male conscripts who were tested on tasks assessing general cognitive ability from the mid-1950s to early 2000, where each yearly cohort was approximately 19 years old (Sundet et al. 2008). Results showed that the general cognitive ability increased more or less linearly and rather steeply (i.e., IQ increased from 100 to 108) from the mid-1950s to 1970, and to a lesser extent thereafter (i.e., IQ increased from 108 to 111). These increases in cognitive ability were strongly

associated with increases in height, thereby pointing to the importance of improvements in nutrition and health care, factors that also influence cognitive performance.

In the SHARE study mentioned above, the investigators wanted to determine whether improvements in living conditions and educational opportunities, with women initially being more disadvantaged than men (Else-Quest and Grabe 2012), would explain why the magnitude of gender differences varied systematically across birth cohorts and regions (Weber et al. 2014). In doing so, a regional development index was created, which was specific for each country and age group. Historical information about each nation's economy, fertility rate, infant mortality, life expectancy, and national education levels corresponding to the years when participants were 25–45 years old was collected. It was found that in countries with a higher regional development index, cognitive performance was also higher. More importantly, it could be seen that women improved in cognitive performance more than men did, suggesting that women were more affected by improved living conditions and education. Although it is unclear why this is the case, one could hypothesize that women benefit disproportionately from societal improvements because they may start from a more disadvantaged level (Else-Quest and Grabe 2012). If this hypothesis is correct, women would be expected to improve their cognitive abilities the most in regions that advance from relatively low levels of living conditions and educational opportunities to higher. Future research need to explore whether this assumption is correct.

Summary

Taken together, there is little evidence to suggest that the rate of decline in cognitive performance over the life span is different for men and women. However, cross-sectional studies, comparing individuals of different ages at the same time point, suggest that the magnitude of gender differences may have changed over time. Improvements in living conditions and better educational

opportunities are factors that may lead to increased gender differences favoring women for some cognitive functions (e.g., episodic memory) and decreased (e.g., numeracy) or elimination (e.g., category fluency) of differences in other cognitive abilities. These changes seem to take place due to a general increase in cognitive performance over time, associated with societal improvements in living conditions and educational opportunities, where women are more affected than men.

Genetics is the study of heredity, or how the characteristics of living organisms are transmitted from one cell to the next or from one generation to the next. A primary focus of genetics is the analysis of how mutations and variations in DNA relate to human characteristics, behaviors, and disorders. Epigenetics on the other hand refers to cellular and physiological phenotypic trait variations that are caused by external factors that switch genes on and off rather than being caused by changes in the DNA sequence itself. Epigenetic change occurs regularly and can be influenced by a range of factors including age, environment, and disease state.

Genetic epidemiologic studies have documented the heritability of clinically psychiatric disorders over and over again.

Introduction

Molecular genetic studies have been challenging to conduct and success has been slow. However, the last decade has seen hundreds of positive genetic findings associated with a myriad of complex human diseases. This reflects the dramatic progress in the development and application of newer methodologies and technologies for the assessment and analysis of large genetic data. As important has been the development of the necessary infrastructure that has enabled large-scale collaborations on an unprecedented scale (Lehner et al. 2015). Resulting bio- and data repositories have made tens of thousands of patient phenotypes and millions of genotypes available to researchers all over the globe. Researchers are sharing data and biomaterials so that their use is maximized. However, with the exception of Alzheimer's disease, large-scale genome-wide association studies (GWAS) of late-life disorders are fewer. The field of late-life cognitive and psychiatric disorders is still dominated by candidate genetic approaches. Genetic approaches to older adults have emphasized outcomes such as cognitive processes, psychiatric disorders, resilience, and longevity.

Genetic Basis of Longevity

According to recent census estimates in the United States, the proportion of older adults (>65 years and over) is expected to double by 2050 (Ortman et al. 2014). Among older adults, individuals aged 85 and over are projected to increase the most, by an astounding 137%. Longevity, typically defined as >85 years of age (Shadyab and LaCroix 2015), is the culmination of a number of factors. Lifestyle (e.g., smoking, exercise) is proposed to play a major role in longevity (Newman and Murabito 2013), and optimal health behaviors can add many years to one's life (Fraser and Shavlik 2001). However, there is evidence that individuals with longevity do not differ in lifestyle from those without (Rajpathak et al. 2011), suggesting that other mechanisms, such as genetics, play a role.

Prior to the advent of genome-wide association studies, family and twin studies were the primary way to determine whether there is a genetic basis to a disorder or trait. Twin studies help us understand the extent to which a trait is heritable by comparing the trait in monozygotic versus dizygotic twins. Approximately 50% of the genome is shared in dizygotic (DZ) twins, while the genome is shared entirely in monozygotic (MZ) twins. Factors that are more concordant in MZ, as compared to DZ twins, may have a stronger genetic basis, whereas factors associated with similar rates of concordance in MZ and DZ twin pairs suggest that there are both genetic and environmental factors at play. Twin and family studies suggest that approximately 20–35% of longevity is due to genetic factors (Ljungquist et al. 1998; Matteini et al. 2010; Newman and Murabito 2013). Siblings of centenarians tend to live longer than the general population as well, further supporting this notion (Perls et al. 2002). Indeed, research on specific genes associated with longevity has largely produced mixed findings. A recent review by Shadyab and LaCroix (2015) identified two genes that have consistently been associated with longevity – apolipoprotein E (APOE) and forkhead box O3A (FOXO3A). APOE is a plasma protein that is implicated in transporting lipids and is involved in the growth and recovery of nerves. It is expressed on chromosome 19 and contains three allelic variants ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$). The presence of the $\epsilon 4$ allele has been associated with Alzheimer's disease (Corder et al. 1993), while both the $\epsilon 2$ and $\epsilon 4$ alleles have been associated with cardiovascular disease (Lahoz et al. 2001). FOXO3A lies within the insulin-like growth factor 1 signaling pathway. While its function is not entirely clear, it is likely associated with oxidative stress, maintaining insulin sensitivity, and cell-cycle progression (Newman and Murabito 2013). Telomere length has been proposed to be implicated in longevity, as telomere length decreases with age (Allsopp et al. 1992; Frenck et al. 1998). However, recent evidence suggests that telomere length is involved in healthy aging, not necessarily longevity per se (Njajou et al. 2009). There is also some evidence that mitochondrial DNA mutations may be associated with longevity as

well, through oxidative phosphorylation (Sevini et al. 2014).

One of the critical questions has been whether genetic markers associated with longevity might in fact subservise the medical illnesses associated with later life. Based on published GWAS investigations, Ganna et al. (2013) generated a genetic score from 707 common SNPs associated with 125 diseases or risk factors related with overall mortality. They then examined the association of the genetic score with time-to-death and also with incidence of nine major diseases, specifically coronary heart disease, stroke, heart failure, diabetes, dementia, and lung, breast, colon, and prostate cancers, in two population-based cohorts of Dutch and Swedish individuals aged 47–99 years. While the genetic score was significantly associated with time-to-death, the association between the genetic score and incidence of major diseases was stronger.

Epigenetic changes are thought to occur as a function of age, and patterns of DNA methylation can change during the lifetime in response to internal and external forces (Ben-Avraham et al. 2012; D'Aquila et al. 2013). Epigenetic regulation includes altered methylated states of regulatory DNA sequences, modifications of histone proteins, as well as expression of regulatory noncoding RNAs (Moskalev et al. 2014). MicroRNA (miRNA), specifically miR-34a, has been implicated in aging, as have miRNA-339 and miRNA-556 (Mehi et al. 2014). Long non-coding RNAs (lncRNAs) have also been proposed as a mechanism of aging (Moskalev et al. 2014).

It is important to acknowledge the effects of demographic selection in studies of the genetic basis of longevity. For example, although the APOE $\epsilon 2$ allele is more frequently observed in populations with longevity, this may reflect the fact that carriers of the $\epsilon 4$ allele have premature mortality (Perls et al. 2002). Additionally, inconsistent or null findings may reflect flaws in study design. Candidate gene studies are the most common design used and focus exclusively on one gene, which may attenuate findings. It is likely that polygenic and pleiotropic contributions, with interactions of different genes – rather than

individual effects – are most relevant in explaining the genetic basis of longevity (Sebastiani et al. 2012).

Genetic Basis of Cognitive Function in Late Life

It is a little over two decades since the first genetic markers began to be defined in association with cognitive function. Given the age-related changes observed in cognition, it is not surprising that the major focus of these investigations was older adults. It began with the observation in 1993 of an association between Alzheimer's disease (AD) and the presence of the APOE $\epsilon 4$ allele that held the promise of a definitive marker for this debilitating neurodegenerative disorder. APOE, a plasma protein involved in the transport and metabolism of lipids, is implicated in the growth and regeneration of nerves following injury. It is expressed by a gene on chromosome 19 with three allelic variants ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$). The $\epsilon 4$ allele is associated with reduced levels of APOE, conferring increased susceptibility and reduced response to neuronal injury (O'Hara et al. 2005). As the years passed, the accumulating evidence suggested that the $\epsilon 4$ allele is more a brain-vulnerability marker associated with impaired neuronal recovery from a range of physiologic challenges than a definitive marker for dementia per se. Multiple sources of evidence since then suggest that APOE $\epsilon 4$ is associated with decreases in memory and cognitive function over time, but not all individuals positive for the $\epsilon 4$ allele develop dementia.

Despite the well-documented association of APOE $\epsilon 4$ with cognitive impairment, decline, and dementia, comparing subjects who were cognitively intact or demented, Valerio et al. (2014) found that the association of APOE $\epsilon 4$ with dementia attenuated with advanced age. This finding is highly suggestive of a survivor effect model for successful aging, consistent with findings of other studies. Yet, not all age effects in genetics of late-life cognitive and/or psychiatric function reflect a survivor effect. Age can profoundly impact the expression of a gene, and physiological

changes with age can result in a very different impact of a genetic marker than occurs earlier in the lifespan.

Over the past two decades, a wide range of genetic markers have been associated in multiple studies with impairments in cognitive function in older adults. These include catechol-o-methyltransferase, which has been particularly associated with age-related changes in prefrontal and other cognitive functions (O'Hara et al. 2006); brain-derived neurotrophic factor (BDNF), which has been associated with improved cognitive function in older adults in a range of domains (Leckie et al. 2014); and serotonin transporter polymorphism (5-HTTLPR), which has been associated with variations in memory and cognitive control. These genetic markers have also been associated with measures of brain structure, activation, and connectivity that are believed to subserve the deficits seen in the cognitive manifestations of these markers (Waring et al. 2014; O'Hara et al. 2007).

While candidate genetic marker investigations of cognitive dysfunction in the elderly abound, large GWAS investigations are few and far between. In one of the most comprehensive, Ibrahim-Verbaas et al. (2016) conducted a GWAS on multiple cohorts of non-demented older adults from the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, aged 45 and older, assessed with multiple measures of executive functioning and information processing speed. They observed a significant association in the discovery cohorts for the single-nucleotide polymorphism (SNP) rs17518584 and in the joint discovery and replication meta-analysis after adjustment for age, gender, and education, in an intron of the gene cell adhesion molecule 2 (CADM2) with performance on digit symbol substitution. The protein encoded by CADM2 is involved in glutamate signaling, gamma-aminobutyric acid (GABA) transport, and neuron cell-cell adhesion. Their findings suggest that genetic variation in the CADM2 gene is associated with individual differences in information processing speed.

It has been speculated that one of the limitations of GWAS approaches to cognitive function with age is the presence of age-related medical disorders. As pointed out by Stacey et al. 2015, cognitive impairment, or decline, is not only a feature of dementia but also results from normal aging. They suggested that genetic association studies focusing on polymorphisms in and around inflammatory genes represented a viable approach to establish whether inflammatory mechanisms might play a causal role in cognitive decline, since cognitive function was frequently also assessed. This enabled the identification of specific genes potentially influencing specific cognitive domains. Some of these studies report significant cognitive domain-specific associations, specifically implicating interleukin 1 β (IL1 β) (rs16944), tumor necrosis factor α (TNF α) (rs1800629), and C-reactive protein (CRP) in a range of cognitive domains. Further, GWAS implicated less direct and less obvious regulators of inflammatory processes in cognitive functioning, including PDE7A, HS3ST4, and SPOCK3. The authors called for better cohesion across studies with regard to the cognitive test batteries administered to participants as a means to further understand the basis of cognitive impairment and decline in older adults.

Just as the pleiotropic effects of genes for inflammation also impacted cognitive function, still others have begun to investigate whether there are pleiotropic effects of genes associated with psychiatric disorders that impact cognitive functioning. Hill et al. (2015) examined the role of pleiotropy in explaining the link between cognitive function and psychiatric disorders. Employing two large GWAS data sets on cognitive function – one from older age, $n = 53,949$, and one from childhood, $n = 12,441$ – they found a genetic correlation of .711 ($p = 2.26e-12$) across the life course for general cognitive function. In schizophrenia, they found a negative genetic correlation between older age cognitive function but not in childhood. They found that the pleiotropy exhibited between cognitive function and psychiatric disorders changed across the life course, with an association of cognition and

psychiatric disorders dependent on the disorder of focus and stage of lifespan.

Genetic Basis of Late-Life Psychiatric Disorders

The study of genetics of psychiatric disorders has blossomed in recent years. Genetic studies of late-life psychiatric disorders have evolved more slowly. The majority of studies examining genetics within late-life psychiatric disorders are based largely on specific disorders or on specific candidate genetic markers (O'Hara and Hallmayer 2014).

Genetics certainly plays a role in the probability of developing a psychiatric disorder, and heritability appears to vary by disorder. For example, bipolar disorder and schizophrenia appear to have the highest heritability (85% and 81%, respectively), whereas panic disorder (43%), major depression (37%), and generalized anxiety disorder (28%) have lower rates of heritability (Bienvenu et al. 2011). A recent meta-review examined 1,519 meta-analyses and discovered 13 genetic variants that were common to two or more psychiatric disorders. These included serotonergic pathways (SLC6A4 5-HTTLPR, HTR1A C1019G, SLC6A4 VNTR, TPH1 218 A/C), dopaminergic pathways (DAT1 40-bp, DRD4 48-bp, COMT Val158Met), vascular pathways (APOE ϵ 4, ACE Ins/Del, MTHR C677T, MTHR A1298C), glutamatergic pathways (DAOA G72/G30 rs3918342), as well as neurotrophic pathways (BDNF Val66Met), which suggests that there are common genetic variants that increase vulnerability to psychiatric disorders across a number of diagnoses (Gatt et al. 2015). The number of genes implicated in specific disorders varies greatly. For example, 97 different genes have been implicated in schizophrenia, and 65 have been implicated in bipolar disorder, but only 6 have been implicated in affective disorders (Gatt et al. 2015).

Such GWAS investigations of older adults are very rare to date. Most recently, Ryan et al. (2016) selected variants within three genes, BICC1,

PCLO, and GRM7, for examination in their own study, since they were identified in a prior MDD GWAS study. They first investigated whether these variants were associated with depressive symptoms in a population-based cohort of 929 elderly (238 with clinical depressive symptoms and 691 controls) and secondly investigated their associations with structural brain alterations. A number of nominally significant associations were identified, but none reached Bonferroni-corrected significance levels. Common SNPs in BICC1 and PCLO were associated with a 50% and 30% decreased risk of depression, respectively. Among depressed individuals, rs9870680 (GRM7) was associated with the volume of gray and white matter. Their results provide some support for the involvement of BICC1 and PCLO in late-life depressive disorders, and preliminary evidence suggests that these genetic variants may also influence brain structural volumes.

Genetic Basis of Positive Traits in Older Adults

In addition to the genetic basis of psychiatric disorders, in recent years, we have seen increased consideration of the genetic underpinnings of positive psychological traits in late life, as they are believed to confer increase resilience to environmental stressors and protect against cognitive and psychiatric aging. Amstadter et al. (2014) examined resilience to stressful life events in 7500 adult twins and found resilience has a genetic heritability of approximately 31%. Mosing et al. (2009) measured optimism and found genetic factors explained 36% of the variation, with the rest due to non-shared environmental factors. Interestingly, they found that the genetic predisposition to high optimism also predisposed to good mental health and self-rated health, suggesting a potentially shared genetic basis among these variables. Twin studies of subjective well-being suggest that approximately 30 to 40% of its basis is genetic (Rietveld et al. 2013).

Arguing that resilience may have a cognitive basis, Mukherjee et al. (2014) defined executive

functioning resilience and conducted a GWAS analysis which found an association between RNASE13 and EF resilience ($p = 1.33 \times 10^{-7}$). They implicated genetic pathways involving dendritic/neuron spine, presynaptic membrane, and postsynaptic density in association with EF resilience.

Another GWAS investigation that could be considered to be examining positive traits was conducted by McGrath et al. (2013) who performed a GWAS of the mental and physical components of health-related quality of life across multiple psychiatric diagnoses. After controlling for psychiatric diagnostic category and symptom severity, the strongest evidence of genetic association was between variants in ADAMTS16 and physical functioning.

Yet another candidate marker for positive traits is CACNA1C, with Strohmaier et al. (2013) finding that genetic variation in CACNA1C was related to lower levels of optimism as well as resilience. CACNA1C is a member of a family of genes implicated in calcium channels and considered to be key for normal function of both heart and brain cells. While findings are mixed, many recent investigations find CACNA1C to be associated with a range of psychiatric disorders, including schizophrenia, depression, and bipolar disorder. This raises a critical issue pertinent to understanding the genetic basis of positive traits. It may be that any genotype associated with a negative outcome, such as a specific psychiatric disorder, will likely have a genotype that is also associated with positive traits that characterize the absence of the disorder. As such, these genetic markers may be nonspecific for positive traits per se, but are associated with a range of positive traits by virtue of not being associated with the negative traits integral to mental health traits or symptoms.

In one of the few investigations to specifically investigate a range of genetic markers associated with positive traits in older adults, Rana et al. (2014) examined 426 women from the Women's Health Initiative study and found no significant SNP associations with optimism and resilience. The authors concluded that positive psychological traits are likely genetically

complex, with no one specific gene or SNP, but rather many loci having small effects that contribute to the phenotypic variation.

Gene by Environment Interactions in Late Life

In older adults, environmental stressors can trigger the onset of a psychiatric disorder just as it can in younger populations. Genetic risk factors well-documented to be associated with the development of psychopathological response to stress are the serotonin transporter polymorphism (5-HTTLPR) and the BDNF Val66Met polymorphism. The 5-HTTLPR short allele and the BDNF Val66Met polymorphism have been shown to moderate the association between stressful life experiences and depression across the lifespan, in older adults, and the presence of both alleles also significantly predicts depression (Kim et al. 2007). Additionally, BDNF methylation has been shown to be associated with late-life depression and suicidal ideation (Januar et al. 2015; Kim et al. 2014), and 5-HTTLPR status has been shown to predict response to antidepressants among older adults experiencing their first major depressive episode (Shiroma et al. 2014).

However, while in a sample of 423 undergraduates, Stein et al. (2009) found *s* allele carriers of the 5-HTTLPR had reduced resilience to stress, this genetic marker was not found to be associated with resilience in an older adult sample, suggesting the association of the 5-HTTLPR with resilience attenuates with age (O'Hara et al. 2012). It has been however associated with poorer cognitive function in late life, with O'Hara et al. (2007) finding the *s* allele of the serotonin transporter polymorphism to be associated with poorer memory performance and reductions in the hippocampal structures that subserve memory. Further, in their 2012 investigation on resilience (O'Hara et al. 2012), the 5-HTTLPR *l* allele was not associated with resilience but was instead associated with better cognitive performance and self-rated successful aging. This raises the possibility that resilience may be a proxy variable for

cognition in older adults. Arguing that resilience may have a cognitive basis, Mukherjee et al. (2014) defined executive functioning resilience and conducted a GWAS analysis which implicated genetic pathways involving dendritic/neuron spine, presynaptic membrane, and post-synaptic density in association with EF resilience. Interestingly, our group found decreased neuroconnectivity among 5-HTTLPR s allele carriers (Waring et al. 2014), also suggesting a neurobiological basis for increased or indeed reduced resilience that would simultaneously impact the cognitive functions subserved by brain connectivity. Although there has been some examination of gene-environment interactions in recent years, further research is needed to further elucidate the mechanisms through which late-life psychiatric disorders are expressed.

Conclusion

The field of genetic inquiry into late-life mental, physical, and cognitive disorders is maturing. The ultimate goal is for studies to be translated into a personalized medicine approach, but this will require larger replication studies before any of these results can be translated into clinical practice. Such replication studies should ideally become the norm for the field of late-life mental, physical, and cognitive health and will require large consortia across sites expert in late-life outcomes and disorders with common characterization of phenotypes in order to yield the appropriate sample size for replication. As eloquently stated by Rana et al. (2014), larger sample sizes that would facilitate GWAS as well as complementary approaches such as sequence-based association studies, copy number variation analyses, and pathway-based analyses are required for us to more fully understand the genetic factors influencing geriatric psychiatric disorders.

Definition

This entry outlines the goals, methods, procedures, and results of the Georgia Centenarian Study, an NIH-funded study of the oldest old 1988–2009.

Phase 1 (1988–1992) was a cross-sectional study. Names of community-dwelling centenarians who had to be cognitively functioning were obtained from voter registration lists. Additional participants were recruited through media, area agencies of aging, and church contacts. The two younger groups (i.e., octogenarians and sexagenarians) were recruited by random digit dialing by the Survey Research Institute at the University of Georgia. Altogether, we recruited 38 male and 53 female sexagenarians, 31 male and 62 female octogenarians, and 35 male and 137 female centenarians, for a total of 321 study participants. The majority of the participants were Caucasian (72.3%), but a sizeable number were African

American (27.7%). The race and gender distributions of the samples were representative of the population in the State of Georgia. There were no proxies involved in Phase 1 of our study.

The study was driven by two primary questions. One, what is a theoretical model of aging that would be appropriate to describe life satisfaction and functioning in extreme old age? Two, what are the strengths (and weaknesses) of cognitively intact and community-dwelling centenarians that could contribute to their longevity, well-being, and life satisfaction?

It can be said that gerontological research in the modern era had been heavy with data and significantly lacking in theories and models to consolidate and make sense of the aging processes. Nevertheless, a multidisciplinary model was needed to test hypotheses on the principal components that could contribute to well-being and satisfaction in extreme old age. The solution in 1988 was to draw upon extant aging models that could be adapted to isolate differences among three cohorts – the 60-year-old individuals, where most aging research had been conducted, and 80s, and 100s. The goal of such a model was to explore potential mechanisms that could contribute to well-being and satisfaction in the oldest old where limited research attention had been expended to date. The resultant model was adapted from the Duke Longitudinal Study of Aging (where Poon was trained as a postdoctoral associate) and the Bonn Longitudinal Study (where Martin did his doctoral study). The hypothetical model began by measuring individual moderating characteristics (age, gender, marital status, number of children, etc.), followed by intervening abilities and resources (cognition, personality, stress and coping, time used, religiosity, social and economic resources) that might provide adaptational mechanisms, as well as nutrition, mental, and physical health. The outcomes of the model were well-being and life satisfaction.

During the 4 years of data collection for Phase 1, it is fair to note that the research team had significant learning curves in understanding and adjusting the research methodologies, especially in sampling, recruitment, and testing of the oldest old. These issues were not trivial as design

and methodologies employed with 60-year-old participants may or may not be applicable to centenarians, even if the centenarians were cognitively intact and community dwelling. Detailed summary of trials and tribulation of centenarian studies can be found in Poon and Perls (2007).

Given the potential confounds between cohort and age in a cross-sectional design, Phase 2 (1992–1998) was a longitudinal follow-up of the three initial age groups (i.e., sexagenarians, octogenarians, and centenarians) to examine variations in results between cross-sectional and longitudinal findings. Sixty-eight centenarians were interviewed for a second time after 20 months, whereas sixty-three octogenarians and seventy sexagenarians were recontacted after 60 months. The primary results of Phases 1 and 2 were described in Poon et al. (1992, 2007), and the following are four noteworthy clusters of findings from the two phases. *One*, variability across individuals is significantly larger among the centenarians compared to the younger 80s and 60s age groups. This finding was replicated with similar measures in the Swedish Centenarian Study (Hagberg et al. 2001). Contrary to the stereotype of centenarians performing more poorly than other age groups, some centenarians performed at the same or higher levels compared to their younger peers. At the same time, centenarians as a group showed the expected lower performance-based scores with steeper decline over time. *Two*, the study uncovered a host of compensatory functions that allowed the centenarians to live independently in their communities. The primary compensatory functions were found in: (a) robust survival personality (i.e., higher scores on dominance and suspiciousness), (b) intact crystallized intelligence, (c) higher nutritional status (e.g., body mass index), (d) social and community support, and (e) good overall levels of mental health. *Three*, an analysis was performed to ascertain whether the collected data could predict the number of days of survival after 100 years (Poon et al. 2000). The five significant predictors were (a) being female; (b) father's longevity, e.g., age of death; (c) higher cognition; (d) better nutritional status; and (e) better social support. The global analysis substantiated the function-specific

analyses in understanding survival mechanics as well as substantiating and extending many public health recommendations for healthy aging, especially at extreme old age. *Finally*, the study found that individuals' subjective compared to objective assessments were more predictive of individuals' well-being and levels of successful aging among the oldest old (Cho et al. 2015). This finding on the utility of subjective assessment of well-being has been supported by studies of the oldest old in other countries.

Phase 3 (2001–2009) was a program project that extended Phases 1 and 2 with population-based samples of centenarians and octogenarians in four projects: (a) genetics, (b) neuropathology, (c) functional capacities (including cognition and neuropsychology, physical exams, medications, kinesiology, everyday functioning, blood chemistry), and (d) resources and adaptation (including personality, social and economic resources, life events, coping, and subjective well-being). The program project required the inclusion of five additional administrative units on (a) administration; (b) sampling; (c) cell, blood, and DNA; (d) data acquisition; and (e) data management. Two biologic archives were initiated to store and share specimen with qualified researchers: (a) centenarian blood, cell, and DNA at the Coriell Institute, New Jersey, and (b) centenarian brains at the Alzheimer's Center at the University of Kentucky. While Phases 1 and 2 were conducted with collaborations from two universities, the added complexity of Phase 3 included faculty researchers among nine universities. Description of the methodologies and selected findings can be found at Poon et al. (2007).

Phase 3 provided a design that could test the generalization of findings obtained from convenient samples of cognitively intact and community-dwelling study participants in Phases 1 and 2. For this study, we recruited population-based samples of 244 centenarians and near centenarians (98 years and older) and a comparison group of 80 octogenarians living in northern Georgia. Participants were recruited from skilled nursing facilities and personal care homes in North Georgia. In addition, we used voter registration lists to enroll additional participants.

The majority of centenarians were female (84.9%) and Caucasian (78.7%). Likewise, more octogenarians were female (66.3%) and Caucasian (82.5%).

Representative samples in Phase 3 contained a wide spectrum of functioning of the oldest old from those similar to Phase 1 to those who were severely demented, institutionalized, and with minimal functional capacities. Another advantage of Phase 3 was the availability of data to test interactions among gene and environment on a variety of outcomes in mortality, morbidity, and functioning among the oldest old.

Specific to geropsychology, Phase 3 was designed to examine cognition, neuropsychology, personality, stress and coping, impact of distal and proximal events, as well as family and social resources and relationships. A description of an examination of prevalence of dementia among a representative sample of centenarians in Georgia is used as an illustration of cognitive study here.

An unanswered question on the cognition of centenarians is a valid estimate of dementia among a representative population. In a review of literature, the reported prevalence was between 27% and 75% with a mean of 60%. Data from Phase 3 was used to validate the Global Deterioration Scale (GDS) (Reisberg et al. 1981) that had not been validated with centenarians, as well as to understand the large variation in prevalence estimates (Poon et al. 2012). Using the Phase 3 data, GDS was found to contain high and significant correlations with MMSE and CDR, two instruments commonly used in global dementia assessment. The GDS was also found to correlate significantly with a battery of neuropsychological tests that are used for dementia assessment (executive functioning, word fluency, memory, abstract reasoning, and similarity). High and significant correlations were found with basic and instrumental functions and mobility as well as with neuropathologic findings in the Braak score, cerebral atrophy, brain weight, and National Institute on Aging Reagan criteria for dementia. Finally, there was a perfect concordance between GDS ratings and blind consensus diagnoses among a clinical team in 27 out of 39 cases (69% agreement, $p < 0.0003$).

The Phase 3 data was also used to provide potential explanations on the wide range of reported dementia prevalence in the literature. One potential explanation was some studies might have used convenient samples, and variation in sampling criteria (convenient versus representative) might have biased the outcome. Another potential explanation is that different criteria might have been used to define dementia. If one uses a criterion of adequacy of everyday functioning (GDS stages 1–3), the dementia prevalence is 52.2%. However, if one uses a strict criterion of any sign of mild confusion to severe dementia (GDS stage 3–7), then the prevalence is 77.5%. Finally, we used Phase 3 data to demonstrate sample characteristics (age, gender, education, and age distribution) could also influence the disparity of dementia prevalence reported in the literature (Poon et al. 2012).

Our 20-year exposure in research with centenarians taught us two major lessons. First, the study of aging at extreme old age may be equivalent to cross-cultural studies in that generalizations of designs and methodologies employed for 60-year-old persons may or may not be applicable to those at the end stage of life. Similar to cross-cultural studies, measurement invariance and large individual variability in abilities and functional capacities must be considered in measurement and analysis. Sampling strategies must be carefully considered. Testing time alone may be lengthened from twofold to fivefold. Second, because of large individual differences in performance outcome, main (direct) and interactive (indirect) effects among variables must be carefully considered to understand the highly variable aging processes.

Finally, since the beginning of the Georgia Centenarian Study in 1988, there are many new centenarian studies reported from different countries around the world. Owing to variations in culture and contexts, the reliability and generalizability of reported findings are unknown at present. We believe it is utmost important to design a metric or approach that would take into account the molar environmental, sociologic, and demographic moderating impact on individualized

biopsychosocial intervening processes in the determination of common outcomes such as mortality, morbidity, and functional capacities. In this manner, we would be able to compare and contrast contributing factors to health and longevity around the world using the same metric.

Geriatric Neuropsychological Testing

Definition

Geriatric neuropsychological assessment involves a comprehensive evaluation of a patient that typically entails review of medical records and relevant medical test results, an interview with the patient and collateral sources, administration and scoring of diagnostically valid tests measuring a wide range of cognitive domains, and communication of results and recommendations to the patient and referral source.

Introduction

With modern advances in science and medicine, the world population is expected to grow and age at exponential rates. According to the United Nations (United Nations Department of Economic and Social Affairs, Population Division 2015), the world population over age 59 will more than double by the year 2050 to 2.1 billion. The number of persons aged 80 and above is expected to more than triple, reaching 434 million over this same time period. As the population ages, it becomes increasingly important to understand the many changes that occur in normal aging and

distinguish them from the signs that herald disease onset. In this regard, neuropsychological assessment can often provide valuable information to assist in early detection of cognitive impairment, differential diagnosis, and patient care.

One of the common causes of abnormal cognition in older adults is Alzheimer's disease (AD), a dementia typically characterized by impairment in memory plus one or more other cognitive domains of sufficient severity to interfere with daily functioning. In the late 1990s, investigators began to recognize that characteristic patterns of cognitive inefficiencies on formal neuropsychological testing could help identify individuals at higher risk for developing AD and other dementia syndromes. Different terminologies were initially used to describe this risk condition, including mild cognitive impairment (MCI) (Petersen et al. 1999), questionable dementia (Devanand et al. 1997), and cognitive impairment, no dementia (Tuokko et al. 2001). The discovery underscored that dementia does not reveal itself overnight but instead develops gradually and can be detected in its early stages by psychometrically sound neuropsychological techniques. Over time, the scientific concepts and diagnostic criteria of mild cognitive impairment (MCI) have become most widely accepted in clinical practice and research, with diagnostic criteria recently updated by a consensus group of the US National Institute of Health and Alzheimer's Association (Albert et al. 2011).

Converging evidence suggests that the neuropathologic process underlying AD and other degenerative dementias most likely begins years, if not decades, prior to the first detectable signs of MCI (Sperling et al. 2011). Longitudinal studies at multiple times before the onset of MCI reveal a period of gradually progressive cognitive decline up to a decade before symptoms reach the threshold of clinical diagnostic criteria. The observed "preclinical" trajectory reflects a long, slow rate of presymptomatic cognitive deterioration followed by accelerated decline in the years immediately preceding MCI diagnosis (Howieson et al. 2008). Although reliable clinical prediction of disease is still not yet possible prior to overt symptom presentation, current research is exploring ways to

combine neuropsychological data with other biomarker information to generate risk profiles for dementia in much the same way algorithms of vascular risk factors are currently used to identify future development of heart disease.

Although effective dementia prevention therapies are not yet available, it remains important to identify neurodegenerative conditions early to provide appropriate symptomatic relief, education for patients and families, and opportunities to participate in clinical trials. It is also important to recognize that many medical conditions other than dementia can impact cognition in later life. Some cognitive impairment may be reversible, such as that due to primary medical or psychiatric disorders. Rehabilitation therapies can help patients with other conditions, such as stroke or traumatic brain injury, recover from or compensate for cognitive impairments. Accurately identifying the nature and potential etiology of cognitive disorders can help guide patient care in meaningful ways.

Goals of Geriatric Neuropsychological Assessment

Neuropsychology is the study of brain-behavior relationships through the use of specialized cognitive assessment techniques. Neuropsychologists use these techniques to answer questions regarding cognitive status raised by neurologists, internists, primary care physicians, hospitalists, mental health providers, other referral sources, and patients themselves. The content and format of neuropsychological assessment depends on the specific referral question, clinical setting, and patient characteristics. In geriatric neuropsychological assessment, a comprehensive evaluation typically entails review of medical records and relevant medical test results (e.g., laboratory studies, neuroimaging), interview with the patient and collateral source to understand the presenting cognitive and behavioral symptoms, administration and scoring of tests measuring a wide range of cognitive domains, and communication of results and recommendations to the patient and referral source.

Commonly assessed cognitive domains in geriatric assessments include: attention (e.g., attention span, working memory, divided attention), memory (e.g., learning efficiency, free recall, recognition memory), language (e.g., naming, fluency, comprehension), visuospatial ability (e.g., perception, construction), and executive functions (e.g., mental flexibility, planning, problem-solving). Neuropsychological test administration follows standardized procedures, with scores derived according to established guidelines and compared to normative standards corrected for appropriate demographic variables. The neuropsychologist interprets the pattern of test scores and integrates them with behaviors observed during the test session and information obtained from the medical record and clinical interview.

The most common referral questions for neuropsychological assessment in older persons pertain to diagnosis (e.g., early detection of disease, differential diagnosis) and/or functional status (e.g., daily functioning, capacity to make decisions).

1. *Detecting cognitive impairment.* Neuropsychological assessment is commonly requested to determine whether perceived or observed cognitive changes are due to normal aging or acquired brain dysfunction. To accomplish this, neuropsychologists administer tests with proven diagnostic validity. Diagnostic validity refers to the sensitivity and specificity of a test. Sensitivity is the probability that someone with true cognitive impairment is identified by the test as being impaired (i.e., “true positive”) whereas specificity is the probability that someone without cognitive impairment is identified by the test as unimpaired (i.e., “true negative”). Because these metrics are probabilities, they range in value from 0 to 1, with values closer to 1 being more desirable (i.e., reflecting higher classification accuracy).

Ideal tests would have equally high sensitivity and specificity; however, in reality these metrics act in opposition to one another such that as one value increases, the other value decreases. Choosing appropriate measures

depends on the question being addressed and the consequences of an incorrect decision. A test with high sensitivity but low specificity is useful when it is imperative to detect everyone with impairment, even if a sizeable number of normal individuals are misidentified as impaired. For example, it may be preferable to identify someone without Ebola as being infected and isolate them for a brief time (i.e., false-positive error) than to release someone with the virus into the general population (i.e., false-negative error). Conversely, choosing a test with high specificity but low sensitivity is useful if one wants to ensure that only those with true impairment are identified. For example, clinical trial outcomes may be misleading if people without the condition of interest are enrolled, such that a test that excludes some eligible candidates may be desirable if all ineligible candidates are excluded by it.

It is important to note that sensitivity and specificity are necessary to select valid measures, but they only describe the function of tests *when the cognitive status of the individual is known*. They do not address the important clinical question of whether a patient with a particular score has true impairment due to disease. This information is conveyed by the positive predictive value (PPV) of a test. A complete review of PPV and other clinical utility metrics is beyond the scope of this entry; however, it is important to know that PPV is disproportionately affected by test specificity, such that increasing specificity increases PPV to a greater degree than an identical increase in sensitivity (Smith et al. 2008).

2. *Normal cognitive aging*. Declines in processing speed, memory, language, and executive functions are common in normal aging (Harada et al. 2013). Older adults learn less with initial exposure to new information and require longer or repeated exposure to learn the same amount as younger adults. They are also less efficient in retrieving learned information, although retention is relatively preserved. Age-associated memory changes may be related to slow processing speed (Luszcz and Bryan 1999), heightened

distraction (Darowski et al. 2008), or inefficiencies in learning or recall strategies (Davis et al. 2013; Delis et al. 2000; Isingrini and Tacconat 2008). Vocabulary and word recognition remain stable with age; however, the ability to come up with specific words or names declines (Singh-Manoux et al. 2012). Executive functions such as novel concept formation and mental flexibility also decline with age (Singh-Manoux et al. 2012; Wecker et al. 2000). Several neurologic correlates to these age-related cognitive declines have been identified, including loss of gray and white matter volume, damage in white matter pathways, and reduced neurotransmitter levels (Harada et al. 2013). These changes, however, are typically of insufficient magnitude to have a significant impact on daily functioning.

3. *Differential diagnosis*. Over the last decade, studies of MCI, AD, and other dementias have informed modern consensus diagnostic criteria, most of which include evidence-based descriptions of characteristic cognitive changes (Albert et al. 2011; Gorno-Tempini et al. 2011; McKhann et al. 2011; McKeith et al. 2005; Rascovsky et al. 2011; Roman et al. 1993). Although psychometrically sound test scores provide the clinician with important quantitative evidence of cognitive impairment, these data must be integrated with the clinical history, neurobehavioral presentation, knowledge of functional neuroanatomy, and knowledge of the literature to fully utilize consensus diagnostic criteria.

Impairment in the ability to learn and retain new information (i.e., episodic memory) is the most common neuropsychological deficit in MCI patients who progress to AD (Albert et al. 2011). By comparison, patients with Lewy body dementia (LBD) demonstrate early deficits in attention and visuospatial functions (Ferman et al. 2013; Hamilton et al. 2012). Disturbances of behavioral regulation and a pattern of relatively weaker executive functions than episodic memory are seen in early behavioral variant frontotemporal dementia (FTD) (Wittenberg et al. 2008), whereas early characteristic speech and

language deficits typify the progressive aphasia variants of FTD and AD (Gorno-Tempini et al. 2011). Patients with vascular cognitive impairment due to strokes often show multifocal neuropsychological deficits reflecting damage to the affected neuroanatomy and/or disconnected brain systems. Patients with chronic vascular risk factors (e.g., diabetes, hypertension) typically demonstrate deficits in processing speed, working memory, and mental flexibility due to chronic ischemic disruption of deep white matter frontal subcortical pathways (Sachdev et al. 2004).

As noted earlier, a number of conditions may produce reversible cognitive impairment in older adults. These include depression, medications, hydrocephalus, nutritional deficiencies, and metabolic/endocrine conditions (Tripathi and Vibha 2009). Neuropsychological profile patterns, medical consultation, and appropriate laboratory tests can often distinguish these disorders from static or progressive cognitive disorders.

4. *Longitudinal assessment.* Neuropsychological assessments conducted at a single point in time can sometimes yield inconclusive diagnostic information or may identify a disease process with a potentially dynamic course. In such cases, it is often helpful to obtain prospective, longitudinal assessments to more reliably establish the diagnosis, identify new patient/caregiver needs, or assess recovery/response to treatment. When a progressive neurodegenerative condition is suspected, neuropsychologists often will include a brief cognitive screening measure, such as the Mini Mental State (Folstein et al. 1975), Montreal Cognitive Assessment (Nasreddine et al. 2005), or Dementia Rating Scale (Jurica et al. 2001) as part of the baseline battery. This ensures the ability to briefly measure broad cognitive status when disease has progressed beyond the point where patients can tolerate a full neuropsychological assessment.
5. *Functional status.* An older adult's independence and other factors contributing to quality of life may be altered by cognitive changes. Not surprisingly, neuropsychological measures

tend to be better predictors of ability to perform activities that place high demands on cognition (e.g., managing finances) and are less robust in predicting ability to perform more basic or habitual self-care activities (Farias et al. 2003). The literature suggests that within geriatric populations, performances on measures of memory and executive functions are most strongly associated with ability to perform higher order activities of daily living (O'Bryant et al. 2011; Tomaszewski Farias et al. 2009).

Neuropsychological findings can help patients and families better understand and manage limitations in daily functioning due to cognitive changes and identify needs for assistance or safeguards. A special category of geriatric neuropsychological assessment is the capacity assessment. *Capacity* refers to one's ability to perceive and understand information accurately and to act on that information in a competent fashion. Capacity evaluations seek to determine if a patient can live independently, make medical decisions, enter legal contracts, manage finances, make or change their will, donate assets, name a power of attorney, etc. Measures of attention, comprehension, learning, recall, integration of information, planning, reasoning, and impulse control contribute valuable information to these important decisions.

Although the ability of neuropsychological assessment to identify cognitive impairment is often highlighted, assessment can also identify areas of cognitive strength that may be exploited to limit or compensate for the impact of disease on everyday functioning. Rehabilitation models have long helped patients with traumatic brain injury and stroke adapt to cognitive changes brought on by their condition, and in recent years, these models have been modified and applied to geriatric populations with MCI and early dementia. Clinical trials demonstrate improved cognition, mood, and psychological well-being after completing such programs (Talassi et al. 2007; Jean et al. 2010); however, these interventions only delay the time to dementia onset and do

not prevent disease progression. Nevertheless, lengthening the timeframe during which patients remain independently functioning can improve quality of life, reduce caregiver stress, and ease financial burdens associated with home health costs and assisted living.

Considerations in Geriatric Neuropsychological Assessment

Regardless of the intended purpose of the neuropsychological assessment of the older adult, clinicians must be aware of the many confounds that may contribute variability to test scores beyond that due to brain disease. Some confounds can be addressed quantitatively by minimizing their influence through normative corrections. Others must be addressed through other means, such as accommodation, modification of procedures, or clinical judgment.

1. *Normative corrections.* Reducing the “noise” in test scores due to confounds increases test specificity which, as noted earlier, improves the probability that a low score is due to true cognitive impairment. Use of appropriate normative data serves this purpose. Since cognition declines with normal aging, correcting test variance due to age is essential in geriatric assessment. Most clinical assessment measures provide age corrections for older adults, although the availability of age-adjusted norms in the oldest old (age 90+ years) remains limited.

In addition to age, many cognitive tests are sensitive to differences in education and cultural diversity. Corrections for years of education are commonly available but considerable work remains to account for differences in test performance related to cultural, ethnic, and language variables. Research shows that these variables often serve as proxies for other societal influences that affect test performance, including socioeconomic status, nutrition, access to health care, health literacy, and lack of comfort/familiarity with testing (Brickman et al. 2006). Individuals from different

cultures, school systems, and language backgrounds are at heightened risk of scoring low on neuropsychological tests for reasons other than true cognitive dysfunction, and thus being mislabeled as “impaired” when no brain disease is present. Availability of ethnic and linguistic norms is growing but remains limited. It is therefore essential that neuropsychologists know when appropriate normative corrections are available, and understand the limitations of findings when patients do not closely match the demographics of the normative sample used.

2. *Testing modifications.* Some age-related changes are universal (e.g., slowed processing) and corrected when age-adjusted normative data are applied to test scores. Other common problems of aging, however, vary considerably from individual to individual and cannot be corrected by group normative data. Effects of these factors on test performance require consideration that may necessitate modifications to the test environment or assessment plan.

(a) *Primary sensory deficits.* Vision impairment is common in older adults due to a combination of age-related changes and higher prevalence of ocular disease (e.g., cataracts, macular degeneration). Hearing loss is also prevalent in older adults, and yet, for example, less than one third of US elders with hearing loss use hearing aids (US Department of Health and Human Services 2014). Such patients can often be accommodated with magnifying or amplification devices. Alternatively, the neuropsychologist may choose tests that minimize the sensory confound (e.g., giving a hearing impaired patient a word-list memory test where the words to be learned are presented in writing). Some patients with primary sensory deficits may require modification of test procedures that break standardization, such as using enlarged stimuli, allowing extra time for sensory-perceptual processing, or repeating misperceived stimuli or instructions. Such modifications should always be reported when interpreting and communicating test results.

- (b) *Sleep disorders and fatigue.* Sleep quality and quantity decrease with advanced age. Healthy older adults are less able to initiate and maintain sleep, and they spend less time in restorative slow-wave and rapid eye movement (REM) sleep (Espiritu 2008). Sleep may be further altered due to nocturia, medication effects, or changing life events such as the death of a spouse. Disorders of sleep such as obstructive sleep apnea, restless legs syndrome, and REM sleep behavior disorder are also more prevalent in older adults (Lee et al. 2008; Ohayon and Roth 2002; Markov et al. 2006).

Chronic sleep deprivation and daytime somnolence impact cognitive efficiency in characteristic ways, including slowed processing and attention deficiencies (Waters and Bucks 2011). Higher order cognitive functions are affected by sleep to the degree that they depend on attention and processing speed. Sleep disturbance has a dose-dependent effect on cognitive impairment, with greater severity of insomnia associated with greater cognitive impairment. Sleep-related cognitive deficits typically improve, however, once normal sleep patterns resume (Waters and Bucks 2011).

