human and computer languages.

In the late 1960s, Dutch biologist ***Aristid Lindenmayer*** *proposed a CA model for the* development of filamentous plants, *such as the blue-green algae* Anabaena. *His model contains the novel feature that the number of cells is allowed to increase with time according to a recipe laid down by the state-transition rule. In this way the model "grows" in a manner mimicking the growth of a filamentous plant.*

Another example is a 2-dimensional cellular grid, say, an infinite sheet of graph paper, where each square is a cell. Let each cell have two possible states (say, black and white), and the neighborhood of a cell consist of itself and the 8 squares touching it. Then there are $2^9 = 512$ *possible patterns for a cell and its neighbors. The transition rule for this CA could be given as a table. For each of the 512 possible patterns, the table would state whether the central square will be black or white in the next time step.*

A special case of this example is known as the Game of Life *(***J.H. Conway***, 1970). This automaton too uses two colors: black and white, with these rules:*

- *A cell that is* white *at one instant becomes* black *at the next if it has precisely 3 black neighbors.*
- *A cell that is* black *at one instant stays black at the next iff it has either 2 or 3.*

In all other cases, cells maintain their color.

Finally we present a simple CA known as the Langton ant, *after its inventor. An ant moves either north, south, east or west on a square grid of black and white cells, following three simple rules:*

- *If it is on a black cell it makes a* 90° *turn to the left.*
- *If it is on a white cell it makes a* 90° *turn to the right.*

- *As it moves to the next square, the one that it is on changes color from white to black, or the reverse.*

You may think that Langton's ant must be a remarkably simple animal, but such is not the case. In fact, it poses a problem that is currently baffling mathematicians.

Suppose you start the ant in an eastward direction on a completely white grid. Its first move takes it to a white square, and the square it started from turns black. Because it is on a white square, the ant's next move is a right turn, so that it is then facing south. That takes it to a new white square, and again the square it has just vacated turns black. After a few such moves it starts to revisit earlier squares that have previously turned black. If you try out the rules you'll find that the ant's motion gets quite complicated — and so does the ever-changing pattern of black and white squares that trails behind it. Every so often during the first few hundred moves, the ant produces a nice, symmetrical pattern. Then things get rather chaotic for about ten thousand moves. After that, the ant gets locked into a cycle that repeats the same sequence of 104 *moves, whose net result is to move it two squares diagonally. It continues like this indefinitely, systematically building a broad diagonal "highway."*

This behavior is curious enough, but computer experiments suggest something even more striking: If you scatter any number of black squares around the grid before the ant sets off, then it still ends up building a highway. For example, when the ant starts inside a particular solid rectangle, it builds a "castle" with straight walls and complicated crenelations at the corners. It keeps unbuilding and rebuilding these structures in a curiously "purposeful" way until it gets distracted and wanders off . . . building a highway. The problem that is baffling mathematicians is that nobody can prove *that the ant always ends up building a highway, for any initial configuration of (finitely many) black squares.*

Cellular automata are often simulated on a finite grid rather than an infinite (i.e. infinitely extensible) one. In two dimensions, the universe would then be a rectangle instead of an infinite plane. The edges are usually handled with a toroidal *arrangement: when you go off the top, you come back in at the corresponding position on the bottom, and when you go off the left edge you come back in on the right (This essentially simulates an infinite periodic tiling). This can be visualized as taping the left and right edges together to form a tube, then taping the top and bottom edges of the tube together to form a* torus *(doughnut shape). Universes of other dimensionalities are handled similarly. This is done in order to eliminate complications due to boundary conditions.*

Returning to the historical evolution of these ideas, it was ***John von Neumann*** *(1948) (relying on* ***A. Turing****'s work) who first asked the question: "What kind of logical organization and functional activities would an object have to posses, to be able to build a copy of itself?" Thus, von Neumann wanted to abstract from the processes of* self-replication *in nature the* logical *form of the reproduction process — independent of its realization in any particular material structure. This "recipe" could then be fed into an automaton which von Neumann named "kinematon". Such a machine was supposed to be able to reproduce (replicate) any machine described in its program, including a copy of itself.*

*Ulam then suggested to von Neumann to use what he named "*cellular space*" to build his self-replicating machine. They succeeded in proving that an abstract pattern* could *create a copy of itself by following a set of fixed rules.*

In fact, **von Neumann** *created a mathematical blueprint for a universal Turing machine consisting of a two-dimensional CA having 29 states per cell. His idea was to represent the initial machine as a particular pattern in this CA array. Self-replication would then be said to have occurred if a rule of state transition (using 5-cell von Neumann neighborhood) could be found that would cause the initial pattern to be duplicated* elsewhere *in the array.*

Von Neumann showed that his 29-state CA could be capable of universal construction*, from which self-replication follows as a special case when the machine described on the constructor's input is the constructor itself.*

There was yet another difficulty that von Neumann had to surmount: suppose we have succeeded in building a universal constructor*. We then feed the plans for the constructor back into it as input, and it will then replicate itself.* But it will not reproduce the instructions describing how to build itself. *Without these* the reproduction will not perpetuate *and will be a useless model for living cells.*

How, then, do we arrange it so that the blueprint, as well as the constructor, are faithfully reproduced?

*Von Neumann's way out of the "*blueprint dilemma*" was to build a supervisory unit into the constructor. This unit functioned in the following manner: Initially the blueprint is fed into the constructor as before, and the constructor reproduces itself. At this point the supervisory unit switches its state from construction-mode to copy-mode and proceeds to copy the blueprint as raw, uninterpreted data. The copy is then appended to the previously produced constructor (which includes a new supervisory unit), and the self-reproducing cycle is complete. The key element in this scheme is to prevent the description of the constructor from becoming a part of the constructor* *itself (i.e. the blueprint is located outside the machine and is then appended to the machine at the end of the construction phase by the copying operation of the supervisory unit).*

The crucial point to note about von Neumann's solution is the way information on the input blueprint is used in two fundamentally different ways. It's first treated as a set of instructions to be interpreted. *These instructions, when executed, cause the construction of a machine somewhere else on the CA grid. Thereafter, the blue print information is treated as* uninterpreted *data, which must be copied and attached to the new machine. These two different uses of information are also found in biological self-reproduction: the interpreted instructions correspond to the process of genetic* translation, *while the blind copying of the uninterpreted data corresponds to the process of genetic* replication. *The separation of these two types of processes prevents an infinite regress of self-referential instructions.*

These are exactly the processes involved in the operation of every living cell, and it's worth noting that von Neumann came to discover the need for these two different uses of information several years before their discovery by biologists working on the mysteries of DNA. The only difference between the way von Neumann set things up and the way nature does it is that he arbitrarily chose to have the copying process carried out after the construction phase, whereas nature copies the DNA early on in the cellular reproduction process.