When assessing older patients with complaints of fatigue or somnolence, consideration should be given to prioritizing/shortening the test battery and including higher order cognitive measures that are less dependent on sustained attention and processing speed. The examiner should be vigilant for signs that fatigue is confounding test performance and consider breaking up the assessment over multiple sessions if necessary.

- (c) *Chronic pain.* Common causes of pain in older adults include arthritic conditions, musculoskeletal disorders, neuropathies, and vertebral compression due to injury or osteoporosis. Neuropsychological studies suggest that chronic pain is associated with deficits in attention and psychomotor

speed (Hart et al. 2000), most likely due to multiple factors, including acute discomfort, distraction due to heightened somatic focus, side effects of analgesic medications, pain-related sleep disturbance, and pain-related mood disturbance.

Chronic pain and its related symptomatology are a source of performance variance that may warrant postponing the neuropsychological assessment when symptoms are acute, severe, or not yet fully evaluated/controlled. When testing an older adult with chronic pain, the test environment may need to be adjusted by attending to appropriate ergonomics (adjusting table height, using large diameter writing implements, etc.), encouraging patients to bring/use orthotics, and allowing patients to stand or change positions as warranted to help minimize distraction due to pain.

- (d) *Mood.* Stress, losses, and illnesses of advanced age disrupt quality of life and contribute to mood changes in later life. Symptoms of late-life depression, however, may be subtle, atypical, or fewer in number than required to meet diagnostic criteria for clinical depression. The prevalence of major depression in community-dwelling elders over age 64 ranges from 1% to 5%; however, clinically significant depressive symptoms are reported by 15% (Fiske et al. 2009). When health concerns are present, the risk of depression increases twofold to threefold (Andreasen et al. 2014; Ali et al. 2006; Spijkerman et al. 2005).

Neuropsychological studies of late-life depression find reduced information processing speed, inefficient memory, and executive dysfunction (Dybedal et al. 2013). Similar to assessment decisions in patients with pain or fatigue, the decision to proceed with neuropsychological testing depends on the degree to which symptoms are managed at the time of testing. Depressed patients can generally sustain

sufficient effort on formal neuropsychological testing to yield valid results (Larrabee 2012); however, those who are acutely grieving or recently presented with an ominous diagnosis may not be able to produce valid neuropsychological profiles. In such cases, clinical judgment should dictate the approach to assessment.

3. *Rapport*. The ability to develop a working relationship with patients is essential to obtaining valid neuropsychological results across all populations; however, establishing rapport with older adults can present unique challenges. Attending to issues of sensory loss, pain, fatigue, and mood symptoms as described above can facilitate rapport because it demonstrates recognition and understanding of the patient's needs. The neuropsychologist should also understand that their assessment may represent the first time a patient has been referred to a healthcare professional whose title contains the word "psychologist." Generational differences in the perceived stigma of such a referral may engender anxiety or defensiveness in an older patient. There is also significant potential for patients to misunderstand the process or goals of neuropsychological assessment. Referring providers may not fully explain the rationale for ordering the assessment or the exact nature of the evaluation. Even when given appropriate information at the time of referral, patients with cognitive deficits may not fully understand or remember what they were told, or they may express trepidation about being evaluated. Moreover, large cohorts of older persons were not afforded the educational opportunities of subsequent generations and may feel intimidated by "testing." These and other expectations can often be identified and managed during the informed consent process at the outset of the assessment. Careful explanation of the nature of the assessment procedures, the type of information gathered, the way the information will be used to help the patient, and the voluntary nature of the process can help reassure otherwise reluctant patients.

Thoughtful attention to respectful interactions is another important component of rapport building with older patients. Oftentimes, the patient may recognize their cognitive decline and feel embarrassed by it. Those who formerly held positions of authority, efficiency, or pride may become uncomfortable or agitated when a much younger examiner begins to ask difficult questions, judge their responses, and observe task performances. Although test standardization may make it difficult to avoid these threats to rapport, a skilled examiner can repair the relationship between tasks by expressing sincere interest in the patient's greater life experience, recognition of their former expertise, or appreciation for important historical events, cultural movements, or values associated with the patient's generational cohort.

Summary

Measuring and understanding cognitive symptoms in older adults is important in geriatric practice given that independent living, decision-making capacity, and other factors affecting quality of life may be affected when cognitive changes are suspected. Clinically meaningful geriatric neuropsychological assessment therefore warrants multiple considerations. The neuropsychologist performing the assessment must be knowledgeable about cognitive changes that accompany normal aging, characteristic symptoms that distinguish normal changes from early disease, underlying brain systems affected by disease mechanisms, and current consensus diagnostic criteria. The reason for assessment must be clear and the neuropsychologist must understand the symptom presentation and clinical history sufficiently to select assessment measures with the appropriate diagnostic validity and clinical utility. Ongoing attention must be given to potential confounds or threats to validity that may introduce variability to test performances, and consideration must be given to the appropriate corrections or accommodations required.

Introduction

Gerontechnology (GT) is an applied field of study and is a fusion of gerontology and technology. It is a relatively new field, with the term itself apparently first coined in the literature just prior to the 1990s (Micera et al. 2008). By its very nature, the field is dynamic, as it is predicated on the application of ever-changing technologies to the needs of an ever-changing birth cohort. It is also by its nature interdisciplinary, comprised of researchers, clinicians, and academicians in fields as diverse as (but not limited to) psychology, computer science, engineering, ergonomics and human factors, geriatric medicine, and architecture. *GT is concerned with the development, adoption, and use of technology for the purposes of maximizing the health, well-being, and functional independence in all domains (including social, occupational, vocational, and psychological) in older adults.*

GT and the “Generation Effect”

The concept of technology generations, borne out of the field of sociology in the 1990s, describes the idea of birth cohorts being defined by their own particular experiences with technology (e.g., referring to youth of today as “internet generation”). Generation effects are a central issue to many aspects of GT and are especially relevant as regards issues such as user interface design, user acceptance, and usability across an array of technological products and applications. For instance, users who have not been exposed to a technology prior to a critical period of exposure (e.g., mid-20s) are far less likely to become fluent users of that technology. Younger adults today who began their lives exposed to search engine technology are far more familiar with the use of Boolean operators (defined as making use of words “and,” “or,” and “not” for the purposes of refining search engine results for greater accuracy) than their older adult counterparts. In contrast, older adults rely more on more familiar system tools, such as online encyclopedias (Rogers and Fisk 2010). More broadly, the idea behind the technology generation effect is that introduction of a *multilayered interface* to individuals socialized to single-layered user interfaces will invariably produce an obstacle toward technology adoption and usage behavior.

An example of a single-layered interface design is what was found in first-generation microwave ovens – with its analog controls, all device functions were fully visible to the user (e.g., dial for cooking time, switch to toggle high-low settings, button for power). In contrast, modern microwave ovens are now equipped with digital controls and menu-based, hierarchical interfaces, where software allows for various options and functions to remain invisible until selected by the user (Harrington and Harrington 2000). The concept of technology generations has received empirical support as an entity independent of cognitive and functional decline common to older adults (e.g., such as slowed processing) (Bouma et al. 2007). Technology generations have been grouped in different ways by various authors, with the predominant interaction style

(e.g., the way the user communicates with the technology) as the principal distinguishing factor. These groups are:

1. *The mechanical generation*, born prior to the 1940s
2. *The electromechanical generation*, born between the 1940s and 1960s
3. *The digital generation*, born from the 1960s on (Harrington and Harrington 2000)

Gerontechnology: Theoretical Perspectives

Gerontechnology is a field relatively rich in data but has been historically poor in explicit theory development or, at least, explicit theoretical articulation – which runs the risk of ageist attitudes and frameworks coloring how inquiry is approached (Rogers and Fisk 2003). For example, the traditional focus on the use of surveillance and monitoring technologies with older adults, such as bed and chair alarms in nursing homes, may work for the laudable goal of insuring safety but may end up inadvertently reinforcing the role of older adults as inherently disabled and dependent.

There are a number of existing theoretical frameworks drawn from lifespan development work, motivational theory, and technology usability research that may be helpful to understanding how to frame GT in a more positive manner. Important theoretical perspectives relating to GT are drawn from motivational theory, theories of successful aging, health psychology, and information systems. Below is a brief selection of some of additional theoretical perspectives from which GT can potentially draw.

Maslow's hierarchy of needs. Abraham Maslow created his motivational theory of the hierarchy of needs in the 1950s as a counterpoint to the prevailing behavioral and psychoanalytic ethos of the time. He posits that all humans (older and younger alike) are motivated to satisfy a series of needs that go from the more basic to the more existential and higher order (Oppenauer 2009), namely:

1. *Physiological*: respiration, food, water
2. *Security and safety*: security of body, health, resources, money
3. *Social*: love, belonging, friendship
4. *Self-esteem*: love and respect of oneself and others
5. *Self-actualization*: morality, creativity, “peak experiences”

Maslow's theory is extremely popular and well-represented in GT literature. It has the benefit of suggesting concrete directions for inspiring technology design that goes beyond the traditional, dependency-driven framework mentioned above. However, it does not have much direct empirical support. The continuing popularity of Maslow's theory in the field of GT (and elsewhere) may be because of its broad interpretability. By the same token, its broad interpretability and the complex nature of needs within Maslow's hierarchy limit its usefulness as a guiding theoretical framework for GT.

Selection, optimization, and compensation. One potentially helpful way to make sense of the chaotic field of GT, and avoid invoking a dependency-focused framework, is to refer back to the extremely influential theoretical framework laid out by Paul Baltes: that of *selective optimization with compensation* (SOC).

Briefly, SOC theory posits that successful aging and adaptation consists first of *selection*, whereby an individual develops and elaborates personal goals, whether due to a freely chosen reweighting of what is personally valued or as a response to losses. There is *optimization*, i.e., the active process of devoting time, energy, and resources into developing or refining a new skill. Finally, there is *compensation*, whereby an older adult actively makes use of a new or alternative behavioral repertoire or activity in order to satisfy personal goals, in the face of physical, functional, or cognitive losses. This suggests that older adults will tend to focus their limited energies and resources on activities (or technologies) they feel will yield the greatest benefit for achieving their goals. For example, an older adult who, due to physical and functional losses, cannot travel to visit family will invest time and energy into

mastering the use of email and social networking applications to maintain valued social and family ties.

If these technologies do not present obvious perceived benefits to older adult users, successful adoption will not take place, and no compensatory benefits will be gained. Some issues that might degrade the perceived benefit of a technology to an older adult include poor user interface (UI) design, which refers to the method by which a computer and human interact. One well-known example of UI design is the “graphical user interface” or GUI – which the Apple Macintosh platform popularized in the early 1990s.

UI is of paramount importance when designing websites, particularly for older adults. If, for example, a website makes excessive use of “pop-up windows” in their website design, it could be confusing for older adults and lead to lower rates of use. Poor target marketing could be another factor in limiting perceived benefit of a given technology (e.g., new technologies are frequently marketed to consumers in their twenties and thirties by default).

Unlike Maslow’s hierarchy of needs, SOC theory does have the benefit of being more narrowly interpretable in certain ways. The theory continues to be refined in terms of its applicability to GT.

Socioemotional selectivity theory (SST). SST is another theory that relates to successful aging. It dovetails somewhat with SOC theory in that it addresses the issue of resource scarcity that is often part of aging. In SST, the issue is scarcity of time.

SST broadly speaks of two goals that appear to motivate adults in their quest for social connection, the first being information seeking, which can be relevant to professional or workplace goals and is instrumental in nature. The second is emotion regulation, with the goal being the maintenance of positive emotional states (the so-called *positivity bias*).

SST posits that as a person ages and their time becomes foreshortened, they will necessarily become more motivated by emotion regulation at the expense of information seeking. In contrast, younger adults tend to be motivated by both information seeking and emotion regulation.

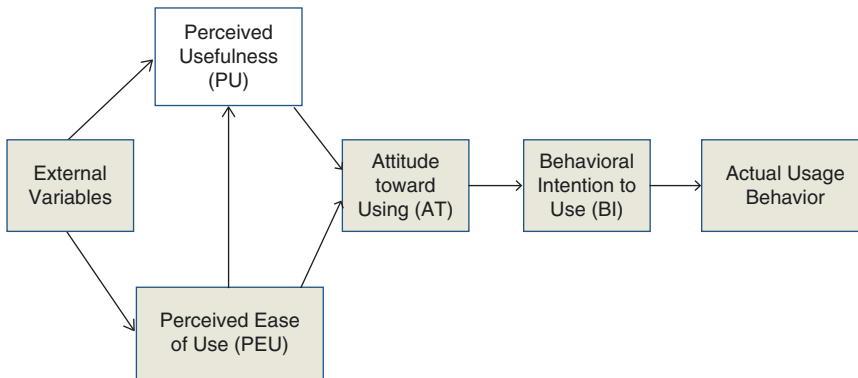

SST has implications for use of technology by older individuals. For example, if an older adult views email as a beneficial strategy for preserving close, intimate personal connections with friends and family, SST tends to predict they will gravitate toward using it. However, if email use is seen primarily as a vehicle for information seeking, older adults will tend not to adopt this technology. Similarly to SOC theory, SST may be more narrowly interpretable and therefore of more practical use as a framework for guiding GT.

Locus of control and self-efficacy. Health psychology also yields potentially important additional perspectives on technology usage behavior in older adults. As the initial development of locus of control theory suggests, people tend to vary in how much they see events being determined by their own behavior (internal locus of control) or by external, uncontrollable events. There is some suggestion that older adult technology users are more likely to feel less controlled by external circumstances and report greater feelings of empowerment. Likewise, self-efficacy about technology usage can be extremely powerful – essentially greater personal belief in technical problem-solving abilities in older adult users tends to predict greater use of positive coping strategies.

While the application of these attributional theories to GT is potentially powerful, their utility for guiding technology design is yet to be fully realized.

Technology Acceptance Model (TAM). Unlike the above theories drawn from gerontology and psychology, TAM was borne of the study of information systems technology and developed and later refined primarily with working-age adults in mind.

For any given technological innovation to be utilized, there needs to be a level of technology *acceptance*. Technology acceptance is a necessary precursor to successful technology *adoption*, both in the straightforward individual sense (e.g., whereby a novice, tentative user transitions to becoming an experienced, regular user of a given application or device) and in the sociological sense (e.g., where a given technology attains to critical mass of users to gain widespread, established use in a given population).

Gerontechnology, Fig. 1 Technology Acceptance Model (TAM)

In TAM, for actual technology *usage behavior* (UB) to occur, a user needs to first have positive appraisals in terms of *perceived usefulness* (PU) and *perceived ease of use* (PEU). Both PU and PEU need to reach a threshold for a *positive attitude toward use* (ATU) and a foregoing *behavioral intention to use* to occur, which then lead to successful UB. The original model is below (Fig. 1):

TAM has been found in limited investigations to have utility in predicting older adult usage behavior as well. However, the applicability of the model has been limited somewhat by the fact that TAM was originally developed and envisioned using working-age adults with the adoption of workplace technology as the target behavior. In other words, the perceived usefulness of a given piece of technology in older adults will typically not be related to its perceived workplace utility. Instead, perceived usefulness will depend on factors such as its ability to improve the safety, security, and daily lives of users.

Usability and Design Issues with Older Adults

Technology acceptance and use in older adults is critically dependent on *usability*, which is generally defined by the learnability and ease of use of a given man-made physical or virtual object.

The acceptance and adoption of new technology in older adults appears to be constrained by

factors that distinguish them somewhat from their younger adult counterparts. These factors include more limited energy as well as greater constraints in the availability of physical and cognitive resources. Although no one, including younger adults, has unlimited resources and energy to acquire and learn new technologies, older adults are by definition in a phase in life where some degree of cognitive and physical loss is expected.

Fortunately, there exist research-based guidelines that take into explicit account issues of task difficulty; age-related changes in cognitive, perceptual, and processing ability; and also cultural and cohort issues that influence technology acceptance and adoption. Some examples of design guidelines that are specific to older adults include (Hardy and Barid 2003; Mynatt and Rogers 2010):

- Strict adherence to ergonomic design principles (say, in home design) to account for the higher incidence of chronic medical conditions in older adults.
- In e-learning and web design, recommend flexibility in presentation (e.g., text, voice, animation) to compensate for sensory limitations.
- Manual and interface design should allow for a modest but significant difference between average literacy levels of older and younger adults.
- Flexible design approach to accommodate slower speeds of older adult users. Slowed speed of older adult operators is both a

consequence of normal, age-related cognitive changes and also may be related to the technology generation effect.

- Introduce design features that take into account single-layered design preferences common to the electromechanical generation (e.g., one control which controls one function, as opposed to a control with a multiple functions). If that is not possible, then have the most commonly used functions be accessible via the topmost layer of the interface.
- Consider the use of skeuomorphic design principles when designing interfaces (e.g., making software features retain features reminiscent of familiar physical objects), which may help to increase comfort and satisfaction of users.
- Consider the use of voice controls, or, if available, touch screen controls to reduce the cognitive load on users.
- Deliberately avoid the “egocentric intuition fallacy” in technology design (e.g., the assumption, often tacit, by technology design staff that they are representative of their end users). This can be avoided by focusing on basic user-centered design (UCD) principles – a process of constant feedback between end users and technology designers as a technological product is being developed.

Special Populations: Dementia Care Recipients and Caregivers

Gerontechnology for older adults with dementia has been primarily devoted to developing surveillance technology for residential care facilities (e.g., chair alarms, bed alarms, and “WanderGuard” zone alarms) and assistive medical devices. When it comes to GT’s attention to this population, it has mostly been focused on older adults who are receiving caregiver, residential care, or both, as opposed to older adults still living and functioning independently in the community (Topo 1998). It is only recently that GT has begun to focus on providing for the needs of this population in the areas of functional enhancement, leisure, comfort, satisfaction, and social connection.

As the population of older adults has surged, the strain of overburdened care facilities and the negative emotional and physical effects of the loss of independence and decreased quality of life associated with admission to care facilities has given rise to the development of technologies that can help older individuals “age in place,” retaining independence and living at home for as long as possible. Telecare, telehealth, “smart home” and surveillance technologies, and cognitive orthotics all have utility in this arena. However, given the significant healthcare costs associated with loss of independent functioning in older adults, it is surprising how little attention has gone thus far toward research into technology purposed (or repurposed) for use by dementia caregivers themselves.

GT is also of potential use for informal caregivers of older adults. An informal caregiver is an unpaid individual (a spouse, partner, family member, friend, or neighbor) involved in assisting others with activities of daily living, including medical and social tasks. There are 43.5 million adults who care for a disabled or ill family member over the age of 50. There exists a correlation between caregiver well-being and health outcomes in both the caregiver and the care recipient. The outcomes for the caregiver are both physical and mental: 40–70% of family caregivers have clinically significant symptoms of depression with about a quarter to half of these caregivers meeting the diagnostic criteria for major depression (Zarit 2006). The caregiver population presents unique challenges for technology innovators. Intervention technologies will address the most prevalent caregiver needs, including:

Coordination. Caregivers become overwhelmed by the quantity of tasks they need to do, as well as the extensive time over which the caregiver role extends. Several tools for caregivers address this need by helping the caregiver compile and prioritize these tasks or delegate the tasks between multiple family caregivers.

Access to resources. National health organizations and academic journals have published extensive educational materials about best practices and disease state information

available to keep caregivers informed and in control. There are also many support groups, both in person and online, tailored to the disease or condition of the care recipient. New technologies should aim to deliver this information to the caregiver more effectively. Better access to social outlets and referrals to human resources should be addressed by innovators.

Decision making support. Many caregivers use support groups and other human resources to make important decisions about their loved ones' care, including when and how to transition to formal care, medications to take, and other facilities or services to use depending on the condition of the care recipient. Technological tools can aid the decision making process by using personalized information about the caregiver and care recipient.

Personal health. Caregivers are able to better provide care if they continue to engage in the activities and interests that will benefit their health. Tech solutions that promote healthy behavior for the caregivers themselves will improve the overall caregiving experience and reduce negative health outcomes.

Because caregivers fall outside the formal healthcare system, special efforts must be made to understand the complex needs of this population and develop technologies that will provide solutions to caregiving demands.

Surveying the Gerontechnology Landscape

An emphasis on maintenance of independent functioning in the demented individual for as long as possible has both implications for preservation of function as well as nonspecific benefits to quality of life, well-being, and dignity for the individual. The gerontology canard "use it or lose it" certainly applies here. This can result in a spiral of low expectations, poor opportunities, and a societally based "de-skilling" phenomenon (Fig. 2).

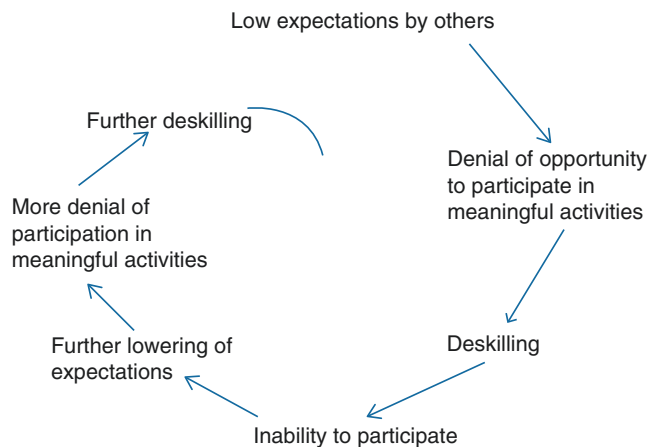

Some reasons for this include the wide range of variability and complexity in older adults that is only magnified by the presence of a dementia, as well as preexisting service delivery limitations, and public perceptions.

Telecare, telehealth, "smart home" and surveillance technologies, cognitive orthotics, and similar advances in technology all have utility in breaking out of this spiral. For example, an older adult who, due to mild dementia, would otherwise occasionally leave a stove on in the home could have a device that could alert him to turn off the stove if it is left on (or turn it off remotely itself), or to turn off faucets, or to remind the older adult to take medication (e.g., combines features of surveillance technologies, "smart" technology, and cognitive orthotics). The landscape of technologies available for these purposes is quite

Gerontechnology,

Fig. 2 Downward spiral of de-skilling that can occur in dementia (Mountain 2013)

broad and continually expanding, and can be broken down into categories that include the following.

Mobility. This is a critical area for older adults, with mobility such as a central area for the maintenance of independence. Sidewalks, cars, stairs, elevators, escalators, and elevators all require attention to insure their accessibility and usefulness for older adults. Wheelchairs are a classic illustration of the transition from mechanical technology (typified by the motorized wheelchair) to electromechanical technology (the electric wheelchair or power scooter), to “intelligent wheelchairs,” where they are equipped with specialized software and sensors to decrease collision risk in users as well as climb stairs and curbs while keeping the user level at all times and allow the users to retain mobility for significantly increased periods than would otherwise be feasible (due to sensory or cognitive decline) (Rogers and Fisk 2003; Kalra et al. 2009). Most recently and significantly, the advent of autonomous vehicle technology or “self-driving cars” are poised to transform the extent and assist the mobility of older adults far beyond the traditional limitations posed by predominantly human-controlled vehicles. Concept vehicles promise the ability to augment or autonomize driving capabilities by monitoring and utilizing context-sensitive, real-time data regarding the vehicle, environment, and driver. Such cars might monitor the human driver’s physiological markers, such as visual attention and heart rate, and provide spatial information regarding the vehicle’s location via advanced navigation systems and monitor environmental conditions and obstacles. Of course, given the new and constantly evolving nature of such technologies, regulatory and liability barriers will need to continue to be addressed as these autonomous technologies become mainstream. As of 2015, only a few American states have passed legislation regarding the issues presented by self-driving cars (Yang and Coughlin 2014; Kalra et al. 2009).

E-health. *E-health* is a term that has been coined to refer to the various ways that people utilize the internet or other digital technology to access or receive health information. E-health

includes a variety of internet functions and applications and includes access to health information on the internet, access to health self-management tools, and access to health records. Surveys suggest that members of the “baby boom” generation (by far the largest group of older adults in North America) use e-health applications and the Internet for health information at rates comparable to their younger adult counterparts, while those of ages beyond the baby boomers (e.g., 65 and older) do so at somewhat lower rates. Second only to email use and search, e-health still remains by far one of the most popular reasons for older adults to access the Internet.

However, usability and design issues specific to older adults are a concern. Also, older adults may be less able to accurately evaluate the reliability and credibility of online health information compared to their younger adult counterparts. This may be due to lower average levels of educational attainment in older adults, lack of sophistication in search strategies (an outgrowth of the generation effect), the high cognitive demand placed on older adults when sifting through such enormous amounts of information on the Internet, or a combination of these and other issues (Roy and Pineau 2007).

Telehealth. Telehealth technology is defined as “the use of electronic information and telecommunications technologies to support long-distance clinical healthcare, patient and professional health-related education, public health, and health administration.” Shifts in the economic landscape of the healthcare market, shifting consumer preferences, and an ever-widening range of technological products and services have all militated to make telehealth technology increasingly attractive for use with older adult populations. Telehealth can include the use of systems to measurement of vital signs, (e.g., heart rate, blood pressure) via sensors and remote monitoring and data collection, videoconferencing, and other forms of communication. It can be used to supplement, or in some cases, replace, medical care and physician office visits but is also viable as a supplement or replacement for in-person mental healthcare appointments, including psychotherapy, and psychological assessments, including cognitive assessments.

Older adults may be homebound, and chronic illnesses may make travel to healthcare appointments a challenge, which militates in favor of wider deployment of healthcare technology for older adults. However – conversely – less educated, more rural older adults, and those with chronic illnesses are less likely to have reliable Internet access (Czaja et al. 2013). There are a number of other obstacles to wider use of telehealth technologies in older adults, which include usability and related issues as well as technology generation effects (e.g., overreliance on multilayered interfaces).

Regarding regulatory issues, mental healthcare delivery is another area where older adults can theoretically greatly benefit from the introduction of telehealth technologies. For example, it has long been recognized that older adults represent an underserved segment of the population as far as mental healthcare delivery is concerned. Secure videoconferencing, telephone, and email communications can all be viable in this regard. However, Medicare (which is the US Federal Government agency which monopolizes the health insurance market for older adults) currently imposes a number of limitations on how so-called tele-mental healthcare delivery is offered to older adults, which effectively denies older adults this service except in rare circumstances (e.g., such as being in a high service need area and receiving the service in a facility or doctor’s office) (Eramo 2014).

Mobile applications and mobile technology.

There has been an explosion of interest in developing mobile applications or apps for older adults, as well as their caregivers. There appear to be several classes of apps out there, such as apps designed for caregivers to help facilitate care coordination, formal support, wander prevention, and enhance the well-being of the caregiver. Another growing class of apps are designed to facilitate reminiscence activities in the care recipient as a way to calm and enhance the well-being of the caregiver. There is also the growing sector of cognitive orthotic apps (Horgas and Abowd 2004), which are apps specifically designed to extend and support the memory and cognitive functioning in older adults with mild cognitive impairment or dementia of mild severity.

According to the FDA, “Mobile applications can help people manage their own health and wellness, promote healthy living, and gain access to useful information when and where they need it.” The ubiquitous, continuous, and data-rich qualities of mobile technology enable these capabilities and align with the needs of the elderly population. In particular, mobile apps are well suited to address the following areas of need for older adults:

- **Chronic Disease Management.** Most older adults have at least one chronic condition (80%), and half have at least two. Mobile technology is well suited to address this area, and many app developers have focused their efforts here. Research of existing mobile tools in this area has found evidence of efficacy in improving disease management adherence.
- **Medication adherence.** Because of the prevalence of comorbidities in the older adult population, medication adherence is an especially critical issue.
- **Safety monitoring.** With the advancements in sensor technology, mobile apps are becoming increasingly able to remotely monitor activities and items in the homes of the older individuals.
- **Access to health information.** Aside from general search engines like Google, specific apps exist to help connect people with information regarding diseases and illnesses.
- **Wellness.** Wellness apps constitute a significant proportion of all mobile health apps and have gained widespread popularity.

However, barriers relating to usability concerns and the generation effect currently impede widespread adoption of mobile tools for the older adults. Increasing smartphone penetration, sophistication of technology, and user familiarity with mobile apps are eliminating previous barriers to adoption of mobile tools in the older adult population.

Robotics. Probably the simplest definition of a robot is a “computational device that can sense and act in the physical world.” Robots vary widely in shape and size and in recent years have been developed to resemble more lifelike creatures

(humans and animals). Robots can be classified into two basic categories: Assistive robotics and social robotics (also known as “carebots”).

Assistive robotics. Robotic technology has now become fairly commonplace and is being used in a variety of industrial, institutional, and home situations. Robotic assistants first came into widespread use in North America in the 1980s to assist with vehicle assembly and manufacturing. One of the first consumer mass-market robots for the home is the Roomba™, an autonomous robot built with sensor technology designed to vacuum as it roams. Institutionally, assistive robots are becoming more and more common and have been developed to assist with dispensing medications, performing “fetch and carry” tasks, and other activities (Roy and Pineau 2007).

Assistive robots have a variety of applications with older adults in the realm of aiding older adults in retaining functional capacities in the face of disability and illness. For older adults who have suffered strokes, exoskeletal-like robotics, or wearable biomechatronic systems that follow the movement of the subject and provide assistance with strength and mobility, will increasingly become an option (Micera et al. 2008). As was mentioned previously, robotic technology is increasingly being used to modify existing mechanical technology widely used with older adults, such as with wheelchairs. Telepresence robots are now beyond the feasibility stage with older adults, with obvious applications for allowing homebound or mobility-impaired older adults to attend outside functions and appointments and even for the purposes of facilitating leisure activities.

Quite simply, future iterations of robotic, “smart” assistive technology have the potential to maintain cognitive, physical, and occupational independence in older adults far beyond what was previously attainable.

Social robotics or “carebots.” Recently, there has been an interest in developing robots that interact with humans for the purposes of eliciting positive psychological variables such as comfort and relaxation and to reduce depression and anxiety. Japan’s Advanced Institute of Science and

Gerontechnology, Fig. 3 The Paro robot

Technology in partnership with the Japanese government helped to develop what is currently one of the sole players in the social robotics field: the Paro robot (Fig. 3).

Paro is modeled on a baby harp seal and is fully animatronic and interactive. It is a product designed to elicit the same psychological and physiological benefits as animal-assisted therapies and has a growing body of literature to support its effectiveness in improving quality of life indicators, as well as managing mood and behavior problems in dementia. There are several other social robots that have been developed, but as of this writing, none have been offered on a mass-market basis (Kachouie et al. 2014).

It seems likely that this is a sector that will grow over time, with fairly obvious utility in residential care facilities for older adults, mainly by virtue of the fact that these kinds of devices will free up nursing staff from providing psychosocial and emotional support and allow them to focus on medical and personal care provision for their clientele.

There appear to be unique ethical concerns posed by the carebot/social robotics sector (Vallor 2011). For example, there is the concern that the use of social robots may lend itself to seeing loneliness as a technical problem to be solved rather than an expression of a universal human condition. There are other concerns – carebots may have the effect of reducing the dignity, quality of care, and privacy of

older adults and have the effect of replacing human contact. There are also concerns that carebots are inherently deceptive, particularly as regards older adults with dementia. So, there are costs to be weighed against the benefits of social robotics with older adults.

Smart homes. Smart home technologies incorporate connected systems of data collection, data processing, and information delivery to provide the user capabilities and knowledge otherwise unavailable. Specific aims of smart home technology include increasing understanding of a person's health and informing appropriate personnel during emergencies. As advancements in sensor technology allow them to be more affordable, discreet, and interconnected, technology capability no longer inhibits the utility and much of the adoption of smart homes. Additionally, as longevity increases, older adults will be in their homes longer at older ages. The confluence of these two developments aligns well with the implementation of smart home technologies.

Several categories of smart home products exist, including emergency detection, mobility tracking, and appliance and electronics monitoring. Additionally, smart homes intersect with the "Internet of things" field. Major companies are developing their own platforms to enable the interconnectivity of many devices, and though initially focused on a younger audience, the products developed for the Internet of things can be directly applied to the older adult category.

However, smart home technology faces several fundamental obstacles to widespread user adoption, including privacy concerns and the loss of autonomy associated with remote monitoring. The ability for developers to appropriately address these obstacles will dictate the adoption of smart homes (Marling 2007).

Conclusion

GT is a continually evolving, vast and many-faceted landscape. As the baby boom generation ages, and humans continue to live longer lives, the growth of the aging population will continue to

drive and necessitate new technologies to enhance health and quality of life. It is hoped that GT will continue to be the exciting, dynamic, and rapidly-changing field it is today. Almost without a doubt, by its very nature, the GT landscape of tomorrow will likely be very different than today. We look forward to further refinement of theoretical frameworks, as well as further research and development that will continue to yield important insights and useful products to help older adults retain their independence, and to promote positive outcomes in all life domains.

Definition

In this current entry, grandparenthood is defined as the role that older people play as grandparents in a family.

Social relationships are associated with subjective physical and mental health outcomes in adulthood. As they age though, they experience changes in their preferences for social partners and the composition of their social network. In this entry, they first introduce age-related changes in social relationships in terms of their closeness and type. Then, they focus on a relationship that is particularly prevalent and important in older adulthood, i.e., grandparenthood. They discuss factors that may influence the meaning of grandparenthood and grandparenting behaviors, focusing specifically on gender and culture, and the outcomes of grandparenthood.

Age Differences in Social Relationships

Number of Relationships

In the aging literature, studies consistently find that the number of social partners shrinks with age (Zhang et al. 2011), with research suggesting this is not simply due to functional losses and mortality (Lang and Carstensen 1994). Despite the change, subjective well-being in older adulthood does not appear to suffer by the decrease in

the number of social partners. In fact, subjective well-being tends to increase with age (Carstensen et al. 1995). Two reasons may explain this phenomenon. First, older adults may enjoy being alone more than do younger adults. For instance, Larson et al. (1985) found that older adults reported a greater sense of control when alone. A study by Lang and Baltes (1997) extended the aforementioned idea by considering the effect of context when older participants were alone. They found that the older old (i.e., those aged 85–103 years) felt the highest sense of autonomy with the least social contacts when they were facing difficulties in everyday life. The authors interpreted the results as a compensation mechanism, in which being alone in daily activities may allow older adults to maintain autonomous functioning and still spend time with people in other daily activities.

The above studies speak to the idea that aloneness in old age may not be as detrimental as conventionally believed. This argument might be particularly true for people from independent cultural backgrounds. In independent cultures, when people get older, they are less likely to attribute their loneliness to personal deficits (e.g., lack of pleasant personal characteristics) than do people in interdependent cultures. A study conducted by Rokach and Neto (2005) found that Canadians, who were from an independent culture, adjusted better in a lonely situation than their Portuguese counterparts, a group who was considered to be more interdependent. Researchers speculated that compared to interdependent individuals, independent individuals may have a less extended social network, which may make it easier for them to attribute being alone to relationship deficits rather than personal deficits – in turn making it easier for them to adjust to lonely situations (Rokach and Neto 2005). Consistent with this are findings from a study conducted in Hong Kong. In the study, a negative correlation between the number of peripheral social partners and self-reported loneliness was found among older adults who were higher in interdependence but not those who were lower in interdependence (Zhang et al. 2011).

Second and more importantly, older adults may be more selective in their social partners. Such

effects cannot be explained by structural factors alone, such as cognitive abilities and perceived health symptoms (Yeung et al. 2008). Compared with younger adults, older adults show a greater preference for close social partners (i.e., people whom the individual cannot imagine life without, typically but not always kin and close friends) (Yeung et al. 2008) over peripheral social partners (i.e., people who are not as close as close partners, but who are still important, such as colleagues and professional helpers). Although older adults have fewer peripheral social partners than do younger adults, they maintain a similar percentage of close social partners in their social networks as do their younger counterparts (Zhang et al. 2011). This may make it easier for them to maintain their subjective well-being or even increase their social satisfaction. Yeung et al. (2008) further examined the mechanism of the age-related decrease in peripheral social partners. They found that the number of peripheral social partners only decreased among those lower (and not higher) in interdependence. Zhang and colleagues (2011) further found that older people with higher interdependence reported lower loneliness when they increased their number of peripheral social partners in a two-year interval, suggesting that older people higher in interdependence could benefit from having more peripheral social partners (Zhang et al. 2011).

Recently, Lang and colleagues argued that, because emotionally close partners were more important for older adults than middle-aged adults, older adults might invest more effort to maintain emotionally close partners (Lang et al. 2013). Examining this question in middle-aged and older adults, Lang and colleagues (2013) found that perceived relationship effort was significantly associated with emotional closeness, such that people invested more effort in people who were more emotionally close. This effect was stronger in older adults than in middle-aged adults. The investment in emotionally close partners may contribute to the greater emotional well-being reported by older adults. In fact, English and Carstensen (2014) found that the social relationships of older adults were associated with less negative emotion and more positive emotion

than those of younger and middle-aged adults in a longitudinal study with three waves of 5-year intervals.

In sum, while the number of peripheral social partners decreases with age, emotionally close social partnerships remain stable across adulthood. Older adults make greater efforts to managing social relationships than do younger and middle-aged adults (Lang et al. 2013). They also benefit more from these social relationships in reducing perceived loneliness (Zhang et al. 2011), reducing negative emotions, and increasing positive emotions (Lang and Carstensen 1994) than do their younger counterparts.

Types of Relationship

In addition to studying social network composition in terms of closeness, researchers have also investigated age-related differences in the types of relationship that older adults value (Fung et al. 2008). In German participants, Fung and colleagues (2008) found that older age was associated with a smaller proportion of nuclear family members and a larger proportion of acquaintances. In Hong Kong Chinese, however, older age was associated with a larger proportion of nuclear family members and a smaller proportion of acquaintances. Fung and colleagues argued that, compared with Germans, Hong Kong Chinese showed a greater family in-group bias in social network composition with age.

In a study using data from the World Values Survey (Li and Fung 2012), Li and Fung examined age differences in trust across 38 countries. They found that age positively correlated with general trust and also trust toward different social groups, including family, friends, neighbors, and strangers. However, the positive association between age and trust toward friends and strangers was weaker in countries that scored lower on individualism.

Friendship is another type of social relationship that can be as close as that experienced by family members but also as peripheral as acquaintances. Building upon the theoretical framework on friendships in old age proposed by Matthews

(1986), Miche and colleagues (2013) found that friendship network types in old age tend to be classified into four categories. In the first group, the discerning friendship style, individuals select a small number of close friends. The second group, independent friendship style, refers to a relatively larger group of friends with lower emotional closeness. The final two groups, selective acquisitive style and unconditional acquisitive style, have the largest number of friends that differ in emotional closeness, with selective acquisition as being emotionally closer than unconditional acquisition.

Despite the variations in styles, older individuals generally have more favorable experiences with friends than with family members (Rook and Ituarte 1999). This finding can most likely be explained by the structural differences between friendship and family relationships. Friendships are mostly formed and maintained on a voluntary basis, while family relationships are more or less predetermined. Older adults usually form friendships with individuals who share their interests and lifestyles and who have reciprocal social relationships with them. Friendships in old age also provide better companionship compared to family relationships. For example, Huxhold et al. (2014) examined the relationship between social activities with different social partners and the changes in affective well-being and life satisfaction among older adults across a 6-year interval. They found that social activities with friends were related to maintenance or positive changes of life satisfaction as well as a reduction in negative affective experiences among older adults. However, social activities with family members were associated with increased negative affective experiences in the sample.

To summarize, despite the decrease in the number of social partners as people age, subjective well-being is maintained or even increased. Research suggests that the change in social network size is more than a product of age-related structural changes such as mortality and functional losses. Instead, older adults actively prune their social network by keeping emotionally close social partners and cutting down relationships with peripheral social partners. The pruning

appears to contribute to the maintenance and even increase in subjective well-being of older adults. One particular emotionally close relationship valued by majority of older adults is that with their grandchildren. They discuss the relevance of grandparenthood in the next section.

Grandparenthood

Grandparenthood is one of the major relationships that older adults maintain. It plays an important role in the subjective well-being of older adults and is increasingly important in older age. Previous research suggests that grandparenting is a goal-directed behavior. How people view grandparenthood is influenced by their perceptions of future time. Fung et al. (2005) summarized three dimensions of meaning associated with grandparenthood: (1) obligation and accomplishment (e.g., “having grandchildren makes me satisfied and complete in this life stage”), (2) beneficial gains (e.g., “life as a grandparent is wonderful”), and (3) perceived loss in absence (e.g., “I feel that my life would have lacked something had I have never been a grandparent”) (p. 135). Fung and colleagues found that when people perceived future time as more limited, they attached greater importance to grandparenthood in all three dimensions than did people who perceive future time as less limited. This finding is consistent with the line of research arguing that when one believes their time is limited, they select emotionally close social partners, such as family members. In another study, Thiele and Whelan (Fung et al. 2005) found that grandparents experienced greater happiness from grandparenting when they adopted the goal of generativity (e.g., pass along knowledge to future generation). These findings suggest that grandparenting behavior is influenced by the goal that older adults adopt.

Gender and Grandparenthood

Previous research consistently reports the influence of socioeconomic factors in grandparenting behavior. For instance, those with lower levels of

education (King and Elder 1998) and better physical health (King and Elder 1998) tend to make more contact with grandchildren and elicit more role satisfaction when engaged in grandparenting behavior. Gender has been found to be another important factor in grandparenthood. The gender differences in grandparenthood tend to be related to gender differences in life expectancy (i.e., women generally live longer than men), social status (i.e., men have higher status than women), financial resources (i.e., men have better financial resources than do women), and socialization levels (i.e., men have more social exposure than do women) (Field and Minkler 1988). Gender roles also influence grandparenting behaviors. Traditionally, women are responsible for interpersonal dynamics within families, and men are responsible for task-oriented involvements outside the family (Szinovacz 1998). In line with this reasoning, research has found that grandfathers are more likely to provide instrumental supports, such as financial assistance, but have greater difficulty expressing their emotions toward grandchildren. In contrast, grandmothers were more likely to provide emotional supports (Smorti et al. 2012).

It also seems that grandmothers play a more diverse role than grandfathers in the work of grandparenting. For instance, grandmothers provide care and emotional support and participate in recreational activities with grandchildren. Therefore, grandmothers report greater contact with their grandchildren than do grandfathers. The grandchildren also perceived themselves as having more contact with, and greater closeness with, grandmothers than grandfathers (Smorti et al. 2012). As a result, grandmothers are more emotionally close and affectively supportive to grandchildren than are grandfathers. Although both grandmothers and grandfathers report similar levels of positive emotion toward their grandchildren and consider their role as supporting and providing care, grandmothers are more satisfied with their role and report a higher level of perceived influence and intimacy.

In addition to the gender of grandparents, the interaction between lineage and gender is another issue that has received much attention.

Two theories in the field of evolutionary psychology have been proposed to explain these effects: the kin-keeper theory and the kin selection theory. The kin-keeper theory argues that women (i.e., grandmothers and mothers) place greater emphasis on intra-family relationships, making them essentially the “kin-keepers” in a family. Due to their higher level of involvement, grandmothers and mothers build closer connections with family members, including the grandchildren, than do grandfathers. Accordingly, the theory would predict that grandchildren should be closer to maternal grandparents than paternal grandparents. In contrast, the kin selection theory is based on the assumption of inclusive fitness, which argues that one favors others who may be able to pass on one’s genes. Because men maintain fertility longer than women and have a greater chance to produce offspring, they invest less in each offspring, including grandchild, than do women (Surbey 1998). In addition, because male offspring may have a greater chance to pass on genes, people may have a closer relationship with grandsons than granddaughters.

Dubas (2001) compared and contrasted the kin-keeper theory and the kin selection theory in grandparenting by examining the moderating role of gender in the grandparent-grandchild relationship. She found evidence that partially supports the kin selection theory. The relation between maternal grandmothers and grandchildren was not closer than the relation between paternal grandmothers and grandchildren. However, granddaughters rated their relation with grandmothers closer and more important than did grandsons. Grandsons, on the other hand, rated their relation with grandfathers closer and more important than did granddaughters. Drawing on these findings, Dubas (2001) suggested that both matriarchal and patriarchal relationships were critical in grandparent-grandchild relationship.

Culture and Grandparenthood

It is well documented that culture shapes human behavior. However, few studies have paid specific

attention to the influences of culture on grandparenting. In one exception, Sandel et al. (2006) investigated the lay theory of “grandmother” role in European Americans and Taiwanese Chinese through in-depth interviews. They found both universal and culture-specific aspects in grandparenting behavior. Grandmothers in both cultures engaged in similar activities and considered the role of being a grandmother to be distinctive from being a mother. However, they interpreted their roles in different ways. Specifically, European American grandmothers saw themselves as friends and playmates of their grandchildren and defined their role of being a grandmother in “companionship” terms. They considered giving advice to the parents (their children) on parenting to be problematic. Taiwanese Chinese grandmothers, however, defined themselves as temporary caregivers. They disciplined misbehaving grandchildren and advised the parents.

Research on ethnicity has also found ethnic variation in grandparenting. African American grandparents reported more contact with grandchildren than did grandparents from White cultures (Field and Minkler 1988). Phua and Kaufman (2008), using the data from US Census in 2000, found that Japanese grandparents were more likely than Asian Indian grandparents to take on the grandparenting responsibility. Collecting data from in-depth interviews with 30 New Zealand women from four different cultural backgrounds (i.e., New Zealand European, New Zealand Maori, Central European, and New Zealand Chinese), both similarities and differences between ethnicities were found (Phua and Kaufman 2008). Armstrong (Phua and Kaufman 2008) summarized that women from all four ethnic backgrounds considered “being a grandmother” to be an indicator of “being old” and of having a “shorter future.” Because their future was limited, the interviewed women expressed placing greater value on their relationship with grandchildren and an increased sense of generativity. Some interviewees even mentioned that they decided to retire early or reduce working hours, in order to take care of their grandchildren. Meanwhile, ethnic differences

were also observed. Different views of grandparenthood were found, in terms of social status, seniority, social renewal, and social integration. For instance, the New Zealand Chinese and Maori interviewees associated old age and being a grandparent with seniority and a higher level of social status. Such a pattern was not found among New Zealand Europeans and Central Europeans. The sense of social renewal is particularly salient in Central European grandmothers, because they all immigrated to New Zealand after World War II. New Zealand European grandmothers associated grandparenthood with an increased social support network and greater social engagement.