In conclusion: a von Neumann machine is a cellular automaton capable of automatically replicate itself. When provided with a blueprint, it can build anything and replicate indefinitely, like a living cell, including a new copy of the blueprint itself as an "attachment" in each successive CA "generation".

It turns out that the automaton invented by **Conway** *(described earlier) has much simpler rules and is able of doing the same kind of thing. Suppose that in this* Game of Life *one starts with an object made up of black cells, and the rest of the board white. Then you follow the rules and watch how that object changes. For example, a 2×1 block dies out at the first move. A 2×2 block doesn't do anything, so it survives indefinitely. More interesting is a simple shape called a glider: It moves. It changes shape in a four-step cycle, after which it has moved one cell diagonally. More complicated shapes, termed "spaceships", move horizontally or vertically. A "glider gun," which changes through a fixed cycle of thirty shapes, fires an endless stream of gliders.*

Conway's Life *evolves in a reductionist and deterministic universe, which really does have a Theory of Everything, namely Conway's rules. Given a starting shape, its future is completely determined by those rules. But in practice it may be very hard to predict what will happen, even though it's all implicit in the rules. Big shapes can collapse, small ones can grow, and* *there are always surprises. Three of the features that emerge from* Life *are* programmability, undecidability, *and* replication.

First, Conway proved the existence of an initial configuration that acts like a programmable computer, using pulses of gliders instead of electrical impulses to carry and manipulate information.

From this he deduced that the outcome of the game is inherently unpredictable, in the following sense: There is no way to decide in advance whether a given object will survive indefinitely, or disappear entirely. He did this by appealing to a theorem in mathematical logic which states the following: There cannot exist a computer program that can decide in advance whether any given program, when run on a given machine, will go on forever, or will stop. The only way to find out is to run the program and watch. If it stops, you know; if it keeps going, you have no idea whether it will continue going, or whether it's just about to stop as soon as you give up and go away. The theorem is called the undecidability of the halting problem, *and the proof was discovered by* ***Alan Turing***.

Once you have programmable computers, it's not hard to pinch von Neumann's trick and design self-reproducing machines. So Life – a two-state cellular automaton with only three rules – has implicit within it, self-reproducing computers. Given that, you could set up self-reproducing "animals" with "genetic programs" that interact with each other (just program the Life computer to simulate such a system). You could "irradiate" the board with gliders to cause random mutations. Then you could sit back and watch evolution at work.

Cellular automata applications are diverse and numerous: Fundamentally, CA constitute completely known 'universes'. Our universe is subject to the laws of physics. These laws are partly known and appear to be highly complex. In a cellular automaton laws are simple and completely known. One can then apply the concepts of CA to gain a better understanding of the global behavior of a simplified universe, of elementary particles, of complex chemical molecules and perhaps the organization of living organisms.

Indeed, CA are being used for the following purposes, inter alia:

(1) *Simulation of* gas behavior: *A gas is composed of a set of molecules whose behavior depends on neighboring molecules ("lattice gas").*

(2) *Study of ferromagnetism according to the* Ising model: *this model (1925) represents the ferromagnetic – domain crystal lattice as a network in which each node is in a given magnetic state. This state is binary – representing the two possible quantum orientations of the spin of a radical or molecule – and the probabilities of any spin value being "up" or "down" depends self-consistently on the state of neighboring nodes.*

(3) *Simulation of percolation processes.*

(4) *Simulation of forest-fire propagation.*

(5) *Numerical solutions of partial differential equations.*

(6) *Configuration of massive parallel computers.*

(7) *Simulation and study of urban development.*

(8) *Simulation of crystallization processes: studies have shown that, starting from one occupied cell (which may be thought of as a single defect, or a nucleation center) in a lattice, the pattern will continue to "grow" in size as time progresses. In some experiments, two different background lattices with adjacent boundaries were used, and the defect propagated from its beginning point in a centered rectangular lattice through the interface of the second lattice.*

Adding a defect to these two-phase systems bears some similarity to seeding supersaturated solutions and watching the crystallization process grow and "hit" the boundary of a solution with a different composition.

(9) *Used as graphics generators.*

(10) *Investigations of ornaments and decorations of various cultures by consideration of their symmetry groups. Indeed, from a purely artistic standpoint, some of the figures produced by CA's are reminiscent of Persian carpet design, ceramic tile mosaics, Peruvian striped fabrics, brick patterns from certain Mosques, and the symmetry in Moorish ornamental patterns. This artistic resemblance is due to the complicated symmetries produced by algorithms.*

(11) *Study of complicated and ordered structures arising spontaneously from "disordered" states, such as snowflakes, patterns of flow in turbulent fluids, and biological systems (e.g. patterns of schools of fishes and flocks of birds).*

(12) *Game theory.*

(13) *Artificial Intelligence.*

(14) *Economics (automata may be used to simulate "agents" seeking to maximize individual advantage through mutual trade and commerce).*

(15) *Non-linear dynamics.*

(16) Emergence phenomena in studies of artificial life:

The notion of emergence first appeared with general system theory. It states that the global behavior is more than the sum of the behaviors of the individual parts. In other words — complex association of elements induces the appearance of new phenomena and mechanisms. It implies that novel, hard–to–predict and complex behavior results from simple interactions among a system's component parts. Thus, the property of emergence is linked to complexity.

At each level (of the prebiotic, biotic and social evolution) of life, new properties appear that cannot be explained by the properties of each part that constitutes the whole. The increase in the diversity of elements, and in the number of links between these elements, and the nonlinear interactions lead to unpredictable behaviors.

The so-called "global" emergence then characterizes the properties of a system that are new in the framework of the properties of its isolated components. Life is undoubtedly such an emergent phenomenon, as are intelligence and social organization.