Positive and Negative Outcomes of Grandparenthood

Much research has summarized the benefits of having grandchildren. According to Timberlake (1981), there are eight benefits of grandparenthood: (1) to support one's social identity as grandparent, (2) to perceive one's own life has being expanded, (3) to help, (4) to increase interpersonal connectedness with others, (5) to provide positive emotional experiences, (6) to provide a goal in older adulthood, (7) to assert influence on others, and (8) to obtain achievements over others. These benefits of grandparenthood correlated positively with better physical health (Hughes et al. 2007), engagement in exercise (Hughes et al. 2007), fewer depressed symptoms (Grundy et al. 2012), and a higher level of life satisfaction (Grundy et al. 2012). Christiansen examined the association between grandparenthood and mortality (Grundy et al. 2012). She found that among women who became grandmothers after the age of 50 years, being a grandmother was associated with a lower mortality rate (Christensen and Walczynski 1997).

Admittedly, grandparenthood can also be perceived as a burden by some older adults. Custodial grandparents report worse health, more symptoms of depression, and more functional limitations than do other grandparents (Grinstead et al. 2003). Such effects may be driven by the fact

that older adults have limitations in conducting activities with high physicality. Custodial grandparents spend considerable time with grandchildren and expend considerable energy that can impair the physical and mental health of the grandparents.

Overall, being a grandparent is a valued and important role for older adults, because it connects them with emotionally close social partners. An appropriate level of grandparenting engagement improves physical and mental health and in general advances life satisfaction in older adulthood. Gender is an important factor, with grandmothers generally building closer relationships with grandchildren than do grandfathers. Such a pattern may be derived from the traditional gender role that women are responsible to foster harmonious relationship within families. In addition to gender, previous studies also observe culture and ethnicity differences in grandparenting behaviors.

Conclusion

Social network size shrinks as individuals age. The shrinkage of network size is associated with the active pruning of social partners by older adults: emotionally close partners are kept in the social circle, while peripheral social partners are reduced. This change in social network structure appears to contribute to maintenance and even improvement in the subjective well-being of older adults. Among these, grandparenthood is an especially valued and emotionally close relationship for older adults that has implications for subjective well-being that differs as a function of gender and culture.

Synonyms

Deep sorrow (caused by someone's death); Mourning (expression of grief); Personal loss

Definition

The term *bereavement* denotes the objective situation of a person who has experienced the death of someone significant. *Grief* then refers to the emotional experience of the psychological, behavioral, social, and physical reactions the bereaved person might experience as a result of this death.

Introduction

The loss of a loved one is a ubiquitous human experience, which is often regarded as a serious threat to health and well-being. This topic is relevant to the study of geropsychology for two reasons. First, there is consensus among researchers and practitioners alike that coming to terms with personal loss is a critical part of successful adult development (Baltes and Carstensen 1996). Second, losses tend to accumulate in late life. This can place survivors in a state of chronic stress and undermine their capacity to deal with any particular loss.

The death of a loved one provides an excellent arena to study basic processes of stress and adaptation to change. Unlike many stressful life

experiences, the death of a person is irrevocable and cannot be altered by the coping efforts of survivors. Indeed, the major coping task faced by those who have experienced the death of a loved person is to reconcile themselves to a situation that cannot be changed and find a way to carry on with their own lives.

The most common loss of a loved one for older adults is the death of a spouse (Carr et al. 2006). Therefore, the bulk of research on late life losses has focused on this type of loss. However, older adults may also experience other types of losses including the death of a child, grandchild, sibling, or close friend. These can also be major losses and may each have unique implications and challenges for the person who is faced with them. Research insights shedding light on these experiences, however, are much more limited. It is thus important to keep in mind that much of our understanding of and thinking about late life losses is derived from work on spousal loss.

Furthermore, it is important to define the key terms that will be used throughout this entry. The term *bereavement* is derived from the Latin word *rumpere* (to break, to carry, or tear away) and refers to the objective situation of a person who has suffered the loss of someone significant. In most cases, bereavement robs survivors of love and companionship, as well as future hopes and plans that they expected to share with the person who died. *Grief* is derived from Latin *gravare* (to weigh down) and refers to the emotional experience of a number of psychological, behavioral, social, and physical reactions to one's loss. The word *mourning* is derived from the Latin word *memoria* (mindful). It refers to actions expressive of grief which are shaped by social and cultural practices and expectations. Pointing to the timeless message of the original meanings of these terms, Jeter (1983) commented that "as the ancients, people today surviving the death of a family member do feel robbed, weighted down, and are mindful of the past, knowing that life will never be the same" (p. 219). But how do individuals cope with such an experience? To address this question, models and approaches that seem most influential to current understanding of bereavement and grief are examined.

Classic Psychoanalytic View

One of the most influential approaches to loss has been the classic psychoanalytic model of bereavement, which is based on Freud's seminal paper, "Mourning and Melancholia" (1917). According to Freud, the primary task of mourning is the gradual surrender of one's psychological attachment to the deceased. Freud believed that relinquishment of the love object involves a painful internal struggle. The individual experiences intense yearning for the lost loved one, yet is faced with the reality of that person's absence. As thoughts and memories are reviewed, ties to the loved one are gradually withdrawn. This process, which requires considerable time and energy, was referred to by Freud as "the work of mourning." At the conclusion of the mourning period, the bereaved individual is said to have "worked through" the loss and to have freed himself or herself from an intense attachment to the unavailable person. Freud maintained that when the process has been completed, the bereaved person regains sufficient emotional energy to invest in new relationships and pursuits. This view of the grieving process has dominated the bereavement literature over much of the past century and only more recently has been called into question (Bonanno and Kaltman 1999; Stroebe 1992; Wortman and Silver 1989). For example, it has been noted that the concept of grief work is overly broad and lacks clarity because it fails to differentiate between such processes as rumination, confrontative coping, and expression of emotion (Stroebe and Schut 2001).

Attachment Theory

Another theoretical framework that has been extremely influential is Bowlby's attachment theory (Bowlby 1969, 1973, 1980; see also Fraley and Shaver 1999; Shaver and Tancredy 2001). In this work, Bowlby integrated ideas from psychodynamic thought, from the developmental literature on young children's reactions to separation, and from work on the mourning behavior of primates. Bowlby maintained that during the course

of normal development, individuals form instinctive affectional bonds or attachments, initially between child and parent and later between adults. He believed that the nature of the relationship between a child and his or her mother or caregiver has a major impact on subsequent relationships. He suggested that when affectional bonds are threatened, powerful attachment behaviors are activated, such as crying and angry protest. Unlike Freud, Bowlby believed that the biological function of these behaviors is not withdrawal from the loved one but rather reunion. However, in the case of a permanent loss, the biological function of regaining proximity with attachment figures becomes dysfunctional. Consequently, the bereaved person struggles between the opposing forces of activated attachment behavior and the reality of the loved one's absence.

Bowlby maintained that in order to deal with these opposing forces, the mourner goes through four stages of grieving: initial numbness, disbelief, or shock; yearning or searching for the deceased, accompanied by anger and protest; despair and disorganization as the bereaved gives up the search, accompanied by feelings of depression and hopelessness; and reorganization or recovery as the loss is accepted and there is a gradual return to former interests. By emphasizing the survival value of attachment behavior, Bowlby was the first to give a plausible explanation for responses such as searching or anger in grief. Bowlby was also the first to maintain that there is a relationship between a person's attachment history and how he or she will react to the loss of a loved one. For example, children who endured frequent separations from their parents may form anxious and highly dependent attachments as adults and may react with intense and prolonged grief when a spouse or partner dies (see Shaver and Tancredy (2001), or Stroebe et al. (2005), for a more detailed discussion). Because it provides a framework for understanding individual differences in response to loss, Bowlby's attachment model has continued to be influential in the study of grief and loss (Shear et al. 2007). Mikulincer and Shaver (2013) have conducted sophisticated empirical research, confirming the importance of attachment security

in the prediction of adjustment to bereavement and providing fine-grained understanding of many associated phenomena.

Getting Past Stage of Grief

While several theorists have proposed that people go through stages or phases in coming to terms with loss (see, e.g., Bowlby 1980; Horowitz 1986), perhaps the most well known of these models is the one proposed by Kübler-Ross in her highly influential book *On Death and Dying* (Kübler-Ross 1969). This model, which was developed to explain how dying persons react to their own impending death, posits that people go through denial, anger, bargaining, depression, and ultimately acceptance. It is Kübler-Ross's model that popularized stage models of bereavement. For many years, Kübler-Ross's model has been taught in medical, nursing, and social work schools. It has also appeared in articles in newspapers and magazines written for bereaved persons and their family members. As a result, stage models have strongly influenced the common understanding of grief in our society.

As research began to accumulate, it became clear that there is little support for the view that there are systematic stages. Although there are studies that purport to support stage models (Maciejewski et al. 2007), the weight of the evidence suggests that reactions to loss vary considerably from person to person and that few people pass through the stages in the expected fashion (see Archer 1999; Attig 1996, for a review). Several major weaknesses of stage models have been identified (Neimeyer 1998). First, they cannot account for the variability in response that follows a major loss. Second, they place griever in a passive role when in fact grieving requires the active involvement of the survivor. Third, such models fail to consider the social or cultural factors that influence the process. Fourth, stage models focus too much attention on emotional responses to the loss and not enough on cognitions and behaviors. Finally, stage models tend to pathologize the reactions of the majority of people who do not pass through the stages. As a result of

these and other critiques and a lack of empirical support, most researchers have come to the conclusion that the idea of a sequence of stages is not particularly useful (Stroebe et al. 2001).

Trauma Theory and Meaning Making

An influential stream of thought in the field of bereavement has come from trauma theory. Even though one could argue that most late life losses may not involve experiences of a traumatic nature, for example, because the occurrence of the death may be considered timely in the context of the life course, there could be traumatic aspects to a loss experience in late life. For example, witnessing a prolonged period of serious illness and intense suffering of a loved one can have elements of trauma, even if the illness and death occur at an expected life stage. Similarly, the death of an older person can be experienced as very sudden, if this person had been in good health and highly engaged in life or even if the person died after years of chronic illness and decline. Therefore, it appears that conceptual thinking coming from trauma theory should be considered even in the context of late life loss.

The model of stress response syndromes by Horowitz and colleagues (1986) purports that traumatic experiences disrupt a person's life via blockage of cognitive and emotional processing. Similar to the notion of grief work as a necessary step toward recovery, the assumption here is that processing the trauma is essential if the person is going to be able to move on and that stressful life events play an important role in the etiology of various somatic and psychiatric disorders due to failure of such processing. A further line of research derived from the related field of trauma was that of Janoff-Bulman (1992), particularly through the identification of shattered beliefs which need to be rebuilt. This has been expanded to the study of "meaning making" particularly by Neimeyer and collaborators (2001, 2006).

The basic idea in the perspective is that major losses challenge a person's sense of identity and narrative coherence. Narrative disorganization can range from the relatively limited and transient

to more sweeping and chronic, depending on the nature of the relationship and the circumstances surrounding the death. According to Neimeyer, a major task of grief involves reorganizing one's life story to restore coherence and maintain continuity between the past and the future. However, difficulties in establishing the role of meaning making in adjustment remain (e.g., studies have not always succeeded in separating the process from the outcome, beliefs from adjustment, or establishing the direction of causality among these factors). Others have distinguished two components of meaning making. Davis, Nolen-Hoeksema, and Larson (1998) identified two distinct processes, making sense of the loss and finding benefit, which entail distinguishable psychological concerns for the bereaved person, with, for example, the former diminishing in importance in time, while the latter grows stronger as time goes on.

Stress and Coping Approach

Over the past two decades, a theoretical orientation referred to as the stress and coping approach, or the cognitive coping approach (Lazarus and Folkman 1984), has become highly influential in the field of bereavement. Stress and coping theorists maintain that life changes such as the death of a loved one become distressing if a person appraises the situation as taxing or exceeding his or her resources. An important feature of this model is that it highlights the role of cognitive appraisal in understanding how people react to loss. A person's appraisal, or subjective assessment of what has been lost, is hypothesized to influence his or her emotional reaction to the stressor and the coping strategies that are employed. To explain why a given loss has more impact on one person than another, stress and coping researchers have focused on the identification of potential risk factors, such as a history of mental health problems, as well as protective factors, such as optimism or social support (for a review, see Hansson and Stroebe 2007; Pearlman et al. 2014; Stroebe et al. 2006, 2007). The appraisal of the loss, as well as the magnitude of

physical and mental health consequences that result from the loss, are thought to depend on these factors.

Caregiving and Bereavement

As most deaths in late life are preceded by chronic illnesses, family members, in particular spouses, are often involved in prolonged periods of caregiving in the years, months, or weeks before their loved one's death. Therefore, conceptual thought that considers the specific case of bereavement after caregiving is particularly relevant to the topic of late life loss. Three major lines of thought derived from stress theory have emerged in the literature (for a review, see Boerner and Schulz 2009; Schulz et al. 2008) regarding bereavement in the context of caregiving. The cumulative stress perspective, or "wear and tear" hypothesis, argues that the combined effects of the stress of caregiving and the death deplete people's coping resources and result in greater adjustment difficulties following the loss. The stress reduction perspective makes the opposite prediction, arguing that the death brings relief because it puts an end to caregiving stressors and the suffering of the person who is dying and so results in more positive bereavement outcomes than found among non-caregivers. Finally, it has been suggested that caregivers more or less expect to be bereaved, which in turn allows at least some degree of anticipatory processing and preparation that may benefit the person after the death.

When all three perspectives are considered, the emerging picture seems to be a combination of depletion, relief, and anticipation effects (Schulz et al. 2008). For example, once the death occurs, the caregiver may feel extremely exhausted, but at the same time relieved that his or her loved one no longer has to suffer and that the immense strain of the caregiving role has ended and also may have had a chance to think about the impending death and their life afterward, possibly have a conversation with the loved one about these topics, and take care of some pragmatic necessities related to the death (e.g., financial planning, funeral arrangements).

The bulk of research studies to date indicate that many caregivers experience some sort of stress relief and/or benefit of anticipation rather than a depletion of their resources or at least that the first can outweigh the latter. However, bereavement outcomes following caregiving may also depend on how the loved one's end-of-life phase was experienced. For example, spouses of patients who died while on hospice care lived longer than spouses of patients who did not use hospice (Christakis and Iwashyna 2003). In contrast, family members were found to have poorer mental and physical health outcomes when aggressive treatments were performed at the patient's end of life (Wright et al. 2008). Besides consideration of such quality of life indicators characterizing the time preceding death, there is evidence that previous notions of anticipatory grief have been based on largely unfounded assumptions of the benefits of anticipatory grieving for post-death adaptation. Rather, findings have linked higher levels of pre-loss grief to higher levels of post-death grief (Liu and Lai 2006). This corresponds with the more general finding in the bereavement literature that those who experience high levels of distress before the death are also at risk of adjustment difficulties post-death (Bonanno et al. 2002; Schulz et al. 2006).

Bereavement-Specific Theories

Much of the theorizing discussed above involved conceptual models that could be applied to bereavement, but they were not developed specifically to account for people's reactions to the death of a loved one. For example, the stage model by Kübler-Ross was developed to describe the experience of dying persons, Bowlby's attachment model was originally designed to explain distress resulting from mother-infant separation, trauma theories addressed the case of various traumatic experiences, and the stress and coping approach dealt with any type of stressor. While coping with the death of a loved one has elements of all these areas, one could argue that there may be unique coping challenges that do not apply in

the same way to other life experiences and that we therefore also need models specifically focusing on bereavement.

Two theoretical models reflecting this aspiration are Bonanno's four-component model (Bonanno and Kaltman 1999) and Stroebe and Schut's (1999, 2010) dual-process model. Bonanno's goal was to develop a conceptually sound and empirically testable framework for understanding individual differences in grieving. He identified four primary components of the grieving process – the context in which the loss occurs (e.g., was it sudden or expected, timely or untimely?), the subjective meanings associated with the loss (e.g., was the bereaved person resentful that he or she had to care for the loved one prior to the death?), changes in the representation of the lost loved one over time (e.g., does the bereaved person maintain a continuing connection with the deceased?), and the role of coping and emotion regulation processes that can mitigate or exacerbate the stress of loss. Bonanno's model makes the prediction that recovery is most likely when negative grief-related emotions are regulated or minimized and when positive emotions are instigated or enhanced (Bonanno 2001). This hypothesis, which is diametrically opposed to what would be derived from the psychodynamic approach, has generated considerable interest and support in recent years.

The dual-process model of coping with bereavement (DPM; Stroebe and Schut 1999, 2010) indicates that following a loved one's death, bereaved people alternate between two different kinds of coping: loss-oriented coping and restoration-oriented coping. While engaged in loss-oriented coping, the bereaved person focuses on and attempts to process or resolve some aspect of the loss itself. Dealing with intrusive thoughts about the death is an example of loss-oriented coping. Restoration-oriented coping involves attempting to adapt to or master the challenges inherent in daily life, including life circumstances that may have changed as a result of the loss. Examples of restoration-oriented coping include distracting oneself from the grief, doing new things, or mastering new skills. Stroebe and Schut have proposed that bereaved individuals

alternate between loss- and restoration-oriented coping and that such oscillation is necessary for adaptive coping. Hansson and Stroebe (2007) applied the DPM to the experience of bereavement in late life, cataloguing specific difficulties for older persons (such as the increased frequency and cumulative impact of multiple bereavements in the loss-oriented sphere and physical impairment, which may prevent the bereaved from carrying out the tasks that the deceased had taken care of, in the restoration-oriented sphere).

Outlook

Today, the fundamental question facing bereavement theorists and researchers alike is the following: Why is it that some older adults are completely devastated by the death of a spouse, while others seem to emerge – sometimes after a period of intense suffering – relatively unscathed or even ultimately strengthened by what has happened? As noted above, accumulating evidence regarding variability in response to loss led researchers to move away from traditional grief models and instead employ frameworks, such as the stress and coping approach, Neimeyer's focus on meaning making, Bonanno and Kaltmann's four-component model, and the dual-process model, developed by Stroebe and Schut, each of which can account for divergent responses to loss. Drawing from these models, investigators are trying to identify risk and protective factors that influence the nature and course of grief following spousal loss. Below, we provide a brief summary of selected new directions that we think should be pursued to refine and expand conceptual thought in the field of bereavement.

To date, most of the bereavement literature has focused on adaptive processes within – rather than between – individuals. An intriguing question, however, is what happens to larger social units, such as families, when group members experience a shared loss in different ways (e.g., one family member expresses intense distress, whereas another shows less distress)? In such a case, would those who are more distressed be likely to benefit from the presence or availability of the less

distressed person? Or would the lack of congruence in the experience of individual members lead to a mismatch and potential interference of coping efforts? Future work addressing these questions would make an important contribution because people rarely face a loss in a social vacuum (Stroebe et al. 2013). Theoretical models that do not address interpersonal processes in grieving lack this vital component of coping with loss.

A related, also understudied, social context topic is the role of cultural influences on grief and bereavement. Ethnicity and cultural background have been found to be related to bereavement outcomes. For example, in a cross-cultural study, Chinese participants seemed to recover more quickly from bereavement emotionally compared to US Americans, but they also reported more somatic complaints (Bonanno et al. 2005). Culturally shaped spiritual convictions may also have an impact on how individuals deal with loss. For example, for a person who believes that life is suffering and death is transcendence, as seen in Zen Buddhism, the experience of loss may be easier to bear. There may also be culture-specific implications of particular losses. For example, in many cultures, losing one's husband involves loss of respect and basic human rights, which is likely to make coping more difficult, in particular for cohorts of older women who were not in a position to develop an autonomous lifestyle or status. Exploring in more detail whether and how the meanings associated with response to loss vary by culture might help us to gain a better understanding of the influence of culture-specific factors such as attitudes and expectations toward loss experiences.

Biological aspects of adaptation to a major loss could also be more important than expected so far (Curtis and Cicchetti 2003). There is some evidence for persistent alteration of stress mechanisms and brain functioning from early trauma. Early life stress apparently produces a sensitization of the cortical corticotropin-releasing neuronal system and the hypothalamic-pituitary-adrenal axis stress response, as well as structural and functional changes in the brain. Further, recent research has identified neurophysiological mechanisms linking stress to various negative

consequences with respect to the immune, gastrointestinal, and cardiovascular systems (O'Connor 2013). Using physiological methods and the means of brain research could enrich ongoing efforts in psychosocial research on bereavement. Finally, combining physiological and psychosocial factors into more complex models to predict reactions to loss might allow us to better understand why some people are devastated by a loss like the death of a spouse, while others weather this kind of life event well or even experience positive development or personal growth in the context of major loss.

Theoretical advancement through more active consideration of areas such as interpersonal and physiological processes, as well as cultural influences, has the potential to deepen our understanding of grief and bereavement. This is particularly important for the case of complications in grieving. However, while recognizing symptoms of complications in grieving is critical to identifying individuals who are at risk for poor bereavement outcomes that persist over time so that adequate support sources can be allocated, the focus on symptom alone does help us understand why a person's response to loss may develop into a derailed adaptation process and perhaps even how this development could be prevented. Therefore, continued conceptual development in the field of bereavement is a vital effort.

representative data; Retirement

Definition

Psychologists are discovering opportunities to explore complex questions using large datasets. This chapter describes and illustrates the value of the Health and Retirement Study (HRS), a nationally representative multidisciplinary dataset on aging in the USA featuring a rich blend of economic, health (including genetics and biomarkers), cognition, and psychosocial information.

Introduction

Psychologists are increasingly using population-based multidisciplinary survey data to examine

questions about health and aging. A major data resource that may be less well known to psychological research scientists is the Health and Retirement Study (HRS). HRS is a nationally representative longitudinal study of more than 37,000 individuals aged 50 to 100+ (and deceased) from about 23,000 households in the USA. The survey, which has been fielded every 2 years since 1992, was established at the direction of the US Congress to provide a national resource for data on the changing health and economic circumstances associated with aging. HRS was the first longitudinal study of older people to collect detailed economic and health information in the same study (Juster and Suzman 1995). The goal was not only to build our understanding of aging but also to provide scientific data for studying national-level social and policy changes that may affect individuals. Indeed, the data are often used to study the effects and implications of different public policies. Thus, the topics covered include resources for successful aging (e.g., economic, public, familial, physical, psychological, and cognitive), behaviors and choices (e.g., work, health behaviors, residence, transfers, use of programs), and events and transitions (e.g., health shocks, retirement, widowhood, institutionalization).

HRS has rich longitudinal measurement of several domains – income and wealth; health (including biomarkers and genetics), cognition, and use of health care services; work and retirement; and family connections – linked to various

external sources of mortality, pension, Social Security, and medical care data. Since 2006, HRS participants have also reported on personal evaluations of their life circumstances, subjective well-being, lifestyle, and stress. The blend of economic, health, and psychosocial information in the HRS provides unprecedented potential to study increasingly complex questions about adult behavior and aging. In addition, HRS has become the model for a network of harmonized longitudinal studies of aging around the world, offering the opportunity for valuable cross-national comparisons (see Cross-Reference for examples).

Most of the data are public and are available at no cost to all registered users. Sensitive health data (such as genetic information) and restricted data (such as Social Security and Medicare records) require a separate application process that is detailed on the website. HRS is a large and very complex dataset. Various resources for getting started using the data are available on the website, and a free online help desk is offered for all users: hqsquestions@umich.edu. To increase the accessibility of this rich data resource, researchers at the RAND Corporation have created a user-friendly version of much of the HRS public data. The RAND contribution is available through the HRS website and is a good starting place for new users. Visit the HRS website (hrsonline.isr.umich.edu), especially under the documentation link, for more information on all of the topics addressed in this chapter.

This chapter describes the HRS study design and provides descriptions of content in areas of particular relevance to geropsychologists including cognition and depression, physical health and limitations, anthropometric measures and physical performance, biomarkers and genetics, and psychosocial functioning. It also illustrates the potential of these data for psychological research.

Study Design

The Sample

Recruited in 1992, the original HRS cohort included individuals born 1931–1941, then

aged 51–61. The Asset and Health Dynamics Among the Oldest Old (AHEAD) study was fielded the next year to include the cohort born 1890–1923, then aged 70 and older. The two studies merged in 1998, and in order to make the sample fully representative of the US population over age 50, two new cohorts were enrolled, the Children of the Depression Age (CODA), born 1924–1930, and the War Babies, born 1942–1947. To keep the sample representative of the population over age 50, HRS refreshes the sample every 6 years with younger cohorts not previously represented. In 2004, Early Baby Boomers (EBB, born 1948–1953) were added, and in 2010, Mid Baby Boomers (MBB, born 1954–1959) were added. In 2016, the Late Baby Boomers (born 1960–1964) will be added. With all of these cohorts, in 2014 HRS includes a wealth of information about the life histories of older Americans over the last 100 years.

The HRS sample is based on a multistage area probability design involving geographic stratification and clustering and oversampling of African-American and Hispanic individuals. Sample weights are derived and provided to account for differential probability of selection and differential nonresponse in each wave (Heeringa and Connor 1995). To determine eligibility for the study, interviewers conduct a brief household screening interview. Adults over age 18 living in the household are listed with their age and couple status. A primary respondent is randomly selected from all age-eligible household members, and if the selected person is coupled, their spouse or partner is also recruited to the study, regardless of age. Household screening efforts have been conducted in 1992, 2004, and 2010. The core survey occurs every 2 years, making 2014 the twelfth follow-up of the initial 1992 participants.

Baseline response rates range from 81.6% to 69.9% more recently. While baseline response rates have been somewhat lower in recent years following national trends, follow-up response rates have remained high, ranging from 85% to 90%. Follow-up rates are based on the sample for which interviews were attempted. At each follow-up, interviewers attempt to locate the entire

sample that participated at baseline. If a respondent is not interviewed in one wave, he or she is contacted again in the next. Complete response rates and sample sizes for each cohort are detailed elsewhere (Sonnega et al. 2014).

Special Design Features

HRS has several design features that enhance potential for psychological research. First, African-American and Hispanic households are oversampled at about twice the rate of whites, proportional to the US population. Ofstedal and Weir (2011) show that HRS has been successful at recruiting and retaining minority participants. In 2010, the minority sample from the Baby Boom cohorts was further increased by a supplemental screening effort. This increases opportunities for important subgroup analyses.

Second, as noted above, HRS enrolls both members of coupled households. In single households, respondents answer all questions. In coupled households, each member of the couple is designated as either a financial or family respondent. Questions about housing, income, and assets are asked of the financial respondent, and questions about family composition and transfers are asked of the family respondent. Individual responses are sought from both partners in a household about work, health, disability, cognitive status, and well-being. Likewise, psychosocial measures are collected individually for both members of the couple. Thus, HRS provides exceptional opportunities for dyadic analysis.

Third, when respondents are unable or unwilling to complete an interview by themselves, HRS interviewers seek a proxy respondent. Proxies are usually a spouse or other family member. In each wave, about 9% percent of interviews are conducted with a proxy respondent, about 18% for those who are 80 and older. Proxy interviews succeed in retaining individuals who are cognitively impaired, reducing attrition bias due to cognitive impairment in a study of aging individuals (Weir et al. 2011).

Fourth, HRS samples community-dwelling individuals in the first wave of data collection. However, respondents who move to nursing

homes after baseline are interviewed there. The result is that HRS now fully represents the US nursing home population. Among other things, this means that research can address the functioning and well-being of the oldest old. Finally, HRS monitors vital status through its own efforts to locate respondents and through linkages to the National Death Index. In addition, in the event of respondent death, HRS attempts an “exit” interview with a surviving spouse, child, or other informant to obtain information about medical expenditures, family interactions, disposition of assets following death, and other circumstances during the final stages of life.

Data Collection

In HRS, the baseline (initial entry) interview is conducted in the respondents’ home face to face (FTF) every 2 years. It takes approximately 3 h to complete and constitutes the bulk of the data. The sample size is around 20,000 at any given wave. At the end of this core interview in every wave, there are 10 or so experimental 3-min modules that provide greater depth on a topic that is in the core or information on a topic that is not in the core but may be of interest. Each module is completed by a different random subsample of the core sample. Module sample sizes are about 1,500. Some psychosocial content is available in modules.

Prior to 2004, the primary mode for follow-up interviews was telephone, except for respondents over the age of 80 who are always offered FTF follow-up interviews. Since 2006, HRS has utilized a mixed-mode design for follow-up interviews in which a random half of the sample is assigned to an in-home FTF interview that is enhanced with physical and biological measures and a psychosocial questionnaire. The other half of the sample completes only the core interview mostly by telephone (again, those over 80 are offered FTF interviews). The half-samples alternate waves so longitudinal information from the enhanced FTF (EFTF) interview is available every 4 years at the individual level, and the expanded content is available at every wave on a nationally representative half-sample. Beginning in 2010, the EFTF begins with the baseline

Health and Retirement Study, A Longitudinal Data Resource for Psychologists, Table 1 Timeline for collection of psychosocial data in HRS

							Planned	
	Prior	2004	2006	2008	2010	2012	2014	2016
Core sample	*+	+	+	+◆	+◆	+◆	+◆	+◆

* Various sample modules, + indicators of depression, ◆ single-item life satisfaction, *A* first random half sample, *B* second random half sample, *NB* physical measures and biomarkers also follow this timeline beginning in 2006

interview and alternates waves from that point on. Table 1 graphically portrays the design of the EFTF.

Finally, to expand data collection at lower cost and respondent burden, HRS also conducts studies in the off years from the core survey. These studies are fielded in subsamples as Internet-based surveys, mailed paper-and-pencil questionnaires, or in-home assessments. Sample sizes for these studies range from approximately 3,000 to 5,000 respondents. Some studies took place only once; others are biennial studies of varying duration.

Linkages to Administrative Records

HRS attempts to obtain permission from all HRS respondents to access and link their HRS survey data to their Social Security earnings and benefit records and from Medicare-eligible respondents to their Medicare records. Linkage consent rates range from 78% to 84%. In addition, HRS attempts to obtain a wide range of pension plan information from respondents’ current and past employers. Finally, health care utilization and other data from the Veterans Affairs (VA) health care system are linked to HRS respondents who have self-reported prior military service and have received VA health care. All of these sources of linked data not only provide validation of self-reported information but also add information not collected from respondents in the survey. These sources of linked data are made available to researchers under restricted data use agreements.

Study Content

Survey content from the 2010 wave of data collection, which is generally representative of the core interview, is summarized elsewhere

(Sonnega et al. 2014). This section highlights portions of the core survey that may be of particular interest to geropsychologists, specifically cognition, depression, physical health, and limitations. It also covers anthropometrics, physical performance, biomarkers, genetics, and psychosocial information, which are all obtained in the EFTF interview. Where available, associated HRS user guide/documentation reports are cited for content areas discussed in this section.

Cognition and Depression

From the beginning of the study, HRS researchers embraced a broad definition of health to include aspects of mental health and cognitive functioning. Measures of cognitive functioning included in most waves of HRS since 1992 include ten-word immediate and delayed recall to assess memory; a serial seven’s subtraction test of working memory; counting backward to assess attention and processing speed; object naming test to assess language; and recall of the date, president, and vice-president to assess orientation (Ofstedal et al. 2005). Information from these survey measures is summarized as a composite score ranging from 0 to 35 where a higher score indicates better cognitive functioning. This composite measure has been widely used to study trajectories of cognitive functioning.

An HRS supplemental study, the Aging, Demographics, and Memory Study (ADAMS), is an in-home neuropsychological assessment designed to provide a diagnostic determination of dementia or cognitive impairment without dementia (Heeringa et al. 2009). The study aimed to estimate the prevalence of dementia as well as risk factors and outcomes. ADAMS was

conducted in a subsample of the HRS population age 71 and older who would be at higher risk for cognitive impairment. The original sample of 1,770 was followed up through in 2002, 2006, and 2008, providing information on incident dementia and other longitudinal cognitive changes.

From its inception, HRS has included a short screening measure of depressive symptoms derived from the Center for Epidemiologic Studies Depression Scale (Steffick 2000). Beginning in the third wave, a short form of the World Health Organization's Composite International Diagnostic Interview was also administered. This scale determines a probable diagnosis of major depressive episode, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, third edition revised.

Physical Health and Limitations

At each wave, HRS assesses a range of health conditions. The survey asks respondents if a doctor has ever (or since the last wave) told them that they have high blood pressure, diabetes, cancer, lung disease, heart disease, stroke, and arthritis. For each of these conditions, respondents also report on whether they are taking any medications for that condition (Fisher et al. 2005). Questions are also included about symptoms such as pain, swollen ankles, headaches, vision, and hearing. The study also tracks several critical health behaviors. Respondents report on their use of alcohol, history of smoking, their sleep quality, and amount of exercise. Preventive health services assessed include mammography screening, breast self-exam, prostate exam, cholesterol screening, Pap smear, and flu shot (Jenkins et al. 2008).

HRS also captures information about physical limitations by asking respondents to report on difficulties with activities of daily living (ADLs) such as bathing, eating, dressing, walking across a room, and getting out of bed. Instrumental activities of daily living (IADLs) include preparing a meal, shopping, using a telephone, taking medication, and handling money. Limitations with these fundamental life tasks can indicate fairly severe disability. The third set of measures, the Nagi items, evaluate less fundamental tasks

including things like jogging a mile, walking up a flight (or several flights) of stairs, pushing a heavy object across the floor, and picking up a coin. These series of questions also include questions about respondents' receipt of help from other people with each of these activities and the use of assistive aids (e.g., walking stick). This section reflects the assumption that respondents need not be asked about relatively easy tasks if they reported being able to do more challenging tasks (Fonda and Herzog 2004).

Anthropometric Measures and Physical Performance

As noted above, the enhanced FTF interview includes physical tests and collection of biological specimens. HRS employs a set of standardized assessments of lung function (peak expiratory flow), grip strength, balance, and walking speed. Arterial blood pressure and pulse are also measured, and height, weight, and waist circumferences are obtained. Before each measure, respondents are asked whether they understand the directions for the measurement and if they feel safe completing it. If the respondent answers no to either question, the measure is not administered. Likewise, interviewers are instructed not to administer a measure if they do not feel it is safe to complete it (Crimmins et al. 2008).

Biomarkers and Genetics

Blood is obtained through fingerprick and is collected in the form of dried blood spots during the EFTF interview. Blood samples have been assayed for five biomarkers: total and HDL cholesterol, glycosylated hemoglobin (HbA1c), C-reactive protein (CRP), and Cystatin C, for which data from the 2006 and 2008 waves are currently available for analysis (Crimmins et al. 2013).

Respondents' saliva is obtained for DNA extraction. HRS saliva samples are genotyped by the Centers for Inherited Disease Research (CIDR) and archived with the database of Genotypes and Phenotypes (dbGaP) at the National Institutes of Health (NIH). To date, HRS has genotyped almost 20,000 respondents from 2006 to 2012. The genotype data through 2008 and a

limited set of phenotype measures have been deposited in dbGaP. In addition, HRS has prepared candidate gene and single-nucleotide polymorphism (SNP) files to provide access to carefully select subsets of the HRS genotype data available on dbGaP. These are smaller and more manageable files designed for users interested in a specific gene or SNP. Researchers wishing to use the HRS genetic data must first apply to dbGaP for access to the genotyped data. The process to request access to any dbGaP study is done via the dbGaP authorized access system. HRS also measures average telomere length using quantitative PCR (qPCR). The 2008 Telomere Data release includes average telomere length data from samples from 5,808 HRS respondents. These data are considered sensitive health data and require permission to use. Detailed access information can be found on each product's page on the HRS website.

Psychosocial Functioning

Table 1 depicts the psychosocial content available in the core survey and in the Participant Lifestyle Questionnaire (PLQ), a questionnaire left behind at the end of the EFTF interview that respondents complete and return by mail. As noted above, HRS has included measures of depressive symptoms and probable depression in the core survey since the second wave (section D in the core). As of 2008, all participants in the core are also asked a single item of life satisfaction (section B in the core). Before 2004, HRS piloted several psychosocial measures that are available as part of experimental module data. In 2004, HRS piloted the PLQ and fielded the revised questionnaire in 2006.

The table also illustrates the design of the EFTF, which was described previously. Beginning in 2006, half of the core sample was randomly selected to participate in the EFTF and receive the PLQ (A). The other half of the sample received that EFTF in 2008 (B). The first longitudinal data from the EFTF and thus the PLQ were collected from half-sample A in 2010. Longitudinal data was collected in 2012 from the second half-sample (B). This rotational design will continue in future waves. Note that this table applies

as well to other data collected as part of the EFTF interview, namely, anthropometrics and physical functioning, biomarkers, and genetics.

As with the core survey, in coupled households, both members of the couple complete the PLQ, and in some cases, the questionnaire is completed by a proxy. A question at the end of the survey asks, "Were the questions in this booklet answered by the person whose name is written on the front cover?" Approximately 1–2% of psychosocial questionnaires are completed by proxy respondents. A caregiver often acts as a scribe for very old participants, especially if the participant is vision impaired or finds it difficult to hold a pen due to arthritis. Because the questionnaire was left with respondents at the end of the EFTF interview for them to complete and mail back to study offices, the questionnaire came to be known as and is referred to on the HRS website as the Leave-Behind and is listed as section LB.

This section describes the psychosocial measures available within each broad content area (summarized in Table 2). Some of the scales and measures in the PLQ are well known and widely used. Others are measures that have been developed by HRS researchers or other research psychologists. More detailed information about the scales and measures through 2010 is provided in the documentation report/user guide available on the HRS website (Smith et al. 2013). The user guide lists the actual items in the questionnaire and reports the response coding and interitem consistency (reliability) information. Variations in variable names across waves are also noted. With a few exceptions, the content of the PLQ did not change substantially from 2006 to 2010; however, variations across waves are documented in the user guide.

Subjective Well-being

Well-being is assessed with several measures. Life satisfaction is measured with the five-item Diener Satisfaction with Life Scale, an established and reliable measure of subjective well-being that has been used extensively in international comparative studies (Diener et al. 1985). Domain satisfaction is assessed with seven items that tap satisfaction in several life domains: housing, city

Health and Retirement Study, A Longitudinal Data Resource for Psychologists, Table 2 Summary of HRS psychosocial content

Well-being	Lifestyle	Social relationships
Life satisfaction	Activities in life	Spouse/child/kin/friends
Domain satisfaction	Neighborhood evaluation	Positive support
Depression	Religiosity	Negative support
Positive/negative affect	Discrimination	Closeness
Hedonic well-being	Lifetime traumas	Loneliness
Purpose in life	Early life experiences	Early parental relationships
Self-acceptance	Stressful life events	Friend contact
Personal growth	Ongoing stress	Child contact
Financial strain		
Personality	Work	Self-related beliefs
Extraversion	Work stress	Personal mastery
Neuroticism	Work discrimination	Perceived constraints
Openness	Work satisfaction	Hopelessness
Agreeableness	Capacity to work	Subjective age
Conscientiousness	Effort-reward balance	Perceptions of aging
Cynical hostility	Work support	Subjective social status
Anxiety	Work/family priorities	Optimism
Anger	Work/life balance	Pessimism

or town, daily life and leisure, family life, financial situation, health, and overall life satisfaction (Campbell et al. 1976). Positive and negative affect is assessed with an adjective checklist (e.g., afraid, upset, determined, enthusiastic, guilty, active, etc.) largely derived from the Positive and Negative Affect Schedule – Expanded Form (PANAS-X) (Watson and Clark 1994). Some items were obtained from other researchers’ work in this area of study (Carstensen et al. 2000). The Ryff Scales of Psychological Well-being (Ryff 1995) includes a seven-item subscale that measures purpose in life. The 2006 version of PLQ also included the dimensions of self-acceptance and personal growth. Beginning in 2012, the PLQ includes a measure of hedonic well-being, which asks respondents to rate how much they experienced seven different emotions

(happy, interested, frustrated, sad, content, bored, or in pain) while they were watching TV, volunteering, exercising, other health-related activity, commuting, socializing, spending time with spouse/partner, or running errands (Smith et al. 2014). A standard item of financial strain (Campbell et al. 1976) was added in 2008 that asks respondents how difficult it is to make monthly bill payments. As noted, depression is captured in the core interview.

Lifestyle and Stress

Activities in life assess the level of social engagement and participation across a range of 20 different activities (e.g., attending religious services, caring for others, work on a hobby or project, etc.) (Jopp and Hertzog 2010). Another set of questions has respondents evaluate the physical disorder (vandalism/graffiti, rubbish, vacant/deserted houses, crime) as well as the social cohesion/trust (feel part of this area, trust people, people are friendly, people will help you) of their neighborhood (Mendes de Leon et al. 2009). A four-item measure of religious beliefs, meaning, and values is used (Fetzer Institute 2003). Two dimensions of discrimination are evaluated. A six-item scale measures the hassles and chronic stress associated with perceived everyday discrimination (Williams et al. 1997), followed by ten potential attributions for discrimination such as age, race, weight etc. (Kessler et al. 1999).

Assessment of lifetime traumas asks about the experience of seven major lifetime traumas from an ongoing longitudinal study of the health consequences of trauma in older adults (Krause et al. 2004). From the same study, early life experiences assess traumatic experiences before age 18 (repeating a year of school, trouble with the police, parental physical abuse, and parental drug or alcohol abuse). Recent stressful life events (last 5 years) include three items related to unemployment, moving to a worse neighborhood, experiencing robbery or burglary, and being the victim of fraud (Turner et al. 1995). The 2006 PLQ included assessment of chronic stressors that includes eight ongoing problems such as financial strain, housing problems, and work difficulties (Troxel et al. 2003).

Quality of Social Ties

A series of questions evaluates respondents' social network (four questions ask respondents if they have spouses/partners, children, family, and friends) and the level of closeness they feel and amount of contact they have with those contacts (Turner et al. 1983). For each category of contact, seven questions assess perceived social support or relationship quality (positive and negative). Loneliness is assessed in 2008 and 2010 using an 11-item scale developed by Hughes et al. (2004) for use in large-scale surveys. The first three items of the scale only are in the 2006 PLQ. The 2008 and 2010 PLQ include two items that assess the quality of early parental relationships (Rossi 2001).

Personality

The "Big Five" personality dimensions of neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness are assessed with 31 descriptive adjectives. The 2006 and 2008 PLQ used 26 items taken from the Midlife in the United States study (MIDUS) (Lachman and Weaver 1997). In 2010, four items derived from the International Personality Item Pool were added to expand coverage of conscientiousness. Cynical hostility is assessed with five items from the Cook-Medley Hostility Inventory (Cook and Medley 1954), which have been used in studies evaluating potential health consequences of hostility. Five items were selected from the widely used Beck Anxiety Inventory (BAI). The Beck Inventory has been shown to distinguish symptoms of anxiety from depression and to be valid for use in older populations (Beck et al. 1988). Finally, the State-Trait Anger Expression Inventory (STAXI) is used to measure state and trait anger (Forgays et al. 1998).

Work-Related Beliefs

HRS uses a 15-item scale to capture job stress and job satisfaction among working respondents. Based on the demand/control model of stress (Karasek 1979) and items like those contained in the Quinn and Staines Quality of Employment Survey, items were chosen and adapted to assess

multiple facets of job satisfaction and multiple work stressors. An eight-item scale taps the experience of chronic work discrimination (Williams et al. 1997). Capacity to work measures the perceived ability to work with respect to a job's physical, mental, and interpersonal demands (Ilmarinen and Rantanen 1999). Two dimensions of work support are captured: three items evaluate coworker support and five items tap supervisor support (Haynes et al. 1999). Twelve questions assess work/life balance and priorities, the extent to which work has a positive and negative effect on one's personal life, and vice-versa (MacDermid et al. 2000).

Self-Related Beliefs

HRS assesses personal control with five widely used items that measure the extent to which individuals feel they are in control of their lives. Similarly, mastery is assessed with a commonly used five-item scale that assesses personal agency and self-efficacy (Pearlin and Schooler 1978; Lachman and Weaver 1998). Hopelessness is measured with two items from Everson et al. (1997) and two items from Beck et al. (1974). Subjective age is very simply measured by asking respondents, "Many people feel older or younger than they actually are. What age do you feel?" (Kastenbaum et al. 1972). An eight-item scale (Lawton 1975) taps into individuals' evaluation of the experience of aging and their positive and negative perceptions of their aging. HRS utilizes the MacArthur Scale of Subjective Social Status based on Cantril (1965). The measure shows respondents a graphic depiction of a ladder with 10 rungs and asks them to place an x on where they are on the ladder of social status. Dispositional optimism and pessimism are assessed with the widely used Life Orientation Test (Scheier et al. 1994).

An International Model

HRS has also become the model for a network of 30 other international studies of aging (see Cross-References). HRS supports the development of

these surveys through technical assistance, interviewer training, and collaboration. These surveys not only provide data for individual countries but also offer the opportunity for cross-national comparisons. The Gateway to Global Aging Data (G2G) is a useful resource for researchers interested in cross-national data, also available through the HRS website. G2G provides interactive tools that allow researchers to find comparable questions across the surveys (www.g2gaging.org).

Research Examples

Researchers are now using this wealth of data to investigate a wide range of topics in geropsychology. The value of the cross-national psychosocial data is illustrated in a study comparing the patterns of disability in the USA and the UK (Clarke and Smith 2011). Older adults in the USA report a very high sense of personal control, whereas older adults in the UK are much more likely to feel that events in life are not always under their control. The study finds much lower disability rates for older US adults with a high sense of personal control compared to their counterparts in the UK. Another study compares cognition in the USA and the UK and finds that older adults in the USA score much better than English adults on a measure of cognition despite the fact that they have more risks for heart disease and other diseases that may lead to poorer cognitive function (Langa et al. 2009). The study shows that American adults tend to be wealthier and better educated and have less depression, which accounts for some of the US cognitive advantage. They are also more likely to be taking medications for hypertension, which may also help cognitive function.

Investigators are beginning to realize the benefits of HRS couples data. For example, Roberts et al. (2009) investigate the impact of conscientiousness on health in older couples. While most research demonstrates that a conscientious personality is associated with a range of positive health outcomes, this study explores the potential impact of an individual's conscientiousness on his

or her spouse or partner's health, what they call compensatory conscientiousness. They show that having a conscientious partner is health enhancing regardless of personal conscientiousness. Similarly, a longitudinal analysis of personal and partner optimism shows that having an optimistic spouse or partner is beneficial for health beyond the positive impact of personal optimism (Kim et al. 2014).

Lastly, Ailshire and Crimmins (2011) examine the social relationships, feelings of loneliness, and satisfaction with life and the aging experience among the oldest old (age 90–104) and older adults (age 70–79). The oldest old report a higher level of social support and maintenance of social relationships with family and friends compared to the 70–79-year-olds. Despite this, the oldest old reported greater loneliness, likely associated with higher rates of widowhood. The older group reported greater life satisfaction overall but more negative perceptions of their aging.

Conclusion

In sum, HRS is a representative sample of the US population over age 50, reinterviewed biennially throughout their lives. HRS encompasses a wide range of multidisciplinary content, and new data on biomarkers and psychosocial factors makes it a potent resource for psychologists interested in the modeling of causal pathways to health and well-being.

Definition

Smoking is the process by which an individual inhales the smoke of burning tobacco through cigarettes, cigars, or pipes. Smoking can also occur by inhaling vapor infused with nicotine via electronic cigarettes. Individuals who engage in this behavior by inhaling smoke or vapor through the direct source are considered active smokers. Those who breathe in the residual fumes released by active smokers are passive smokers, also called secondhand smokers (Samet 2001; Groner et al. 2011).

Smoking behaviors vary across cultures and age cohorts. It has come under much scrutiny over the decades with voluminous amounts of literature documenting its adverse effects. Chronic cigarette smoking is linked to several physical health conditions for the elderly, which impact longevity and quality of life (Samet 2001; Groner et al. 2011; Rezzani and Rodella 2012; Cataldo 2007; Jha et al. 2013). Additionally, this behavior is associated with diminished cognitive capabilities (Durazzo et al. 2010). These well-documented disadvantages of smoking have paved the way for anti-smoking campaigns highlighting the short- and long-term health benefits of smoking cessation.

Prevalence Rates of Older Adult Smokers

Current data looking at age cohort tobacco usage show a gradual decline in the prevalence of cigarette smoking across age groups in the United States over the past few decades (US Department of Health and Human Services 1990). Little statistical data is available regarding the number of current older adult smokers. However, past data from the 1999 Surgeon General Report indicated 10.5% men and 10.7% women aged 65 and older were current smokers. This statistic has since dropped, and in 2001, the CDC reported approximately 8.8% of older adults aged 64 and older are smokers. Another research indicates that smoking has declined for this population because of increased smoking cessation but also because of the relatively high mortality rates smokers experience versus never smokers (Burns 2000). However, this number has remained

fairly consistent since then. In 2008, the American Lung Association reported that more than 17 million Americans who are at least 45 years old are currently smokers. Of that 17 million, approximately 9% of Americans aged 65 and older currently smoke tobacco (American Lung Association 2015).

Tobacco Smoke

There is a multitude of health effects associated with the long-term use of tobacco. The etiology of the detrimental health effects is due to the toxicity of the smoke inhaled by users. Tobacco cigarettes are composed of several additive compounds, such as tobacco, paper, and various organic materials (Samet 2001). When flames ignite a cigarette, the resulting smoke is comprised of a multitude of toxic chemicals, such as carbon monoxide, nicotine, acetaldehyde, hydrogen cyanide, benzene, benzo(*a*)pyrene, and several other harmful compounds and carcinogens (Samet 2001). There are two types of tobacco smoke: sidestream smoke and mainstream smoke. Sidestream smoke is the smoke that is released from the burning end of the cigarette. This type makes up approximately 85% of tobacco smoke released (Groner et al. 2011). Mainstream smoke is what is inhaled and exhaled by the active smoker and accounts for the remaining 15% of tobacco smoke. Substantial data has been collected to identify the composition of mainstream smoke (the smoke that is breathed). They have found that nearly 4,000 constituents have been found to make up mainstream smoke. Further data has shown that 400 chemical compounds are present in both mainstream smoke and sidestream smoke. For example, both forms of smoke contain carcinogens, mutagens, toxicants, and sensory irritants. Sidestream smoke, however, contains higher traces of toxic chemicals than mainstream smoke (Samet 2001; Groner et al. 2011).

Physical Health Effects of Smoking

There are several physical health effects associated with chronic cigarette smoking that

significantly impacts older adults. An overwhelming amount of evidence suggests that smoking is linked as one of the most common causes of death in old age (Samet 2001). Furthermore, smoking is also associated with many ailments, disabilities, and chronic illnesses common in this age cohort (Rezzani and Rodella 2012). This section of this entry will describe some of the most common physical conditions older adults experience due to cigarette smoking. The most common types of ailments associated with prolonged smoking are cardiovascular complications, respiratory disorders, and cancer (Samet 2001; Rezzani and Rodella 2012).

Cardiovascular Complications

There are several cardiovascular issues associated with tobacco use. These include coronary heart disease, strokes (cerebral vascular accidents), atherosclerosis (aortic aneurysm), and myocardial infarctions (heart attacks) (Samet 2001; Groner et al. 2011; Rezzani and Rodella 2012). These physical complications may occur as early as 40s or 50s, but are more commonly seen in populations 65 years and older (Rezzani and Rodella 2012).

Tobacco smoke has been causally associated with atherosclerosis (Samet 2001; Rezzani and Rodella 2012). This is a condition where the walls of the arteries narrow. There is also a considerable buildup of plaque within the arteries. Cigarette smoke also increases blood coagulation leading to a restriction of blood flow and an increased risk of blockages causing myocardial infarctions (Samet 2001). This greatly restricts blood flow causing certain areas of the heart and several other organs to be deprived of oxygenated blood. Tobacco smoke has been linked to several mechanisms of atherosclerosis, such as endothelial damage, increased proliferation of vascular smooth muscle cells in lesions, and reduced levels of high-density lipoprotein cholesterol (HDL-C) (Rezzani and Rodella 2012). The damage to endothelial functioning is largely responsible for atherosclerosis. This cardiac condition can affect any artery within the body, which could lead to several different types of complications (Rezzani and

Rodella 2012). If there is a reduction of blood flow to your heart muscle, chest pains (angina pectoris) or heart attack may occur increasing the risk of mortality (Samet 2001).

Another cardiovascular risk associated with smoking is stroke. Cerebral vascular accidents occur when there is bleeding in the brain resulting in the brain tissue not receiving sufficient oxygen, ultimately leading to tissue damage or death (Samet 2001). The other way in which strokes occur is when a clot blocks an artery in the brain resulting in a restriction of blood supply to particular areas (Samet 2001; Rezzani and Rodella 2012). The three types of strokes are ischemic strokes, hemorrhagic strokes, and transient ischemic attacks (TIAs). Ischemic strokes are the most frequent type of stroke comprising approximately 85%. This stroke occurs when the arteries in the brain become blocked or narrowed by plaque, severely restricting blood flow. Hemorrhagic strokes are caused by ruptured arteries in the brain causing bleeding. The bleeding places a significant amount of pressure on brain cells, causing them to become damaged. Lastly, TIAs involve a temporary restriction of blood flow to the brain caused by blood clots or other matters. Smokers have a significantly high probability of experiencing one or more strokes.

Cardiovascular risks have also been identified with passive smokers. Research literature demonstrates that individuals exposed to secondhand smoke are at a 30–50% increased risk of experiencing acute cardiac syndrome compared to nonexposed individuals (Groner et al. 2011; Rezzani and Rodella 2012). While passive smokers are more likely to experience cerebrovascular disease, their tobacco smoke exposure is less than 1% that of active smokers consuming 1 pack per day (Groner et al. 2011; Rezzani and Rodella 2012). The best recommendation for these individuals is to limit exposure to secondhand smoke to limit damage to the cardiovascular system.

Respiratory Complications

The most common respiratory complication associated with prolonged tobacco use is chronic

obstructive pulmonary disease (COPD). Tobacco usage is the leading cause of COPD (Anzueto and Martinez 2009). This respiratory disorder includes two conditions: emphysema and chronic bronchitis (Samet 2001). This respiratory condition is a progressive disease that restricts breathing, leading to excessive coughing, large amounts of mucus secretion, shortness of breath, chest tightness, and other symptoms (Samet 2001; Anzueto and Martinez 2009). Typically, these symptoms are also called the “smoker’s cough.” In emphysema, the alveoli (air sacs) within the lung walls are damaged, causing them to lose their normal shape (Anzueto and Martinez 2009). This damage also deteriorates the wall linings of these air sacs, causing them to decrease in quantity within the lungs. This results in a decreased amount of oxygen getting absorbed into the bloodstream. Repeated irritation and inflammation of the airway linings are characteristic of chronic bronchitis, resulting in thickened airway linings (Samet 2001). This causes the body to secrete mucus in the airways, which makes it more difficult to breathe. Emphysema and chronic bronchitis commonly co-occur when an individual is diagnosed with COPD.

Since COPD is a progressive respiratory condition, those afflicted can expect for the condition to continue to worsen over time (Anzueto and Martinez 2009). It develops slowly, and people may notice that they slowly are having more difficulty with tasks they used to perform with ease (Samet 2001). In the later stages of this disease, basic activities, such as bathing, cooking, and walking, might prove too difficult for people to perform on their own (Samet 2001). It is common with individuals diagnosed with COPD to constantly feel as though they are suffocating. Due to the slow development of this disease, it is commonly diagnosed in middle-aged individuals and older adults. The prognosis is poor for both age groups, but the elderly are at greater risk for mortality (Samet 2001; Anzueto and Martinez 2009).

Older adults with COPD are at a greater risk of respiratory infections, such as the common cold or flu (Samet 2001). These respiratory infections are the leading cause of death among older adults with COPD. In general, a number of cohort studies

found that mortality from respiratory infections is higher in smokers compared to nonsmokers (Samet 2001). Unfortunately, there is no cure for COPD and the damage inflicted on the lungs is permanent. The main goal of treatment symptom relief is to slow down the progression of the disorder, preventing respiratory infections and trying to keep those afflicted active (Anzueto and Martinez 2009). Medications, such as steroids and bronchodilators, can be absorbed into the lungs via inhalers. These medications relax the muscles in the airway and reduce inflammation making it easier to breathe. In a recent study, 22,000 elderly COPD patients given steroid treatment were shown to have a reduced risk of readmissions to hospitals and decreased mortality rates (Anzueto and Martinez 2009). Surgical procedures may be necessary for air passage complications that restrict inhalation. This includes creating a hole in the neck and trachea of COPD patients in order to maintain appropriate breathing. In severe COPD cases, oxygen therapy can help patients breathe better by directly giving them oxygen through a mask or nasal prongs. This treatment is especially crucial in these severe cases because it helps these individuals perform more activities with symptom reduction, improves sleep quality, protects the heart and other organs, and increases longevity (Anzueto and Martinez 2009). Treatment of this disease is crucial because COPD accounts for nearly 80,000 deaths per year in the United States (Samet 2001).

Cancer

Lung Cancer. The most common health association people make with smoking is lung cancer. A significant amount of evidence draws causal associations of cigarette smoke to this type of cancer. The carcinomas develop in the respiratory airways and alveoli of the lungs when cigarette smoke deposits the carcinogens during smoking inhalation (Samet 2001; Shames et al. 2008). When the cancer cells grow, they produce the symptoms associated with the condition and eventually spread to other areas of the lung or surrounding body tissues creating more

physiological damage (Samet 2001; Shames et al. 2008). Cells located within the lung airways of smokers show mutations causing them to become cancerous. The primary carcinogen in cigarettes, benzo(a)pyrene, binds to the *p53* gene, which has been found to be mutated in smokers with lung cancer (Samet 2001; Shames et al. 2008). Data has shown that there are specific differences in the patterns of mutations of smokers compared to nonsmokers (Samet 2001). Lung cancer has one of the highest mortality rates of any type of cancer, with approximately 13% of patients surviving 5 years post-diagnosis (Samet 2001). Studies additionally show causal associations of developing lung cancer with prolonged tobacco usage. It is estimated that there is a tenfold increased risk for tobacco smokers to develop lung cancer compared to nonsmokers. Studies have also found that the amount of cigarettes smoked per day and duration of smoking are associated with different lung cancer risks (Samet 2001). Specifically, higher doses and longer duration were associated with more aggressive forms of cancer and an earlier diagnosis than those who consume cigarettes on a less frequent basis (Shames et al. 2008). Data also provides benefits of smoking cessation, with the risk considerably decreasing following smoking cessation.

Laryngeal Cancer. Laryngeal cancer results from damage to the vocal cords. This cancer manifests similarly to lung cancer in the sense that the carcinogens infused in the smoke attach to the fibrous structures of the vocal cords, which closely resemble lung cells, allowing the cell mutations to begin (Samet 2001). Common early symptoms of this type of cancer are coughing, vocal hoarseness, and coughing blood. This type of cancer is less virulent, and most cases can be treated with surgical removal of affected areas combined with a course of radiation treatment. Similar to lung cancer, cohort studies have shown that developing this type of cancer is highly associated with tobacco smoking (Samet 2001). It has been found that a higher proportion of males develop this type of cancer due to smoking compared to females. It has also been observed that certain lifestyle choices, combined with cigarette smoking, increase one's risk of

developing this type of cancer. Specifically, individuals with heavy chronic alcohol consumption and that smoke are at greater risk of developing laryngeal cancer (Samet 2001). Similar to lung cancer, individuals who restrict their cigarette usage or completely quit greatly decrease their risk of getting this type of cancer.

Oral and Esophageal Cancer. Oral cancer is localized to the mouth and the throat. It is typically caused by squamous cancer cells, which grow on the surfaces of the oral cavity. Tobacco smoke creates nonmalignant lesions called leukoplakia within the mouth (Samet 2001). With continued cigarette smoking, the carcinogens in the smoke lead to genetic mutations in the oral cells, causing the cancer. In the mouth, the initial symptoms of oral cancer might arise as aching lumps, which might bleed. Recovery rates for this type of cancer are high and treatment is typically surgical removal of cancerous cells. This however might result in permanent disfigurement (Samet 2001). Esophageal cancers are also mostly caused by squamous carcinomas, similar to oral cancer, and their growth in the esophagus causes throat blockages. Data demonstrates that smokers are at a nearly five times as likely of developing this type of cancer compared to lifelong nonsmokers (Samet 2001).

Cognitive Effects of Smoking

While it has been established that smoking adversely affects the physical health of older adults, how does it impact their mental thinking skills? There are several consequences associated with chronic cigarette smoking that impair cognitive processes. There is a substantial amount of research on the effects of smoking on a disease that is almost exclusively experienced by older adults: Alzheimer's disease (AD). Literature has consistently demonstrated that smoking is a risk factor related to AD (Durazzo et al. 2010; Chang et al. 2014). For a long time, there was conflicting evidence as to whether smoking was associated with the development of this disease, but with more epidemiological studies and brain imaging surfacing, tobacco use is correlated with AD

(Chang et al. 2014). Imaging studies have found that there is a strong correlation between chronic smoking and reduced gray matter densities and volumes in brain regions highly associated with AD (Chang et al. 2014). Smoking also plays a role with another neurodegenerative disease affecting older adults closely related to AD: vascular dementia.

The direct health effects of cigarette smoking on the heart have already been established. These serious cardiac issues are sometimes accompanied by neurological decline related to heart complications (Chang et al. 2014). Vascular dementia is a neurodegenerative disease where one experiences declining abilities in various cognitive domains following certain cardiac episodes (Chang et al. 2014). The extent of the cognitive decline is strongly associated with the severity and type of cardiac episode. Cognitive changes are mostly observed following a stroke, but cognition changes also accompany damage to blood vessels and reduce blood circulation. Smoking, high blood pressure, and high cholesterol are the biggest risk factors for developing vascular dementia.

There has been substantial data looking at smoking and how it correlates with Parkinson's disease (PD) (Chang et al. 2014). Results show that there are possible protective factors of cigarette smoking with PD. Past research has shown that there is possibly a 50% reduction of developing PD in chronic smokers (Chang et al. 2014). It is hypothesized that the protective effects come from the nicotine in cigarettes. Specifically, it is thought that nicotine can slow the production of a protein responsible for creating Lewy bodies within the brain: alpha-synuclein. Studies have found that chronic cigarette smokers had reduced Lewy-related pathology (Chang et al. 2014).

Smoking has also been found to decrease cognitive functioning unrelated to neurodegenerative diseases. Most of the research done in this area has concentrated on middle-aged or older adults (Durazzo et al. 2010). Data demonstrates that older adults who have been smokers for the majority of their lives are at risk of experiencing decline in certain neurocognitive domains. The

various cognitive domains are important for daily functioning and maintaining independence. It is common to see age-related decline in nearly all domains, but research shows that people with any history of cigarette smoking had diminished overall cognitive functioning (Durazzo et al. 2010). Despite achieving poorer scores on measures of global cognitive functioning, there is one area of cognition that is more affected by smoking than others (Durazzo et al. 2010). Some research has found that current older adult smokers demonstrated an abnormal decline in auditory-verbal memory, meaning they had difficulty recalling verbal details after a delay (Durazzo et al. 2010). This provides evidence that smoking cigarettes can impact parts of a person's memory functioning.

Demographic and Social Contributors to Smoking

There are several demographic and social factors that influence smoking rates and maintenance in older age. Statistics of current smokers demonstrate that the prevalence rates in that population demographic decline as one approaches old age (Wray 2007). More specifically, as smokers approach old age (65 years and older), the likelihood of adult smokers quitting as they enter old age increases mostly due to the risk of mortality and health issues. Another reason for this decline is due to smoking-related mortality in middle-aged adults. Even though the current rates of quitting smoking between younger adults and older adults are the same, older adults are more likely to quit smoking cigarettes altogether compared to their younger counterparts (Wray 2007). While health issues are a large contributing factor to the decrease in smoking trends as one progresses toward old age, there are other contributing factors.

One research study discovered that nearly half of older adults in the United States (44%) are former smokers (Wray 2007). Looking at current trends, there are factors that are associated with higher rates of smoking as one enters old age. Statistics have found that the majority of smokers

in older adults are men, while women make up the majority of nonsmokers within this age demographic (Wray 2007). Differences have also been found between different races. European American, Hispanic, and Asian men had the lowest smoking rates compared to African American and American Indian men. Similarly, American Indian women had the highest rates of smoking, while Caucasian women were least likely to currently smoke cigarettes (Wray 2007).

Other factors that impact whether one continues smoking into old age are their economic and relationship status. Older adults with a higher social status are more likely to have never smoked or be past smokers compared to those in lower socioeconomic statuses. For example, since the 1960s, literature shows that individuals graduating from college are associated with quitting cigarettes at significantly higher rates than those only graduating from high school (Wray 2007). Marital status also plays into whether smoking persists into old age. Specifically, single older adults are more likely to be smokers than married older adults (Wray 2007).

One more factor that is correlated with higher smoking in older adults is physical activity level. Literature has demonstrated that the health, activity, and smoking status are correlated. Specifically, it has been observed that older adults currently smoking cigarettes are less likely to engage in physical activity (Wray 2007). These rates are amplified if the current smoker has completed less years of education and is experiencing multiple physical health complications (Wray 2007).

Smoking Cessation and Health Effects

The information presented in this entry indicates that smoking in the older adult population is certainly a health issue. Smoking can be hazardous to health, but for older adults, smoking is associated with poorer quality of life, which includes deficits or a decrease in mobility, increased stress, decrease in happiness, and dissatisfaction in social

relationships (Cataldo 2007). Thus, smokers who are at least 65 years of age are at higher risk of death compared to nonsmokers in the same cohort (Samet 2001; Rezzani and Rodella 2012). Additionally, older adult smokers are at an increased risk of clinically significant cognitive decline (Durazzo et al. 2010; Chang et al. 2014). Smoking cessation is not always easy and there are a number of barriers to quitting among older adults. For many older adults, smoking has been a lifelong habit that cessation may be challenging at the least. This difficulty may be due to psychological effects of addiction to nicotine or an inability to imagine life smoke-free (Appel and Aldrich 2003). Older adults who do decide to begin cessation may encounter barriers to doing so successfully, such as cravings, loss of pleasure from smoking, symptoms of anxiety such as feeling tense and irritable, boredom, fear of failing to successfully quit, difficulty concentrating, and altered sleep (Orleans 1988). Other obstacles to initiate cessation include misinformation about the process, incorrect beliefs regarding smoking and cessation, and nicotine addiction (Appel and Aldrich 2003). Long-term smokers who decide to undergo smoking cessation may also experience some nicotine withdrawal symptoms such as anxiety, irritability, and anger, which may influence their quality of life and ability to continue cessation and completely quit (US Department of Health and Human Services 1990). However, a number of health benefits can be gained from smoking cessation. Some research posits that older adults are often motivated to seek smoking cessation for better health but also from social pressure. Thus, medical providers should take care to inform and educate the elderly about smoking and smoking cessation because of the frequency in which older adults make contact with their physicians (Kehlet et al. 2015).

One of the major benefits to smoking cessation is an increased life expectancy of 2 years for men and 3.7 years for women (Taylor et al. 2002). With added longevity, there is also the potential for an overall increase in quality of health and changes in quality of life. Individuals who are able to engage

in smoking cessation often find improvements in sleep, reduced pain, and increase in energy (Goldenberg et al. 2014). Smokers who suffer from cardiovascular disease and are able to quit reduce their risk of suffering from recurrent myocardial infarction. Smoking cessation can result in a reduced risk of cardiovascular disease, especially if one has not already acquired the disease, reduced risk of developing lung and other cancers, and a slower reduction in pulmonary function in general (Samet 2001; Groner et al. 2011; Rezzani and Rodella 2012; Anzueto and Martinez 2009; Shames et al. 2008). After a year of abstinence from smoking, an improvement in lung function is evident (Burns 2000) which can equate to a greater capacity and tolerance for exercise. A decreased risk of hospitalization for smoking-related issues including COPD also occurs with smoking cessation (Samet 2001; Anzueto and Martinez 2009). This decrease in hospitalizations allows individuals to stay home longer resulting in less family stress and improved interpersonal relationships. Smoking cessation may also lead to increase sense of self-control and a boost in self-esteem (Taylor et al. 2002).

Improvements in health continue long after smokers quit. Individuals who have successfully quit smoking will have a 30% decrease of cardiovascular mortality for every 5 years of sobriety (Mons et al. 2015). Such improvements are seen within the older adult population, as well. Older adults who quit smoking have a reduced risk of premature death, and those who stop smoking between the ages of 55 and 64 can expect to gain about 4 years of life (Jha et al. 2013; Sachs-Ericsson et al. 2009). Additionally, an added benefit of cessation is that individuals who quit cigarettes between 45 and 55 years old reduce the risk of mortality due to smoking-related disease (Jha et al. 2013).

Conclusion

Chronic cigarette smokers expose their bodies to various toxic chemicals and carcinogens causing severe and, sometimes, irreparable damage to

their bodies and brains. Both active and passive smokers are at risk of developing several life-threatening medical issues that will not only impact their health but also their quality of life. It has been well established that chronic cigarette smoking leads to several physical conditions that are especially dangerous for the older adult age cohort. Cardiac complications include an increased chance of stroke and heart attack, along with blood flow irregularities. Older adults are also at risk of developing COPD, which severely restricts breathing and their quality of life. Older adult smokers are also susceptible to developing several different types of cancers. Smokers are also more likely to develop a certain neurodegenerative disease in later life, such as AD and vascular dementia, which will cause them to lose certain cognitive skills. The best way to promote good health and quality of life in old age is to abstain from smoking. Smoking cessation is shown to improve cardiac and respiratory health and can increase longevity by several years.

Health in Centenarians

Signe Hoei Rasmussen and Karen Andersen-Ranberg

Epidemiology, Biostatistics and Biodemography, Institute of Public Health, University of Southern Denmark, Odense C, Denmark

Background

Extreme longevity has always fascinated mankind, as long-lived individuals were thought to hold the secrets of successful aging, i.e., aging without disease (Franceschi and Bonafe 2003). Many anecdotal descriptions supported this notion until the last quarter of the twentieth century, where the number of centenarians in the industrialized world increased exponentially (Vaupel 2010). The first centenarian studies embraced the successful aging theory and found centenarians to be exceptionally healthy. However, these studies were limited by selection bias, i.e., the more healthy centenarians were more likely to participate in research.

The idea of centenarians being living proofs of successful aging is in contrast to the knowledge that advancing age is associated with increasing morbidity and multimorbidity (Barnett et al. 2012). As both aging and illness result in a decline in physical health, centenarians ought to be more dependent on help than younger oldest-old. Centenarian studies from the last decade of the twentieth and the first decade in the twenty-first centuries have shown that there is more to it: centenarians can be healthy or unhealthy.

Investigating health in centenarians requires not only proper epidemiological methods but also consideration of the challenges related to this extreme age groups' high risk of suffering from disabling diseases. First, a representative sample drawn from a population register is desirable. Second, high participation rates are needed to avoid selection bias toward the more healthy centenarians. Third, personal interviews in the centenarian's domicile are better than telephone interviews or filling in postal questionnaires.

Fourth, self-reported, including proxy-reported, health information may suffer from information bias, recall bias, and desirability bias. Fifth, physician-reported health information and register-based health records are more valid and also less biased with respect to recall and socially desirable factors. Sixth, some conditions may have very few or subtle symptoms mimicking aging-associated declines and are therefore not recognized as potential diseases, e.g., myocardial infarction, which needs to be confirmed by an electrocardiogram (ECG). Seventh, very old and frail people, who include many centenarians, may be subject to less aggressive diagnosing, or even ageism, leading to underdiagnosing and undertreatment. Finally and eighth, as cognitive impairment is common in very old subjects, misreporting is likely.

The various studies describing health in centenarians differ with respect to sample size, sampling, and survey methodologies, which makes it difficult to overview the occurrence of diseases and functional health. For the purpose of this work, we mainly focus on larger and mostly population-based, cross-sectional centenarian studies. To interpret the reported findings, the survey methods of the selected studies are described. In a second part, the results of each of the included studies are reported, although some studies have limited information on objective health. It should be noted that although dementia is a very common disease in very old people, it is not included here.

Presentation of Centenarian Studies

(Survey year in parentheses)

Earlier Centenarian Studies

It was not until the beginning of the 1960s, when centenarians became less rare in countries with low mortality, that it became possible to conduct descriptive surveys of centenarians, and since then many studies have appeared. Noteworthy are the pioneer studies in the 1960s by Haranghy (1965) and Franke et al. (1970). Later, i.e., in the 1980s, the remarkable second Hungarian

Centenarian Study (Beregi 1990) followed, which had a cross-disciplinary team of medical specialists who drove around in Hungary in a bus equipped to do extensive clinical examinations (e.g., chest X-rays). Unfortunately, the most frail centenarians were excluded from the study.

The Finnish Centenarian Study (1991)

This study was the first to assess a nationwide birth cohort of centenarians identified in the national Central Person Registry (Louhija 1994). The study was carried out by a specialist geriatrician, who traveled around in Finland to visit the centenarians at their domicile. Totally, 185 centenarians from the birth cohorts born in 1891 and earlier were eligible, and 181 participated in the study yielding a participation rate of 79% (including in the denominator eligible subjects deceased before interview). Females comprised 84% of the population, and 97% of the study population participated in the clinical examination. During the visit, a health interview, blood sampling, and an objective clinical examination were obtained. The health interview encompassed a wide range of diseases, hospitalizations, use of medication, and activities of daily living (ADL), of which the basic ADL comprised three questions: (1) assistance in having meals, (2) assistance in standing up, and (3) assistance in getting dressed. A final question on the need of daily assistance was also incorporated. The objective clinical examination included an ECG and blood samples. The data were supplemented with health records from the primary health-care physician, and cancer diagnoses were obtained from the Finnish Cancer Registry.

The Danish 1895 Birth Cohort Study (1995–1996)

A few years later, the first Danish Centenarian Study, also named the 1895 Birth Cohort Study, was launched and included only centenarians aged 100 years (Andersen-Ranberg et al. 2001). Eligible were birth cohort members born in April 1, 1895–May 31, 1896, who were consecutively visited at their domicile as they turned 100 years. This method was used to minimize selection bias toward the more healthy individuals. As in the

Finnish study, all centenarians were identified in a national Central Person Registry. Of the 276 eligible, 75% ($n = 207$) participated in a personal interview at their domicile, which involved a health interview including ADL functions, and an objective clinical examination. Katz ADL (Katz et al. 1963) was used to assess basic activities of daily living, and the results were reported according to three groups: relatively independent (groups A–C), some dependency (groups D–E), or totally dependent (groups F–G) upon help. The objective examination also included an ECG, blood pressure measurement, and blood sampling. About three-fourths of the centenarians accepted to participate in the clinical examination. Supplementary health information was retrieved not only from primary care physicians but also from the national register of hospital discharge diagnoses (in existence since 1977) and the national Danish Cancer Registry (in existence since 1943).

The Tokyo Centenarian Study (2000–2002)

Japan has the highest proportion of centenarians in the industrialized world, and many centenarian studies have been carried out. One of the most recent, the Tokyo Centenarian Study, was conducted on centenarians aged 100–108 years identified in a residential list of the Tokyo area (Gondo et al. 2006; Takayama et al. 2007). Of the identified 1,735 centenarians, a random sample of 1,194 (70%) was invited to participate in the study. In a first round, a postal questionnaire was launched, in which 593 (43%) participated. In a second round, questionnaire participants were invited to a home-based interview conducted by health professionals. The participation rate dropped to 26% ($n = 304$) of the originally eligible centenarians. The interview was carried out by a medical doctor, a psychologist, and a geriatric nurse and involved among others a health interview including functional ability, a broad range of diseases common in old age, and current medication. The clinical examination included blood pressure measurement ($n = 253$; 21%), ECG, and blood sampling, but only results related to blood pressure have been reported.

This study used another ADL scale, the Barthel Index (Mahoney and Barthel 1965), to assess

activities of daily living, and included feeding, grooming, bathing, dressing, bowel function, bladder function, toilet use, transfers (from bed to chair and back), mobility, and walk on stairs. The index is divided into the following groups: (1) independent, Barthel score 80–100; (2) minimal help, Barthel score 60–79; (3) partially dependent, Barthel score 40–59; (4) very dependent, Barthel score 20–39; and (5) totally dependent, Barthel score < 20. Those who obtained a score below 60 were categorized as “totally dependent,” “very dependent,” and “partially dependent,” in contrast to a score of 60–100, which categorized centenarians into “minimal help” or “independent.”

The Galician Longevity Study (2001)

In 2001, a population-based study, from the province of Galicia, identified all 99-year-and-older persons in a central registry (Rabunal-Rey et al. 2012). Out of 84 eligible, 80 (95%) accepted the invitation of a home visit by a doctor and a nurse. The questionnaire included information on diseases and ADL functioning by the Barthel Index, as in the Japanese study. The objective examination included blood pressure measurement, blood sampling, and ECG.

The Korean Centenarian Study (2005)

The Korean Centenarian Study investigated factors associated with ADL dependency (Kim et al. 2012). This study included 796 participants aged 100 years or older and is thus the largest centenarian study. Subjects were drawn from a national census survey in November 2005 and surveyed by regional officials within a few months. Data were collected on several functional disabilities and health states, where health state would be defined by questions on having had eight specific diseases common in old age. The number of reported diseases was trichotomized into “0,” “1,” or “2 or more” diseases. The functional status was obtained by information on basic ADL according to the Katz Index (Katz et al. 1963), and participants were classified into two groups: disabled, i.e., participants reporting having difficulties, i.e., “cannot do it all without help” in one or

more of the ADL items, and those not disabled, i.e., “can do it with no difficulty or some difficulty.”

The Danish 1905 Birth Cohort Study (2005)

This cohort study was launched by the same research group that launched the 1895 Birth Cohort Study 10 years earlier (Andersen-Ranberg et al. 2001). In the 1905 cohort, almost the same questionnaire was used (Engberg et al. 2008), but in contrast to the 1895 cohort, home-based interviews were carried out by trained interviewers from the Danish Institute of Social Research. Out of 364 eligible 100-year-olds, 225 (62%) participated. The 1905 cohort was initially surveyed at baseline in 1998 as 92–93-year-olds, and follow-ups were made in 2001, 2003, and 2005. All eligible birth cohort members were invited to participate in the 2005 survey irrespective of whether they had participated in the earlier waves or not. Activity of daily living was assessed by self-reported information on questions from a modified Katz ADL (Engberg et al. 2008), which used the same indexes as in the 1895 cohort: bathing, dressing, toileting, feeding, and getting up from a chair/bed but leaving out incontinence. For each item, the centenarian was scored to be either independent or dependent in carrying out that particular activity. Self-reported information on diseases and use of medications was also collected but has not been reported from the 2005 survey.

The Australian Centenarian Study (2007–2009)

A different sampling procedure was employed in the Australian Centenarian Study. The investigators used a convenience sample of 188 centenarians (100+-year-olds) who were surveyed in 2007–2009 (Richmond et al. 2012). The in-home interview collected information on 14 specified common age-related illnesses, and functional level was assessed by Katz Index of ADL (Katz et al. 1963). For a subset of 142 centenarians living in aged care facilities, further health information was retrieved from medical records. In addition, a blood pressure was measured during the in-home interview.

The Health and Retirement Study (HRS) (2010)

All data were retrieved from the HRS, a prospective US study on aging, which launched its first wave in 1993, and included a representative sample of noninstitutionalized (from 1998 also institutionalized) individuals aged 70 years and older. Follow-up interviews were made every second year. The study was from the 2010 wave, thereby including data from 1993 to 2010 (Ailshire et al. 2015). The response rate at baseline and at follow-ups was 83% and > 90%, respectively. A study sample was selected from the total number of respondents who were born in 1910 or earlier and had undergone at least one follow-up survey ($n = 1,158$). Out of these, a distinction was made between the “nonsurvivors” and the “centenarian survivors.” The “nonsurvivor” group consisted of individuals who died before reaching the age 100 ($n = 1,045$), and the “centenarian survivor” group included the population reaching the age of 100 ($n = 113$). Centenarians who had been in the HRS for fewer than 3 years were excluded from the survivor group, leaving the current study sample at 96 centenarians (survivors). Health was assessed according to six specified age-associated diseases. Classification of survival pathways was defined by “survivors,” “delayers,” and “escapers,” as in the NECS (Andersen et al. 2012). But in this study, the classification was used not only with respect to morbidity profiles but also in relation to functional ability. The latter was being assessed by the Katz Index of ADL (Katz et al. 1963).

The Hong Kong Centenarian Study (HKCS) (2011)

The Hong Kong Centenarian Study used a quota sampling method based on the density of 85+ -year-olds in 18 geographical areas. Centenarians were recruited through two different networks: a social and a clinical (Cheung and Lau 2015). In the social network, 628 letters of invitation were sent to various community centers for elderly, to home support teams, and to the University of the Third Age centers. By this approach, 200 near-centenarians and centenarians were reached, of which 56 accepted to participate (participation rate 28%). In the clinical network,

a database of the elderly health clinic helped identify 210 centenarians and near-centenarians, of which 97 participated (participation rate 46%) (Cheung and La 2016). An in-home or center-based interview of the total 153 participants aged 95–108 years old was carried out in 2011. The interview comprised, e.g., self-reported information on 30 common age-related diseases and functional ability assessed by Katz Index of ADL (Katz et al. 1963). Additionally, blood pressure and physical performance tests, e.g., handgrip strength, together with a venous blood sample were obtained.

The Spanish Centenarian Study (2011–2013)

This study was also based on a convenience sample of centenarians recruited from nine Spanish centers, where they were hospitalized (Martínez-Sellés et al. 2015). Among the 118 100+-year-olds, 62% were included on the day of hospital discharge. The health interview focused on cardiovascular morbidity and was obtained by direct interview with subjects and caregivers. In addition, an objective clinical examination was carried out, including not only an ECG but also an echocardiography. Due to sampling frame being in hospitals, it is likely that these centenarians were biased toward the less healthy centenarians.

The New England Centenarian Study (NECS) (2011)

The NECS is an ongoing study, which has enrolled centenarians since 1994 (Andersen et al. 2012). In the present study, data was based upon 1418 long-lived participants divided into three age groups: supercentenarians ($n = 104$), semisupercentenarians ($n = 430$), and younger centenarians ($n = 884$). Moreover, a group of nonagenarians ($n = 343$) and a control group consisting of 436 individuals aged 47–96 years old also participated. The data was collected from 1994 via telephone or postal questionnaires. The participants were followed for an average of 3 years (range 0–13 years). From 2003, an annual follow-up was initiated, and the last follow-up was in 2011.

The respondents reported on different age-related diagnoses (CVD, hypertension, cancer,

chronic lung disease (COPD), dementia, diabetes, osteoporosis, and stroke) and their approximate age of onset. The response rate was 83%.

Based on the abovementioned information on diseases, three morbidity profiles were created: “survivors,” “delayers,” and “escapers.” From the list of the age-related diseases, “survivors” were those participants diagnosed before age 80 with at least one age-related disease. “Delayers” encompassed those who were not diagnosed with at least one disease before at least attaining age 80 and before age 99, and the “escapers” included those who were diagnosed for the first time after turning 100 years or not at all.

ADL scores were collected from 91% of the participants ($n = 1,605$) and were obtained by the Barthel Index in the same way as described in the Tokyo Centenarian Study (Mahoney and Barthel 1965).

The Swedish Centenarian Study (2011)

About the same time, a population-based sample of Swedes born in 1911–1912 was surveyed with home-based interviews conducted by trained survey agency interviewers (Parker et al. 2014). The study population included an oversampling of male centenarians to compensate for their low proportion compared to their female peers. Of the eligible 360 centenarians, 76% ($n = 274$) participated (including in the denominator eligible subjects deceased before interview). The representativeness of the sample is high with a participation rate of 76% but included a high level of proxy-reported information (41%). No clinical examination was done, but the interview included questions on symptoms, diseases, and activities of daily living.

Other Studies

The Swedish Study on Medicine Prescription (2008)

Medication can be used as a proxy for disease. A study based on a national Swedish register on prescription medicine was used to study the use of

medications of all Swedish centenarians born in 1908 or earlier (Wastesson et al. 2011).

From this summary of relevant studies published within the last 25 years and reporting cross-sectional results of the health of centenarians, it is quite clear that the employed methodologies and sampling procedures vary a lot. This is important to keep in mind when interpreting the reported results. Tables 1 and 2 give an overview of the various studies with respect to diseases and activities of daily living.

Diseases and Functional Health

The Finnish Centenarian Study (1991)

This relatively early study was one of the firsts to show that centenarians are not healthy survivors. The most common diagnosis group, cardiovascular diseases, was present in 70% (Louhija 1994). Hypertension was 19%, when defined by a measured systolic blood pressure of ≥ 160 mmHg and a diastolic blood pressure ≥ 90 mmHg. No information was given on the use of antihypertensives alone, but cardiovascular medication was used by 61%, and more among home-dwelling than among institutionalized. Based on ECG, 17% had atrial fibrillation/flutter, 10% had pathological Q-wave indicating prior myocardial infarction, and 11% had diabetes. Lifetime cancer prevalence, including low-grade malignant skin cancers, based on data from the Finnish Cancer Registry, was about 30%. No comorbidity data have been published.

Of the three basic ADL activities, 17% males and 31% females needed assistance in having meals, and 28% and 43% needed assistance in standing up, while 41% and 53% needed assistance in getting dressed, males and females, respectively. Overall, 55% of males and 60% of females needed some assistance daily. The male centenarians tended to have better functional health than women, but not statistically significant.

The Danish 1895 Birth Cohort Study (1995–1996)

As in the Finnish study, a high prevalence of diseases and common chronic conditions was

identified among Danish centenarians (Andersen-Ranberg et al. 2001). Cardiovascular diseases were present in 72%, when including hypertension, while osteoarthritis in major joints was present in 54%. Hypertension ($>140/>90$ mmHg) was present in 52%, chronic heart failure in 32%, ischemic heart disease in 28%, atrial fibrillation in 17%, and diabetes in 10%. Cardiovascular medications were the most frequently used (by 64% of participants). The majority of the study population ($n = 144$) had between three and six comorbidities (defined as actual and chronic diseases). The mean number of comorbidities was 4.3.

The clinical objective examination included blood pressure measurement ($n = 158$) and electrocardiogram ($n = 142$). The results from the clinical objective examination showed higher prevalence of hypertension, atrial fibrillation, myocardial infarction, and ischemia of the heart when compared to physician-reported diagnoses. Disease prevalence based on self-report was even lower than physician-reported diagnoses (Andersen-Ranberg et al. 2013).

According to Katz ADL (Katz et al. 1963), 41%, 24%, and 35% were relatively independent (groups A–C), had some dependency (groups D–E), or were totally dependent (groups F–G) upon help. Only 12% could be classified as autonomous, i.e., being cognitively intact, relatively independent in Katz ADL, and noninstitutionalized. A significantly larger proportion of male centenarians were relatively independent in ADL. For the reason of comparison with the 1905 cohort study, this ADL scale was used in a modified form, and results are given later.

The Tokyo Centenarian Study (2000–2002)

Japanese centenarians have self-reported hypertension as the most common disease affecting 64% (including measured hypertension ($\geq 140/\geq 90$)), followed by cataract (46%), heart disease (29%), gastrointestinal disease (21%), cerebrovascular disease (16%), respiratory disease (13%), renal disease (13%), non-skin cancer (10%), and diabetes (6%) (Takayama et al. 2007). Among those who had a blood pressure measured, 56% had a systolic blood pressure

SBP systolic blood pressure

MI myocardial infarction (defined by pathologic Q wave recorded on electrocardiogram)

^an/a not available

^b $\geq 160/\geq 90$ mmHg: only measured blood pressure

^c $\geq 140/\geq 90$ mmHg: measured and antihypertensive medication

^d $\geq 140/\geq 90$ mmHg: only measured blood pressure

^eBased on echocardiography on a subsample ($n = 55$)

^fLimit for hypertension not defined

^gResults estimated on a graph

≥ 140 mmHg (Shimizu et al. 2008). Although medical medications acting on the cardiovascular system, including hypertension, were used by 43%, the reported higher proportion of cardiovascular diseases indicates that either Japanese centenarians are undertreated or their self-reported disease prevalence is overreported.

ADL assessed by the Barthel Index (Mahoney and Barthel 1965) showed that 34% were totally dependent, 15% very dependent, and 14% partially dependent and 13% needed minimal help, while 24% were independent in activities of daily

living (Gondo et al. 2006). All in all, 63% were in the category of being totally dependent, very dependent, and partially dependent, while less than 10% were totally independent. Males had significantly lower levels of dependency than females.

The Galician Longevity Study (2001)

This study focused on objective examination on cardiovascular diseases and identified that 30% of centenarians suffered alone from ischemia and/or heart failure (Rabunal-Rey et al. 2012).

^aKatz ADL: An index to rank individuals according to performance and using the categories, A, B, C, D, E, F, and G. The index summarizes overall performance in six basic ADL functions: bathing, dressing, feeding, transferring, going to the toilet, and continence. Gr. A–C, relatively independent; Gr. D–E, relatively dependent; Gr. F–G, very dependent

^bKatz modified: 1 point for each of 5 items performed independently in Katz (bathing, dressing, toileting, transferring, feeding)

Range: 5 (independent in all items), 0 (dependent in all items)

^cKatz ADL: six items (as in ^aKatz ADL). Independent = Gr. A; dependent one to two items = Gr. B–C; dependent ≥3 items = Gr. D–G

ADL Barthel: Score range, 100 (independent in all items), 0 (dependent in all items). A score below 60 indicates being partially, very, or totally dependent in ADL functions

^dDisabled defined as needing daily assistance

^eF female, M male

^fn/a not available

^gBased on Katz items but reported as “nondisabled” defined as “can do it with either no difficulty or some difficulty,” “disabled” defined as “cannot do it at all without help”

^hReported as needing assistance in B-ADL

Hypertension, defined as a measured blood pressure above >140/>90 mmHg, was identified among 26% centenarians but did not include subjects adequately treated with antihypertensives. By ECG examination, 26% suffered from atrial fibrillation, and 16% had a Q-QS pattern indicative of prior myocardial infarction. Only 8% had a normal ECG. Diabetes was present in 13%. Out of the 80 participants, 81% used a medication on a daily basis (mean 3.2 (SD 2.1); range 0–11). The Barthel score showed that 46% scored ≤ 60, i.e., being dependent on help.

The Korean Centenarian Study (2005)

Although this large study had a main focus on functions, a count of diseases, which included heart diseases, hypertension, diabetes, stroke, liver diseases, dementia, osteoarthritis, and cancer, were also reported (Kim et al. 2012). A majority of 45% reported having no present disease, while 14% reported having two or more diseases. According to Katz Index of ADL (Katz et al. 1963), participants were divided into two groups, disabled or nondisabled. Almost three-fifths (59%) of Korean centenarians were disabled

and needed help with basic ADL. Female participants were significantly more disabled than males.