In 1983 ***Stephen Wolfram*** *published the first of a series of papers systematically investigating cellular automata. The unexpected complexity of the global behavior stemming from simple rules — and the failure of mathematical methods to meaningfully describe them — led Wolfram to suspect that complexity in nature may be due to similar mechanisms, and that it, too, might not be amenable to traditional mathematical analysis.*

1944–1960 CE **Gregory Goodwin Pincus** (1903–1967, USA). Physiologist. Developed the oral contraceptive pill [with **John Rock** (1890–1984) and **Min Chueh Chang** (1908–1991)], using synthetic hormones to inhibit ovulation in mammals; the hormones mimic the condition of pregnancy in women, thus effectively preventing impregnation.

Pincus was born in Woodbine, NJ to Jewish parents and studied at Cornell and Harvard. In 1944 he co-founded the Worcester Foundation for Experimental Biology in Shrewsbury, MA. There he began his research on steroid hormones, which was encouraged by birth-control pioneer **Margaret Louise Sanger** (1883–1966, USA).

Synthetic hormones became available in the 1950s, and Pincus organized field trials of their anti-fertility effects in Haiti and Puerto Rico in 1954. The results were successful and oral contraceptives ('*the pill*') have been widely used since their first marketing in 1960, despite concern over some side effects.

Their success is a pharmaceutical rarity; synthetic chemical agents do not usually show nearly 100 per cent effectiveness in a specific physiological action, or have such remarkable social effects.

1944–1971 CE **Robert Burns Woodward** (1917–1979, U.S.A.). Organic chemist. Known especially for work in determining structures of complex organic compounds. Synthesized *Quinine* (1944), *Penicillin* (1945), *Strychnine* (1947), *Cortisone* and *Cholesterol* (1951), Lysergic acid (1954), *Reserpine* (1956), *Chlorophyll* and *Oleandomycin* (1960), *Tetracycline* (1962), *Vitamin* B_{12} (1971).

Woodward was born in Boston, MA. Entered M.I.T. at the age of 16 and received his Ph.D. there at the age of 20. He went to Harvard (1937) and remained there for the rest of his life. Received the Nobel prize in chemistry (1965) for his contribution to organic synthesis.

Woodward made fundamental contributions to organic chemistry covering structural elucidation, total synthesis, biosynthesis and *reaction mechanism*. His work was based on meticulous attention to detail, a logical and highly analytical approach, a profound understanding of the electronic and stereochemical behavior of molecules and a prodigious memory. During his work on vitamin B_{12} he recognized the role of *orbital symmetry* in the determination of the stereospecifity of concerted reactions[1035]. The generality of these ideas (1971) represents one of the fundamental advances in organic chemistry since WWII.

1945 CE First radar signals reflected from the *moon* by U.S. Army Signal Corps.

1945 CE, July 16 First successful test of the atomic bomb, near Alamogordo, NM.[1036]

1035 Together with **Ronald Hoffman** (Nobel prize for chemistry, 1981) he extended the range of applicability of simplified quantum-mechanical calculations to cover all organic molecules — the *Woodward-Hoffman rules* which explain why some reagents react easily while other pairs do not do so at all. The basis for the rules lies in the symmetry properties of the molecules concerned, and particularly in the disposition of their *electrons*. New chemical bonds are formed when the electrons involved form a complete circuit.

Table 5.20: Destructive power — man vs. nature

$$(1 \text{ kT} = 4.2 \times 10^{19} \text{ erg}, \qquad 1 \text{ MT} = 4.2 \times 10^{22} \text{ erg})$$

Event	Yield
First atomic bomb, July 16, 1945	19 kT
Device exploded over Hiroshima	13 kT
All explosive of WWII, combined	2 MT
Hydrogen bomb	10 MT
Nuclear arsenal of the world, combined	10^5 MT
Thunderstorm	1 kT
Tunguska bolide explosion (1908)	10 MT
Hurricane (average kinetic energy)	10 MT
Magnitude 8 earthquake	100 MT
Cyclone (average kinetic energy)	100 MT
Tambora volcanic Explosion (1815)	2×10^4 MT
Tuba volcanic Eruption (73,500 BCE)	6×10^5 MT
Yucatan asteroid impact (65 million years ago)	2×10^6 MT

1945 CE First atomic bomb dropped on Hiroshima, Japan (Aug. 6, 8: 15 AM; nuclear fission bomb based on uranium-235). By sudden incineration and lingering death some 200,000 people died. A plutonium-based fission-bomb was exploded over Nagasaki (Aug. 9). This bomb killed only 70,000 because hills deflected the blast and radiation. Its yield was about 20 kT of TNT. This marked the end of the *military* engagement with Japan; the *economic* conflict would, however, enter a new phase.

Paradoxically, the adoption of **Shewhart's** philosophy and practice of quality control of industrial processes by the Japanese during the five decades after WWII, hampered American economic supremacy.

Before the war, Japan's vital export markets had accepted the shoddy products supplied. But only few Japanese understood the productive strength of the US. Thus, the Japanese High Command could not foresee that the US overwhelming productive capacity and its progressive management techniques would be a major factor in winning the war.

However, the Japanese surrender aboard the USS Missouri (2 September 1945) had only marked the end of military hostilities. Before this (in mid-August 1945), secret discussions were taking place at ministerial level in Tokyo about a recovery strategy that would, in the words of the Foreign Minister Shigeru Yoshida, ensure that:

> "*we could indeed rebuild Imperial Japan out of this way of defeat... science will be advanced, business will become strong with the introduction of American capital, and in the end our Imperial country will be able to fulfill its true potential. If that is so, it is not so bad to be defeated in this war.*"

With General MacArthur's acceptance of Japan's surrender, there arose the imminent need to enable the defeated people of Japan to support themselves at a time when the occupation powers had removed the 1,500 or so top managers of the powerful traditional zaibatsu (vertical groupings) of industry (by imprisonment or enforced retirement). It was then necessary for the middle managers to take over and rebuild their companies along new, more efficient, lines. But management training was non-existent in the years immediately following the end of the war.

An American electronics engineer, **Homer Sarasohn**, in his late twenties and fresh from wartime service with MIT Radiation Labs and Raytheon (where he had distinguished himself in rapidly converting experimental electronic equipment into production-line ready hardware) established (1946) in Tokyo a radio receiver industry so that the occupation powers could broadcast to the Japanese people.