The Danish 1905 Birth Cohort Study (2005)

According to the modified Katz ADL, 21% women and 22% men were nondisabled (Engberg et al. 2008). The corresponding proportions for moderately disabled women and men, respectively, were 43% and 39% and, in severely disabled, 36% and 39%. There was no significant difference between genders. No results on morbidities have been published, but based on Danish nationwide hospitalization register data, in the period from 1977 to 2007 of all members of the 1905 birth cohort, those who attained the age of 100 had fewer hospitalizations at any age compared to those who died before the age of 100, thereby suggesting that centenarians in the past had fewer or less severe diseases compared to their cohort peers (Engberg et al. 2009).

The Australian Centenarian Study (2007–2009)

This study showed that the most prevalent self-reported conditions were ocular diseases identified in 71% (mainly cataracts), followed by arthritis (58%); hypertension (40%); heart disease, including angina, heart attack, cardiac arrhythmia, or congestive heart failure (31%); osteoporosis (28%); skin cancer (27%); and respiratory condition (including asthma, previous pneumonia, chronic obstructive pulmonary disease) (24%) (Richmond et al. 2012). Based on blood pressure measurements, about 33% had hypertension defined as $\geq 140/\geq 90$ mmHg (Richmond et al. 2011). Including those who were under current antihypertensive treatment, the proportion rose to 38%. A history of cardiovascular disease (heart disease or stroke) was indicated by 29%. Activities of daily living were assessed by Katz (Katz et al. 1963), and a mean score of 3.65 (SD = 1.8) was reported (Richmond et al. 2011).

The Health and Retirement Study (HRS) (2010)

In parallel to the hospitalization register study in the 1905 cohort, the HRS study (Ailshire

et al. 2015) could show that those who survived to become centenarians (survivors) had significantly lower overall disease prevalence in the past compared to those who did not attain the age of 100 years (nonsurvivors), 35% and 43%, respectively. For the six diseases, only cancer was equally present in survivors and nonsurvivors, while heart disease, stroke, lung disease, and diabetes prevalences were significantly lower and hypertension was insignificantly lower. According to morbidity profiles, 56% were “survivors,” 21% “delayers,” and 23% “escapers.”

In terms of basic ADL functions, there was no difference in the average ADL score between nonsurvivors and centenarians at baseline.

The Hong Kong Centenarian Study (HKCS) (2011)

The most common diseases based on self-report were cataract (75%); hypertension (65%); heart disease, including coronary heart disease, irregularly irregular pulse, and congestive heart failure (28%); and diabetes (13%) (Cheung and La 2016). The mean number of age-related diseases was 2.9, and the Charlson Comorbidity Index, which covers serious health conditions, was 6.6 (Charlson et al. 1987).

Based on Katz Index of ADL (Katz et al. 1963), 56% were independent in all six items, while 32% and 12% were dependent in one to two items and ≥ 3 items, respectively.

The Spanish Centenarian Study (2011–2013)

This study focused on cerebro- and cardiovascular diseases, which were found to be prevalent in this convenience sample of centenarians recruited from hospitals. Reported heart failure was the most prevalent (34%), followed by stroke (15%) and myocardial infarction (13%) (Martínez-Sellés et al. 2015). Based on the objective clinical assessments, atrial fibrillation/flutter was identified in 26%, and 15% had a pathologic Q-wave indicating prior myocardial infarction. In a subsample ($n = 55$), echocardiography showed diastolic dysfunction affecting almost 70% of the examined centenarians. Other very common echocardiographic conditions were left atrial enlargement (62%), left ventricular hypertrophy (45%), and moderate-severe pulmonary artery hypertension.

According to Katz index of ADL (Katz et al. 1963), 42% had minor or no dependency (group A–C) at all, and 21% were moderately dependent (group D–F), while 37% were totally dependent upon help (group G–H).

The New England Centenarian Study (NECS) (2012)

The morbidity profiles in the age groups were determined by the age of onset of six age-related diseases (cancer, CVD, COPD, dementia, diabetes, and stroke) (Andersen et al. 2012). The prevalences of these diseases were not mentioned in the article. The results showed that the disease-free period (escapers) was extended in the highest ages compared to the younger groups. In the group of supercentenarians, 69% was escapers and, in the semisupercentenarian group and centenarian group, 56% and 30%, respectively.

The Barthel scores were higher at the time of inclusion among the supercentenarians than in the semisupercentenarian group. And the semisupercentenarians had a higher Barthel score than the centenarians. Men had significantly higher Barthel scores than women.

The Swedish Centenarian Study (2012)

Based on self-report or proxy report, disease prevalence was high for cardiovascular diseases (42%) and for hypertension (about one-third) in Swedish centenarians (Parker et al. 2014). Diabetes prevalence and chronic lung disease were present in about 6% each. Disabling symptoms were very common: 60% reported pain in the musculoskeletal system, 44% complained about dizziness, 40% suffered from incontinence, and 31% from edema of lower extremities. According to Katz ADL assessment, about one-third were able to take a shower or bathing without any help. In all the other Katz ADL items, more than 50% could do them independently. A significant higher proportion of females (71%) needed help with basic ADL, compared to males (52%).

The Swedish Study on Medicine Prescription

Of the total 1,775 100+-year-olds alive in Sweden in 2008, 94% ($n = 1,672$) took a prescribed medication, and 60% of the study sample was

institutionalized. On average, the centenarians used 5.1 medications per person. Institutionalized centenarians used a median number of five drugs, whereas noninstitutionalized used a median number of four drugs. The most commonly used types of medications were high-ceiling diuretics (40% and 47%, community-dwelling and institutionalized, respectively), minor analgesics (25% and 49%), antithrombotic agents (38% and 35%), beta-blockers (22% and 15%), hypnotics/sedatives (29% and 36%), opioids (12% and 16%), medicine for peptic ulcer and gastroesophageal reflux (15% and 19%), and antidepressants (11% and 23%). Moreover, compared to equivalent data from octogenarians surveyed at the same time, centenarians used significantly more high-ceiling diuretics, potassium-sparing diuretics, analgesics (both minor and opioids), hypnotics/sedatives, and anxiolytics, while ACE inhibitors, beta-blockers, antithrombotic agents, and antidepressants were used significantly less.

Conclusion

The centenarian studies described here show a huge variation in methodology, sample size, and survey design. This probably explains the variation in the results. However, based on those studies using the best survey methodology and the highest participation rates, which should minimize a selection bias toward the more healthy centenarians, it is clear that centenarians cannot be described as healthy even though only a limited range of diseases have been reported such as cardiovascular diseases (myocardial infarction, atrial fibrillation, stroke, and hypertension), cancer, diabetes, and chronic lung diseases. Of these, hypertension was the most prevalent affecting at least 50% when defined as having a high measured blood pressure ($\geq 140/\geq 90$) or ongoing antihypertensive medication. Defined by self-reported hypertension alone or hypertensive blood pressure, measurement alone lowered the prevalence to about 25–30%. Also, objective signs of previous myocardial infarction were present in 10–16% and atrial fibrillation in 17–26%. It is important to note that the prevalence of atrial

fibrillation, myocardial infarction, and blood pressure measurement was higher in objective examinations compared to self-report, and it shows how important it is to include such examination when assessing the health of centenarians. Few studies have reported on other chronic and disabling somatic diseases than the previously mentioned, such as osteoarthritis, depression, incontinence, osteoporosis, and vitamin deficiencies, or on symptoms, such as pain, dyspnea, dizziness, poor vision, poor hearing, edemas in lower extremities, falls, and insomnia. Osteoarthritis affected more than half of the Australian and Danish centenarians, and more than 60% of Swedish centenarians reported pain in the musculoskeletal system.

Disability, assessed according to various definitions, affected about every second centenarian, and studies show quite similar proportions (50–60%). However, although similar they may not be directly comparable due to methodological discrepancies. Also, the comprehension of when a given physical ability is reduced to a level where it is perceived as a disability may vary according to sociocultural background. The unchanged high proportion of disabled centenarians observed over the course of the past 25 years should therefore not be interpreted as a constant condition, which cannot be improved. In fact, the comparison of two centenarian birth cohorts 10 years apart and from the same country and research unit, the Danish 1895 and 1905 Birth Cohort Studies, has shown an improvement in basic ADL functions in the most recent cohort, although only for women (Engberg et al. 2008). But whether this improvement was due to a cohort or a period effect could not be established. However, in a recent study comparing a 93-year-old of the 1905 birth cohort with a 95-year-old of a 1915 birth cohort, it was shown that the most recent cohort performed better than the former despite being 2 years older (Christensen et al. 2013). Interestingly, there was a parallel improvement in cognitive functions. Although this study was carried out in nonagenarians, the result is indicative of improving functional health in at least the nearest future cohorts of centenarians as well. Whether the same improvements will be seen with respect to

diseases remains to be seen. But in the meantime, it should not be forgotten that many centenarians are capable of living an independent life despite functional limitations and morbidities. This is, though, not to be interpreted as centenarians being healthy.

Behavior change strategies; Health education; Promoting healthy behaviors

Definition

Health promotion is “the process of enabling people to increase control over, and to improve, their health” (World Health Organization 2009). Health promotion involves the development of individual, institutional, community, and policy-level strategies to influence health-related behavior and, ultimately, to create environments supportive of health. Health promotion for older adults is often focused on the prevention and management of disability and chronic disease in order to improve health outcomes and quality of life for those aged 65 years and older. Increasing healthy life expectancy, or the expected number of remaining *healthy* years, in addition to extending life expectancy, is of primary concern in health promotion for older adults (Haber 2013).

Introduction

The proportion of the population classified as “older adults” has increased dramatically in

recent decades. Globally, the number of older adults is expected to almost triple in the coming decades, increasing from an estimated 524 million in 2010 to 1.5 billion by 2050 (National Institute on Aging et al. 2011). Soon, for the first time in recorded history, older adults (65 years and older) will outnumber children under 5 years of age (National Institute on Aging et al. 2011). As the proportion of older adults increases, there is a concomitant shift in the leading causes of disability, disease, and death. Thus, there is a growing need for the development and implementation of strategies for the prevention and management of chronic diseases that are tailored to the specific needs of the aging population.

A Brief History of Health Promotion

The twentieth-century introduction of the concept of health promotion can largely be attributed to the World Health Organization's 1984 release of the paper, *Concepts and Principles in Health Promotion* (World Health Organization 2009). This paper introduced a definition, key principles, priorities, and challenges in health promotion and led to the first International Conference on Health Promotion in 1986. Countries across the world came together to discuss future directions and, more importantly, to identify strategies for moving toward a new public health. Five key action areas were identified during this conference including to (1) create supportive environments, (2) build healthy public policy, (3) develop personal skills, (4) strengthen community action, and (5) reposition health services. While new factors have emerged since 1986, such as increased recognition of health inequalities, global environmental changes, urbanization, and new consumption and communication patterns, these five actions remain priorities in health promotion. Today, health promotion focuses on understanding the role of individual, community, environmental, and social factors in influencing and changing health behavior.

Health and Health Behavior Among Older Adults

Promoting healthy aging involves addressing the various dimensions of health related to social,

physical, and mental well-being. These dimensions can interact and impact each other, as well as affect overall health. For example, research has established the existence of a bidirectional relationship between mental and physical health among older adults, where increases in physical activity correspond to improved mental health and vice versa (Steinmo et al. 2014). Successful health promotion involves understanding how each dimension impacts the others and also overall health.

Health promotion includes approaches for reducing lifestyle risk factors (e.g., smoking) and increasing healthy behaviors (e.g., physical activity). Because older adults are at increased risk for chronic disease and certain geriatric conditions, targeting behaviors that directly relate to these conditions is crucial for improving health and quality of life in this population. A healthy diet, including fruit and vegetable consumption, can reduce likelihood of chronic disease and risk of mortality and improve physical function among older adults (Nicklett and Kadell 2013). However, many older adults are not eating the recommended amounts of fruits and vegetables and, therefore, may not be obtaining the necessary amounts of certain vitamins and minerals (Nicklett and Kadell 2013). Similarly, physical activity among older adults has been shown to decrease disability, increase quality of life, and extend years of active independent living (Sun et al. 2013). While many older adults participate in physical activity, certain groups of older adults, such as women and older age groups (85 and up), are less likely to exercise regularly (Sun et al. 2013). Certain behaviors, such as substance use, are frequently misidentified and underdiagnosed and represent a growing health concern among the older adult population. Alcohol and tobacco use, while less prevalent among older compared to younger adults, are still common among older adults (Crome and Wu 2015). Participation in other preventive behaviors, such as screenings and immunizations, is also important for healthy aging. Yet, older adults disproportionately experience morbidity and mortality as a result of vaccine-preventable diseases (High 2007). In order to successfully increase healthy behaviors and decrease risky

behaviors, theory-driven and evidence-based approaches should be used for health promotion research and practice.

Health Behavior Theories and Models in Aging

When selecting a theory for understanding or predicting a health behavior, it is most useful to consider the ecological factors that affect the behavior. Ecological models focus on the interrelationships among individual characteristics, social influences, and one's physical and sociocultural environment. An ecological perspective concentrates on creating policies and environments conducive to making healthy choices and then educating and motivating individuals to make those choices. According to Sallis and Owen (2015), there are five core principles related to the ecological perspective of health behavior: (1) multiple levels of influences exist, (2) environmental context can form or constrain determinants of health behavior, (3) influences interact across levels, (4) ecological models should be specific to a behavior, and (5) interventions addressing multiple levels should be most effective for behavior change. Ecological models provide a framework for incorporating multiple health behavior theories and building comprehensive approaches for health promotion interventions (Sallis and Owen 2015). A variety of theories and models are available for guiding health promotion interventions and research for improving health among older adults. Five theoretical frameworks commonly applied in the field of health promotion, which have been applied for targeting older adults, will be briefly described below.

Social Cognitive Theory

Social cognitive theory (SCT) describes behavior using a three-way, reciprocal model in which personal cognitive, socioenvironmental, and behavioral factors continually interact with each other (Bandura 1986; Kelder et al. 2015). Personal cognitive factors refer to a person's ability to self-regulate behaviors and to reflect and analyze experience. There are three main constructs related to personal cognitive factors including

knowledge (*level of understanding about engaging in a behavior*), self-efficacy (*confidence in ability to perform a behavior*), and outcome expectations (*judgments about the likely outcome of a given pattern of behavior*). Socioenvironmental factors include features of the physical or perceived environment that promote, allow, or discourage participation in a specific behavior. The constructs directly related to these factors include observational learning (*influential role models*), normative beliefs (*cultural beliefs about the perceived prevalence and social acceptance of a behavior*), and social support (*the perception of support received from one's social network*). Finally, behavioral factors include behavioral skills existing as behavior capability or coping skill, one's intention or goals to add or modify a behavior, and reinforcement or the rewards or punishment received for engaging in a behavior. Reciprocal determinism, a key construct of SCT, suggests that the environment and human agency interact and influence each other, which in turn leads to individual and social change (Kelder et al. 2015). In this sense, an individual can be seen as both a responder to change and an agent of change. SCT has been applied to understand physical activity in older adults. For example, in an 18-month prospective study of older adults, researchers tested the utility of a model based on SCT for predicting physical activity behavior (White et al. 2012). Self-efficacy was found to be the strongest predictor of physical activity. Further, the results indicated that self-efficacy was directly and indirectly (through outcome expectations) related to physical activity (White et al. 2012). While SCT has served as an action-oriented approach to understanding human behavior, its primary focus on individual change has sometimes led to limited research on the environmental influences. It is important to understand and assess multiple constructs of SCT at different levels of the social and physical environment.

The Transtheoretical Model

According to the transtheoretical model (TTM), there are different stages of readiness in health behavior adoption (Prochaska et al. 2015). More specifically, there are six stages of behavior change

including precontemplation (*no intention or interest in taking action within 6 months*), contemplation (*thinking about taking action within 6 months*), preparation (*plans to take action within a month and has made behavioral steps toward this plan*), action (*has adopted behavior change for less than 6 months*), maintenance (*has maintained ongoing behavior change for more than 6 months*), and termination (*does not have temptation to stop and has 100% confidence*). There are ten processes of change, or activities used to advance through stages, that have received the most empirical evidence. These processes include consciousness raising, dramatic relief, self-reevaluation, environmental reevaluation, self-liberation, helping relationships, social liberation, counterconditioning, stimulus control, and reinforcement management (Prochaska et al. 2015). The TTM was applied in the development of a health promotion program, HealthStages, aimed at promoting physical activity among older adults (Lach et al. 2004). This program developed specific activities for each stage of change. For example, bone density testing and a bone health fair aimed at increasing osteoporosis awareness were targeted at individuals in the precontemplation stage. Other intervention activities, such as informational brochures on bone-strengthening exercises, were aimed at those individuals in the complementation stage. Strength-training exercise courses were used to target individuals in the action stage. Finally, ongoing exercise and walking groups were targeted at those in the maintenance stage. While the TTM has been applied to as many as 48 different behaviors in various populations, this model also has limitations and future research needs (Prochaska et al. 2015). More research is needed to understand the effectiveness of TTM across different cultures and the adaptations of the model necessary within specific cultures. Furthermore, more research is needed to enhance the understanding of the stages of change and processes of change across a broad array of behaviors and in diverse populations.

Theory of Planned Behavior and Theory of Reasoned Action

Both the theory of planned behavior (TPB; Ajzen 1991) and theory of reasoned action (TRA; Ajzen

and Fishbein 1980) posit that subjective norms, attitudes, and perceived control affect behavior intention, which, in turn, affects behaviors. The TRA states that behavioral intention is the most important determinant of behavior. Behavioral intention is directly determined by one's subjective norms related to the behavior and their attitudes toward participating in the behavior. The TPB includes these same constructs and is an extension of TRA that adds perceived control as a direct determinant of intention. An individual's attitudes are determined by their belief about attributes or outcomes of participating in a behavior (or behavioral beliefs). Individual subjective norms are determined by their normative beliefs or whether or not referent people approve or disapprove of participating in the behavior. Perceived control is determined by control beliefs (*the availability of facilitators and barriers to performing a behavior*) and weight by perceived power (*impact of each control factor to serve as a facilitator or barrier to the behavior*). The TRA and the TPB have been applied to explain variance in intention and to predict behaviors related to a variety of health behaviors such as smoking, exercises, and nutritional choices (Montaño and Kasprzyk 2015). For example, the TPB has been applied to understand factors that influence participation in strength training among older adults. In a study with older individuals living in seniors' centers in Ontario, Canada, researchers found that subjective norm and perceived behavioral control were the strongest predictors of intention to engage in strength-training behavior (Dean et al. 2007). Attitude, however, was not significantly related to intention. The results of the study also showed intention to be a significant predictor of strength-training behavior (Dean et al. 2007). While there is evidence that supports the effectiveness of TRA and TPB in explaining changes in intention and behaviors, there are limitations to these two theories. Currently, these theories do not specify relevant beliefs about normative referents, control beliefs, and behavior outcomes that should be measured. These beliefs should be differentiated for each group and behavior and likely vary across populations.

Health Belief Model

The Health Belief Model (HBM) was originally developed in the 1950s by the US Public Health Service to explain the large-scale failure of individuals to participate in disease prevention and detection programs (Hochbaum 1958). Since then, the HBM has been expanded and used to inform health behavior change interventions related to a variety of different behaviors (Skinner et al. 2015). The HBM suggests that an individual is most likely to engage in a behavior under the following conditions: (1) they believe they are susceptible to the disease, (2) they perceive the consequences of disease to be serious, (3) they believe they will benefit from taking action, and (4) they believe the barriers to taking action are outweighed by the benefits. There are six key concepts within HBM, which include perceived susceptibility (*beliefs about the likelihood of contracting a condition*), perceived severity (*beliefs about the seriousness of contracting a condition*), perceived benefits (*beliefs about the positive outcomes of taking action*), perceived barriers (*obstacles to taking action*), cues to actions (*external or internal factors that could trigger a behavior*), and self-efficacy (*one's confidence in their ability to perform a behavior*) (Skinner et al. 2015). According to a recent literature review, the HBM is one of the most commonly used theoretical models for predicting colorectal cancer screening in older adults (Beydoun and Beydoun 2008). Perceived barriers, such as no recommendation from a physician, lack of knowledge, fear, and embarrassment, have consistently been shown to significantly influence colorectal cancer screening behaviors in the elderly (Beydoun and Beydoun 2008). Other constructs, such as perceived susceptibility (e.g., family history), have also been used for predicting colorectal cancer screening behavior (Beydoun and Beydoun 2008). Although the HBM has been used for more than half a century and has been shown to be useful in predicting certain behaviors (e.g., cancer screening), more research is needed to understand the relationships among the HBM constructs. Studies are also needed to understand the factors that moderate the effect of HBM constructs on behaviors.

Evidence-Based Practice and Research in Health Promotion

Evidence-based practice and research in health promotion are essential for developing effective health promotion interventions and programs, and the concept of evidence-based public health (EBPH) is critical to this process. EBPH combines science-based interventions with community preferences to enhance population health (Brownson et al. 2015). Jacobs and colleagues summarize six key elements of evidence-based public health practice: (1) engaging the community during assessment and decision-making process, (2) systematically utilizing data and information systems, (3) making decisions based on available peer-reviewed quantitative and qualitative evidence, (4) using program planning frameworks, (5) conducting sound evaluation, and (6) disseminating lesson learned (Jacobs et al. 2012). There are many barriers to implementing EBPH, such as limited funding, lack of time and cultural and managerial support, inconsistency in the definition of evidence, and perceived lack of priority for EBPH in institutions (Brownson et al. 2015). Despite these barriers, there are many free, online resources available that can be used to facilitate EBPH. One such resource is the Guide to Community Preventive Services, which was developed by the Centers for Disease Control and Prevention and is overseen by the Community Preventive Services Task Force. The Guide to Community Preventive Services (www.thecommunityguide.org) consists of a panel of independent, unpaid experts in preventive services, public health, health promotion, and disease. The task force provides evidence-based findings and recommendations regarding preventive services, programs, and policies to improve community health. The official collection of recommendations and reviews from this task force is housed on the Community Guide website. The Community Guide provides credible information, obtained through a scientific systematic review process, on the current evidence for specific types of interventions within particular populations. Topics span a wide range, including alcohol consumption, asthma, cancer, cardiovascular disease, diabetes, mental health, obesity, and many more.

Other organizations and websites provide resources and recommendations for facilitating EBPH in the aging population. The Evidence-Based Leadership Council (EBLC) is a collaboration of individuals representing 11 health programs and 4 organizations committed to increasing the use of evidence-based programs for older adults (Haynes et al. 2014). EBLC's website provides a centralized resource for selecting, implementing, and evaluating health programs ([Evidence-Based Leadership Council n.d.](#)). Similarly, the National Council on Aging (NCOA), a nonprofit advocacy organization for older adults, has a website that includes information for planning, implementing, evaluating, and sustaining evidence-based programs ([National Council on Aging n.d.](#)). EvidenceToPrograms.com is web-based toolkit that guides users through the process of building, evaluating, and sustaining a health promotion program for healthy aging (Stevens et al. 2015). Finally, the journal, *Frontiers in Public Health*, has a research topic dedicated to EBPH for older adults. This research topic, which is available online, features research on proven health promotion programs and the factors that impact the reach, implementation, and sustainability of these programs (Ory and Smith 2015).

The Austrian Red Cross also has published recommendations for evidence-based health promotion specifically for older adults (Lis et al. 2008). These guidelines share many similarities with general evidence-based recommendations for health promotion research and practice. These guidelines include tailoring health promotion programs to the needs and resource of the population of interest while understanding the diversity of different groups (cultural competency, health literacy, sociodemographic characteristics). Moreover, the guidelines recommend involving multiple stakeholders throughout the process and utilizing individual and community empowerment strategies, as well as developing multilevel, comprehensive interventions. The application of mixed-method approaches and use of an interdisciplinary team of researchers and professionals are also recommended for ensuring accessibility and sustainability of health promotion programs for older adults.

Planning Models in Health Promotion

Proper application of a planning model will ensure that all key elements of EBPH are addressed during the development, implementation, and evaluation of a health promotion program. Two well-developed planning models often applied in health promotion are the PRECEDE-PROCEED Model and Intervention Mapping (Bartholomew et al. 2015). Both models use a comprehensive approach to addressing a health issue and allow for integration of multiple theoretical frameworks. These models allow practitioners and researchers to develop evidence- and theory-based interventions using logic models. Logic models are diagrams that depict plausible causal relationship among variables associated with a health issue and their solutions. The PRECEDE-PROCEED Model, an eight-phase, population-based planning framework with an ecological perspective, has been applied to hundreds of programs (Bartholomew et al. 2015). The first three phases in the model assist the planner in developing a logic model of the problem, where planners examine the causes of health problems using an ecological perspective. These phases include Phase (1) social assessment; Phase (2) epidemiological, behavioral, and environmental assessment; and Phase (3) educational and ecological assessment. These three phrases focus on the determinants of health-related behavior and environment and the interrelationships among individuals and their psychological, biological, and behavioral characteristics and their environment. In Phase 4, administrative and policy assessment and intervention alignment, the planner determines what program components and interventions are required and what administrative, policy, and organizational resources exist to develop the program. In this particular phase, the concept of intervention matching, mapping, pooling, and patching is applied. More specifically, this phase requires (1) matching program components to the ecological levels; (2) mapping interventions to particular predisposing, enabling, and reinforcing factors; (3) pooling from previous interventions and work; and (4) patching interventions to address gaps in evidence-based practices. In Phase 5, the planner prepares for

implementation by using data collected from the previous four phases to develop materials and resources to facilitate program delivery. In the final three phases, the planner develops plans for data collection in order to conduct process, impact, and outcome evaluations. Process evaluation determines the extent to which a program was implemented as intended, while impact evaluation examines changes in predisposing, reinforcing, and enabling factors, as well as behavioral and environmental factors. Outcome evaluation assesses the impact of the program on health and quality-of-life indicators.

Intervention Mapping (IM) consists of six steps that are complementary to the PRECEDE-PROCEED Model's planning phrases (Bartholomew et al. 2015). This framework expands on the logic model of the problem outlined in the PRECEDE-PROCEED Model by focusing on the defining determinants of behavioral and environmental change and matching theory-based methods to these determinants. In Step 1, the planner conducts a needs assessment in order to develop a logic model of the problem. In Step 2, the planner uses theory and previous evidence to develop a logic model of change. The logic model of change describes the hypothesized casual pathways from the intervention through the determinants of behavior to the health-promoting behaviors and environmental change agents to the ultimate changes in health outcomes. In Step 3 (*program planning*) and Step 4 (*program production*), the planner uses the model of change developed in Step 2 to understand, design, and develop the intervention. In Step 5, the planner applies theory and evidence to develop an implementation plan for the intervention. In the final phase, the planner outlines methods for conducting process and outcome evaluations.

Conclusion

As older individuals continue to represent more of the population, proportionally, the need for effective strategies to prevent and manage chronic diseases and disabilities becomes ever more critical. Health promotion for older adults builds on the

foundational principles of health promotion for all ages. Successful health promotion for older adults requires tailoring to the needs, resources, and unique problems experienced by this particular population. The theories and evidence-based practices described in this article are broadly depicted and should be used in combination with assessment of the intended population (Bartholomew et al. 2015).

New Zealand Longitudinal Study of Aging

Definition

The Health, Work, and Retirement (HWR) longitudinal study is a nationally representative cohort study that has been following a sample of middle-aged and young-old New Zealanders (aged 55–70) across multiple data collection waves since 2006. The broad aim of the HWR study is to determine the factors that promote health and independence of older New Zealanders in the transition from work to retirement, with a particular focus on successful aging in older Māori (the indigenous people of New Zealand).

Description of the HWR

The HWR study is New Zealand's only nationally representative government-funded longitudinal study designed to understand the factors that determine health and independence in older adults. Government funding for the HWR study was provided amid growing concern in New Zealand about the future viability of the country's universal health and pension provision (New Zealand Treasury 2009). Historically, New Zealand has low rates of personal retirement savings (Scobie et al. 2004). In addition, there is a lack of knowledge of how chronic inequities in health, wealth, and well-being which develop in midlife between Māori and non-Māori (Dixon and Maré 2007; Ajwani et al. 2003; Robson 2004) impact their capacity for successful aging. In Wave 1 in 2006, the HWR study sampled a cross section of community-dwelling New Zealanders aged 55–70 to assess their current health, wealth, social, working, and demographic status. Those completing the Wave 1 cross-sectional study were subsequently invited to participate in the longitudinal study. The HWR study has followed this sample on a biennial basis with data waves in 2008, 2010, 2012, and 2014. A supplementary data collection wave in 2013 was funded specifically to investigate older adults' levels of interconnectedness and social support. Further government funding has resulted in two further data collection waves planned for 2016 and 2018. The inception of the HWR study was timed such that the fiscal and social impact of key policies and initiatives aimed at addressing aging-related issues in New Zealand could be monitored closely and long-term outcomes comprehensively assessed. For example, the HWR study can examine the outcomes associated with the establishment and maintenance of KiwiSaver accounts (a 2007 employer-based contributory superannuation scheme) in a representative sample of New Zealand's young-old population, as the scheme began operation between the first and second waves of data collection. The HWR study is designed to be comparable to international longitudinal studies of aging, such as the *Health and Retirement Study* (HRS), the *English*

Longitudinal Study of Ageing (ELSA), and the *Survey of Health, Ageing and Retirement in Europe* (SHARE).

Research Design

Characteristics of the sample: In 2006 equal probability random sampling procedures were used to select a study sample from the 55–70-year-old population registered on the New Zealand electoral roll. Registration on the electoral roll is mandatory for all New Zealanders eligible to vote in government elections. A total of 5,260 adults aged 55–70 (including Māori and non-Māori) were selected from the electoral roll to represent the 55–70-year-old general population. From those remaining on the electoral roll, a further sample of 7,780 Māori aged 55–70 were then randomly selected using the Māori descent indicator on the roll to increase the Māori subsample. Māori oversampling was undertaken to combat the historically low research participation rates found internationally in older ethnic minority populations (Moreno-John et al. 2004). A combined total of 13,040 New Zealanders received an HWR study questionnaire in 2006. Subsequently, 551 (210 from the general subsample and 341 from the Māori subsample) were excluded from participation due to ineligibility (e.g., deceased, institutionalized, or unable to be contacted), thus lowering the participant pool to 12,489. Of this revised total, 6,657 (53%) participants returned surveys in 2006 (henceforth “Wave 1”). Of this, 3,104 (61% response rate) were from the general subsample, and 3,553 (48% response rate) were from the Māori subsample. Following completion of the 2006 survey, all participants were asked whether they would complete a follow-up survey in 2008 (Wave 2). Those indicating willingness to join the longitudinal study (approximately 3,200) were approached for the 2008 data collection wave, and subsequent HWR study data collection waves target prior wave completers.

Table 1 compares the characteristics of the HWR study sample across all current waves (2006–2014) with the characteristics of New

Health, Work, and Retirement Longitudinal Study, Table 1 Comparison of the Māori and non-Māori HWR study participants across all waves with New Zealand's 50+ general population as at baseline (unweighted)

Note: The 2014 data collection is still in the field. Sample N and characteristics for that wave are not available

^aWave 5 reflects a supplementary wave not synchronized with the normal biennial data collection and comprises participants who have been part of the study since 2006

^bWave 6 is split into the HWR longitudinal cohort and a new “refresh” subsample geared toward a steady-state design. All 2012 participants were recontacted for participation in 2014 (hence the higher participation rate than in 2013). The refresh subsample saw the inclusion of new participants at younger ages, thus increasing sample size and reducing mean age

^cParticipants present in all sampling waves

Zealand's 50+ general population as of 2006 (Statistics New Zealand 2006). As the HWR study sample represents one of the only national-level studies in the world comprising a significant cohort of indigenous older people, the baseline characteristics are displayed for participants with Māori ethnicity and non-Māori ethnicity (e.g., European, Asian, Pacific Island) separately. Although the Wave 1 cross-sectional survey in 2006 which underpins the HWR study cohort comprised 6,657 respondents, Table 1 provides information only on those from Wave 1 who consented to be included in the longitudinal survey.

Move from cohort-based to steady-state design: From Wave 1 (2006) to Wave 5 (2013), the HWR study reflected a cohort-based study following an established group of New Zealanders who were aged 55–70 at Wave 1 through to aged 62–77 at Wave 5. From Wave 6 (2014) onward, the HWR study moved from a cohort design to a steady-state design which will make biennial additions of participants aged 55–56 and thereby generate a longitudinal study that is nationally representative of New Zealanders aged between 55 and the oldest age group per wave. In 2015 the same sampling framework outlined for Wave 1 was utilized to add a sample of New Zealanders aged 55–61 to achieve this steady-state design as the youngest HWR study participants were 62 in 2015. Subsequent biennial HWR study waves (e.g., Waves 7 and 8) will each add participants aged 55–56 to ensure that the study sample is continually refreshed every 2 years to maintain the sample as nationally representative of New Zealanders aged over 55 years.

Data collection and measurement: The HWR study is based around a biennial postal survey. In addition to these postal surveys, face-to-face interviews of a subsample of participants occurred in 2010 ($n = 1,001$), and this same subsample was interviewed again in 2012 ($n = 903$). Table 2 illustrates the seven broad topic areas measured across all waves in the HWR study and includes assessments utilized in both postal and face-to-face components. In addition to this quantitative data, the HWR study has also included several

qualitative interview studies with participants drawn from the longitudinal sample. In 2006 60 HWR study participants were interviewed about their earlier life to establish pathways from early-life to late-life work and retirement decisions (Pond et al. 2010). Fifty of these participants were reinterviewed in 2008, and 15 partners of these participants were also interviewed. In 2008 48 participants were interviewed about their family life and social connections (Breheny and Stephens 2010). Interview data was combined with survey responses from these participants in a mixed methods approach to discursive analysis. In 2010, a longitudinal qualitative interview study with HWR study participants examined the importance of practices such as gifting and passing on objects to maintaining identity in later life. Undertaking in-depth qualitative interview studies with the participants of the longitudinal study provides a unique opportunity. Quantitative data can be used to select and categorize older people into groups for analysis, and quantitative data from the same participants can be used to understand the qualitative findings.

Research Areas

Data from the HWR study has been used by national and international researchers to explore a diverse range of topics associated with healthy and successful aging. The following domains reflect particular themes under which there is a consistent and growing stream of HWR-related research.

The determinants of physical and mental health in later life: The maintenance of good physical and mental health is a key predictor of longevity and successful aging. Since its inception, the HWR study has had a strong focus on exploring the range physical and mental health profiles of older New Zealanders and identifying the primary predictors of health change over time. Work on the Wave 1 data established the psychometric properties and validity of the internationally validated SF36v2 measure of physical and mental health in older New Zealanders (Stephens et al. 2010). Building on this work, research

undertaken on subsequent HWR study waves has explored the influence of multiple factors on the physical and mental health of older New Zealanders, including social inequalities (Stephens et al. 2011a), social support and loneliness (Stephens et al. 2011b), and the role of caregiving (Alpass et al. 2013). With the addition of cognition assessments in the 2010 and 2012 HWR study face-to-face interview, a further stream of cognitive health research has been initiated. The first published article from this stream established the key differences in cognitive health between HWR study participants and US counterparts in the HRS (Stephens et al. 2015).

Living standards of older adults: Living standards are a key aspect of the experience of later life. Within the HWR study, there has been a strong focus both on identifying the primary indicators of living standards for older adults and on how inequalities in such living standards influence the capacity of older adults to age well. Work involving the HWR study data has aided the development of a robust measure of living standards based upon Sen’s capability approach (Breheny et al. in press). This measure was designed to assess living standards in terms of the ability to achieve across six domains valued by older people (health care, social integration,

contribution, enjoyment, security, and restriction). A key aspect of this measure is the way it assesses living standards as varying from constraint to freedom, rather than conventional measures that conceptualize living standards as varying from hardship to comfort. Both qualitative and quantitative research in the HWR study has demonstrated that the living standards of older people have ramifications beyond the material conditions of their lives. Living standards impact upon the ability of older people to contribute to the lives of others, to experience enjoyment, and to be viewed as a person of value as they age (Breheny and Stephens 2010). In examining living standards, the focus is not on individual responsibility for ensuring adequate living standards as people age. Instead, this research aims to reveal enduring structures that limit people’s lives across the life course.

Older adults’ quality of life: Quality of life (QOL) in older adulthood is a primary indicator of independence, well-being, and life satisfaction. The HWR study has multiple streams of work on the assessment of QOL and the investigation of factors determining QOL in specific subpopulations. Since Wave 3, the HWR study has included the CASP12 which is an older adult-specific measure of QOL utilized primarily in European

studies such as the ELSA and SHARE. Exploration of the CASP12 factor structure among older Māori and non-Māori indicates that the QOL of both Māori and non-Māori older adult reflects consideration of the same key factors, but that these considerations are slightly different to those expressed in European older adults (Towers et al. 2015). Specifically, shortage of money does not appear to be a primary influencing agent for QOL in New Zealand older adults. Furthermore, three core CASP12 items reflecting feelings of energy and positive future outlook provide a very effective brief indicator of the general QOL of older New Zealanders regardless of ethnic background. A core thread of QOL research within the HWR study has focused on modeling the impact of mobility as a key determinant of QOL in older adults in general and specifically in older adults with vision impairments. Ongoing research utilizing the HWR study data shows that visual impairment is associated with significantly poorer economic, physical, and mental health status, a significant lack of social support, and greater social isolation (La Grow et al. 2009). Furthermore, it is now clear that mobility (i.e., the ability to get around one's environment) is a key factor facilitating QOL in older visually impaired people (Yeung et al. 2015).

Ethnicity and aging: The HWR study was specifically designed to understand differences in the experience of aging between Māori and non-Māori and to facilitate an assessment of the experience of aging for other minority group members in New Zealand. From the outset, oversampling of Māori to ensure meaningful ethnic group analyses could be undertaken. The HWR study has confirmed that older Māori have poorer health and lower living standards and are more socially isolated than older non-Māori (Dulin et al. 2011). Ethnicity is entwined with socioeconomic status; differences between ethnic groups are often explained by disparities in access to social and economic resources. To address this, the HWR study data has enabled more detailed analyses of the relationship between ethnicity and experience of later life. For example, older Pacific people in New Zealand have poorer health and lower living standards than either Māori or

non-Māori non-Pacific people. After controlling for multiple health risks, socioeconomic and demographic variables, ethnicity continues to predict lower levels of physical health among Pacific people, suggesting that there are other factors associated with ethnicity which contribute to higher rates of poor health for older Pacific people (Lotoala et al. 2014). As the HWR study matures, further analyses of the longitudinal data will enable an examination of how disparities in health of minority ethnic groups develop over time.

Synonyms

Active aging; Aging well; Positive aging; Productive aging; Successful aging

Definition

In the last 40 years, there have been many attempts to define healthy aging and its synonyms. The evolution of the definitions of healthy aging and its many synonyms has reflected contemporary thinking and a high level of interest in the health and quality of life of older people.

The WHO now defines healthy aging as:

The process of developing and maintaining the functional ability that enables well being in old age. (World Health Organization 2015, p. 40)

An earlier similar definition was provided by Health Canada as part of a systematic research

program on aging and the maximization of quality of life.

A lifelong process of optimising opportunities for improving and preserving health and physical, social and mental wellness, independence, quality of life and enhancing successful life-course transitions. (Health Canada 2001, p. 1)

The European Union Healthy Ageing Project (Swedish National Institute of Public Health 2006) defined it as “. . . *the process of optimising opportunities for physical, social and mental health to enable older people to take an active part in society without discrimination and to enjoy an independent and good quality of life.*”

Other definitions include:

. . . the development and maintenance of optimal physical, mental and social well-being and function in older adults. It is most likely to be achieved by individuals who live in physical environments and communities that are safe and support the adoption and maintenance of attitudes and behaviors known to promote health and well-being; and the effective use of health services to prevent or minimize the impact of acute and chronic disease on function. (US Health Promotion Research Centre Healthy Aging Research Network)

. . . a process whereby people can achieve or maintain the best possible state of physical, cognitive and mental health and well being, meaningful and positive engagement with people, community and institutions, and a personal sense of security, choice and autonomy, with active adaptation to ageing processes from the individual, familial and societal perspectives. (Browning and Thomas 2007)

Introduction

While the exact forms of words differ across these definitions, essentially there is a consensus among them that healthy aging involves a process that optimizes health status and quality of life and is determined by a multitude of interacting biological, psychosocial, and environmental factors. These definitions of healthy aging go well beyond narrow survival and physical health criteria and are conceptually derived from the influential WHO definition of health which itself is now over 60 years old. It states: “Health is a state of complex physical, mental and social well-being

and not merely the absence of disease or infirmity” (World Health Organization 1952, p.100). The concept is that health and healthy aging is not an end state in itself but rather a process that occurs across the life course. Moreover, health is widely seen by older people themselves as a resource that enables them to live their lives fully (Kendig and Browning 2010a).

The WHO World Report on Ageing and Health (World Health Organization 2015, pp 40–41) emphasized promoting healthy aging by focusing on functional ability rather than particular disease states, recognizing diversity in aging experiences and outcomes, and understanding the impact of health inequities in old age and across the life course. The WHO definition of healthy aging assumes that older people’s physical and mental capacities and the environment in which they live are not static and that the interactions between these internal and external resources influence the aging trajectory. In this chapter we examine the strategic importance of healthy aging, conceptual and measurement issues, predictors of healthy aging, and programs and services to promote healthy aging.

The Strategic Importance of Defining Healthy Aging

The concept of healthy aging influences and is influenced by national governmental actions. It is a constructive influence guiding governmental actions that can improve the health, well-being, and productivity of aging people across global communities in the developed and developing world. As reviewed in this paper and elsewhere in this volume, humanity is experiencing rapid demographic changes, markedly increased human longevity, and rapidly changing patterns in health and illness, especially in noncommunicable diseases (NCDs) that are impacted by aging. We now briefly review each of these factors in terms of their association with healthy aging.

Rapid Demographic Changes

One of the key reasons for the current focus on healthy aging is the rapid demographic change in

Healthy Aging, Fig. 1 Years for growth from 7% to 14% of population aged 65+ by country

societies in the last 50 years. Kinsella and Phillips (2005) presented seminal demographic data demonstrating that the rapidity of growth from 7% to 14% of the populations aged 65 years and older had changed dramatically in the last century (see Fig. 1).

These data illustrate how the time for the proportion of the population aged 65+ to grow from 7% to 14% has lessened in a range of countries. The changes are remarkable and reflect continuing unprecedented growth in numbers of older people across a wide range of countries and globally. They are, of course, directly related to improvements in life expectancy at older ages, reductions in maternal and child health mortality, and changing migration patterns. Additionally, in some cases such as China, concerted policy measures that restrict population growth have had the consequence of rapidly changing the country’s age pyramid.

Increased Longevity

The remarkable changes in longevity have posed the contemporaneous challenges of living better and living longer (“adding life to years”). According to the World Bank Development Indicator Dataset, global life expectancy at birth has grown from 52.5 years in 1960 to 71.2 years in 2013 (World Bank 2015). For China the growth over the same period has been from 43.5 years to

75.4 years, a stunning increase of 32 years in the space of 50 years. Figure 2 shows the trends in increasing longevity for selected countries and regions from the World Bank Development Indicator Dataset.

The US National Institute on Aging (2011) notes that “the dramatic increase in average life expectancy during the twentieth century ranks as one of society’s greatest achievements” (p. 6).

Aging, Chronic Illness, and Health Costs

Another key reason for the high level of interest in healthy aging is the robust relationship between aging, prevalence of chronic disease, and health-care costs that follow from rapidly aging populations. In the “Burden of Disease” entry in this encyclopedia, we have noted that the World Economic Forum has reported that NCDs represent 63% of all deaths being “the world’s main killer” (Bloom et al. 2011). The Forum asserted that over the next 20 years, NCDs will cost USD30 trillion (or 48% of 2010 global GDP) and that they will have devastating global economic impacts. Population aging is considered to be a major driver of this.

However, we have argued elsewhere that rhetoric concerning the economic “burden of aging” often verges on ageism. Maximizing health and

Healthy Aging, Fig. 2 Longevity trends across selected countries and regions

well-being in old age is a basic human right and a response to ageism that challenges the stereotype that declining health is an inevitable consequence of old age (Browning and Kendig 2003). Social determinants that are potentially modifiable, such as income, housing, education, and access to health services, impact on different social groups across the life span potentially leading to the accumulation of disadvantage in health outcomes in old age (Kendig and Browning 2010b). Focusing on disease and its relationship to aging is essential for treatment but can diminish attention to preventative actions and interventions that can improve health and illness trajectories. This complementary preventative approach requires understanding and responding to the impact of social inequalities on healthy aging, as well as the modifiability of behavioral risk factors which impact the onset and progression of multiple chronic conditions.

Wider constituencies globally – including policy makers, service providers, health professionals, researchers, advocates, and the broader public – are increasingly attuned to the impacts of aging upon our communities and societies as

well as economies and service systems. Terms and concepts such as “healthy aging” hold out hope for management of what in global terms is likely to be unprecedented exciting and challenging opportunities for societies and governments. These demographic and social changes are transformational in the space of a generation. It is therefore appropriate that we focus on healthy aging, what it means, and how it can be promoted and maximized for the benefit of all communities.

Conceptual Issues in Healthy Aging

WHO Framework for “Adding Life to Years.” The definitions of healthy aging we have just discussed are predicated upon the assumption that progress for societies should not be judged solely by increased longevity (survival) and the attainment of a narrow definition of physical health but also by the quality of the lives of their older citizens (Glass 2003). While increasing longevity is a cause for celebration globally, the World Health Organization (WHO) has called for “adding life to years,” which is explicit

recognition of the importance of quality of life in addition to longevity for older people (World Health Organization 2015). Policy approaches that promote healthy aging reflect the desire to support older people to remain active, valued, and engaged citizens for as long as possible and, during the last years of their life, to live a comfortable, meaningful life. Such approaches are now strongly advocated globally (Rechel et al. 2013; WHO 2002). Nations such as France and Great Britain and many other European Union countries have invested in major programs of measurement of national well-being (Randall and Corp 2014) across the life span in a systematic attempt to include social capital considerations in policy and performance monitoring for their societies to augment the basic economic indicators.

Similarly, a compendium on the “Successful Aging of Societies” has advanced thinking on social and policy actions that can complement earlier thinking centered on the health and aspirations of individuals (Rowe 2015). Further, comparisons between societies can shed light on the contextual influence of varying policies and socioeconomic developments (Kendig and Nazroo 2016).

Most of the definitions of successful, healthy, active, positive, and productive aging concepts also include broad definitions of aging that are not simply confined to the presence or absence of physical ill health or survival. They include explicit consideration of psychological and social factors as well as the ongoing influence into later life of earlier life experiences as well as transitions through later life (Kendig and Nazroo 2016). We consider that an acceptable and credible definition of healthy aging must incorporate logical extensions of the widely accepted foundation WHO conceptualization and definition of health that has now been in existence for over 60 years. The WHO definition includes the central idea that health is best conceptualized as not just avoiding death or disease and the definitions of successful, healthy, active, positive, and productive aging should similarly be more broadly focused. Definitions of healthy aging and related concepts that are solely biologically focused are not consistent with the wider view proposed by WHO of what being “healthy” should encompass.

Maslow’s Hierarchy of Needs. There is also another influential theoretical framework that has contributed to current conceptualizations and definitions of healthy aging and related concepts. This is Maslow’s hierarchy of needs (Maslow 1954). Although Maslow’s work has attracted some critique (Yang 2003), the idea of a hierarchy of needs ranging from basic physical survival to self-actualization and high levels of well-being has an attractive intrinsic simplicity and conceptual robustness. We consider that Maslow’s hierarchy is entirely compatible with the WHO definitions of health and healthy aging. Maslow’s model fits comfortably with most of the current conceptualizations and definitions of healthy aging and related concepts. Maslow’s hierarchy continues to be used by various gerontologists in their research and intervention programs. Its development was an important step in advancing the cause for inclusive definitions of healthy aging.

Potency of Well-Being as Health Indicator. The reasoning behind the inclusion of psychosocial factors in the discussion of health and aging is not just ideology or theory. There is considerable evidence that well-being is strongly linked as both a cause and effect of health status across the life span. Diener and Chan’s (2011) comprehensive analysis of these linkages provides a range of evidence to support this proposition. Steptoe et al.’s (2015) article in the *Lancet* is also a very useful resource. The OECD (2010) report on Social Capital, Human Capital and Health also provides a similarly useful analysis of these linkages.

Measurement Issues in Healthy Aging

Inventories of Standardized Tools. Since those early days, a very significant research effort has been implemented in measuring well-being and quality of life. The research literature is replete with tools to measure these concepts. Extensive research has been conducted involving their application to almost every possible condition and social group including older people. Emery et al. (2005) describe the development of the Quality of Life Instruments Database (QOLID)

and the large numbers of measurement tools that are now included within it (see www.proqolid.org). The database itself includes details of many studies involving the measurement of quality of life in older people. The quality of life and well-being measurement movements are a natural consequence of the adoption of the WHO conceptualization of health. We consider that the inclusion of similar concepts in the widely used definitions of successful, healthy, active, positive, and productive aging is also a direct consequence of the broader focus embraced by the WHO definition and the availability of standardized tools to measure them.

Operationalization of Key Concepts. In providing a contemporary of definition of healthy aging, we need to consider its many current synonyms and antecedent definitions as well as its operational definition. Specificity in how a general concept is to be measured is helpful because such matters inform the development of key performance indicators for government and programs. It also assists researchers in terms of measurement of program outcomes so that interventions may be realistically benchmarked against one another. While there is nevertheless still considerable development occurring in the measurement of burden of disease, the existence of mature shared operational definitions of key burden of disease concepts such as disability-adjusted life years and quality-adjusted life years has been very helpful in that field.

Definition of Active and Healthy Aging. The time is ripe for greater agreement about the operational measurement of healthy aging. To that end, in October 2014, the European Innovation Partnership on Active and Healthy Ageing met to specify an Operational Definition of Active and Healthy Ageing. Unfortunately, the meeting did not produce a useful consensus concerning how to operationally measure healthy aging. It was acknowledged at this meeting that several key elements of healthy aging cannot currently be adequately measured.

Indeed, the WHO Report on Ageing and Health (Beard et al. 2015) has proposed the priority action

of “Agree on metrics, measures, and analytical approaches for healthy ageing,” and this is a pressing need. Lord Kelvin’s commentary from the early nineteenth century on the need for usable metrics to guide science and policy actions neatly summarizes the importance of good operational definitions to guide policy: “When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind: it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science.”

This is not to say that there has been no progress in operational definitions for healthy aging, but there are currently many measurement tools with no clear consensus as to which ones are best. The development of a consensus concerning high-quality and practical measures of healthy aging is now recognized as an important global priority by several influential agencies. This development will greatly assist better economic modeling and evaluation of policy initiatives and evidence-based policy formulation.

Influences on, and Predictors of, Healthy Aging

A substantial knowledge base concerning risk and protective factors for various outcomes in old age is now available based on longitudinal investigations. A difficulty is that varying study purposes has led to the use of varying outcome measures that often are not comparable. Further, they often do not incorporate healthy aging concepts into their measurement suite while including a preponderance of measures of physical decline. We now illustrate some of the findings in the relevant extant literature.

Stuck et al.’s (1999) systematic review found that the most significant risk factors for functional decline were cognitive impairment, depression, disease burden, under- or overweight, lower limb functional limitation, low social activity, low

physical activity, poor self-perceived health, no alcohol use, smoking, and vision impairment. Many studies and reviews have confirmed the role of behavioral and social factors such as not smoking, physical activity, normal weight, moderate alcohol use, and social integration in physical functioning, cognitive functioning, and mortality in older people (Depp and Jeste 2006; Lee et al. 2010; Peel et al. 2005). Lantz et al. (2010) in their 19-year prospective study of mortality among people in the United States aged 25 years and older found that low physical activity and smoking were significant predictive factors. A 17-year follow-up of the Whitehall II study (Britton et al. 2008) found that successful aging – as indicated by cognitive capacities, absence of disease, and good functional health – was predicted by socioeconomic factors in midlife and a range of key health behaviors earlier in life, including diet and exercise, as well as work support for men. Research from the English Longitudinal Study of Ageing (ELSA) (McMunn et al. 2009) has identified substantial social class inequalities in the onset of illness and survival of older people. An analysis of threats to aging well in Melbourne, Australia, over a 12-year period (Kendig et al. 2014) found major gender differences: major threats for women included being under weight, low physical activity, and urinary incontinence, while for men, these threats included being a current smoker, low strain, and perceived inadequacy of physical activity

Thus, there is a body of longitudinal research examining the associations between older people's characteristics and behaviors and their subsequent experiences in terms of various measures of healthy aging. The usefulness of the research has been limited by difficulties distinguishing between causal influences and outcomes as the same measures are sometimes used as both independent and dependent variables (Glatt et al. 2007). In addition examination of single outcomes and/or single risk or protective factors may be confounded by other factors not included in the analyses. Physical and mental/

emotional health components of aging well are rarely examined together as a multidimensional healthy aging outcome. Finally, many of the studies do not provide subgroup analyses to examine the impact of gender and other social subgroups.

Programs and Services to Promote Healthy Aging

In line with the underlying principle that aging processes are modifiable, over the past 30 years, there has been development and evaluation of different interventions for improving the health and quality of life of aging individuals and their caregivers. As an example, in the United States alone, there are now several inventories of evidence-based interventions associated with a variety of health and well-being enhancements across the life course (see <http://www.wsipp.wa.gov>). One of the most successful programs, the Stanford Chronic Disease Self-Management Program (Lorig 2015), has reached hundreds of thousands of older adults.

There are broad-based evidence-based programs focused on modifying healthy lifestyles and environments (e.g., increasing physical activity and healthy eating) and other more specific ones for addressing major geriatric problems such as risks for falls and other injuries or enhancing mood and cognition in later life (Ory and Smith 2015). While many interventions have traditionally been based on theories about the important influence of social cognitive processes, more recent interventions are building on socio-ecological models that stress the importance of providing supportive built environments or policies designed to make the right lifestyle choice the easy one.

The evidence is now overwhelming that such evidence-based programs can help meet the triple aims of health reform including better health, better health care, and better value (Ory et al. 2013). The research questions have changed from “what works” to “how can we implement

what is known to work” to “how do we sustain such efforts for long-term health effects?”

The growing intervention research base is built upon our conceptualization of healthy aging as possible as well as our understanding that the best interventions are multilevel and address the multiple clinical, psychosocial, and environmental risk factors. An advance in recent years is the adoption of common planning and evaluation frameworks such as the RE-AIM framework (Gaglio et al. 2013) as well as pragmatic research instruments for rapidly assessing intervention impacts in a variety of home, health care, and community settings.

Conclusion

Healthy aging is a topic of central interest to communities, societies, and governments. It has been argued that this interest stems from a variety of sources including rapid demographic changes, markedly increased human longevity, and rapidly changing patterns in health and illness especially in non-communicable diseases that are impacted by aging. The recent efforts to define healthy aging including the WHO’s most recent 2015 definition “The process of developing and maintaining the functional ability that enables well being in old age” now incorporate well-being and psychosocial factors and these are welcome and appropriate additions. Further work is underway on developing societal and policy-focused directions in healthy aging. The complexity of the field and the varied applications of healthy aging make it difficult to achieve consensus on measurement, but further development would strengthen the knowledge base and applications to economic modeling and the evaluation of policy initiatives and evidence-based policy formulation. Programs that are designed to promote healthy aging now have a substantial evidence base, so with appropriate investment, many of the challenges posed by our aging societies can be addressed.

Definition

The Heidelberg Centenarian Studies are two population-based investigations conducted 11 years apart. They inform about physical and cognitive functioning, health, need for care, and well-being at the age of 100 years in Germany. Cohort differences between individuals born around 1900 and around 1911 are assessed in central domains of functioning and care.

Early Research on Longevity and Centenarians in Germany

The Heidelberg Centenarian Studies have their roots in earlier centenarian research conducted in Germany. In the 1960s, German scientists started to investigate extraordinary longevity and to conduct studies with centenarians (Franke 1985; Lehr 1982). These studies were characterized by a broad interdisciplinary perspective and tried to provide comprehensive answers on longevity issues instead of focusing on disciplinary

specific research questions. Biological, medical, psychological, and social factors were equally considered. Ursula Lehr, a German developmental psychologist, proposed a longevity model that attracted worldwide attention. Length of life and quality of life were the two equally important outcome dimensions in her model (Lehr 1982).

Hans Franke, a physician, was the first German researcher who systematically investigated individuals at the age of 100 years and older (Franke 1985). He was aware of the rapid increase of the number of centenarians and highlighted the importance of age validation in this age group. Between 1965 and 1983, his team contacted and examined 575 centenarians. While a detailed description of the exact sampling strategy is not available, it is known that Franke contacted all centenarians whom he could identify via newspaper announcements and word of mouth, regardless of their physical and mental status. Interestingly, his main conclusions resulted in two insights: that cumulative disability and multimorbidity were highly prevalent and that centenarians showed tremendous interindividual differences. In order to characterize the centenarians better, he grouped his sample into three levels of vitality. The first group consisted of active and well-functioning centenarians (“Rüstige,” 29%), the second group were frail and rather sick individuals who were limited in everyday activities (“Kränkelnde,” 48%), and the third group had advanced disease and total dependence and was often bedridden (“Sieche,” 23%). Based on his observations and in line with Lehr’s longevity model, Franke raised the question whether life was still worth living at the age of 100 years and beyond.

Stimulated by Franke’s work, Lehr initiated a centenarian study in the Bonn-Cologne area (Lehr 1991) with a focus on coping behavior. This meant that centenarians had to be rather cognitively intact and able to participate in a comprehensive interview. Although the participants were therefore clearly positively selected, the interindividual differences prevailed as one of the key findings. Furthermore, findings indicated that the coping behavior played a central role for an active life and social integration, even in the

face of functional limitations and disease burden (Rott 1999). Most of the centenarians felt that they were actively shaping their life and were striving to make the best of their situation.

The First Heidelberg Centenarian Study (HD100-I)

Although these two early German centenarian studies provided valuable insights into very long lives, they bear at least two major limitations. First, it was unclear to what degree study findings were representative of the centenarian population in Germany. Given the lack of well-described sampling procedures, this is unclear for Franke's study, and the Bonn-Cologne study was clearly not population based. Secondly, the data were not collected with standardized instruments but rather with qualitative interviews. Thus, it is difficult to compare the results with those from other centenarian studies being now conducted around the world. A major impetus for a new German centenarian study came from the Georgia Centenarian Study (Poon et al. 1992), not only with respect to sampling and instruments but also with respect to research questions. Building on experiences and results from the Georgia Centenarian Study, the aims of the First Heidelberg Centenarian Study were to assess objective and subjective quality of life and their interrelations, addressing three main domains: (1) cognitive functioning, (2) functional health and care, and (3) subjective well-being. To be comparable with other studies, internationally established instruments were administered (e.g., to assess autonomy and everyday functioning: ADL and IADL scales by Fillenbaum 1988) and a population-based sampling strategy was applied (Rott et al. 2001). There were no exclusion criteria. Within a clearly defined geographical area about 60 km around Heidelberg, 172 cities and communities provided names and addresses of 281 eligible persons (age 100 years at the time of assessment). Of these, a substantial number, namely 125 persons (44.5%), could not be verified: Either they died in the interim (that is, between nomination and the first contact with the family: 93 centenarians), could not be found

in spite of intensive inquiry (22 persons), or their age was wrong (younger than stated; 10 persons). A direct contact was established with 156 persons or their relatives. In 65 cases, participation in a face-to-face interview was refused for various reasons. However, some basic demographic and health information could be obtained via telephone from 42 centenarians of the refusal group. Full study participants were 91 centenarians who were visited in their place of residence (i.e., apartment or care institution). Of these, 56 provided reliable information about themselves. In addition, 86 primary contacts (i.e., proxies) provided information on the centenarian, complementing the centenarian as information source (for 95% of the centenarian sample). These proxies were mostly children or other relatives in close contact with the centenarian; the remaining 5% of the centenarians did not want their proxies to be contacted or did not have any close contacts. The interviews were conducted in the years 2000 and 2001. After 18 months, a subgroup of individuals ($n = 36$) was again assessed with a subset of the baseline measures. Moreover, centenarians were followed by contacting their proxies every 6 months until they died. The last of the HD100-I participants died in 2009.

The mean age of the participants was 100.2 years ($SD = 0.41$). Eighty-five percent of the centenarians were women, most of them (78%) were widowed, and about three-quarter (72%) had an elementary school degree. Thirty percent lived in an own apartment, 20% lived with relatives, and half of them resided in institutions.

Replicating prior findings, interindividual differences played a major role in all areas. Domain-specific results can be summarized as follows:

Cognitive Status

Cognitive functioning was evaluated with a shortened version of the MMSE (i.e., items sensitive to visual, dexterity, or literacy deficits were removed, as proposed by Holtsberg et al. 1995) and the Global Deterioration Scale (GDS; Reisberg et al. 1982). Not surprisingly, results revealed that centenarians differed significantly from each other with respect to their cognitive

capacities (Kliegel et al. 2004a). A key finding was that dementia was less prevalent than expected: While about half of the population (52%) showed moderate to severe cognitive impairment, one quarter was found to be cognitively well intact. In a second step, MMSE and the GDS scores were combined to evaluate whether the centenarians had sufficient cognitive capacity to live independently. This was the case for almost half of them (46%; Becker et al. 2003). On the other hand, cognitive functioning of one-quarter of the sample was so severely restricted that continuous monitoring and care was necessary.

Analyzing cognitive change of survivors ($n = 36$) over a period of 1.5 years revealed distinct patterns of intraindividual change (Kliegel et al. 2004a). Five centenarians (14%) were characterized by reliable improvement, 22 centenarians (61%) showed stability (some on the bottom level), and 9 centenarians (25%) revealed decline which was often a rather radical drop to the bottom level of functioning. Further reflecting substantial individual differences in terms of functioning, centenarians were found to remain stable at low as well as high levels of functioning. Specifically, those centenarians who had an MMSE score of 0 had already reached this status about 2 years (730 days) before death. In contrast, there were also centenarians who maintained intact cognitive functions until they died.

Additional noteworthy findings were related to the extent to which distal influences such as education as well as prior life style determined cognitive functioning at age 100. Analyzing the influence of early education, occupational status, and intellectual activities on cognitive status in very late life revealed independent, significant, and strong influences of both formal school education and intellectual activities on the cognitive status, even after controlling for occupational status (Kliegel et al. 2004b).

Functional Health and Care

The instrument to evaluate levels of activities of daily living (ADL) was taken from the OARS (Fillenbaum 1988). We prioritized the proxy information because it was evident that the

self-reports of the centenarians represented an overestimation of functioning (Schönemann-Gieck et al. 2003). Results demonstrated a severe loss of independence. Whereas about two-third of the centenarians could eat by themselves, the degree of independence in most other activities was between 30% and 40% only. Bathing as the most complex basic activity of daily living could be performed independently by 13% (Becker et al. 2003).

In 1995, the German Long-Term Care Insurance Program was implemented with the goal of providing financial means to individuals in need of care to pay for professional services or to reimburse care provided by the family. However, care needs were assessed only on the basis of physical functioning, and cognitive restrictions were not considered, ignoring the levels of dependency caused, for example, by dementia. As a reaction to this, Becker and colleagues developed a category system including physical and cognitive limitations to analyze the HD100-I data, to allow for a more comprehensive evaluation of independence and care need. Specifically, ADL functioning was combined with cognitive performance, and this more complex measure was categorized into four levels analogous to the German Long-term Care Insurance (Becker et al. 2003). Level 0 indicated sufficient physical and cognitive capacity to live independently, level 1 required nursing care once a day, level 2 three times a day, and level 3 made continuous care 24 h a day necessary. Level 0 was present in 9% of the centenarians, indicating physical and cognitive independence (functional competence), a level that was similar to the results of the Danish Centenarian Study (Andersen-Ranberg et al. 2001). Thirteen percent of the centenarians needed care once a day (level 1), 45% three times a day (level 2), and one-third (33%) was fully dependent (level 3). A comparison of these alternative criteria to determine care need with those used by the German Long-term Care Insurance suggested that existing care needs were often not addressed adequately. Almost half (44%) of the HD100-I centenarians were categorized at a lower level of care compared to our categorization of independence and care need (Becker et al. 2003).

Subjective Well-Being

HD100-I centenarians reported better well-being than one would expect given the obvious constraints in health and cognition, as well as the extensive care needs. Specifically, we considered two well-being constructs, valuation of life, and happiness. Valuation of life (VOL; Lawton et al. 1999b) refers to an individual's feeling of being attached to his/her life and to experiencing life as worth living. In contrast, happiness as an aspect of emotional well-being refers to the immediate experience of positive feelings, which should be influenced by the centenarians' daily struggle with loss and restriction. Comparing VOL levels of the HD100-I centenarians with the septuagenarians interviewed by Lawton and colleagues (1999a), findings indicated that centenarians had significantly lower VOL levels, yet the difference was rather small (HD100-I: $M = 48.1$, vs. 70s: $M = 50.2$). Considering predictors of VOL in the centenarians, the strongest predictor was extraversion, followed by IADL competence. Other objective factors such as health or cognition did not account for any interindividual differences in VOL (Rott et al. 2006).

Regarding happiness, centenarians felt at least as happy as middle-aged and older individuals, when compared with participants of the ILSE Study, a study representative for German middle-aged and older adults (Jopp and Rott 2006). Thus, it appears that centenarians do not experience reduced subjective well-being when considering more emotional aspects such as happiness, relative to younger individuals. Underscoring the findings on VOL, health was not found to be among the predictors of happiness, which suggests that centenarians are able to experience happiness even in the face of objective negative conditions such as their deteriorating health status. Other basic personal resources, such as education (job training), cognition, social network, and extraversion, were associated with happiness, but when considering self-efficacy and optimistic outlook as mediators, some of the effects became nonsignificant or had only indirect effect via the mediators. The strongest predictor of happiness were self-efficacy and optimistic outlook, indicating that beliefs about one's capacity

and more general attitudes towards one's life are more important for feeling happy at very advanced age relative to basic resources such as health (Jopp and Rott 2006).

Conclusions from the First Study

The First Heidelberg Centenarian Study confirmed the impression from prior, more unsystematic German centenarian studies that interindividual variability in central domains clearly existed. In addition, differences in intraindividual change in cognition could be observed even in close proximity to death. While nearly all of the centenarians were physically frail and about 90% needed nursing care, the proportion of individuals with poor cognitive functioning was much lower. Thus, it seemed that cognition was better maintained than physical functioning in these very old persons. Those who could give reliable self-reports seemed remarkably robust psychologically and in most cases evaluated their life as worth living. Attitudes towards life seemed to be more important for well-being than objective conditions such as health.

The Second Heidelberg Centenarian Study (HD100-II)

Inspired by promising results from a cohort study in Denmark demonstrating that later born female centenarians were better off regarding mobility and ADL functioning (Engberg et al. 2008) and being aware of limitations of the first investigation, the Second Heidelberg Centenarian Study (HD100-II) was launched in 2011. One aim was to examine cohort differences in cognition and physical functioning/care between centenarians born approximately 10 years apart. Other objectives were to take a closer look at social networks and care arrangements, a more comprehensive assessment of health and diseases and to investigate the interplay of psychological strengths and well-being.

The same sampling procedures as in the first study were used. For recruitment, we requested contact information of all individuals born in

1911/1912 from the same city registries (in and up to 60 km around Heidelberg, Germany). To ensure the greatest possible degree of representativeness, no exclusion criteria were applied. Of the 485 eligible individuals, 298 centenarians either died between nomination and first contact, refused any participation, or no contact could be established. Seven centenarians and 73 primary contacts provided only basic information via telephone. Reasons for refusing full study participation were cognitive restrictions/dementia (43%), concern the interview would be too exhausting (28%), no interest (16%), poor physical health (9%), and other reasons (4%). We could enlist 107 centenarians or their primary contact to participate in a face-to-face interview. Five additional centenarians nominated themselves after having heard of the study. These participants are not considered for cohort comparisons. In total, 112 centenarians were interviewed at their residence (private home or elder care facility). When the centenarian was no longer able to answer reliably (e.g., due to cognitive impairment), the primary contact served as the only information source ($n = 18$).

Data were collected in the years 2011 and 2012. The mean age of the participants was 100.5 years ($SD = 0.47$). Most study participants were exactly 100 years old; 5% were 99 and 10% were between 101 and 103 years old. Eighty-nine percent of the centenarians were women and most of them (83%) were widowed. About two-third (61%) had an elementary school degree. A majority (59%) resided in the community, whereas the remaining 41% lived in an elder care facility.

Better Cognitive Status of Later Born Cohort

Cognitive functioning was evaluated in both studies with the Global Deterioration Scale (Reisberg et al. 1982). The participants of the second study revealed a significantly better cognitive status compared to those from the first study. Specifically, the proportion of centenarians with no or only little limitations had increased from 41% to 52%, while the percentage of individuals with strong limitations had decreased from 28% to 22% (Jopp et al. 2013).

Improved Functional Health But Same Amount of Care

Activities of daily living (ADL) were evaluated in the same way as in the first study. The instrument was taken from the OARS (Fillenbaum 1988), and we prioritized the proxy information. The proportion of independent functioning significantly increased in three out of seven activities of daily living (Jopp et al. 2013). While in the first study 63% could eat by themselves, 83% were able to do so in the second study. The rate of independence in getting in and out of the bed without assistance rose from 34% to 53%; and 51% were able to take care of their own appearance in the second study compared to 32% in the first study. In spite of these improvements, the rate of dependency was still very high. About only one-third of the centenarians in both studies were able to walk without assistance, a requirement for independent living and social participation. Taking a bath or shower independently, representing the most complex activity of daily living, stagnated at a rate of 13%. Thus, that the more recent cohort of centenarians showed improvements in some activities of daily living compared to those individuals who were 100 years old about 11 years ago did not reduce the amount of care granted by the German Long-Term Care Insurance.

Similarities and Differences in Social Networks and Care Arrangements

Comparative analyses were conducted for all social network and care arrangement indicators that were available in both studies to identify cohort differences. Interestingly, most of the social network indicators did not differ between the first and the second study. Centenarians were very similar with regard to marital status (80% widowed, 12% never married, 4% married, and $\leq 4\%$ divorced), having a living child (71%), spending time with people they do not live with, in the past week (2–6 times per week, on average), seeing family as often as they want (46–54%), and having anyone to confide in (94–96%). There was only one marginal difference, for number of children, with centenarians in the second study having slightly fewer children on

average compared to the first study ($M = 2.1$ vs. $M = 2.6$).

Whereas these basic indicators showed mainly similarities, noteworthy differences emerged with regard to living arrangements (living alone, with at least one person in household, or in an eldercare facility), use of professional help (community-dwelling centenarians only), and perceptions of loneliness. Centenarians of the second study were significantly more likely to live alone (29% vs. 13%). They were also more likely to utilize professional help to address low or high intensity needs (16% vs. 6% for help with house cleaning, and 16% vs. 4% for help in multiple care domains). Group differences were not significant for moderate care needs (11% vs. 8% for help in one care domain). Finally, centenarians of the second study were significantly less likely to report loneliness. Thus, findings suggested that the recent cohort of centenarians from the second study stay in the community and live independently longer, get more professional help, and experience less loneliness. What may have contributed to less experienced loneliness in the recent cohort is an interesting question that our data cannot fully answer. However, correlational analyses indicated that more time spent with others not living in the same household was significantly associated with less loneliness. It is possible that reports of time spent with others included professional helpers and that thus an increased use of professional help contributed to preventing or reducing experiences of loneliness in centenarians. The increased use of professional help is also reassuring, given that in the wake of dramatic increases in the very old population (Christensen et al. 2009), combined with low birth rates and, in some cases, increasing childlessness (Statistisches Bundesamt 2013), the primary reliance on children as support providers does not seem like a realistic prospect for many future centenarians (Boerner et al. 2016).

Better Understanding of Health and Disease

The Second Heidelberg Centenarian Study offered also a more detailed insight regarding health conditions in centenarians. Specifically, drawing on information from centenarians and

proxy informants, the Heidelberg centenarians were found to have on average about five recent and chronic health conditions, indicating substantial comorbidity (Jopp et al. *in press*). No centenarian without a health problem was found, 4% had only one, 12% had two, and 9% had three conditions. The health conditions most often reported were vision and/or hearing impairments (94%), mobility problems (72%; e.g., falls, difficulty with balance/walking), and musculoskeletal conditions (60%; e.g., arthritis, osteoporosis). Heart conditions (57%; e.g., high blood pressure, heart diseases) and problems with the urinary system (55%) had similar prevalence rates (Jopp et al. *in press*).

In spite of a notable comorbidity, the overall number of diseases with high mortality risk was rather low. Considering the three most common lethal illnesses, heart diseases, stroke, and non-skin cancer, not one of the centenarians was found who was affected by all three of them. One-third of the centenarians had only one, and only 10% had two of them. Another noteworthy finding came from reports on pain. Specifically, 30% of the centenarians reported frequent pain (19% indicated often, and 11% indicated always). Of those reporting any pain, the largest group said their pain was bearable (57%). Yet, a total of 36% of the centenarians reported pain stronger than bearable (Jopp et al. *in press*). In sum, patterns of health issues are dominated by sensory and mobility impairment and not by specific diseases.

High Level of Subjective Well-Being and Pronounced Psychological Strengths

Subjective well-being was assessed with different self-report measures to which those centenarians answered who were cognitively able to provide reliable responses. The single item asking whether they would laugh easily, as well as the question whether they would be as happy as at younger ages received affirmative responses from over half of the sample. Both questions were answered in the negative way by about one-tenth. That the remainder of the sample, namely about one-third of the centenarians, had difficulty to decide between yes or no despite sufficient cognitive

capacity, may suggest that questions about quality of life are not easy to be answered in very old age. Still, comparing the more recent cohort of centenarians with those of the first Heidelberg Centenarian Study suggests that today's centenarians felt more often as happy as when they were younger (Jopp et al. 2013). Using the Life Satisfaction Scale by Pavot and Diener (1993), a substantial majority of the sample, namely over 80%, indicated that they were satisfied with their lives. Comparing levels of life satisfaction between the HD100-II centenarians and young-old and old-old control groups revealed that the centenarians were on average as satisfied with their lives as the young-old and old-old controls (Jopp et al. 2013).

Among the demographic, health, social, and psychological variables, psychological strengths including self-efficacy, optimistic outlook, meaning in life, and will to life showed the strongest links to life satisfaction. Optimistic outlook was the strongest significant predictor of individual differences in life satisfaction. Thus, psychological strengths are, in comparison with health and various objective conditions, very important for experiencing life as satisfying at age 100 (Jopp et al. 2013), a finding that replicates and extends prior analysis from HD100-I.

Conclusions from Both Studies

The Heidelberg Centenarian Studies revealed that substantial interindividual differences exist at the end of the human life span confirming the hypothesis that even extremely long living individuals do not age in the same way. Intraindividual variability was observed between domains (physical functioning, cognition, and well-being) and within one area (cognitive functioning). Noteworthy are cohort differences favoring the later born, they are less physically frail and to a larger extent cognitively intact. In spite of these improvements in physical and cognitive functioning, the high need for care is unchanged. This result raises the question what can be done to increase capacity levels to maintain autonomy and reduce care need.

Regarding health, the pattern of findings seems to highlight that centenarians are protected from lethal diseases, maybe due to their genetic dispositions. Sensory and mobility impairments are the dominating health problems. Emerging health profiles further indicate that even in very advanced age, quality of life may be improved by enhanced diagnostics and optimal disease management as well as preventive measures and interventions. Care arrangements of the very old will be different in the future with more professional help and less family support, which calls for the adjustment of current service models and related policy to account for the unique needs of this growing population.

Although living at the age of 100 is in many cases characterized by strong limitations, substantial health problems, and the risk of reduced social networks, both cohorts coped remarkably well with these challenges. The psychological makeup of centenarians seems to be more adequate for a very long life than the physical architecture.

Synonyms

Allostatic load; Bioindicator; Stress

Definition

A biomarker is an indicator that reflects both normative and pathological biological processes.

Historical Origins

It is always difficult to date the birth of a new approach without disregarding the important contributions of many scholars that paved the way long before its emergence. However, it seems safe to say that the late 1940s created a unique breeding ground for aging research to combine both psychological and medical perspectives, which subsequently led to a proliferation of new theoretical models and empirical evidence on how psychological and biological factors interact to shape aging outcomes (Birren and Schroots 2000). An increased recognition of demographic changes as well as altered disease patterns during this period launched the founding of a new multidisciplinary society for the study of aging that continues to foster the cross-fertilization of psychosocial and biomedical science perspectives (Gerontological Society of America in 1945), the development of an aging unit within the National Institutes of Health in the United States of America (1946), and the World Health Organization's definition of health which explicitly recognizes the important role of not just biomedical but also psychosocial factors in shaping health and well-being across the lifespan (Birren 1961; World Health Organization 1948). Today, many prominent theories of lifespan development and aging explicitly call for an examination of the complex interplay between psychosocial and biomedical factors (Baltes et al. 2006; Finch and Seeman 1999; Schaie 2001). The purpose of this entry is to provide a theoretical backdrop for the kinds of questions that can be addressed when including biomarkers in psychological aging research, to highlight recent advances in the field, and to foreshadow avenues for future research involving biomarkers.

Aging Research at the Intersection of Psychology and the Medical Sciences

Contemporary psychological and biological aging theories both call for an interdisciplinary approach to the study of adult development and aging (Baltes et al. 2006; Finch and Seeman 1999). For example, a central tenet of lifespan psychology is the inherently incomplete architecture of human ontogeny according to which biological make-up and psychological, social, and material resources influence each other in systematic ways from conception to very old age. In this context, development is characterized by three factors: (a) an age-related decrease in biological plasticity across the lifespan; (b) an increased need for psychosocial, material, and knowledge-based resources (culture); and (c) an age-related reduction in the efficiency of psychosocial, material, and knowledge-based resources in counteracting biological losses. Despite the interdisciplinary anchoring of this perspective, the ultimate goal of lifespan psychology remains to delineate the specific psychological mechanisms, such as selective optimization with compensation, that promote successful aging (Baltes et al. 2006). Stress theories of aging also embrace a uniquely interdisciplinary perspective by explicitly taking into account the role of social and environmental factors when trying to better understand individual differences in biological wear and tear and how it is associated with age-related pathologies. Notwithstanding this clear interdisciplinary orientation, the main focus of this perspective consists of identifying the specific biological mechanisms underlying age-related losses in resiliency as well as increases in disease risk (Finch and Seeman 1999). The high value that is placed on interdisciplinary approaches and the explicit recognition that a better understanding of the multi-directionality and dimensionality of aging requires a coordination of efforts between different disciplines has not only resulted in the launch of a substantial number of highly influential aging studies (Schaie and Hofer 2001); it has also created a platform for the

generation and communication of findings that matter across traditional disciplinary boundaries.

Advantages and Challenges of Using Biomarkers in Geropsychology

Geropsychologists profit from recent advances in the biomedical sciences which provide the field with a historically unprecedented large repertoire of biomarkers reflecting different biological processes that can be utilized to better understand how psychosocial factors influence health with aging (Miller et al. 2009; Piazza et al. 2010). Commonly used biomarkers indexing sympathetic-adrenal-medullary and hypothalamic-pituitary-adrenal activity as well as immune functioning have been summarized by Piazza and colleagues (Piazza et al. 2010) along with a brief definition, their specific functions, any age-related changes, and their association with specific diseases. Importantly, this tremendous opportunity comes with the challenge to be crystal clear about which biomarkers may be best suited to address a specific question under investigation. For example, there is a certain appeal to including biomarkers such as salivary cortisol in psychological studies because they are easy to collect. However, salivary cortisol is but one biomarker that may be worth considering. There is in fact a whole array of established neuroendocrine, cardiovascular, immune, or metabolic markers targeting different biological systems that can be collected using specimens such as saliva or blood or by taking electronic readings (Piazza et al. 2010). Furthermore, depending on the research question, it may make sense to specifically target one biomarker, for example, cortisol, or to sample multiple markers that may provide answers to systematic interactions between different biological systems (e.g., cortisol to index hypothalamic-pituitary-adrenal activity, alpha amylase for sympathetic-adrenal-medullary activity, and proinflammatory cytokines as immune system markers; (Nater et al. 2013a)). Finally, different biomarkers capture processes that occur on vastly different timescales and that involve different system

levels. For example, a psychologist interested in psychosocial predictors of hypothalamic-pituitary-adrenal activity has to make a priori decisions about whether to sample cortisol in saliva which fluctuates on an order of minutes, whether to collect cortisol in hair which changes on an order of months, or whether to target DNA methylation patterns in glucocorticoid receptor genes that may reflect relatively long-lasting early-life experiences (Miller et al. 2009; Nater et al. 2013a). Taken together, the tremendous array of different biomarkers that is available today has the potential to truly propel psychological aging research forward, but it also comes with the need to be mindful about which biological mechanism(s) to target and what time course to select to meaningfully interpret respective findings.

Biomarkers in Geropsychology: The Sample Case of Research on Social Relationships

The following sections introduce a small subset of studies on social relationships and health that have been conducted over the past decades to illustrate a number of different research approaches that have significantly added to the current knowledge on the mechanisms linking social factors and health with aging. In doing so we point to the different methodological approaches that have been taken and highlight the role of biomarkers in identifying different pieces of the larger overall puzzle.

In the late 1970s, the Alameda County study provided groundbreaking evidence that an individual's number of social ties predict all-cause mortality over and above the important role of age, gender, socio-economic status, body mass, health behaviors, health care utilization, and self-reported health (Berkman and Syme 1979). This landmark finding has been replicated across several long-term longitudinal studies (House et al. 1988) and put social relationships on the map of health psychological and aging research, stimulating a broad array of subsequent research

aimed at better understanding underlying psychological mechanisms and biological pathways.

One such approach that has been pursued since the 1990s, for example, in the context of the MacArthur Studies of Successful Aging, combines different biomarkers into an allostatic load index (Seeman and Gruenewald 2006). The model of allostatic load is based on the idea that a repeated or chronic activation of various bodily systems that are activated in response to different stressors can lead to bodily wear and tear and a loss of resiliency that increase the risk for a broad spectrum of negative aging outcomes including but not limited to accelerated cognitive decline, chronic disease, and early mortality (Seeman and Gruenewald 2006). Allostatic load has been operationalized as a cumulative index that quantifies the number of biomarkers across multiple biological systems (cardiovascular system, hypothalamic-pituitary-adrenal axis, sympathetic nervous system, metabolic and inflammatory markers, lung and renal function) for which an individual scores in the highest risk quartile (Seeman and Gruenewald 2006). Long-term longitudinal research using this biomarker-based index of allostatic load filled the gap between previous evidence on the association between one's number of social ties and mortality by demonstrating that individuals with high-quality social relationships showed reduced stress-related wear and tear in midlife and old age (e.g., Seeman et al. 2002). One core strength of this approach is the comprehensive assessment of biomarkers across multiple biological systems, which has significantly increased our understanding of how not just the quantity but also the quality of social relationships get "under the skin" to shape health with aging.

Another more recent line of research has targeted processes that occur on much shorter timescales, such as hours or days, using combinations of repeated daily life assessments and concurrent assessments of biomarkers in saliva (Piazza et al. 2010; Hoppmann and Riediger 2009; Stawski et al. 2013). For example, research from the National Study of Daily Experiences has shown that the occurrence of daily life stressors such as arguments with others or work overload is

associated with an increased overall secretion of cortisol on that day (Stawski et al. 2013). In another study, it has further been shown that positive social exchanges such as intimacy with one's partner buffered the negative effect of chronic stress on daily cortisol outputs (Ditzen et al. 2008). To date, salivary cortisol is probably the most frequently used biomarker in studies using daily life assessments (Piazza et al. 2010). Despite its popularity and ease of use, salivary cortisol is only one biomarker that can be fruitfully implemented to delineate the mechanisms underlying social relationship-stress links. More recent work has also targeted other salivary biomarkers related to the hypothalamus-pituitary-adrenal axis, such as dehydroxyepiandrosterone-sulfate (DHEA-s), demonstrating that family members providing care to individuals with dementia display elevated daily DHEA-s outputs on days after using adult day service programs and when experiencing increased positive mood (Zarit et al. 2014). Furthermore, daily life assessments have included markers of sympathetic-adrenal-medullary activity such as salivary alpha-amylase (Nater et al. 2013b). A particular strength of study designs combining daily life assessments and biomarkers in aging research is their ability to capture life as it is lived. However, repeated daily life assessments also involve unique requirements regarding procedures for the assessment of biomarkers, for example, regarding ease of use and nonintrusiveness.

Finally, there is a large body of experimental research using biomarkers that has led to a much better understanding of the role of social relationships in modulating biological stress responses. For example, the introduction of the Trier Social Stress Test (TSST) has led to a proliferation of research searching for psychosocial moderators of the well-documented association between social-evaluative threat and hormonal as well as cardiovascular stress responses (Dickerson and Kemeny 2004; Kirschbaum et al. 1993). Of note, recent research using this experimental paradigm has started to integrate biomarkers at different system levels. For example, a recent study demonstrates that being supported by a close social other is associated with reductions in TSST-induced

cortisol responses but that such reductions depend on the presence of specific oxytocin receptor gene polymorphisms (Chen et al. 2011). This little snippet of the much larger experimental literature on social relationships and health showcases the value of taking the rich findings that have been generated by long-term longitudinal aging studies as well as studies using daily life assessments back into the lab to pinpoint the psychological mechanisms and biological pathways that link social relationships with aging outcomes under controlled laboratory conditions.

The selection of studies on social relationships and health described above illustrates the potential of implementing biomarkers into psychological aging research. However, they only represent a small segment of research in this area. Similar arguments could have been made regarding the role of other psychological factors for aging outcomes such as cognition, personality, or emotions and the use of different indices (e.g., cardiovascular reactivity, health behaviors).

Future Directions

Biomarkers have a tremendous potential to enrich psychological aging research. In the next section we highlight several issues that demand further attention and that should be tackled to move the field forward.

Biomarkers clearly are a “hot” topic in geropsychology. However, they have to be taken for what they are – markers that reflect biological processes in a specific system of the body. Something that is sometimes overlooked but nevertheless important is that any given biomarker is influenced by a multitude of different factors including psychological, biological, and environmental processes which have to be taken into account in order to make sense of the generated findings. For example, there is a proliferation of psychological aging research looking at salivary cortisol as a biomarker of stress. Yet, this biomarker captures far more than just the psychological origins of stress that may be of core interest to a given researcher. In fact, biological and environmental factors with documented influence on

salivary cortisol include age, sex, body mass, menstrual cycle, certain neurological disorders, infections, time of day, medication and substance use, and physical activity just to name a few (Kudielka et al. 2012) which have to be considered as well when aiming to draw conclusions about the association between psychological stressors and hypothalamic-pituitary-adrenal reactivity. Salivary cortisol consequently should not be mistaken as an “objective” measure of psychological stress but rather as an additional indicator that may be fruitfully used to complement self-reported measures of psychological stress or negative affect because it provides an additional perspective.

Lifespan psychologists have long called for an integration of processes that occur along different timescales (Gerstorf et al. 2014; Nesselrode 1991). For example, combining repeated daily life assessments that capture processes that unfold on a timescale of hours or days with assessments of long-term longitudinal change that occur over years or even decades represents a quantum leap in aging research because it helps address such key questions as how daily life experiences may accumulate over time to shape long-term health outcomes. For example, recent evidence shows that affective reactivity to daily life stressors is associated with an increased risk of reporting chronic health problems 10 years later (Piazza et al. 2013). In addition, there is merit to combining the strengths of experimental and long-term longitudinal approaches. For example, recent evidence from the Whitehall II cohort shows that individuals responding with more pronounced cortisol secretion to a lab stressor had an increased risk of having hypertension 3 years later (Hamer and Steptoe 2012).

Finally, much has been said about the merit of interdisciplinary endeavors, but a lot less is typically mentioned about the challenges that go along with it. Cultivating interdisciplinarity while at the same time making sure that each researcher contributes the unique insights of their specific discipline probably requires a rethinking of academic training to better prepare the next generation of aging researchers for navigating complex interdisciplinary endeavors and

adding value to them based on their discipline-specific expertise. Consequently, new training programs have emerged that are situated at the intersection of psychology and the medical sciences including health psychology and gerontology programs, whose graduates will take psychological aging research that uses biomarkers to the next level. Graduate programs that focus on specialized topics, such as human development in a changing world, integrate an even richer array of psychological, biological, sociological, educational, and anthropological perspectives.

History of clinical psychology of aging

Definition

History of applying the knowledge and methods of psychology to understanding and helping older

persons and their families to maintain well-being, overcome problems, and achieve maximum potential during later life.

Introduction

The second half of the twentieth century witnessed the emergence of the scientific study of aging for many medical as well as social science disciplines. Psychological research on cognition, emotions, and psychopathology in later life gained momentum in the 1950s and 1960s, first through cross-sectional studies and eventually progressing to longitudinal and sequential research paradigms. In the 1970s and 1980s, practice and training in clinical geropsychology took root, with the application of the science of the psychology of aging to improving the lives of older adults, their families, and the communities wherein they reside. In the 1990s, progress in neuroscience methods and findings contributed greatly to a richer understanding of biological processes of aging and their influence on psychological functioning. From 2000 onward, a greater emphasis on positive psychology in general, and its application to later life specifically, has again broadened the understanding of the experience of aging. Alongside these scientific gains are challenges for meeting the mental health needs of growing numbers of older adults in both the developed and the developing world. Clinical geropsychology – through research, practice, training, and advocacy – continues to contribute to meeting these growing needs and, as a profession, seeks to increase its ranks to meet the demographic challenges of the coming decades.

In this entry, we have four principal aims. First, we describe how the theory and science of geropsychology – in domains of theory of adult development, cognition and intelligence, emotional and personality, and sociocultural contexts – inform clinical geropsychology as a professional field of practice. Second, we review findings in the growing science of clinical geropsychology in domains of psychopathology, assessment, intervention, and integrated care. Third, we provide an overview of growing

resources for the field of clinical psychology in terms of professional organizations, journal, and books. Finally, we share developments in the growth of clinical geropsychology as an area of professional practice and training in the United States and globally, including areas of challenge and opportunity.

Clinical Geropsychology Defined

Clinical geropsychology refers to the application of the knowledge and methods of clinical psychology to meet the behavioral and mental health needs of older adults and families. Older adults are generally defined as those persons over the age of 65, with the decades after 65 usually denoted as “young-old” (65–75), “old-old” (75–85), and “oldest old” (85+). Changing demographics globally mean that, in both the developed and the developing world, the proportion of people over 65 continues to grow, with the greatest growth seen in those over age 85.

According to the American Psychological Association definition of the specialty of geropsychology, this field works toward “understanding and helping older persons and their families to maintain well-being, overcome problems and achieve maximum potential during later life. Professional geropsychology appreciates the wide diversity among older adults, the complex ethical issues that can arise in geriatric practice and the importance of interdisciplinary models of care.” (See <http://www.apa.org/ed/graduate/specialize/gero.aspx> for more details.)