By the end of the forties his efforts had so impressed MacArthur that he supported Mr Sarasohn's recommendation that, together with another engineer, **Charles Protzman**, they set up a university level management training programme so as to spread their experience further into Japan's slowly reviving economy. This course drew upon the work of Shewhart in ensuring that only reliable and successful products were produced.

Thus did two young but insightful engineers shape the early course of postwar economic history by passing on simply and clearly what they had been taught during the war by the Western Electric training programme. Little did they realize that their efforts would slowly undermine American economic supremacy.

Indeed, just 50 years later the chairman of the world's largest manufacturing company, GM, formally admitted defeat to the superior economic and manufacturing practices of the now globally dominant Japanese companies (such as Toyota, NT&T and Matsushita) and modern vertical groupings, or *keiretsu*, (such as Matsui, C Itoh and Mitsubishi).

Table 5.20 lists yields of natural vs. man-made events.

From Atomic theory to Nuclear Technology (460 BCE–1945 CE)

ca 450 BCE **Leucippos of Miletos** introduced the idea of the *atom* — an indivisible unit of matter.

ca 420 BCE **Democritos of Abdera** stated that all matter is made of indivisible particles called *atoms*.

The Greeks gave much to the development of physics by developing the basis of fundamental modern principles such as the conservation of matter, atomic theory, and the like. Very few new developments occurred for about 22 *centuries.*

1473 **Lucretius'** *De rerum natura* (*on the nature of things*) is translated back into Latin, making the *atomic theory* of Democritos and Leucippos known to scholars in the West.

1649 **Pierre Gassendi's** study of Epicuros *Syntagma philosophice Epicuri*, asserts that matter is made up of *atoms*.

1666 **Robert Boyle's** *The origine of formes and qualities* contains his view that everything is built up of *atoms* and reflects his mechanical view of nature.

1781 Planet *Uranus* discovered by **William Herschel**.

1789 Element *Uranium* discovered by **Martin Klaproth**.

1803 **John Dalton's** atomic theory of matter: since chemicals combine only in integral proportions, *atoms* must exist.

1812 **Jöns Jacob Berzelius** asserted that *atoms* have electrical charges. This is based on the assumption that electrical and chemical forces are identical.

1828 Element *Thorium* discovered by **Berzelius**.

1872 **James Clerk Maxwell** maintained that *atoms* remain in the precise condition in which they first began to exist.

1874 **George Stoney** developed a theory of the *electron* and estimated its mass: He proposed that electricity was made of negatively charged particles he called "*electrons*".

1881 **Hermann Ludwig von Helmholtz** showed that the electrical charges in *atoms* are divided into definite integral portions, suggesting the idea that there is a smallest unit of electricity.

1890 **Hendrik Antoon Lorentz** proposed that *atoms* may consist of charged particles that produce visible light by oscillating.

1896 **Henri Becquerel** discovered *radioactivity*.

1897 **Joseph John Thomson** discovered the *electron*, the first known particle smaller than an *atom*.

1898 **Marie and Pierre Curie** discovered and separated the radioactive elements Radium and Polonium.

1905 **Albert Einstein** proved the equivalence of mass and energy: $E = mc^2$, within the framework of the *special theory of relativity.*

1911–1914 **Ernst Rutherford** established experimentally that the atom was made of a very small dense *nucleus*, positively charged, surrounded by electrons (1911). Discovered the *proton* (1914).

1913 **Niels Bohr** constructed a planetary model theory of *atomic structure* based on *quantum* ideas.

1919 **Francis William Aston** discovered the existence of *isotopes.*

1925 **Patrick Blackett** made the first photograph of *nuclear reactions* mediated by neutrons.

1931 **James Chadwick** discovered the *neutron.*

1933 **Leo Szilard** concocted the first idea of *nuclear chain reaction* mediated by *neutrons.*

1935 **Hideki Yukawa** initiated the *meson* theory of nuclear forces.

1942–1945 The Manhattan Project.

July 16, 1945 First successful test of the atomic bomb, near Alamogordo NM.

1945 First atomic bomb dropped on *Hiroshima* (Aug 6). A second dropped on *Nagasaki* (Aug 9).

Science Progress Report No. 20

The Gas Centrifuge Story, or — Stealing the Fire[1037] *(1945–2002)*

Fission (exothermic splitting of a heavy nucleus, such as uranium, into two fragments of comparable size) as a *natural* process is very rare. Thus, the uranium *isotopes* $^{235}_{92}U$ and $^{238}_{92}U$ that we find in uranium ores have been sitting for billion of years, their nuclei securely held by the surface tension and without enough energy to vibrate and become long enough to go over the fission barrier.

The usual method of producing fission *artificially* is to excite the nucleus. The threshold (minimum activation energy) required for fission of a heavy nucleus is from 4 to 6 MeV. One of the most effective means of inducing fission is by neutron capture. This is, for example, the case of the nucleus $^{235}_{92}U$, which undergoes fission after capturing a *slow* (or thermal) neutron.

For other cases, in order for fission to take place, the neutrons must have some kinetic energy – of the order of 1 MeV – in addition to the binding energy. This is what occurs with $^{238}_{92}U$, which fissions only after capturing a *fast* neutron. The reason for this different behavior lies in some details of the structure of the different nuclei. The nucleus $^{235}_{92}U$ is even-odd, with 143 neutrons, and when a neutron is captured, an even-even nucleus, $^{236}_{92}U$, is formed. The captured neutron is paired with the last odd neutron of $^{235}_{92}U$, releasing the additional pairing energy $\delta \sim 0.57$ MeV. On the other hand, $^{238}_{92}U$ is an even-even nucleus, with 146 neutrons, all paired, and when a neutron is captured, an even-odd nucleus, $^{239}_{92}U$, results, with no extra pairing energy available. For the same reason $^{239}_{94}Pu$, with 145 neutrons, undergoes fission by slow neutron capture.

Thus it is much easier to cause fission in $^{235}_{92}U$ than in $^{238}_{92}U$ and the former in the more valuable isotope for producing nuclear weapons[1038]. Unfortunately from the standpoint of producing power, but perhaps fortunately

[1037] **John S. Friedman** and **Eric Nadler**, film documentary, Oct 2002.