Historical Trends in Geropsychological Science: Implications for Clinical Geropsychology Practice

The science of psychology and aging has grown tremendously in the past few decades. Growing understanding of cognitive, emotional, and social aspects of aging are critical for informing geropsychology practice. Several areas of geropsychology theory research that have implications for clinical practice are highlighted here.

Theories of adult development. Theoretical frameworks in geropsychology have evolved over time. In speaking about aging processes, Birren and Renner (1977) acknowledged that persons can experience incremental as well as decremental changes over time, and later Birren and Cunningham (1985) commented on geropsychology’s interest in differences and changes in behavior which occur with age, but also its interest in “patterns of behavior shown by persons of different ages in different periods of time” (pg. 18). Earlier theories focused more so on decremental changes over time. For example, disengagement theory (Cumming and Henry 1961) posited that later life was characterized by physical, psychological, and social disengagement, viewed as a response to declines in functioning and an increased interest in turning inward, away from active engagement in the world. In contrast, more recent conceptual frameworks emphasize adaptive strategies by older adults with agency to pursue active and successful late-life trajectories. For example, Selection, Optimization, and Compensation (SOC) theory (Baltes and Baltes 1990) proposed a framework to understand successful development and aging, by the individual’s active use of strategies involving selecting goals, optimizing means to achieve said goals, and utilizing compensatory strategies as required in the face of diminished resources or other constraints. Similarly, Carstensen’s (1992) theory of socioemotional selectivity posits that, later in life, individuals are aware of diminishing time left to them and so actively pursue a strategy of focusing on a more selective network of socially fulfilling relationships.

These theoretical perspectives are critical for informing hopeful attitudes about change in late life, for both practicing psychologists and their older adult patients. For too long, and still, there have been common beliefs that older adults could not change longstanding habits nor benefit from psychotherapy. While this has been disproven by research evidence, stereotypes can be difficult to challenge. Clinical geropsychologists understand that older adults have many strengths and strategies for adapting to difficult problems in late life.

Cognition/intelligence. When first studied in earnest, cognitive functioning in general and intelligence in particular were presumed to decrease in the face of increasing age. The cross-sectional cognitive studies of the 1940s and 1950s, which compared younger and older cohorts, appeared to support this view of steep and inevitable declines in intelligence with aging. However, data from longitudinal studies of cognitive functioning, such as the Seattle Longitudinal Study (Schaie 2005), have largely discredited this view. In fact, research supports a more nuanced view of cognitive functioning in later life, with some aspects of cognitive functioning holding steady into even advanced old age. For example, crystallized intelligence (learning from past experiences or prior learning) generally declines minimally later in life compared to fluid intelligence (Christensen 2001). Verbal abilities, particularly vocabulary and language usage, also have minimal declines in later life (Anstey et al. 2003). In contrast, speed of cognitive processing, some aspects of executive functioning such as performance on tasks requiring divided attention, and memory, particularly episodic memory, reflect aspects of cognition that not only decline with increasing age, but also may have a relatively accelerated rate of decline at more advanced ages (Anstey et al. 2003; Verhaeghen 2011).

Geropsychologists must understand and adapt psychological interventions to the cognitive strengths and challenges of older adults with whom they work, on an individualized basis. It is important not to assume cognitive decline nor to ignore possible cognitive changes that may need to inform a treatment plan. Most older adults maintain some (if not many) cognitive strengths and these can be optimized. Likewise, interventions can be adapted for slower processing speed (e.g., slow the pace and ensure points are being understood), possible changes in executive functioning (e.g., provide structure for sessions), and memory (e.g., keep a therapy notebook to track lessons being learned). As needed, family or team members can be engaged to support psychological interventions.

Emotion and personality. Like cognitive functioning, in contrast to assumptions, stereotypes,

and early theories of emotion and personality in late life, aging does not generally bring negativity, depression, declines in well-being, nor disengagement from relationships. Research over the past few decades has painted a complex and nuanced picture of emotional life in old age. In general, aging is associated with lower negative affect, stable positive affect, higher positive versus negative affect, and increased subjective well-being (Charles and Carstensen 2010). The maintenance of well-being in the context of frequent physical and interpersonal losses in late life has a number of elegant theoretical explanations related to increased capacity for emotional regulation and/or self-management in late life, including SOC, socioemotional selectivity theory, strength and vulnerability integration (Charles 2010), and self-management of well-being (Steverink et al. 2005). Many empirical studies have supported the basic tenets of these theories, with increasing attention over time to understanding individual and cultural differences (e.g., Fung et al. 2008). Likewise, the study of personality and aging has been characterized by diverse approaches for understanding nuances of inter- and intraindividual stability and change in traits over time and strategies for maintaining one's sense of self and identity (Ruth and Coleman 1996). In contrast to simple ideas regarding the impact of aging on personality, personality is increasingly viewed as both shaping and being shaped by one's experiences across the life span (Griffin et al. 2015).

This nuanced view of emotional functioning in late life is critical for geropsychology practice, again, for confronting ageist assumptions of both patients and clinicians. Patients who state "of course I'm depressed. . . I'm old" can be educated that depression is not a normative part of aging. Or, those who believe "you can't teach an old dog new tricks" can be taught about plasticity and adaptation across the life span and that behaving differently can help us to feel differently. Clinical geropsychologists can turn to these elegant theories of emotional adaptation in late life to help their patients with problem-solving, including the importance of optimizing strengths, identifying compensatory strategies, and emphasizing

positive life experiences (“pleasant events”) for optimizing positive affect.

Social/cultural/environmental contexts. Increasingly, the aging individual’s adaptation is viewed in social, environmental, and cultural contexts. Social relationships – positive and/or negative, with family, friends, and others – and their changes over the life course are critical determinants of health and well-being, in complex ways. Theoretical and methodological developments have helped to sort out some of these complexities (Antonucci et al. 2014). Early work by anthropologists studying aging highlighted the importance of sociocultural context on individual experiences of aging (Perkinson and Solimeo 2014). Older adults are tremendously diverse – in regards to gender, ethnicity, sexual orientation, religion, socioeconomic status, countries/regions of origin, and otherwise; experiences of aging interact with these multiple other components of diversity. These individual differences influence health beliefs, access to health care, family constellations and patterns of formal and informal caregiving, and health and mental health outcomes. Likewise, early work on the importance of fit between the individual’s abilities and environmental demands in influencing individual affect and behavior (Lawton and Nahemow 1973) have informed a growing field of design of living and work environments for older adults (e.g., Gitlin 2003).

Understanding and respecting diversity among older adults is a core component of competency-based geropsychology practice (APA 2014; Knight et al. 2009; Pachana 2015). Geropsychologists continually question assumptions and get to know the individual elder, allowing him/her to share his/her unique life experience, informed by the historical and cultural context in which he/she has lived. Likewise, geropsychologists ensure that their assessments include consideration of social and environmental factors that may be affecting the older adult’s functioning. These factors should inform development of a treatment plan. In many cases, intervening at the family system, health-care team, or residential community level may have a greater impact than intervening at the individual level

(especially in the case of older adults with significant cognitive impairment).

A Growing Science of Clinical Geropsychology

Psychopathology in late life. Research over the past several decades has helped to inform perspectives on the epidemiology, phenomenology, and etiology of mental illness across the life span. Psychopathology in late life is often characterized by complex comorbidities between medical, neurocognitive, and psychiatric conditions (Knight and Pachana 2015). For example, comorbidity between anxiety and depression in later life is high. In a study by Beekman and colleagues (2000), nearly 50% of those with major depressive disorder also met criteria for anxiety disorders, and just over a quarter of those with anxiety disorders also met criteria for major depressive disorder. There are extensive data about the negative reciprocal relationship between depression and medical illnesses in later life (Katon 2003) and a growing body of research about the similar reciprocal effects of comorbid anxiety and medical illnesses (Culpepper 2004). Increasing research has focused on suicidality in older persons as a serious mental health issue, both in terms of assessment and treatment. The evidence suggests that older adults who die by suicide are more likely than those at younger ages who die by suicide to be depressed and socially isolated, are more likely to use a firearm, are less likely to have substance abuse problems or to have made previous suicide attempts, and are more likely to have physical illnesses or functional impairments (Conwell and Thompson 2008).

There is also an increased literature on protective factors with respect to psychopathology and associated adverse outcomes. For example, with respect to risk of suicide, research has demonstrated that older adults with more psychological well-being and meaning in life (Heisel and Flett 2008), with a greater future orientation (Hirsch et al. 2006) and more positive affect (Hirsch et al. 2007), and with more reasons for continuing living (Britton et al. 2008) generally tend to have

lower levels of suicidal ideation. Current behavioral treatments for those at risk for suicide also make use of such data on protective factors (O'Riley et al. 2015). Similarly, protective factors for anxiety in later life include high levels of perceived social support, regular exercise, and higher levels of education (Vink et al. 2008).

Late-life anxiety and depression are also commonly expressed later in life in subthreshold presentations (Cassidy et al. 2005). Nevertheless, subclinical symptoms that do not meet formal diagnostic criteria for a mental disorder – e.g., minor depression – can affect functioning and health outcomes in older adults and are important targets for clinical intervention. An important issue is whether the criteria that define mental disorders (cite DSM-5) are always wholly appropriate for older adults, with risks of either over- or underdiagnosis of clinical problems.

Psychological assessment with older adults. The clinical interview is probably the most important part of assessment in general, and particularly with older adults, who may present with complex medical and psychosocial histories. Structured or semi-structured interviews hold distinct advantages over unstructured interviews with respect to reliability and validity (Edelstein and Semenchuk 1996) and are superior in assessing the presence and severity of psychiatric disorders and in monitoring change in symptoms over time, as compared with self-report instruments (Dennis et al. 2007). In terms of assessment tools, an increasing number of instruments have been developed specifically for older adults, focused on psychiatric symptoms, specific disorders, functionality, quality of life, and so forth, with more published every year. Also, normative data for mainstream tests, such as standardized batteries of intelligence, cognition, and personality, have improved normative databases for use with older persons. Although both assessment and intervention strategies have a paucity of data on their use in the oldest old populations, the proliferation globally of longitudinal aging studies and particularly centenarian and super-centenarian studies are both providing data as well as spurring increased research on this population.

Some interesting trends in the assessment of older adults are tests designed for particular cultural populations (e.g., the Kimberley Indigenous Cognitive Assessment tool, or KICA, by LoGiudice and colleagues, 2006), and online tests are increasingly used for diagnosis of dementia and related disorders (e.g., the Cambridge Neuropsychological Test Automated Battery, or CANTAB, by Sahakian and colleagues (1988)). Psychologists are also strengthening their visibility in several assessment domains including competence and decision-making capacity assessments (Lichtenberg et al. 2015b; Moye et al. 2013), and elder abuse and neglect (Mosqueda and Olsen 2015).

Geropsychological intervention. In the health and mental health-care arena, out-dated ideas that older adults are rigid and unlikely to change in later life have been countered by growing research demonstrating that older adults are just as likely as younger adults to benefit from psychological interventions to address problems including depression, anxiety, sleep difficulties, pain, sexual dysfunction, diet, and exercise (Lichtenberg et al. 2015b; Perkinson and Solimeo 2014; Scogin and Shah 2012). Over the past 20–30 years, research is demonstrating that older adults can benefit from behavioral, cognitive-behavioral, interpersonal, problem-solving, and a range of other psychotherapy approaches, with similar efficiency and efficacy rates to younger populations (Cuijpers et al. 2014; Pinquart et al. 2006, 2007). Further, studies of real-world effectiveness of evidence-based psychotherapies in the Veterans Health Administration are demonstrating that older Veterans benefit from these interventions as much as do younger Veterans (Karlin et al. 2013; Karlin et al. 2015a, b). In recent years, adaptations to psychotherapeutic approaches are being made to meet the needs of older adults with mild to moderate cognitive impairment (e.g., Kiosses et al. 2015; Simon et al. 2015). Likewise, research has grown demonstrating effectiveness of psychological interventions for addressing aging-specific concerns including non-pharmacological management of behavioral concerns among people with dementia (Logsdon et al. 2007), stress/distress among caregivers of

older adults (Gallagher-Thompson and Coon 2007), and cognitive training to improve cognitive abilities and everyday functioning (Willis et al. 2006).

Integrated care models. Most older adults access mental health services through primary care, or other medical care, settings rather than through specialty mental health services. Research over the past decade increasingly supports integrated models of care, wherein collaborative, care management, and stepped care models allow for recognition, treatment, monitoring of treatment response, and referral to specialty care as needed. Such integrated care models have research support for the management of late-life depression (Hunkeler et al. 2006), suicidality (Alexopoulos et al. 2009), serious mental illness (Mueser et al. 2010), and alcohol abuse (Oslin et al. 2006). Ongoing research on clinical outcomes and cost-effectiveness will hopefully inform policy that supports funding for psychological practice in primary and other integrated care settings.

Growth of a Field: Professional Organizations, Training, and Publications

Professional organizations. Within psychology in the United States, the American Psychological Association's Division of Adult Development and Aging (Division 20) was established in 1946, originally called "The Division on Maturity and Old Age." This Division focuses broadly on the study of psychological development and change throughout the adult years, rather than specifically on clinical practice, but counts among its members many clinical geropsychologists. Psychologists in Long-Term Care (PLTC) was established in 1981. PLTC is "a network of psychologists and other professional dedicated to the enhancement of mental health and quality of life for those involved in long-term care through practice, research and advocacy" (from www.pltcweb.org). In 1993, "Section 2," that is, the section of clinical geropsychology, of APA's Division of Clinical Psychology was established.

That section, now called the Society of Clinical Geropsychology, states its vision as follows: "to foster the mental health and wellness of older adults and wellness of older adults through science, practice, education and advocacy and to advance the field of professional geropsychology" (from www.geropsychology.org). The APA Committee on Aging (CONA) was established in 1998, with the mission to ensure that older adults receive the attention of APA governance, in activities related to science, practice, policy, education, public interest, and public affairs. The APA Office on Aging was established to coordinate APA activities related to aging and geropsychology (see www.apa.org/pi/aging/). As described further below, the past decade has seen multiple initiatives to advance the profession of geropsychology in the United States, including publication of the APA's *Guidelines for Psychological Practice with Older Adults* (APA 2004, 2014) and establishment of the Council of Professional Geropsychology Training Programs (CoPGTP).

The past several decades have seen the growth of a range of professional organizations outside of the United States with either a focus on, or inclusive of, geropsychology. The multidisciplinary International Psychogeriatric Association (IPA) is concerned with promoting better mental health for older people (<http://www.ipa-online.net/>). IPA hosts annual conferences and has a particular focus on cross-national information sharing with respect to mental health, particularly with respect to the developing world. IPA has also developed a well-respected set of resources on behavioral and psychological symptoms of dementia – the *IPA Complete Guides to Behavioral and Psychological Symptoms of Dementia (BPSD)*. Various national psychological associations have sections devoted to geropsychology (e.g., the Faculty for the Psychology of Older People (FPOP), within the Division of Clinical Psychology of the British Psychological Society, and the Psychology and Ageing Interest Group (PAIG) of the Australian Psychological Society (APS)). There are also free-standing geropsychology groups in many countries (e.g., the New Zealand Psychologists of Older People (NZPOPs) group).

Journals. In recent decades, there has been an explosion of peer-reviewed geropsychology

research published in the field, in both journals devoted to psychological issues of aging as well as general psychology/mental health and/or gerontology/geriatric journals that increasingly include geropsychology topics. Common outlets for research on geropsychology more broadly include the APA's *Psychology and Aging* and the GSA's *Journals of Gerontology: Psychological Sciences*. Others more specifically aimed at clinical research, including clinical geropsychology, include *Aging and Mental Health*, *Clinical Gerontologist*, and *International Psychogeriatrics*.

Books. The earliest scholarly books on psychology and aging were published in the late 1950s through early 1970s as the science was developing at that time (e.g., Birren 1959). The late 1970s through to early 2000s saw increasing numbers of books published on adult development and aging, cognitive aging, and the clinical psychology of aging (e.g., Hersen and Van Hasselt 1998; Edelstein 2001). Over time, handbooks in geropsychology have provided scholarly updates in the field. One of the most widely known of these resources, *Handbook of the Psychology of Aging*, is in its 7th edition (Schaie and Willis 2011), initially published in 1977 (Birren and Schaie 1977); clinical geropsychology perspectives have always been prominent in this series. In the clinical geropsychology arena specifically, such handbooks provide scholarly updates of wide-ranging late-life behavioral and mental health concerns, and their assessment and treatment. Recent examples include *Handbook of Assessment in Clinical Gerontology, Second edition* (Lichtenberg 2010), *APA Handbook of Clinical Geropsychology* (Lichtenberg et al. 2015a), and *Oxford Handbook of Clinical Geropsychology* (Pachana and Laidlaw 2014), the latter with a more international focus. Textbooks on adult development and aging, psychology and aging, and mental health and aging abound, in comparison to very few such resources just four to five decades ago.

Developments in Clinical Geropsychology Practice and Training

Geriatric health and mental health care. Psychology as a field was relatively slow to join other

health-care professionals that were developing specialized practices regarding care of older adults. The interdisciplinary geriatric health-care team for decades has included physicians, nurses, social workers, pharmacists, and others but only more recently, in some care systems, psychologists (e.g., Karlin and Zeiss 2010). Across professions, however, there is a geriatric health-care workforce crisis (Institute of Medicine 2008). The global geriatric health and mental health workforce will fall far short of the health-care needs of older adults going forward, in all countries of the developed and the developing world (National Institute on Aging and World Health Organization 2011). The projected estimated needs for mental health specialists in general and geropsychologists in particular has been a concern for many years (Institute of Medicine 2012; Karel et al. 2012). Given demographic trends, this situation is of growing concern internationally (Laidlaw and Pachana 2009).

A historical perspective on mental health and aging in the United States over the past 4–5 decades is presented in a series of papers by Margaret Gatz and Michael Smyer (Gatz et al. 1980; Gatz and Smyer 1992; Gatz and Smyer 2001; Karel et al. 2012). They track epidemiological, societal, policy, health system, and professional factors that have influenced mental health care for older adults. The 1970s and 1980s saw very little systematic or coordinated attention to the mental health needs of older Americans, although 1989 did see expansion of Medicare, the primary health-care insurer of older adults, to cover services by psychologists. The 1990s saw some progress in higher profile recognition of the issue (e.g., Surgeon General's report and White House Conference on Aging resolutions on mental health and aging), early advocacy for integrated care models, expanded publication of practice guidelines related to geriatric mental health conditions, and growing evidence base regarding the efficacy of psychotherapy with older adults (despite emphasis on medication treatments). The early 2000s saw ongoing development and policy support for integrated care models, move toward parity of Medicare funding for mental health services, national attention to the geriatric

workforce crisis, a growing evidence base to inform geropsychology practice, and delineation of a competency-based geropsychology training model. Ongoing challenges include funding for geriatric mental health practice, training, and research, and the need to prepare a health-care work force to meet the health and mental health needs of an aging population.

Clinical geropsychology in the United States. In the United States, a series of conferences dedicated to clinical geropsychology training have supported the development of training models, resources, and programs over time. The 1981 *Conference on Training Psychologists for Work in Aging* was held in Boulder, Colorado, and thus dubbed the “Older Boulder” conference, after the historic 1949 Boulder Conference that established the scientist-practitioner model of clinical psychology training in the United States. The 1981 conference focused on graduate education curriculum development, continuing education and retraining, recruitment and retention, services and settings, psychosocial knowledge base, and biopsychological knowledge base for geropsychology training (Santos & VandenBos 1982). However, despite a constructive vision of training in the field, many barriers existed for implementation of conference recommendations (Hinrichsen *in press*). In 1992, the “Older Boulder II” conference (held in Washington, DC) was sponsored by the National Institute of Mental Health and the APA; the conference continued to define the knowledge base for clinical geropsychology practice and demarcated three levels of geropsychology training/competence: exposure, experience, and expertise (Knight et al. 1995). Of note, a task force established at that conference drafted a report that was later adopted and published as the APA’s *Guidelines for Psychological Practice with Older Adults* (APA 2004, 2014).

The National Conference on Training in Professional Geropsychology, held in Colorado Springs, CO, in 2006, aimed to delineate attitude, knowledge, and skill competencies for clinical geropsychology training and training models at graduate, internship, fellowship, and post-licensure levels. The conference outcome

was the *Pikes Peak Model for Training in Professional Geropsychology* (Knight et al. 2009), which has helped to inform training program development in recent years. Shortly after the “Pikes Peak conference,” the Council of Professional Geropsychology Training Programs (www.CoPGTP.org) was formed, in order to recognize programs (both within the United States, and more recently, internationally) that provide training consistent with the Pikes Peak model and to share training resources. A CoPGTP Task Force developed the Pikes Peak Geropsychology Knowledge and Skill Assessment Tool (http://www.copgtp.org/uploads/documents/Pikes_Peak_Evaluation_Tool.pdf), which can be used by trainees and supervisors alike to define training needs in the field. The GeroCentral website (<http://gerocentral.org/>) – a cooperative effort to bring together resources for geropsychology practice, training, policy, and research – offers an online version of this competency self-assessment tool.

These efforts to delineate a training model for the field lead to APA recognition of Geropsychology as a specialty area of psychological practice in 2010. The American Board of Professional Psychology (ABPP) started to provide Board Certification in Geropsychology in 2013 (see www.abpp.org).

Clinical geropsychology globally. Europe, as the seat of the World Health Organization (WHO), has been concerned with health practice and policy on a global scale. The European Federation of Psychologists’ Associations (EFPA) set up a task force on geropsychology on the continent, in order to better coordinate its responses to European and global health and policy initiatives concerning aging (EFPA 2005). Data was collected on the state of geropsychology with respect to profiles of research productivity and training goals, to delineate contexts where geropsychologists could contribute their expertise toward improving the well-being of older persons. Countries surveyed ($N = 25$) included Austria, Belgium, Byelorussia, Bosnia-Herzegovina, the Czech Republic, Denmark, Estonia, Germany, Great Britain, Greece, Hungary, Iceland, Israel, Italy, Lithuania, Macedonia, Netherlands, Norway, Portugal, Serbia, Spain, Sweden,

Switzerland, and Turkey. Some interesting findings from this survey included the relative focus of cognitive and dementia-related research relative to research on intervention and prevention, and the fact that overall more funding for geropsychology research was obtained from foundations as opposed to state/national research funding schemes. With respect to teaching, geropsychology postgraduate programs were available in Austria, the Czech Republic, Denmark, Germany, Greece, Israel, Netherlands, Norway, Switzerland, Sweden, and Spain. Approximately 30% of countries reported geropsychology is a regular topic of postgraduate training in clinical psychology or psychotherapy training programs. One strong recommendation of this task force was to increase publication of aging research within European journals (whether or not in English), and the (at that time) new European Journal on Gerontology was seen as an important step forward (see also Wahl et al. 2013). Since then other new European journals (e.g., *GeroPsych: The Journal of Gerontopsychology and Geriatric Psychiatry*) have been established.

Geropsychology or, more accurately, psychology with older adults has had a shorter history outside of Europe and North America (Pachana 2014). In Australia and New Zealand, societies or interest groups for psychologists interested in older persons have flourished with increasing numbers for the last 25 years. In Asia and South America, geropsychology and its interest in research, clinical practice, and training is more recent but growing swiftly, again driven in part by aging demographics in these countries and partly by the growing visibility of older adults and aging on the global stage (Pachana 2015).

Areas of challenge. Health-care costs continue to rise in line with the aging of the population globally and the rising instances of chronic disease and dementia later in life, which impacts on mortality, morbidity, and burden of disease (Lozano et al. 2012; WHO 2014). Despite shrinking research budgets, there are increasing calls in the literature for research on aging and ways to improve health and longevity (Jin et al. 2015). Calls for increased training of a geriatric literate mental health workforce, including psychologists,

have long been argued, but we are no closer to bridging the gap between future need and current workforce (Halpain et al. 1999; IOM 2012; Knight et al. 1995; Robiner 2006). Both training and research in geropsychology need to have an international focus to meet global mental health-care needs (Pachana 2014).

Areas of opportunity. Behavioral and mental health care are increasingly being conceptualized as important components of overall health care, in health-care systems around the world. Integrated care, wherein behavioral/mental health services are offered in primary care and other traditionally “medical” care settings, addresses the reality that stress and other behavioral factors contribute significantly to many health conditions and, conversely, that medical illness can contribute to or exacerbate mental health concerns. Expansion of geropsychological services in primary and geriatric health-care settings will allow greater access to these services for older adults. In the United States, these integrated care models are common in the Department of Veterans Affairs Health Care System (e.g., Kearney et al. 2014) and expected to grow given policy facilitators for such addressed in the Affordable Care Act (Rozenky 2014). An APA 2008 Presidential initiative addressed how psychologists can contribute to integrated health care for an aging population (APA 2008). Time will tell whether these promising care models will be widely adapted, and in what countries.

Increasing focus on wellness and adaptation in late life, including the concepts of “successful” or “positive” aging (Bar-Tur and Malkinson 2014; Depp and Jeste 2006; Hill 2011), is likely to see ongoing research and development of self-help, preventive, and clinical interventions. As consumers take increasing investment in health promotion, strategies for optimizing physical, cognitive, and emotional health will continue to grow. Psychologists will contribute to resources for an aging population to plan for positive adaptation in late life. For example, the APA Committee on Aging’s Life Plan for the Life Span provides recommendations for younger, middle-aged, and older adults to address well-being in domains of health and health care, legal and financial matters, work life and retirement,

psychological issues, and social roles and resources (<http://www.apa.org/pi/aging/lifespan.pdf>).

Technology will play an increasing role in health and wellness promotion for aging adults and for geropsychology practice. As the baby boomers are increasingly comfortable with computer technology, they will utilize growing Internet-based and smartphone applications related to health and mental health promotion, including cognitive training (e.g., Christensen et al. 2002) and caregiver interventions (Chi and Demiris 2015). Senior online communities provide expanding opportunities for social connection (Nimrod 2014). Smart home technologies are facilitating aging at home with optimal independence, safety, and quality of life (Demiris and Hensel 2008). At the same time, the use of assistive technologies will continue to raise a number of ethical questions including impact on privacy and autonomy (Zwijnsen et al. 2011). Geropsychology services may become accessible to growing numbers of older adults through tele-mental health technologies (e.g., Gellis et al. 2014; Ramos-Rios et al. 2012) and via expert distance consultation (e.g., Catic et al. 2014).

Conclusion

M. Powell Lawton, in his autobiographical contribution to *A History of Geropsychology in Autobiography*, concluded in part by saying: “In psychology [of aging] the major conceptual change I have observed is the move from the view of the elder as a pawn of biology and society toward one with overwhelming self-determining capacity” (Lawton 2000, p. 195). This observation provides an excellent summary of the historical trends presented here. The opportunities for plasticity, growth, and enhanced well-being in late life have, in part, driven development of research and practice in geropsychology. Psychologists around the world are able to work with older adults, their families, health-care teams, and communities to provide evidence-based psychological services to address problems, enhance coping, and promote well-being in late life. The opportunities

for “making a difference” in the lives of an aging population are limitless. A critical challenge is encouraging greater number of psychologists to join in this most meaningful and rewarding work, whether in research, teaching, or applied contexts.

have made major contributions to our current state of knowledge.

Introduction

Mental abilities have long been valued in Western culture as the basis for learning, problem solving, and adjustment. Thus, intelligence and cognitive development quickly became one of the major concerns for the earliest psychologists. Great efforts were made to define intelligence, to measure it, and even to try to increase it. The study of cognition has had a long and often stormy history. Indeed, the controversies are no less stormy today, as perhaps should be expected when dealing with a field of knowledge so highly esteemed.

The questions that we seek to answer are fairly simple, such as “Does intelligence increase or decline with age?” The answers, however, are more complicated; they vary with age, the specific intellectual function we are considering, and even the year in which the individual was born. This latter influence, which comprises a number of “generational” or “cohort” factors, is analyzed in some detail.

History of Cognitive Aging Research

Definition

Cognitive aging research includes the fields of intelligence and human abilities from young adulthood through advanced old age. It includes the major theoretical and methodological issues of concern in these fields as well as the identification of major findings of those systematic studies that

Adult Stages of Intellectual Development

What is the nature of intelligence in adults? How is it similar to the intelligence of young persons, and how does it change? If we are going to construct tests that are fair to older people, we must know more about adult cognition; we need to know in what sense people might increase their competence as they grow older.

The famous Swiss psychologist Jean Piaget described the ways in which children's intelligence increases as they develop (Flavell 1963). They learn simple but basic ways of perceiving and reacting to the world. “With the onset of speech, children enter a stage in which they grow primarily in the conceptual-symbolic rather than purely sensory-motor arena” (Flavell 1963, p. 121). This stage, called *preoperational*, is

History of Cognitive Aging Research, Fig. 1 Schaie's stages of adult cognitive development (Source: Schaie and Willis 2000)

H

succeeded around the age of 6 by the stage of *concrete operations*.

In Piaget's theory, operations are the mental routines that transform information in some way, for example, adding two numbers to get a third or categorizing, as in placing all red objects together. The stage of *formal operations* is entered around the age of 12 and is defined by the ability to use mental operations on abstract material. For example, an adolescent can solve a problem such as "If a suitcase can eat four rocks in 1 day, how many can it eat in 2 days?"

Younger children cannot imagine a suitcase that eats rocks, so they will refuse to solve the problem; they cannot disregard the content of the problems (its concrete aspects) and reason in a purely hypothetical way (using the form, or formal aspects, of the problem). Intellectual development, of course, is not complete at the age of 12 when the average child enters the stage of formal operations, but Piaget provides us with little detail on later development.

Although we can assume that there are advances in the use of formal operations, as people progress from "rock-eating suitcases" to elegant mathematical theories of the physical universe, no new Piagetian stages were specified for adulthood (Flavell 1970; Piaget 1972).

Psychologists who focus on adult development find this child-centered approach restrictive and wish to expand it so as to delineate those changes in the quality of intellectual function that they observe in adult study participants. As Erik Erikson and Daniel Levinson expanded the psychoanalytic stages of ego development to the adult years, these psychologists have done the same for Piaget's stages of intellectual development (see Commons et al. 1989, 2014; Commons and Ross 2008; Sinnott 1996).

A Stage Model of Adult Cognitive Development

K. Warner Schaie and Sherry Willis (Schaie 1977; Schaie and Willis 1999, 2000) have used findings from research on adult intellectual development to formulate six adult stages (Fig. 1). We begin with the observation that Piaget's childhood stages describe increasing efficiency in the acquisition of new information. It is doubtful that adults progress beyond the powerful methods of science (formal operations) in their quest for knowledge. Therefore, if one is to propose adult stages, they should not be further stages of acquisition; instead they should reflect different uses of intellect.

Application and Achievement. In young adulthood, for example, people typically switch their

focus from the acquisition to the application and integration of knowledge, as they use what they know to pursue careers and develop their families. This is called the achieving stage. It represents most prominently the application of intelligence in situations that have profound consequences for achieving long-term goals. These situations are not the hypothetical ones posed on IQ tests or encountered in classroom studies, nor are they the problems of childhood, whose solutions are closely monitored by parents and society. Instead, they are problems that the adult must solve for him- or herself, and the solutions must be integrated into a life plan that extends far into the future.

The kind of abilities exhibited in such situations is similar to those employed in educational tasks, except that it requires more careful attention to the possible consequences of the problem-solving process. Attending to the context of problem solving as well as to the problem to be solved may be thought of as being a quality control process like that used in industry when the consequences of a mistake are severe.

Social Responsibility. Young adults who have mastered the cognitive skills required for monitoring their own behavior and, as a consequence, have attained a certain degree of personal independence will next move into a stage that requires the application of cognitive skills in situations involving social responsibility. Typically, the responsible stage occurs when a family is established and the needs of partner and offspring must be met. Similar extensions of adult cognitive skills are required as responsibilities for others are acquired on the job and in the community (Hagestad and Neugarten 1985).

Executive Stage. Some individuals' responsibilities become exceedingly complex. Such individuals – presidents of business firms, deans of academic institutions, officials of churches, and a number of other positions – need to understand the structure and the dynamic forces of organizations. They must monitor organizational activities not only on a temporal dimension (past, present, and future) but also up and down the hierarchy that defines the organization. They need to know not only the future plans of the organization but

also whether policy decisions are being adequately translated into action at lower levels of responsibility. Attainment of the executive stage, as a variation on the responsibility stage, depends on exposure to opportunities that allow the development and practice of the relevant skills (Smith et al. 1994).

Reorganization. In the later years of life, beyond the age of 60 or 65, the need to acquire knowledge declines even more and executive monitoring is less important because frequently the individual has retired from the position that required such an application of intelligence. What, then, is the nature of competence in an elderly adult? As Schaie (1977) puts it, there is a transition from the childhood question “What should I know?” through the adult question “How should I use what I know?” to the question of later life “Why should I know?” This stage, *reintegration*, corresponds in its position in the life course to Erikson's stage of ego integrity. The information that elderly people acquire and the knowledge they apply is, to a greater extent than earlier in life, a function of their interests, attitudes, values, and physical health (Bowen and Staudinger 2013; Diehl et al. 1995; Heidemeier and Staudinger 2015). It requires, in fact, the integration of all of these.

The elderly are less likely to “waste time” on tasks that are meaningless to them. They are unlikely to expend much effort to solve a problem unless that problem is one that they value or that they face frequently in their lives (Berg and Klaczynski 1996; Staudinger and Glueck 2011). This stage also frequently includes a selective reduction of interpersonal networks in the interest of reintegrating one's concern in a more self-directed and supportive manner (Carstensen 1993; English and Carstensen 2014; Scheibe et al. 2013). Such efforts are likely to involve a reduction in information-seeking activities while increasing the importance of emotional regulation involved (Carstensen et al. 1997; Schaie and Carstensen 2006).

The original stages (Schaie 1977) were formulated some 30 years ago. Since that time we have learned a lot about the differentiation of our older population into distinct life stages. In the research

literature distinctions are now commonly made between the young-old, the old-old, and the oldest-old (or very-old). This differentiation is informed by the fact that today's young old are distinguished from the middle-aged primarily by the fact that the vast majority in this life period involves transition from the world of work full time to other pursuits. A major effort is now required to *reorganize* one's life in order to replace the earlier engagement with raising families and job responsibilities with meaningful pursuits for the last part of life (English and Carstensen 2014).

Efforts must also be directed toward planning how one's resources will last for the remaining 15–30 years of postretirement life that are now characteristic for most individuals in industrialized societies. These efforts include active planning for that time when dependence upon others may be required to maintain a high quality of life in the face of increasing frailty. Such efforts may involve changes in one's housing arrangements, or even one's place of residence, as well as making certain of the eventual availability of both familial and extrafamilial support systems. The activities involved in this context include the making of or changing one's will, drawing up advanced medical directives and durable powers of attorney, as well as creating trusts or other financial arrangements that will protect resources for use during the final years of life or for the needs of other family members.

Although some of these activities involve the same cognitive characteristics of the *responsible* stage, we believe that the objectives involved are generally far more centered to current and future needs of the individual rather than the needs of their family or of an organizational entity. Efforts must now be initiated to reorganize one's time and resources to substitute a meaningful environment, often found in leisure activities, volunteerism, and involvement with a larger kinship network. Eventually, however, these are activities also engaged in with the finitude of life in clear view, for the purpose of maximizing the quality of life during the final years and often with the objective of not becoming a burden for the next generation. The unique objective of these demands upon the

individual represents an almost universal process occurring at least in the industrialized societies, and designation of a separate reorganizational stage is therefore warranted.

Reintegration. The skills required for the reorganizational stage require the maintenance of high levels of cognitive competence, which is increasingly exercised within the parsimonious principles of selection, optimization, and compensation (cf. Baltes and Carstensen 1996; Baltes 1997; Baltes et al. 1999). In addition, maintenance of flexible cognitive styles is needed to be able to restructure the context and content of life after retirement, to relinquish control of resources to others, and to accept the partial surrender of one's independence (Schaie 1984, 1996).

More and more older persons reach advanced old age in relative comfort and often with a clear mind, albeit a frail body. Once the reintegrative efforts described above have been successfully completed, and perhaps temporally overlapping with them, there is yet one other stage that is frequently observed.

Legacy creating. This last stage is concerned with cognitive activities by many of the very old that occur in anticipation of the end of their life. We call this a legacy-creating stage that is part of the cognitive and psychosocial development of many, if not all, older persons. This stage often begins with the self- or therapist-induced effort to conduct a life review (Butler et al. 1991). For the highly literate and those successful in public or professional life this will often include writing or revising an autobiography (Birren and Schroots 2006).

There are also many other more mundane legacies to be left. Women, in particular, often wish to put their remaining effects in order, and often distribute many of their prized possessions to friends and relatives, or create elaborate instructions for distributing them. It is not uncommon for many very old people to make a renewed effort at providing an oral history or to document family pictures and heirloom to the next generation. Last but not least, directions may be given for funeral or memorial arrangements, occasionally including donation of one's body for scientific research, and there may be a final revision of one's will.

An approximate time line for the Schaie stage model is provided in Fig. 1. But it should be stressed that the precise chronological age at which these stages occur may be quite variable in different societies as well as for individuals at different levels of intellectual competence and personal engagement. What is important is the sequential process of these developmental stages.

Assessment of Cognitive Functions

Psychological tests were developed originally to identify individuals varying in intellectual function. Francis Galton (a half-cousin of Charles Darwin) believed that human intelligence is mostly inherited and, as a result, he urged his country (England) to begin a program of selective breeding. By allowing the most intelligent people to have the most babies, the English population would become smarter and smarter, claimed Galton; it would evolve to even greater heights in Darwin's phylogenetic tree.

A Test of Intelligence

How could the most intelligent people be identified? A test of intelligence would need to be created. Galton (1883) took on the job and in 1883 published the first intelligence test influenced by British philosophers who considered intelligence to be based on the ability to process sensory information. Galton devised a series of tasks designed to measure how well a person could see, hear, smell, taste, and feel. For example, in one task, the person was asked to lift two weights and say which was the heavier.

Galton's "mental test" (as he called it) was not very successful; it showed only trivial correlations with measures of intellectual competence in the real world, such as scholastic performance (Wissler 1901). Recent investigators, however, have revisited the relation between sensory functions and intelligence showing that Galton's intuitive choice of measures was not as off the wall as some contemporaries thought (cf. Galton 1883).

Almost 20 years later, a French psychologist by the name of Alfred Binet tried again to construct a test of intelligence. Binet did not intend to

better the French genetic stock. He had been given a much more practical problem to solve by the French Ministry of Public Instruction. They needed a test to distinguish students of low ability (mentally retarded) from those of adequate ability but low motivation.

Binet held a more traditional view of intelligence than Galton, believing, for example, that playing chess was a better indicator of intelligence than smelling vinegar. He decided to assess "reasoning, judgment, and imagination" by a series of cognitive problems rather than sensory tasks. Instead of lifting weights, for example, the child was asked to tell the difference between "yesterday" and "tomorrow." Because Binet's miniature tasks were quite similar to those that children experienced in school, scores on his test were highly correlated with scholastic performance. First published in 1905, Binet's test (Li et al. 1999) was quickly translated into other languages, including English. In the United States, his test was translated and revised by Stanford psychologist Lewis Terman in 1916 and became known as the widely employed Stanford-Binet Intelligence Scale.

Terman's first revision of the Stanford-Binet scale introduced the concept of the intelligence quotient, or IQ. Binet had arranged his test in age scales, each consisting of four to eight items, such that children of a certain age should be able to pass. A 6-year-old child who passed all the items for 7-year-olds (but no more) was said to have a "mental age" of 7, even though his or her chronological age was 6.

Terman divided the mental age obtained from the test by the chronological age to get the child's IQ. In our example the child with a mental age of 7 and a chronological age of 6 has an IQ of $7/6 = 1.17$, multiplied by 100 to clear the decimal, or 117. An average IQ by these standards is obviously 100, and 117 indicates a somewhat brighter than average youngster.

The Nature of Intelligence

From the very beginning, there has been a great deal of debate about the nature of intelligence and whether there may be different kinds of intelligence. Is intelligence a single, general ability or

are there several different intellectual abilities? Binet favored the idea of a “general ability” (sometimes called the “g” factor), but later researchers have favored the notion of several factors in intelligence.

Some intelligence tests have a number of subtests covering different content and skills. The Wechsler Adult Intelligence Scale (WAIS – R) is the test most frequently used by neuropsychologists for the individual assessment of adult intelligence (Wechsler 1997). It has 11 subtests. Six of these subtests make up the verbal scale, so named because the tests rely heavily on language. Examples are the vocabulary subtest, in which the study participant is asked the meaning of various words, and the comprehension subtest, in which the study participant is asked to explain items such as proverbs (designed to measure common or cultural knowledge).

Five of the subtests make up the performance scale, so named because the test problems can be solved without recourse to language. In the block design subtest, for example, the participant tries to reproduce a design with colored blocks. Performance tests were first used in World War I to test illiterate draftees and those with English as a second language. Older people generally do not do as well on these performance subtests (Attix and Welsh-Bohmer 2006; Blazer and Steffens 2009).

The fact that there are slightly different subtests on an intelligence test is of course no guarantee that these subtests actually measure different intellectual abilities; they may simply be different ways of measuring a single ability: “general intelligence.” Further exploration has therefore taken the form of factor analysis, a statistical procedure that identifies the number of basic dimensions or factors in a set of data.

In a factor analysis of the WAIS subtests, for example, the major dimension was found to be that of general intelligence, a large factor that accounted for about half of the information contained in the test (Cohen 1957). Three much weaker factors were also identified and labeled “verbal comprehension,” “perceptual organization,” and “memory.” The labels are not important for our purposes. What this analysis means is that

the WAIS can be described fairly well with a single factor. Three other factors appear to be important for some purposes. For example, an individual high in perceptual-organizational abilities might do better on the block design subtest than we would expect from his or her general intelligence alone. One finding of interest in this study is that the memory factor, a relatively weak factor among young study participants, became a major factor for persons over the age of 60. This means that there are wider individual differences in memory among older people, affecting scores on more of the subtests.

With the advent of major survey studies of virtually every issue that might be public policy relevant, there has been an attempt to include short tests of intelligence in major population surveys. These simple scales do not have the reliability and validity of the standard intelligence tests used in laboratory work. These brief tests as measures of cognition are particularly problematic for adults with limited testing experience, and who may have some difficulty in properly understanding questions (Knäuper et al. 1997). We will therefore limit our discussion to data obtained from direct administration of individual or group tests.

Intelligence as Multiple Abilities

If one’s goal is to map the broad scope of intelligence and not simply that of global intelligence (e.g., the WAIS), many different intellectual tasks must be administered to a large number of people. Factor analysis of a wide variety of intellectual tasks has regularly identified between 6 and 12 primary mental abilities, some of the most prominent of which are listed in Table 1. These abilities have sometimes been described as the “building blocks” or basic elements of intelligence (Thurstone and Thurstone 1941). The “purest” tests of these factors are sometimes administered as tests of the “primary mental abilities.” The most recent adult version of these tests is called the Schaie-Thurstone Adult Mental Abilities Test (STAMAT) (Schaie 1985, 1996, 2013).

More recent work on intellectual dimensions. Sternberg suggests that the normal course of intelligent functioning in the everyday world involves adaptation to the environment (Sternberg

History of Cognitive Aging Research, Table 1 Primary mental abilities discovered through studies using factor analysis

V	Verbal comprehension: The principal factor in such tests as reading comprehension, verbal analogies, disarranged sentences, verbal reasoning, and proverb matching. It is most adequately measured by vocabulary tests
W	Word fluency: Found in such tests as anagrams, rhyming, or naming words in a given category (e.g., boys' names, words beginning with the letter T)
N	Number: Most closely identified with speed and accuracy of simple arithmetic computation
S	Space (or spatial orientation): May represent two distinct factors, one covering perception of fixed spatial or geometric relations, the other manipulatory visualizations, in which changed positions or transformations must be visualized
M	Associative memory: Found principally in tests demanding rote memory for paired associates. There is some evidence to suggest that this factor may reflect the extent to which memory crutches are utilized. The evidence is against the presence of a broader factor through all memory tests. Other restricted memory factors, such as memory for temporal sequences and for spatial position, have been suggested by some investigations
P	Perceptual speed: Quick and accurate grasping of visual details, similarities, and differences
R	General reasoning: Early researchers proposed an inductive and deductive factor. The latter was best measured by tests of syllogistic reasoning and the former by tests requiring the study participant to find a rule, as in a number series completion test. Evidence for the deductive factor, however, was much weaker than for the inductive. Moreover, other investigators suggested a general reasoning factor, best measured by arithmetic reasoning tests

and Lubart 2001). But intelligent persons also tend to select their real-world environments that are relevant to their lives and they shape or adapt to these environments. Intelligent behaviors involve adaptation to novelty, automatization of information processing activities (i.e., performing information processing without conscious awareness of it), or both. A person who automatizes processing efficiently can allocate resources to cope with novel situations; conversely, efficient adaptation to novelty will allow automatization to occur earlier in one's experience of new tasks and situations.

The notion of allocation of intellectual resources is particularly relevant to the study of intellectual aging. Recent data and thinking suggest that the response of older persons to tests is far more selective than that of youngsters, and such allocation is often directed to optimize functions that meet the individual's needs and goals. Baltes further distinguishes between the *mechanics* (or basic processes) of intelligences, the efficiency of which decreases with increasing age, as contrasted to the *pragmatics* (or substantive content) of intelligence, which in many circumstances can increase until very old age (Baltes 1997; Staudinger et al. 1995).