[1038] The fact that for each neutron absorbed in order to produce one fission, more than two new neutrons are emitted (on the average) suggests the possibility of a chain reaction. That is, if things are arranged in such a way that, after each fission, on average more than one of the new neutrons produces another fission, and of the neutrons released in this fission, again more than one produces a fission, and so on, then a self-sustaining exponential process, or chain reaction, results. (Chain reactions are very common in chemistry. Combustion *for the interim stability of world politics, the more useful isotope is much more rare: uranium in nature occurs as 0.7 percent* $^{235}_{92}U$ *and 99.3 percent* $^{238}_{92}U$. *There are also some exceptions*[1039].

We now come to the question of separating the two isotopes of uranium from one another or at least obtaining uranium that is richer in the rare isotope than the uranium occurring in nature. The main point here is to appreciate the enormous difference between the case of separating elements in chemical reactions and the difficulty of separating isotopes of the same element that all behave almost the same way chemically because they have the same number of electrons. Because of their different number of electrons, most atoms of different chemical elements are easily separated from one another, many of them in large-scale industrial processes in which are prepared many of the substances used in everyday life.

The separation of isotopes is much more costly and difficult. However, separation is less difficult for light elements than for heavy elements. The usual separation processes depend on the fact that a light molecule moves

---

is a chain reaction. Burning requires that a molecule have a certain activation energy so that it can combine with an oxygen molecule. But once the first molecules are excited and combine with oxygen, the energy liberated is enough to excite more molecules of the fuel, and burning results.) If in each stage of the process more than one neutron per fission produces a new fission, the number of fissions increases exponentially and a divergent chain reaction results. This is what happens in a nuclear fission bomb. But if, on the average, only one neutron of each fission produces a new fission, a steady chain reaction is maintained under controlled conditions. This is what happens in a *nuclear reactor*.

In *fast* nuclear reactors the neutrons are used at the same energies (1 to 2 MeV) at which they are released in the fission process. But in a *thermal* nuclear reactor the neutrons are first slowed down by allowing them to collide with the nuclei of some other substance, called a *moderator*, until they come to thermal equilibrium with the substance. The neutrons are then called *thermal*. The moderator must be a substance which has small mass number and a small neutron capture cross section. Water, heavy water, and graphite are the substances most used as moderators.

The energy released in a nuclear reactor is extracted by means of a circulating fluid called a coolant. In power reactors this energy is used for heating or for the generation of electric power. In research reactors the neutrons are used for different kinds of experiments, or for isotope production.

[1039] Natural mineral veins with 70 percent of $^{235}_{92}U$ were found (1972) in the mines of Oklo in the Central African country of Gabon, as well as significant amounts of Plutonium-239 in natural state.

about more quickly and easily than a heavy molecule. When two kinds of molecules are mixed together in a gas at a given temperature, they have the same average kinetic energy, $\frac{1}{2}mv^2$ which means that the ones with the larger m have smaller v.

Originally, isotopes were studied for the sake of increasing our knowledge of the structure of matter. Today, isotopes are an indispensable aid to industry as well as to molecular physicists, chemists, and biologists, for isotopes are being used for identifying and tracing individual atoms among a large number of chemically similar ones. Therefore, science and technology are greatly interested in obtaining pure isotopes, i.e., in separating as completely as possible the various isotopes of an element. This interest was strongly stimulated by the modern utilization of nuclear energy.

The best method of separation, though suited only for small quantities, is that of mass spectroscopy. *For this purpose, mass spectrographs are used with large high-intensity ion sources and with collectors for the various isotopes. Some tenths of 1 gram of pure isotopes can be produced per hour in such "electromagnetic separators".*

For technical purposes however, relatively pure isotopes are needed in ton quantities. To satisfy this need, methods of enrichment by numerous repeated steps are applied. Each of these steps produces a relatively small change in the relative abundance of isotopes; but sufficiently numerous repetitions lead to high enrichment of the desired isotope. In this way it was possible to produce the technically very important heavy water, D_2O, in a concentration of better than 99.8%.

Essentially, 3 different methods of separation are used.

- Ultra-centrifuge: *in a high-rpm centrifuge, the heavy isotope is moving outwards, the lighter one toward the axis. This method is used, e.g. for separating gaseous uranium hexaflouride (UF_6)*

- Pore-diffusion: *through filters with very small pores, light isotopes diffuse better than heavy ones. In the* thermal-diffusion *method an isotope mixture streams along a temperature gradient.* ***Gustav Hertz*** *(Germany)conducted the first experiment (1932) on separation of neon isotopes by the pore-diffusion method.*

  With uranium the problem is much more difficult because the two isotopes differ in mass by only a little over 1 percent, about 238 nucleon masses for ^{238}U as compared with about 235 for ^{235}U. In this case the difficult separation is carried out in an enormous and very expensive gaseous diffusion plant that also uses a great deal of electric power. The first large-scale plant using pore-diffusion was built in Oak Ridge, *Tennessee*[1040]*, during World War II and others have been built since in the US (at Paducah, Kentucky, and Portsmouth, Ohio) as well as in France and China. The fact that these plants are extremely costly and sophisticated has been an important obstacle to the easy dissemination of nuclear bomb-making capability to various nations.*

- *The electromagnetic method* *consists of accelerating molecular ions and sending them between the poles of a magnet. This requires using gases at extremely low pressures which makes it difficult to handle large amounts of material. For this reason, this method is usually used only for further concentration or complete separation of the concentrated output from the gaseous diffusion plant.*

The Centrifuge Timeline

1940 *German physicist* **Fritz Lange** *(1899–1987) conducted the first experiment with centrifuges. His centrifuge was a mammoth structure, weighting about a ton. Because the future applications for Lange's centrifuge were unclear, all centrifuge research in Germany was suspended during the WWII years 1940–1945.*

1941 ***Jesse Wakefield Bears*** *(1898–1977; USA), pioneered centrifuge method for separation of uranium at the University of Virginia. There he conducted with his colleagues the first known separation of* $^{235}_{92}U$ *and* $^{238}_{92}U$ *using a gas centrifuge: the slightly heavier 238-isotope containing molecules in the* UF_6 *gas are forced closer to the inside wall of the rotor than the 235-isotope. The radial separation factor is proportional to the absolute mass difference between the two isotopes.*

[1040] As a commentary on the way government institutions can work, it is interesting that the diffusion plant at Oak Ridge was built in the period 1942–44 with almost half a billion dollars that was appropriated by Congress without Congress knowing anything about it or about the highly secret atomic bomb project of which it was part. The whole atomic project involved expenditure of two billion dollars during the war and was hidden in the even larger general military budget under the distracting code name "Manhattan District" of the United States Army Corps of Engineers.

1946–1956 *Austrian physicist* **Gernot Zippe** *(1917–) the German physicist* **Max Steenbeck** *(1904–1981) and the German physicist* **Manfred von Ardenne** *(1907–1997) built for the Soviets a light-weight inexpensive gas-centrifuge. They were captured by the Russians in Germany (1945) and brought to Sukhumi with a group of about 300 German scientists*[1041] *to help the Soviets built an atomic bomb. The Zippe–Steenbeck machine reached a 30 percent degree of enrichment*[1042].

1956–1958 *On Zippe's return form Russia, the CIA immediately snatched him to work on US centrifuge technology with Jesse Beams.*

1957 *Zippe returned to West Germany and signed up to do centrifuge work with Degussa*[1043] *(Deutsch Gold-Und Silver-Scheide Anstalt). He conceived a large array of high-speed*

1041 Among the leading German scientists who worked in Russia (1945–1955) on the first Russian bomb were: **Nikolaus Riehl**, **Gustav Hertz**, **Max Vollmer**, **Peter Thiessen**, **Wilhelm Menke**, **Reinhold Reichmann**, **Gerhard Krueger**, **Heinz Barwich**, **Werner Schuetze**, **Gunther Wirths** and **Robert Doepel**.

1042 One of Germany's most important contributions to the Soviet bomb program was the uranium confiscated from Germany. It greatly accelerated the pace of the Soviet nuclear project: Despite all its efforts, the Soviet Union was catastrophically short of uranium for its nuclear project (10 kg of metallic uranium and 300 kg of uranium oxide and nitrate). The Germans had large amounts of uranium, including some acquired from the Belgian Congo: 300 tons of uranium oxide and other uranium compounds were brought to the USSR from Germany.

In conclusion, while the Soviets did not need the Germans to built a nuclear weapon, their contributions certainly accelerated the Soviet's push to become a nuclear weapons state: The Soviets benefited considerably from German technology, expertise, and raw materials. The German contributions undoubtedly accelerated the program by *several years* and enhanced the Soviet's stature on the world's stage.

1043 *Degussa* was a large German firm engaged in metal refining and production of chemicals including Zyklon-B cyanide tablets used by the Nazis to liquidate millions of Jews in the gas chambers. *Degussa* was also the company that supplied the uranium for the Nazi atomic bomb project. Degussa held an exclusive contract with the Nazis for re-smelting items taken from the Jews in the concentration camps including *dental gold*. *Degussa* built a smelter at Auschwitz, where the *daily* yield of gold at the camp was 12 kg. While looting the Holocaust victims of their gold and silver, *Degussa* supplied the poison gas to the concentration camps used to annihilate the owners of these metals.

centrifuges, each feeding the next with gas that is successively richer in uranium-235. Since 1958 his centrifuges remain the primary means for obtaining uranium-235. As the technology improved both power production and bomb-making got easier.

1994 *Trial of* ***Karl-Heinz Schaab*** *in Munich for treason. Accused and convicted for illegal selling of stolen classified blueprints of the Zippe ultracentrifuge to Iraq. The first person in the world convicted of 'nuclear espionage' in an open trial in the past 50 years. Schaab was linked to Degussa and Leybold, a Degussa subsidiary. He received an extremely light sentence upon conviction of 100,000 German marks fine and 5 years' probation. In 1990, Degussa was fined $ 800,000 for illegally re-exporting nuclear weapons-related material to North Korea. If Iraq had not invaded Kuwait, it could have managed to build a gas centrifuge facilities by the mid-1990s. The Scud-B technology Iraq used in the Gulf-War was 90 percent German and its nuclear technology was 60 percent German.*

1945–1950 CE **Wilfred Thesiger** (b. 1910–2003, England). Explorer of the Arabian desert. Mapped the *Empty Quarter* and other areas (over a total distance of $16,000$ km) between Yemen and Oman, never before explored by a European. In his book *Arabian Sands* (1958), Thesiger recorded the many journeys he has made by camel through and around the parched sands of Arabia's *Empty Quarter*.

Following in the tradition of **Richard Francis Burton** (1821–1890), **Charles Montagu Doughty** (1843–1926), **Thomas Edward Lawrence** (1888–1935), **Harry St. John Bridger Philby** (1885–1960) and **Bertram Thomas** (1892–1950), Thesiger is perhaps the last of the Great British explorers of the terra incognita.

Thesiger was born in Addis Ababa and educated at Eton and Oxford, spending the WWII years in the Sudan. Since the war he traveled in Southern Arabia, Kurdistan, the Marshes of Iraq, the Hindu Kush, the Karakorams, Morocco, Abyssinia, Kenya and Tonganaika, always on foot or with animal transport.

1945–1952 CE **Alan Lloyd Hodgkin** (1914–1998, England) and **Andrew Fielding Huxley**[1044] (b. 1917). Biophysicists. Described the ionic mechanism by which neurons transmit electrical impulses[1045] (1952). Awarded the Nobel prize for medicine (1963). Their model relates the response of the action potential to the changes in membrane permeability that accompany a change in voltage. The model does not explain why the membrane permeability changes; it relates the shape and conduction velocity of the impulse to the observed changes in membrane permeability. Nonetheless, the work was a triumph.

Most of their experiments were carried out on the giant axon of the squid. This is *single cell*, several cm long and 0.5 mm in diameter. The removal of axoplasm from the preparation and its replacement by electrolytes has shown that the critical phenomena all take place in the membrane.

Hodgkin and Huxley were educated at Trinity College, Cambridge. They started their work in 1939, but it was interrupted by WWII. Hodgkin was first to implant electrodes into squids' giant nerve fibers. Their Nobel prize was shared with **John Carew Eccles** (1903–1997, Australia) who developed techniques for intracellular recording from fine neurons.

1945–1972 CE **Wernher von Braun** (1912–1977, Germany and USA). Rocket engineer. Directed teams that built the rockets that sent the first American into space (1961) and made possible man's first landing on the moon (1969).

Von Braun was born in Wirsitz, Germany (now Wyrzysk, Poland). He became advisor in the rocket program of the German Army (1932), and played a major role in developing the V-2 rocket, with which Nazi Germany bombed Allied cities during WWII. In particular, he was technical director of the German test facility at Peenemünde (1936–1945) that launched V-2 rockets into London[1046].

[1044] The Huxley "tribe": **Thomas Henry Huxley** (biologist; 1825–1895) was the father of **Leonard Huxley** (editor and author; 1860–1933). Leonard's first wife was Julia Arnold. Their sons were: **Julian Sorell Huxley** (neo-Darwinist zoologist; 1887–1975) and **Aldous Leonard Huxley** (novelist and critic; 1894–1963). Leonard's second wife, Rosalind Bruce, begot him **Andrew Fielding Huxley**. Someone said of them: "*Not a dynasty, nor a clan, but an élite.*"

[1045] Hodgkin, A.L. and A.F. Huxley, A quantitative description of membrane current and its applications to conduction and excitation in nerve, *J. Physiol.* **117**, 500–544, 1952.

[1046] He was quoted as saying: "I aim at the stars, but sometimes I hit London".

In 1945 von Braun surrendered (with 116 other scientists) to the American Forces and was sent to the US to work on guided missile systems. His team developed ballistic missiles for the army, including the four-stage Jupiter-C rocket that launched *Explorer I*, the first United States earth satellite.

Another of the group's rockets, the *Redstone*, launched the flight of America's first astronaut, Alan B. Shepard Jr. (1961).

Other von Braun projects included the *Saturn* rockets. In 1969, a Saturn V rocket launched the astronauts who made man's first landing on the moon. In 1970, NASA (National Aeronautics and Space Administration) appointed von Braun deputy associate administrator for planning.

1946 CE **John Prosper Eckert** (1919–1995) and **John William Mauchly** (1907–1980) at the University of Pennsylvania built the ENIAC (Electronic Numerical Integrator and Computer). It was based on ideas borrowed from the world's first digital electronic computer, the ABC, built in 1939 by **John Vincent Atanasoff**.

The ENIAC used 18,000 vacuum tubes, was programmable, but programs could not be stored in a memory. In 1952, its successor, the EDVAC (Electronic Discrete Variable Computer) incorporated ideas of **John von Neumann**, such as program storage memory. It processed binary numbers serially, and its functioning was based on Boolean logic.

Algorithmic Vs. Dialectic Mathematics

The mathematics of Egypt, of Babylon, and of the ancient Orient was all of the algorithmic *type. The Babylonian, for example, found (ca 1700 BCE) an excellent approximation for* $\sqrt{2}$ *in their* base-60 *notation, which is equivalent to* $\sqrt{2} = 1.414\ 212\ 963$ *in decimals.*

Dialectic *mathematics — strictly logical, deductive mathematics — originated with the Greeks. But it did not displace the algorithmic variety.* ***Pythagoras*** *(550 BCE) was perplexed by the existence of* $\sqrt{2}$ *as the diagonal of the unit square on one hand, and by its non-existence as a fraction on the other. In the work of* ***Euclid****, the role of dialectics is to justify a construction — i.e., an algorithm.*

It is only in modern times that we find branches of mathematics with little or no algorithmic content, which we could call purely dialectic.

One of the first investigations to exhibit a predominantly dialectic spirit was the search for the roots of a polynomial of degree n*. For 300 years, mathematicians searched in vain for algorithms that would render closed formulae for* $n > 4$*. The theorems proved by* ***Gauss*** *(1799) and* ***Galois*** *(1829) are dialectic, providing no algorithm for the actual location of the roots. Since then, until WWII, pure mathematics has been existence-oriented rather than algorithm-oriented.*

However, the advent of electronic computers has led since the 1970s, to renewed interest in and need for numerical algorithms and their mathematical analyses within the framework of the new computer science, as well as in new computer-driven branches of applied mathematics.

The intrinsic features of each approach could be summarized as follows:

dialectic mathematics	*algorithmic mathematics*
• Rigorously logical, statements are either true or false, objects with specified properties either do or do not exist.	A tool for solving problems.
• An intellectual game played according to rules about which there is a high degree of consensus.	The rules of the game vary according to the urgency of the problem at hand and the computing equipment available.
• Invites contemplation.	Invites action.
• Generates insight	Generates results.

Annals of Computers (1642–1950)

Man's first conscious mathematical operations probably involved only simple counting: the number of faces in a tribe, the number of cattle in the herd, etc. When the numbers involved exceeded the number of fingers (or perhaps toes), some new form of reckoning had to be invented. Piles of sticks and stones and marks in the sand or on cave walls would have been logical calculating aids for primitive man. Addition and subtraction could be carried out merely by adding and erasing symbols from the crude tally sheets. (Today, modern electronic digital computers count in this same simple way. The cave wall is replaced by arrays of iron rings strung on wires or magnetized domains on a rotating disc or electrical activity in circuits. Instead of drawing or crossing out a mark on the wall, we now magnetize metalic domains or change currents and voltages in semiconductor devices.

One method of proceeding beyond the anatomical limit of hands, said to be still in use in Africa, is to enlist the aid of a second man. The first counts the units up to ten on his fingers, while his partner counts the numbers of groups of ten so formed. The next major step, taken by the first civilizations of Egypt and the Asian river valleys, was to represent numbers by means of pebbles arranged in heaps of ten. This in turn led to the development of the abacus*, or counting frame.*

The abacus was in use in so many widely separated cultures that many authorities believe it was invented independently in several centers.

Man's mathematics has progressed far beyond the simple notion of counting to algebra and the calculus. The electronic digital computer, moreover, with counting as its only stock in trade, has followed closely behind mathematical advances. It seems that any calculational problem, whether it is figuring the best move in a chess game or checking airline seat reservations, can be reduced to counting alone.

Simple counting *is not the only way to compute. One can* measure *too. Surely early man must have noticed how the shadows of trees swung slowly around as the sun moved across the sky. The passage of time could be measured by the progress of shadows on such natural sundials. With no trains to catch, primitive people needed no refinements. Later, of course, early civilizations developed more accurate natural clocks. The arrangement of huge stones at Stonehenge, England, for example, told the ancient priests when Midsummer's day, eclipses, and other key events of religious significance were about to occur.*

The basic idea behind sundials, modern clocks, slide rules, thermometers, and automobile speedometers is the measurement of some secondary quantity whose variations mimics or simulates the thing we wish to know. Thus, distance around the rim of a sundial simulates time, and the height of mercury in a thermometer is the analog of temperature.

Two families of computers, the analog *and* digital *machines, have evolved from the simple concepts of measuring and counting, respectively. The word* computer *is commonly reserved for a* digital computer*.*

By the beginning of the 17^{th} *century the victory of the Arabic system of enumeration — for both calculation and recording — was complete in most of Europe. As a result the abacus went out of use in the countries west of Russia. It was a long time, however, before even the basic processes of calculation became either commonly understood or widely practiced. Even in the second half of the* 17^{th} *century, multiplication and division of large numbers required the skill of professional mathematicians!*

The blockage was cleared by two inventions — one quite minor and the other of the very first importance — which effectively reduced all arithmetical calculations to addition and subtraction. Both these inventions are due to ***John Napier*** *of Murchiston, near Edinburgh.*

His minor invention (1617) was a simple mechanical device known colloquially as 'Napier's Bones'. It was just an improvement of an old method that had been in use in the East for multiplication of large numbers. Napier's major achievement, which really took the sting out of multiplication and division, was the invention of logarithms (1614). The importance of Napier's invention was immediately recognized by the practicing human computers of his day and within a few years the first steps were being taken to mechanize the process. Logarithms were plotted along a straight line and multiplications and divisions were performed by adding or subtracting the corresponding lengths with the aid of a pair of dividers. Since numbers are represented on the slide rule by lengths on a certain scale (on a logarithmic scale), the device is an analog computer[1047]*.*

An analog machines is restricted in the kind of calculation it does. This is true even of the versatile slide rule — which cannot help much with addition or

[1047] Applying *Ohm's law* in electricity, a simple electrical circuit can be used as an analogue of multiplication. According to this law, the difference in electric potential (in volts) between two points on a wire is the product of the resistance (in ohms) between the points and the current (in amperes) flowing along the wire. Thus we could obtain the product of two numbers (x and y) by arranging for a current of x amperes to flow through a resistance of y ohms, and measuring the voltage difference.

subtraction. The more complicated analog machines are even more restricted; most of them are designed to deal with specialized calculations such as arise in science and engineering — for example, harmonic analysis or the solution of certain types of differential equations. Digital machines, on the other hand, since they operate directly on numbers in the same way as does a human being when he calculates with pencil and paper, can be used for any kind of computation which can be broken down into arithmetical or logical steps.

The first mechanical calculating machine was completed in 1642 *by the French philosopher and mathematician* ***Blaise Pascal*** *(1623–1662). Some of his models are preserved in Paris. He conceived the design at the age of seventeen in order, so the story has it, to assist his father, who was a tax collector. Pascal's machine is digital, decimal and operated with a stylus*[1048]*. Numbers are carried to adjacent wheels by gears inside the machine. It was essentially an adding (and subtracting) device; multiplication had to be treated as repeated addition, the number to be added at each step being set separately.*

The next major advance was due to ***G.W. Leibniz*** *(1646–1716), the famous philosopher and mathematician and co-inventor (with Newton) of the calculus. He took the next logical step and mechanized multiplication. His first machine was constructed about 1671. The crucial feature of the whole design was the stepped wheel*[1049]*, an elegant device which is still used in the*

1048 One of the fundamental problems of the machine designer is that of arranging for *carry* from one digital position to the next, more significant position. This can be done in several ways, one of the simplest being the method adopted for recording domestic gas consumption – i.e.through the direct gearing of successive shafts with *gear ratios* of ten to one. Another possible scheme is the *stripped gear* method for carrying: a gear with 20 teeth all round its edge is engaged with another wheel of equal size that is stripped of all but two of its teeth. Each time the stripped wheel makes a complete revolution, the 20-teeth wheel turns through 1/10 of a revolution.

1049 The Leibniz *stepped wheel* consists of a cylindrical drum containing nine teeth of graduated lengths. A smaller pinion wheel engages a varying number of teeth, depending on its position. The two wheels are mounted on parallel axles and the pinion wheel can be displaced along its axle by means of a pusher. We may assign a length of 9 units to the longest tooth on the cylinder, 8 units to the next longest, and so on, in decreasing sequence. Thus one revolution of the cylinder will cause the pinion wheel to engage 0, 1, 2, etc., up to 9 teeth, depending on its axial position as determined by the pusher. We have in effect, therefore, a gearwheel containing a variable number of teeth.

The 'wheels of multiplication' consist, then, of a set of Leibniz stepped wheels *mounted on a common axle*; the digits of the multiplicand are set by moving the pushers associated with the appropriate pinion wheels. Each stepped wheel *form Leibniz left it, in some contemporary calculating machines.*

The crucial steps were taken, then, by Pascal and Leibniz in the 17^{th} *century. Since then the story has been one of continuous improvement in detailed design to give greater convenience of use, increased speed and improved reliability. During the* 18^{th} *century, many attempts were made to design a machine that could be mass-produced, but the degree of mechanical precission needed was beyond the capabilities of the production engineering techniques of that time. It was not until* 1810 *that the first successful commercial machine was made by* ***Charles Thomas*** *of Colmar, Alsace.*

Some 1500 *machines which embodied the Leibniz stepped wheel mechanism, are believed to have been made over a period of about* 60 *years. A variant of the Leibniz wheel was patented by* ***F.J. Baldwin*** *in* 1875, *and a number of machines using Baldwin's device were made by* ***W.T. Odhner*** *a little later. A vast number of Odhner type machines have been made in many countries since then.*

The first man to put forward detailed proposals for an automatic all-purpose calculating machine was ***Charles Babbage*** *(1792–1871). The various calculating devices discussed hitherto are non-automatic in the sense that they require the frequent attention of a human operator. An automatic calculating machine is able to carry out extensive calculations without human intervention.*

Babbage was born into an England where mathematics (during the century since Newton's death), had all but stagnated. The few who were literate could not, for the most part, figure sums accurately. Financial accounts were snarled, logarithm tables were full of errors, and insurance data were

---

is connected to the corresponding 'wheel of addition'. It is clear that multiplication by an arbitrary multiplier can be achieved with this device by rotating the stepped wheels, for each digit of the multiplier, a number of times corresponding to that digit, axially offsetting any two consecutive stepped wheels such as to effective add one more tooth at each digital stage. This procedure is, in fact, adopted in most of the simpler calculating machines today.