The history of studies of adult intelligence according to Woodruff-Pak (Willis et al. 2006) has also had discernible secular trends in relative emphases on different aspects of adult intelligence that cut across theoretical positions. She identified four stages: In the first, lasting until the mid-1950s, concerns were predominantly with identifying steep and apparently inevitable age-related decline.

The second stage, in the late 1950s to mid-1960s, involved the discovery that there was stability as well as decline. External social and experiential effects influencing cohort differences in ability levels identified during this period led to a third stage, beginning with the mid-1970s. The field was dominated by attempts to alter experience and manipulate age differences via brief interventions or providing aids or supports in the testing situation. In the latest stage, the impact of successful demonstrations of the modifiability of intellectual performance (Willis et al. 2006; Rebok et al. 2013) has led investigators to expand definitions of intelligence and explore new methods of measurement.

Relevance of Test Instruments to Stages of Intellectual Development

The simple tasks in the traditional IQ tests are well suited to measure progress in the performance of many basic skills through the stages of knowledge acquisition described by Piaget (Binet and Simon 1905). But they are decidedly less adequate for the assessment of adult competence. Even a test that was constructed explicitly for adults, the WAIS, is

deficient in several respects. First, the test was designed with the intent of measuring cognitive dysfunctions in clinically suspect individuals, and second, it was originally normed on young adult samples, those who in our conceptual scheme would be classified as being in the achieving stage, although norms for adults are now available.

Practical or Everyday Cognition

Some would argue that intelligence in adults should be studied by asking well-functioning people how they go about solving their everyday problems (Sternberg and Lubart 2001). This is what is known as a “naive” theory of intelligence; that is, it is not derived from objective analyses of experts but rather from the collective perceptions of laypersons. Perhaps it is indeed the conceptions of adults about their own competence that ought to be the basis for defining intelligence. But there is the distinct danger that in this process we would confuse intelligence with socially valued or culturally defined behavior. Moreover, the attributes of intelligence obtained in this manner may be characteristic only of the specific group of persons interviewed or may be governed by time-specific and context-specific conceptions. We would be remiss, then, if we were to discard the objective knowledge of mental functioning that is now in hand and is directly applicable to adult intelligence (Schaie and Willis 1999; Willis and Schaie 2006). Instead, we may wish to consider how the basic intellectual processes that are important at all life stages relate to everyday tasks (also see Diehl 1998; Marsiske and Margrett 2006; Wettstein et al. 2014; Yam and Marsiske 2013; Willis and Schaie 1986). The importance of basic processes is also evident in technology-based everyday activities (Taha et al. 2010; Czaja and Lee 2010).

There have been a number of efforts to develop objective measures of people’s abilities to engage in effective problem solving and performance on tasks required for daily living (see Marsiske and Willis 1995; Willis 1996; Willis et al. 1992). For example, the Educational Testing Service (Salthouse 1996) developed a test to assess whether high school graduates had

acquired the necessary information and skills to handle everyday problems in current society; various US states then developed similar measures.

This test includes tasks such as interpreting bus schedules, tax forms, labels on medicine bottles, advertisements in the yellow pages, and understanding instructions for the use of appliances and the meaning of newspaper editorials. The test has been given to large samples of adults ranging in age from the twenties to the nineties (Schaie 1996, 2013). The test correlates with a number of the primary mental abilities; in fact, most of the individual differences on the test can be predicted from knowledge of scores on the basic abilities test.

Another effort to measure everyday problem solving was a test constructed for older adults or proxies to rate the skills that old people are thought to need to function independently in the community. These skills, called the instrumental activities of daily living (Schaie 2009), focused on everyday domains such as competence to engage independently in food preparation, housekeeping, medication use, shopping, telephone use, transportation, and financial management activities. Obviously, each of these activities requires the exercise of practical intelligence.

Willis (1997) collected written materials (e.g., medication labels, bus schedules, telephone instructions, mail order forms, appliance instructions, etc.) that are actually used for each of the seven types of activities. She had these items rated as to their relevance by professionals working with older people and then constructed a test that measured proficiency with the information to carry out each activity of daily living independently.

This measure was validated further by observing individuals in their homes actually using these materials to engage in activities such as measuring out medications, using a microwave oven, and so forth (Diehl et al. 1995). Again, approximately half of individual differences on this everyday problems test could be explained by the performance of individuals on the basic ability tests (Schaie 2013; Marsiske and Willis 1995; Willis 1996).

History of Cognitive Aging Research,

Fig. 2 Age Differences in Verbal and Performance Subtest Scores on the WAIS (Source: Adapted from Wechsler, D. (1958). *The measurement and appraisal of adult intelligence* (4th ed., p. 28). Baltimore, MD: Williams & Wilkins, Co. Copyright © 1958 Dr. David Wechsler)

Cognition and Age

What happens to intelligence with age? This is the key question in this essay, although our previous discussions should alert the reader to the fact that the answers are many and complex. It is argued by some that intelligence enters a process of irreversible decline in the adult years, because the brain becomes less and less efficient, just like the heart and lungs and other physical organs. Others contend that intelligence is relatively stable through the adult years, with the human brain providing more than enough capacity for anything that we would want to contemplate until serious disease and declines in sensory functions set in late in life.

Another view is that intelligence declines in some respects (perceptual speed, for example) and increases in others (in knowledge about life, or wisdom, for example; see (Staudinger and Glueck 2011)). Some argue that individual differences can be explained by compensatory experiences for those who age well, while others place emphasis in the above-average maintenance of physiological and psychological resources for these favored individuals (cf. Salthouse 1996; Schaie 2009).

Early Cross-Sectional Studies

The interpretation of early cross-sectional studies, examining age differences in cognition, seemed fairly straightforward: An individual's intellectual abilities were thought to decline gradually but

inexorably over the adult years. David Wechsler, creator of the WAIS, believed that the "decline of mental ability with age is part of the general senescent process of the organism as a whole" (Wechsler 1972, p. 30, Wechsler 1997).

Researchers have noted that certain subtests on the WAIS declined less than others. Wechsler (Willis 1997) proposed to use the term "hold subtests" for those subtests on which older adults do about as well as younger adults in contrast to "don't hold" subtests that showed a greater decline. In general, the verbal subtests "hold" and the performance subtests "don't hold" (Fig. 2). It has been shown that there is improvement on the WAIS from 40 to 61 years on the information, comprehension, and vocabulary subtests; mixed change on picture completion (improvement on easy items and decline on difficult items); but decline on the digit symbol and block design subtests (Educational Testing Service 1977; Sands et al. 1989).

Why should some tasks show almost no decline and others show the older persons doing much more poorly than the younger study participants? One possible explanation is that the subtests in which older people do poorly are all highly timed or speeded tests; the scores reflect the time that it takes for the person to solve the problem, or it reflects the number of responses in a given time interval.

One might conclude older people are just slower but not necessarily less able. This type of

research, of course, changes the “problem” from “How long does it take you to solve it?” to “Can you solve it at all?” In fact, those who do not solve the problem at all contribute to the slower average speed of solution among older persons in large part.

Crystallized and Fluid Intelligence

One of the most prominent theories of “hold” and “don’t hold” tests was formulated by Raymond Cattell and elaborated by John Horn. In factor analyses of cross-sectional studies of several intellectual tasks (not from the WAIS), Cattell and Horn repeatedly found that the tests on which older adults do well compared to younger adults are defined as a factor that they call crystallized intelligence (G_c). As represented by tests of general information and vocabulary, crystallized intelligence is said to reflect the mental abilities that depend on culture and experience with one’s world – on education in the broad sense, including both formal schooling and informal learning experiences in everyday life. The “don’t hold” tests were defined by another factor, termed fluid intelligence (G_f). Fluid intelligence is more akin to what Wechsler called “native mental ability,” reflecting presumably the quality of one’s brain: how quickly a signal can get in and out, how well organized are the neurons involved in associations, pattern recognition, and memory (Sands et al. 1989; Horn and Hofer 1992).

Adult intellectual development, viewed in terms of the G_c - G_f theory, implies progressive deterioration in the neural and biological structures underlying intelligence and, thus, systematic decline in fluid intelligence. Crystallized intelligence, as long as we do not require speedy responses or highly abstract reasoning, should not be affected as much; it may even increase as a result of adult educational experiences (Schaie et al. 2005; Schaie 2011; Willis and Schaie 2009). The theory is a popular one, for it more clearly specifies the intellectual tasks that can be used to represent each type of intelligence.

Differential decline of intelligence that supports the G_c - G_f theory also comes from a variety of longitudinal studies in various Western countries that show greater decline for measures of

fluid abilities (Rott 1993, Germany; Rabbitt 1993, England). However, as will be shown below, in the detailed discussion of a major American longitudinal study (Schaie 1996, 2013), this pattern may not hold for all abilities and in addition may be attenuated in advanced old age, when crystallized abilities also show substantial decline (Bosworth et al. 1999; Gerstorf et al. 2011).

Longitudinal Studies

Widespread use of intelligence tests among college freshmen began in the United States in the 1920s. By 1950, therefore, it was possible to find a sizable group of 50-year-olds who had taken an IQ test some 30 years earlier. Several psychologists, seeing their chance to run a relatively inexpensive longitudinal study, seized the opportunity by retesting these middle-aged individuals. No one expected results different from those found in cross-sectional studies, which suggested a marked decrease in IQ scores after the age of 25 or 30.

Thus, it came as somewhat of a surprise to find that not only did the longitudinal studies find virtually any decline in IQ by middle age; instead they showed an increase! The average person seemed to have gotten smarter with age, at least up to age 50 (Owens 1966). Later follow-ups showed that the participants in the Owens study actually maintained their intellectual abilities into the sixties (Cunningham and Owens 1983).

One large-scale study combined features of both cross-sectional and longitudinal designs (Schaie 1994, 1996, 2013; Willis and Schaie 2009; Gerstorf et al. 2011; Schaie and Zuo 2001). In 1956, people ranging in age from 22 to 70 were tested in a cross-sectional study. In 1963, as many of the original study participants as could be found and convinced to participate once again were retested. This procedure was repeated a third time in 1970, a fourth in 1977, a fifth in 1984, a sixth in 1991, a seventh time in 1998, and another follow-up of previously tested participants in 2005. Thus, the researchers had seven cross-sectional studies in addition to longitudinal data covering a period of up to 49 years.

The cross-sectional studies showed the typical pattern of intellectual decline in the adult years; the longitudinal data, however, told a quite

different story. Consider, for example, “verbal meaning” (the ability to understand ideas expressed in words), one of the “primary mental abilities” assessed by the investigators. Figures 3 and 4 provide the most dramatic way to represent the difference between cross-sectional data and an estimate of what the longitudinal data would look like if the youngest group of study participants were followed for the rest of their lives (Schaie 2013).

The cross-sectional data (Fig. 3) show a peak between ages 25 and 39, followed by a relatively sharp decline except for verbal and numeric abilities which show negative age differences only by age 60. In striking contrast, the longitudinal data suggest increases in these abilities until 53 or 60, with a small decline thereafter; and even at age 74 the estimated performance is better than at 25 for verbal comprehension (Schaie 2013; Schaie and Willis 1993). Similar comparisons were made with tests of reasoning ability, numerical ability, word fluency, and spatial visualization.

More recently longitudinal data for six mental abilities have been reported at the factor level from the expanded investigation, covering 1956–2005, a period of 49 years (Schaie 2013). Representative findings, shown in Fig. 4, suggest

little if any decline, on average, in most abilities until the age of 60; in several instances, increases occur during the adult years, with peaks in mid-life. Even after age 60, average decline is slight until age 74 or 81 in the case of verbal and numeric ability. In fact, for both abilities the 81-year-olds do better than the 25-year-olds (The mental abilities investigated in this study are described in Table 1).

Other investigators also have observed the fact that even in fairly advanced age, change in abilities proceeds quite slowly and in fact is difficult to document in studies that extend only over 2 or 3 years (Hultsch et al. 1992; Zelinski et al. 1993). Once the high eighties and nineties are reached, however, declines become more rapid and extend across most abilities because of the increasing failures of sensory capacities and other physiological infrastructures (Li et al. 1999; Baltes et al. 1999; Salthouse et al. 1998) and there is increasing risk of preclinical decline related to dementia.

The data in Fig. 4 are actually quite conservative because they were adjusted for the various sources that typically confound longitudinal studies. These adjustments take into account experimental mortality (attrition) and reactivity (practice effects), which tend to make unadjusted

History of Cognitive Aging Research,

Fig. 3 Cross-sectional age difference gradients for six mental abilities (Source: From Schaie (2013), Fig. 4.7. p. 120)

History of Cognitive Aging Research,

Fig. 4 Effects of age on six mental abilities in longitudinal studies (Source: Schaie 2013, Fig. 5.8, p. 164)

longitudinal findings often look unduly optimistic. However, no adjustments were made for the well-documented decline in perceptual speed that puts older people at successively greater disadvantage (Salthouse 1996). Nor were any of the participants removed who were later known to have been in the early stages of dementia, thus perhaps underestimating mean levels for the normal elderly (cf. Sliwinski et al. 1996). In a study by Schaie (1989), the contribution of perceptual speed was removed statistically from the scores of 838 adults ranging in age from the twenties to the eighties. This adjustment removed most of the observed age decrement for highly practiced tasks and markedly reduced aging effects for novel tasks. Findings from a Swedish twin study suggest much of the correlation between cognitive measures and speed may be genetically mediated (Finkel and Pedersen 2000).

Cohort Differences

What accounts for the difference between the cross-sectional and longitudinal results, with the latter not only showing no decline through midlife and early old age but also, in some cases, clear increases in intellectual abilities? Why do longitudinal studies give us such a different picture from earlier, cross-sectional studies?

The reason longitudinal studies give different results from cross-sectional studies is that

cross-sectional studies compare people of different ages and of different cohorts. Many of the differences that have been attributed to age must, for the most part, be relegated to differences among groups of people differing in year of birth.

Cross-sectional studies make it appear that intelligence declines steeply over the years, but much of this apparent decline is a confound of age and cohort effects. Longitudinal studies suggest generally that each generation is higher functioning than prior cohorts on many but not all abilities (e.g., number); however, there is also some evidence of a slowing of the cohort effects in recent US generations.

The pervasive differences in intellectual performance levels have been studied in young adults for populations in many different countries and are sometimes referred to as the “Flynn effect” (Schaie et al. 2005; Dickens and Flynn 2001; Skirbek et al. 2013). Flynn and colleagues have reported that the largest cohort differences in intellectual functioning were found for what are commonly known as fluid abilities. Smaller cohort gains have been found for acculturated skills acquired through schooling and commonly known as crystallized intelligence. However, these assertions were based almost exclusively on differences found between two particular cohorts differing approximately 30 years in age.

Massive cohort gains are reported for the post-World War II cohort with most data cited being for those born in the 1950s. Although data from a number of developing countries including Japan are cited, the data are largely limited to these two birth cohorts. From a US perspective, it is immediately evident that these cohorts represent the Baby Boomers and their parent generation, sometimes referred to as the Depression cohorts (cf. Schaie et al. 2005; Schaie 2011).

Why is one cohort more advantaged in intelligence than another? Why is it that people born more recently earn higher averages on IQ tests than their parents or grandparents? Various answers are suggested.

Over the last several generations in most countries, years of education have increased and in some cases quality of education has improved. In the United States, among the members of the oldest cohorts now living, the majority may have achieved no more than a high school diploma and relatively few have had college experience. The spectrum of occupations has shifted from manual labor to a majority of jobs requiring a variety of fluid and crystallized skills (Schaie 2011; Schooler and Caplan 2009; Schooler et al. 2004). Nutrition has vastly improved in the last 70 or 80 years, and so has medical care,

particularly treatment of cardiovascular disease; these improvements in health may be reflected in healthier neural functioning in adulthood. The use of tests like those for IQ has burgeoned, and thus later generations may be better than earlier generations at performing well on such instruments because of the added experience.

Because experiences that may be relevant to differential performance across different cohorts are due to many different influences we still are unsure of the psychological mechanisms involved. Laboratory studies have employed popular recreational activities such as crossword puzzles or jigsaw puzzles to determine whether regular performance on these activities is related to age differences on related abilities. Crossword puzzles have been related to verbal (crystallized) and memory ability and jigsaw puzzles to spatial (fluid) ability (Allard et al. 2014; Pillail et al. 2011).

Cohort differences in intelligence are not uniform across different abilities. Figure 5 shows the change in cohort level in percent of the performance of the earliest cohort for 13 cohorts born from 1889 to 1973. Almost continuous gain occurred for each successive cohort for the primary mental abilities of inductive reasoning, spatial orientation, perceptual speed, and verbal memory. However,

History of Cognitive Aging Research,

Fig. 5 Cumulative cohort differences from oldest to youngest cohort for five mental abilities (Source: Schaie 2013, Fig. 6.3, p. 183)

gain peaked in 1952 for verbal memory. Number ability and verbal comprehension peaked in 1924 and then decreased below the level of the oldest cohort. These differential findings suggest that older cohorts are at a particular disadvantage on the fluid abilities but may have an advantage with respect to number skills (Schaie 1996, 2013; Willis 1989). Interestingly enough a cross-cultural study of cohort differences in number skills comparing young and old Chinese with Americans has shown that the advantage generally shown by current Chinese over American students may be due to positive cohort change in numeric ability in China co-occurring with negative differences in the United States (Geary et al. 1997).

The cohort differences data described above come from the study of unrelated individuals, but generational differences of very similar magnitude have been observed also in studies comparing parents and their adult children when compared at the same ages. This kind of data can, of course, be collected only in studies conducted over long periods of time (Schaie 2008; Schaie et al. 1992).

There is some evidence that the differences between generations have begun to turn in favor of the earlier-born cohorts (e.g., numerical ability). Average test scores on the Scholastic Aptitude Test have been declining since 1962;

before 1962, averages were stable or increasing. The decline has been blamed on many factors, but chief among them are poorer educational standards in our schools, more students taking the SAT and “the passive pleasure, the thief of time” – television (Hanford 1991). For whatever reason, the youth of today are doing somewhat less well on some cognitive tests than their elders did at the same age, and this fact will eventually be evident in cross-sectional studies of intelligence.

Frequency of Decline

In addition to knowing the age at which the average person declines, it is also important to know what proportion of people are likely to decline at a given age. Such knowledge is useful in at least two ways. First, it alerts us to the fact that there may be more stability than change in intellectual aging and that some persons may still grow even at an advanced age. Second, just as longevity tables permit life insurance companies to forecast the odds of someone’s dying, a knowledge of the proportion of those declining at a given age permits us to determine the probability that intellectual changes will have important consequences. Frequency distributions were prepared for several thousand participants in the Seattle Longitudinal Study to determine what proportion had declined

History of Cognitive Aging Research,
Fig. 6 Cumulative hazard rate of significant decrement in different abilities occurring to successive ages from 32 to 95 years (Source: Schaie 2013, Fig. 19.2, p. 459)

significantly over each 7-year age range from 25 to 32, 60 to 67, and so on until age 88 to 95 (Schaie 1989, 2013).

The researchers examined frequencies for the five primary mental abilities: verbal meaning, inductive reasoning, word fluency, numerical ability, and spatial orientation. The proportion of persons who maintained their level of functioning over every 7-year period is shown in Fig. 6. Note that, although abilities varied greatly, in the various abilities tested, by age 60, as many as 50% of those studied declined on Word Fluency while only 25% declined on Verbal Meaning. By age 74, decline was observed for 60% on Word Fluency but only for 35% on Verbal Meaning. However, by age 81, more than 60% of the study participants had declined on all abilities.

Conclusion

What happens to one's cognitive functions, as one grows older? This has been the primary question in this entry, and we do have a tentative answer based on considerable research (also see Schaie 2016). In addition we also suggested that it may be useful to expand the stage model of development suggested by Jean Piaget by describing additional adult stages which most of us experience as we pass through adulthood.

Average cognitive ability scores were at first thought to indicate a gradual decline after the age of 25. Later studies showed this interpretation to be wrong, to be an artifact of increasing abilities with successive generations.

We now believe that the pure numbers decline only later in life, largely after the age of 60. Although decline occurs for persons at all ability levels (Christensen and Henderson 1991), advantaged groups, such as college graduates, often decline very late and may remain well above the average level of young adults until their eighties and nineties (Marsiske and Margrett 2006; Schaie 1989).

Performance levels for certain tests, those variously called "speeded" or "fluid" or "performance" or whatever, drop somewhat more rapidly, but the reasons for this remain the most

controversial. These may be the basic biological aspects of intellect, as some theories assert (Birren and Fisher 1992). Or these may be the abilities most subject to variations in training, motivation, and historical circumstances (Abeles and Riley 1987). The decline in cognitive test scores after the age of 60 is similarly subject to several interpretations. In addition to notions of inevitable biological decrement, we could attribute intellectual decline to social isolation, decreasing motivation to perform irrelevant intellectual tasks, disease (including disease related to impending death and terminal drop), or some combination of such factors (cf. Fillit et al. 2002; Hülür et al. 2015). Some people decline in intellectual ability; others increase.

Historical events that change patterns of opportunity and exposure to societal resources may result in profound generational differences in performance levels and rate of change (Schaie et al. 2005; Schaie 2011). The patterns of change for different abilities and even different measures of the same ability differ remarkably (Schaie and Willis 1993).

Some abilities seem to be increasing with each new generation; others seem to be decreasing. An environmental event (e.g., the development of television) can change trends for some people and have little effect on others. Thus, the search goes on, but it is a search now for the determinants of change or stability and much less for inevitable and irreversible decrements.

If you keep your health and engage your mind with the problems and activities of the world around you, chances are good that you will experience little decline in intellectual performance in your lifetime. That's the promise of research in the area of adult cognition.

Synonyms

Complexity hypothesis; General slowing; Processing speed; Process-specific slowing

Definition

Age-related cognitive slowing refers to the common finding that humans tend to slow down in cognitive processing with increased adult age.

Individual Differences in Processing Speed

As Birren and Fisher (1995) noted, current research on slowing in cognitive aging is built on the foundation of research on individual differences in the late nineteenth century and early twentieth century, for example, Galton's "anthropometric measurements" obtained at the 1884 International Health Exhibition in London. Related work by Cattell in 1890 and Koga and Morant in 1923 suggested that individual differences in reaction time (RT) in elementary sensory tasks were potentially important measures of cognitive performance. Further, individual differences in the RT measures were not attributable entirely to peripheral, sensory processes but instead appeared to represent basic properties of the central nervous system. Birren (1965) also emphasized that age-related slowing was a central, rather than peripheral, phenomenon and that slowing was related to task complexity. That is, as information processing task complexity increased, older adults showed progressively larger slowing effects. Welford (1977) suggested that slowing was due largely to increased neural noise (i.e., disruptions of the neural networks responsible for cognitive functioning). Following Birren (1965) and Welford (1977), reaction time and related measures of processing speed have emerged to become critical dependent variables in research on age-related differences in cognition and central nervous system functioning (Madden 2001; Salthouse 1996).

Brinley Plots

Brinley (1965) introduced a method for plotting the differences in RT between younger and older adults, and this has become an influential research method for research on age-related slowing. Brinley introduced this type of analysis as a method for investigating age group differences, but in theory the method can be applied to any two-group comparison. In a Brinley plot, for each of the individual conditions within a behavioral task (e.g., target present vs. target absent, low

vs. high memory load, etc.), the mean performance of the older adults is plotted (on the y-axis) as a function of the mean performance of the younger adults (on the x-axis). Typically, mean reaction time (RT) within each task condition is the measure of interest, but in theory accuracy can also be analyzed in this manner, and Brinley discussed plots of both RT and error rate. Thus, increasing values along the x-axis represent increasing task difficulty, in terms of the mean RT or error rate associated with the individual task conditions, and the more task conditions that are included in the analysis (from either the same or different experiments), the more accurate will be the estimation of the function relating the younger and older adults' data points. In theory, there is no reason for the relation between older and younger adults' performance values to be linear, but Brinley found that plots for both RT and error rate were linear with a slope greater than 1.0. For RT, with 21 data points, he observed a linear slowing function with a slope of 1.68 and an intercept of -270 milliseconds (ms) – and the most surprising outcome was that this linear equation accounted for 99% of the variance! That is, age differences on 12 different task-switching tasks could be precisely described using a single variable – age-related slowing. To characterize the age-related differences in performance, it was not necessary to describe or understand the individual task conditions, only the nature of the overall change in performance across the task conditions.

However, Brinley plots do not always account for 99% of the age-related variance. Processing domain (e.g., lexical vs. nonlexical) or processing stage (e.g., encoding vs. response decisions) can also show domain- or stage-specific age effects. To illustrate how age-related slowing can be affected by processing stage, the Brinley plot method will be applied to data from a word-naming study. In this naming study, two experiments were conducted on 80 younger adults and 80 older adults; there were three other independent variables: case type (consistent lowercase vs. mixed case), phonological condition (exception words, exception controls, regular-inconsistent and regular-inconsistent controls), and word frequency (low vs. high). The data

from these two word-naming experiments, with 32 task conditions (Allen et al. 2011), are illustrated in a Brinley plot in Fig. 1 with 32 data points. Unlike the Brinley (1965) study, however, the linearity of the older-younger RT function accounted for just 69% of the variance. While this is still a large effect size (again, suggesting that perhaps a single variable – processing speed – might account for almost all age-related difference), as will be discussed later on in this entry, a more complex model of age-related slowing will account for more of the model variance. This brings up an important aspect of the processing speed literature as noted by Madden (2001) and others – namely, there are macro and micro perspectives on age-related slowing. The macro perspective has emphasized what common effects in aging occur (e.g., are age-related differences in basic cognitive processes mediated by a common factor?) and tends to be based on a psychometric approach such as structural equation modeling (SEM), whereas the micro perspective has emphasized whether age-related differences in cognitive processes are moderated by other variables and so tends to emphasize an experimental approach (e.g., ANOVA). This entry will begin with micro approaches and then discuss macro approaches to capture the chronological order of this research in the aging literature.

Generalized Slowing

Early studies using Brinley plots typically found that these functions exhibited a negative intercept value. However, in theory the intercept should be positive, that is, older adults' RT should always be above that of younger adults. This feature suggests that the Brinley plot is not entirely accurate and that a single factor of general slowing does not account for all of the age-related differences observed in RT. Cerella (1985) suggested that the negative intercepts and positive slopes occurred because there were both peripheral (relatively small) and central (relatively large) slowing factors. In his seminal 1985 *Psychological Bulletin* paper, meta-analyzing the response time results from 35 studies using 189 data points, Cerella

suggested that this two-factor linear slowing model could account for a substantial proportion of age-related difference on cognitive tasks.

Salthouse (1985) further elaborated on age-related slowing and proposed six different potential mechanisms from information processing theory that might account for this effect. Of these six, the “cycle-time” hypothesis was favored – the idea that older adults might have slowing processing cycle time (i.e., each processing stage took longer for older adults – this is analogous to the “clock rate” of a digital computer CPU). This is a “hardware” effect rather than a “software” effect. Consequently, if older adults’ clock rate were to be 1.5 times slower than younger adults, then one would expect generalized slowing at the same rate across task complexity. Salthouse also warned about the importance of assessing potential speed-accuracy trade-offs in slowing research. That is, errors must be approximately constant across age, or this could affect the overall performance level, for example, if older adults’ slowing represents greater caution in decision-making.

Myerson et al. (1990) extended the generalized slowing idea to show that nonlinear models could also accurately predict age-related differences in response time performance across a wide variety of cognitive tasks. In their information loss model, they assumed that across functionally serial and discrete information processing stages, information was lost at each successive stage – resulting in a nonlinear “general slowing function.” The information loss model is based on an exponential, rather than linear, relation between younger and older adults’ RTs.

Potential Methodological Issues with Brinley Plots

There are important methodological issues to consider when using Brinley plots. First, this approach assumes that both age groups are using the same processing architecture. If older adults use different strategies than younger adults, then a direct comparison of the two age groups is difficult, because the measurement scale would not be

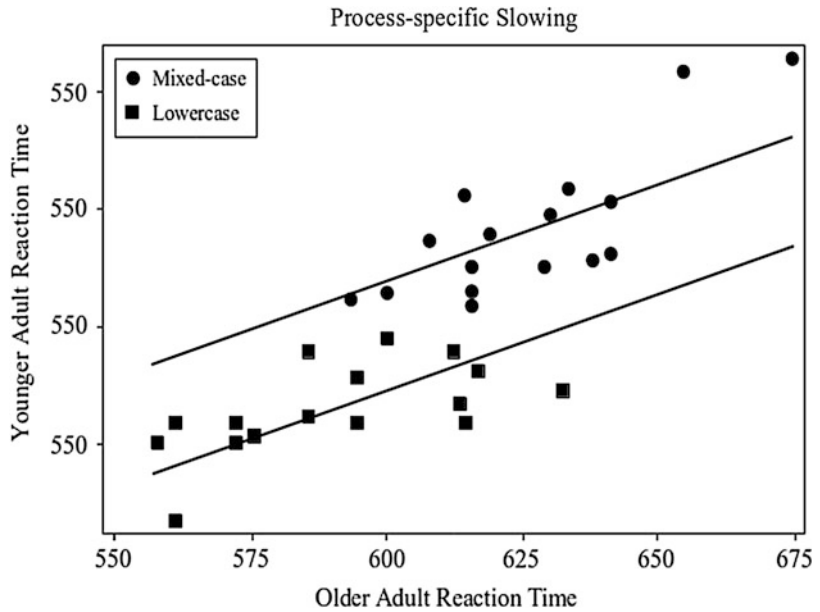

comparable. It appears that there are no studies that have specifically addressed the issue of potentially different measurement scales for younger and older adults. It is assumed that the relationship between levels of an independent variable and the performance (dependent) variable is the same in terms of interval scaling, but this has never been tested. That is, is the magnitude of the difference for any one-unit increase in complexity different across age groups? This issue needs additional consideration.

Another issue in Brinley plot research was noted by Perfect (1994). He noted that different tasks placed on the same Brinley plot frequently show gaps between data points on the plot. When examined as a group, these data points fit nicely on a single regression equation (i.e., a very large *r*-square value). However, these tasks frequently result in an Age \times Task Type interaction. Thus, when there are regions of dense data points intermixed with wide regions of no data points followed by other regions of data points, this can result in exaggerated *r*-square values compared to separate Brinley plots of the different clusters of data points. Because older adults’ reaction times are almost always higher than younger adults’ response times, this forces a positive correlation – and as the magnitude of the horizontal dispersion increases, *r*-square will increase. This means that the Brinley plot method is biased to show large *r*-square values.

Finally, it is important to note that the Brinley plot is a method for analyzing mean RT. Analyses of mean values as estimates of central tendency assume that the underlying distribution is Gaussian (i.e., normal). However, when the complete distribution of an individual participant’s RTs is examined, that is, all the trials contributing to the mean, the frequency distribution of fastest to slowest RTs is virtually never Gaussian but is instead positively skewed, with more responses at the slower end than on the faster end. Empirically, RT distributions are better characterized by what is termed an ex-Gaussian distribution, which is the convolution of exponential and Gaussian (normal) distributions. Across different task conditions (or groups of participants) the mean of an RT distribution may remain constant even though

History of Cognitive Slowing Theory and Research, Fig. 1

Process-specific Brinley plot (one slope and two intercepts) of mean RT data from Allen et al. (2011)

the shape of the distribution varies. Distribution analyses of RT use the parameters of different mathematical distributions, most often the ex-Gaussian, to obtain more specific information about the cognitive processes contributing to the response that are not revealed in analyses of mean RT (Balota and Yap 2011).

Process-Specific and Task-Specific Slowing

Analysis of variance (ANOVA) is commonly used in cognitive aging research. In order to test for age-related differences in cognitive processing, researchers frequently examine whether there is an Age \times Condition Type interaction. If the interaction is significant, then it is assumed that an age-related difference exists. However, even if significant interactions with age are present in ANOVA, this does not rule out the possibility that such results are still consistent with general slowing. Madden et al. (1992) reported a quantitative transformation of younger adults' latencies that allows the interpretation of interactions with age group using ANOVA. These authors proposed first creating the Brinley plot for the data to be analyzed and then using the regression equation

defined by the Brinley plot as a transform for the younger adults' data. Thus, an Age Group \times Task Condition ANOVA interaction that remained significant following this transform could be viewed as slowing beyond the level described by the Brinley plot. Faust et al. (1999) described other approaches, including the standardization of individual RT values, for taking age-related slowing into account within the ANOVA framework.

Several other studies provided evidence of domain-specific slowing – in particular, age-related slowing rates for lexical tasks were attenuated relative to nonlexical tasks. In addition, task-specific and/or process-specific effects occurred within the lexical domain. In order to illustrate this observation, the 32 data points illustrated in Fig. 1 will be revisited. As noted earlier, the r-square value for the Brinley plot of these data is relatively low: r-square = .69. In Fig. 1 it is apparent that the data points for the consistent-case conditions lie below the data points for the mixed-case conditions (as illustrated by the two regression equations superimposed over the scatter plot). Indeed, Allen et al. (2011) observed an Age \times Case Type interaction in both experiments. Even after these data were transformed using the Faust et al. (1999) z-transformation method, the Age Group \times Case Type interaction persisted

($p < .001$), indicating that a single slowing function could not adequately describe these data. However, when we allow different intercepts for both levels of case type, but a single slowing slope, this model now accounts for 84% of the variance, and this increases to 87% when different intercepts and slopes are used (i.e., much higher than 69%). Consequently, these data from Fig. 1 require two separate slowing functions – one for each case type. These results suggest that age-related differences in visual word encoding are much greater than age-related differences in lexical access or phonological processing, so process-specific slowing can moderate generalized slowing.

Processing Speed as a Construct

As noted earlier, there are two broad approaches used to examine age-related difference in processing speed – a micro approach typically involving experimental methods to assess whether age-related differences are moderated by generalized slowing (or not) and a macro approach typically involving psychometric methods to assess whether age-related differences in cognitive processing are mediated by a common factor (in particular, processing speed). Perhaps the seminal paper reviewing the evidence for the common-factor account of age-related difference in processing speed was that presented by Salthouse (1996). The key finding in this study is that when processing speed is controlled for, age-related differences in first-order cognitive processes (e.g., perception, attention, memory) tend to be eliminated or at least attenuated. Salthouse then followed up on this research with a series of studies that tested whether age-related differences in a number of cognitive measures were mediated by age-related differences in what he termed processing. As with the Brinley analysis approach, this single common factor of processing speed seemed to account for almost all age-related differences in cognitive performance for fluid tasks. The advantage of using the psychometric approach, though, is that SEM takes into consideration individual differences, and because it uses latent factors, rather than

manifest variables (as are used in path analysis), this method typically estimates error more accurately than regression or path analysis methods.

However, for some time there has been evidence of differential age-related effects in cognitive processes (e.g., Allen et al. 2011; Madden et al. 1992). In SEM terminology, this would mean that indirect paths from age to first-order specific factors (e.g., word encoding, lexical access, and phonological processing) are present in addition to a direct path from age to a higher-level, common factor (what all three of these processes hold in common in describing overall age-related differences). Allen et al. (2001) conducted such an SEM test of process-specific (all age effects are described by first-order cognitive factors), common-factor (all age effects are captured by a single common factor), and hybrid models (both common-factor and process-specific age effects are required). These authors analyzed four SEM data sets from previously published articles to assess whether process-specific age-related differences were present. In three of the four data sets, a hybrid model fit the best, and in the fourth, a process-specific model fit optimally. These results indicated task-specific age-related differences were present, in addition to common-factor age effects.

Methodological and Conceptual Issues in the Psychometric Approach

Lindenberger and Pötter (1998) provided a note of caution concerning the application of hierarchical regression, path analysis, and SEM psychometric approaches to aging research. The goal of these psychometric approaches is typically to assess whether the relationship between age (the exogenous variable) and a cognitive variable (episodic memory) is unique or whether it is shared with or explained by some other variable (e.g., processing speed). If the relationship between age and episodic memory is statistically significant, but is no longer significant after processing speed is added (total mediation) or at least the relationship is attenuated (partial mediation), then it is assumed that the relationship between age and episodic memory is mediated by processing speed. Lindenberger and Pötter,

however, noted that these methods technically do not test the mediation assumption – instead they provide information on shared and unique sources of variance if the mediation assumption were in fact true. These authors emphasize the importance of theory development and longitudinal methods so that the direction of effects can be determined.

Another methodological issue with the psychometric approach has to do with capitalizing on chance. Whereas the micro approach with its experimental approach emphasizes replication to minimize the chances of a type I error (rejecting a true null hypothesis), the macro psychometric approach typically uses larger sample sizes within a study. In SEM approaches, optimal model fits are frequently obtained with the assistance of modification indexes. Thus, the reported model may reflect chance variation specific to the obtained sample (and not to the total population). A solution to this problem is to collect both validation and holdout samples, develop the model on the validation sample, and then impose this model on the holdout sample to confirm that it fits. In other words, replication across samples is important.

Finally, a conceptual issue with the common-factor models of cognitive aging concerns what is meant by “common.” It is absolutely imperative that researchers be explicit when defining “common” aging factors – if it is actually processing speed, then the same common factor should be used across all studies (not simply using SEM methods to statistically estimate a common factor and then assume that it reflects processing speed). If the common factor is not carefully explained, then it simply becomes a “black box” with no theoretical utility. For example, the potential common factors in cognitive aging research that are often mentioned are processing speed, neural noise, sensory deficits, and inhibitory control deficits. It is imperative that researchers identify their “common cause” in a given study.

Cross-Sectional, Longitudinal, and Sequential Designs and Slowing

The majority of the studies conducted in cognitive aging research are cross-sectional, in the sense of

studying different samples of younger and older adults tested at approximately the same point in time, with data analyses relying on ANOVA, linear regression, or related methods. Sliwinski and Hall (1998), however, proposed that maximum likelihood estimation (MLE) with hierarchical mixed models allowed individual differences to be modeled more precisely and that using mixed model methods resulted in more process-specific age-related difference. Consequently, the greater precision afforded by mixed model designs (in which the individual is modeled using a random effect in addition to the traditional fixed effects) in modeling individual differences in ANOVA designs should be considered when analyzing experimental data because considering individual differences frequently has an impact on generalized vs. process-specific outcomes.

Intuitively, the best method for measuring age-related change would be a longitudinal design, in which the same individuals are tested at different points in time. Purely longitudinal studies are difficult to implement because the time frame needed to characterize change may be on the order of decades. Hofer and Sliwinski (2001) proposed a different approach. They suggested that using Schaie’s (1965) sequential design applied to mixed models would incorporate a longitudinal component into a cross-sectional design, as well as modeling individual differences. In this alternative approach, the sequential design, different age groups (e.g., those in their twenties vs. those in their sixties) are followed longitudinally for a period of time (e.g., several years) to characterize individual-level correlated rates of change. However, both longitudinal and sequential designs have a limitation in that they introduce repeated testing and practice effects that may obscure, to some extent, true age-related change. For example, in a longitudinal analysis of data from 1,616 individuals 18–80 years of age, Salthouse (2010) found that after adjusting for the practice effects, the changes in cognitive performance across approximately 2.5 years were less positive at younger ages and slightly less negative at older ages.

Cohort Effects in Processing Speed?

The Flynn (1987) effect illustrates the finding that students from a 1980 cohort scored significantly higher on standardized scores of fluid reasoning than did students of the same age from a 1950 cohort. Because processing speed is a major indicator for fluid reasoning performance, an important question is whether the Flynn effect generalizes to aging. That is, do more recent cohorts of older adults show increased processing speed relative to earlier cohorts of older adults? There is some evidence that older adults from the present age cohort are showing increases in processing speed relative to earlier cohorts of older adults. For example, in their Long Beach Longitudinal Study of Aging, Zelinski and Kennison (2007) found that fluid abilities of reasoning for their Cohort 2 ($n = 456$; born between 1908 and 1940) were significantly higher at the same age than they were for their Cohort 1 ($n = 482$; born between 1893 and 1923). Overall across multiple processing domains, their Cohort 2 at age 74 showed equivalent performance to Cohort 1 at age 62. Consequently, there is accumulating evidence that processing speed/fluid reasoning for older adults is improving with each successive birth cohort.

Neuroimaging Measures of Age-Related Slowing

As Birren (1965) emphasized, RT measures are indicators of age-related effects at a central rather than peripheral level. Modern brain imaging techniques are beginning to provide new information regarding the properties of brain structure and function that are relevant for age-related slowing, but definitive conclusions are not yet available. It is likely that measures of both gray and white matter volume and integrity, as well as measures of both task-related and resting-state brain function, will be relevant. It appears that age-related differences in the brain are multifactorial and interactive in their relation to speed. Currently, many neuroimaging studies use a *disconnection model* of cognitive aging to interpret age-related

differences in brain structure and function. From this perspective, age-related decline in cortical volume or microstructural integrity of white matter is viewed as contributing to the decreased efficiency of the connections among the neural networks mediating cognitive function.

For example, Kievit et al. (2014) combined gray matter volume measures of prefrontal regions with measures of white matter tracts connecting those regions, in a large, population-based sample of 567 individuals with both behavioral and imaging data. An SEM analysis of two related measures of executive function, fluid intelligence and multitasking ability, indicated that the paths of statistical influence between the neuroimaging and behavioral variables differed for the two behavioral domains. Both regional gray matter volume (Brodmann area 10) and white matter integrity (genu of the corpus callosum) were significant mediators of the age-related decline in fluid intelligence, whereas integrity of the anterior thalamic radiations (frontostriatal tract) mediated multitasking ability. Thus, as a general principle, aging may represent a form of gradual disconnection of the neural networks responsible for elementary perceptual speed, and ultimately, more complex forms of cognition. The influence of disconnection, however, may vary across behavioral domains and may interact with changes in regional volume.

Neuroplasticity and Age-Related Slowing

With the advent of cognitive training software (e.g., Posit Science and Lumosity), another issue pertinent to the present discussion of cognitive slowing in increased adult age is whether cognitive training can affect cognitive performance. That is, can the older adult brain benefit from training in a manner that would suggest some level of neuroplasticity – even in older adults? While this is a very complicated research issue, Mitchell et al. (2012) provided both positive and negative evidence for neuroplasticity in aging. First, in an analysis of four different longitudinal studies, these authors found that a change in cognitive activity was associated with an increase in cognitive

performance (e.g., learning to play the violin at 70 improved overall cognitive performance). However, the amount of baseline cognitive activity at an earlier age was not correlated with later cognitive performance – although the general amount of time spent on cognitive activities tended to decline with increased adult age in three of the four longitudinal studies included in the Mitchell et al. study. Therefore, the amount of baseline cognitive activity may not be significantly correlated with later cognitive performance because of older adults' typically decreasing time spent on cognitive activities. Alternatively, cognitive training may provide just a relatively brief cognitive performance benefit.

Conclusion

Processing speed tends to decrease with increased adult age, and very early in the history of cognitive aging research, investigators recognized that this age-related effect is a property of the central nervous system rather than a peripheral, sensory-motor effect. Age-related slowing is evident across a variety of task conditions and expresses a general effect of task complexity – as hypothesized by Birren (1965). A number of studies also suggest, however, that age-related differences in processing speed are moderated (or mediated) by specific cognitive processes or processing domains – as hypothesized by Welford (1977). Thus, researchers continue to develop more fine-grained analyses of the relative contribution of general and task-specific slowing to the age-related differences in RT. Different methods including RT distribution analyses and variations on longitudinal vs. cross-sectional testing continue to be explored. As these different perspectives become combined with methods from neuroscience and neuroimaging, it is hoped that a more complete account of age-related slowing will emerge.

(Re)Constructing the History of Longitudinal Statistical Analysis

Longitudinal statistical analysis has a long past but a short history. In fact, until very recently, longitudinal statistical analysis did not exist as a subject, but was inextricably tied to substantive research in different disciplines. Even today, most publications on longitudinal statistical analysis are written from the perspective of a certain discipline and focus on a specific research design and data structure. Examples include pertinent work on large sample panel data (Hsiao 2014) and single-subject time series data (Lütkepohl 2005) in economics, crossover experimental designs in medical and pharmaceutical research (Jones and Kenward 2014), and the typical applications in the social sciences, often involving multiple individuals and a moderate number of repeated measurement occasions (Singer and Willett 2003). Depending on the field of research and the focus on a specific design or data structure, the history of longitudinal statistical analysis may thus be construed quite differently. This encyclopedia entry is primarily devoted to the history of longitudinal statistical analysis in relation to geropsychology and developmental psychology. As a field, however, modern geropsychology is highly interdisciplinary and thus subject to various influences. As the influences of neighboring disciplines wax and wane, so does the importance of their historical backgrounds. For this reason a description of the history of longitudinal data analysis remains always preliminary, reflecting our present-day view on the most important trends and influences that have shaped the field up to now. As the field changes, the perception of its history may change as well. Taking on today's notion of the main rationales of longitudinal research and the best way to address them, this encyclopedia entry will sketch the development of the most prominent approaches to longitudinal statistical analysis in geropsychology. Thereby, the focus lies on identifying relevant historical trends rather than presenting a chronology of discrete events. Specific dates mentioned in the following are thus best understood as exemplary milestones of more general developments.

Early Origins of Longitudinal Research

“The study of change became the business of science” (p. 7) ever since Galileo’s law of inertia overthrew Aristotle’s conception of a stable and harmonic universe (Gottman 1995), thus turning the analysis of things into the analysis of *change* of things. Other protagonists in this conceptual revolution were Copernicus who preceded Galileo and argued for the heliocentric model and planetary motion as well as Newton, whose refinement of Galileo’s work led to the laws of motion. The subsequent development of differential and integral calculus by Newton and Leibniz in the seventeenth century did not only feature in the emergence of classical mechanics in physics, but the according concepts and formulations also lie at the heart of many modern approaches to longitudinal statistical analysis. However, it took well over two and a half centuries until they gained ground in the social sciences.

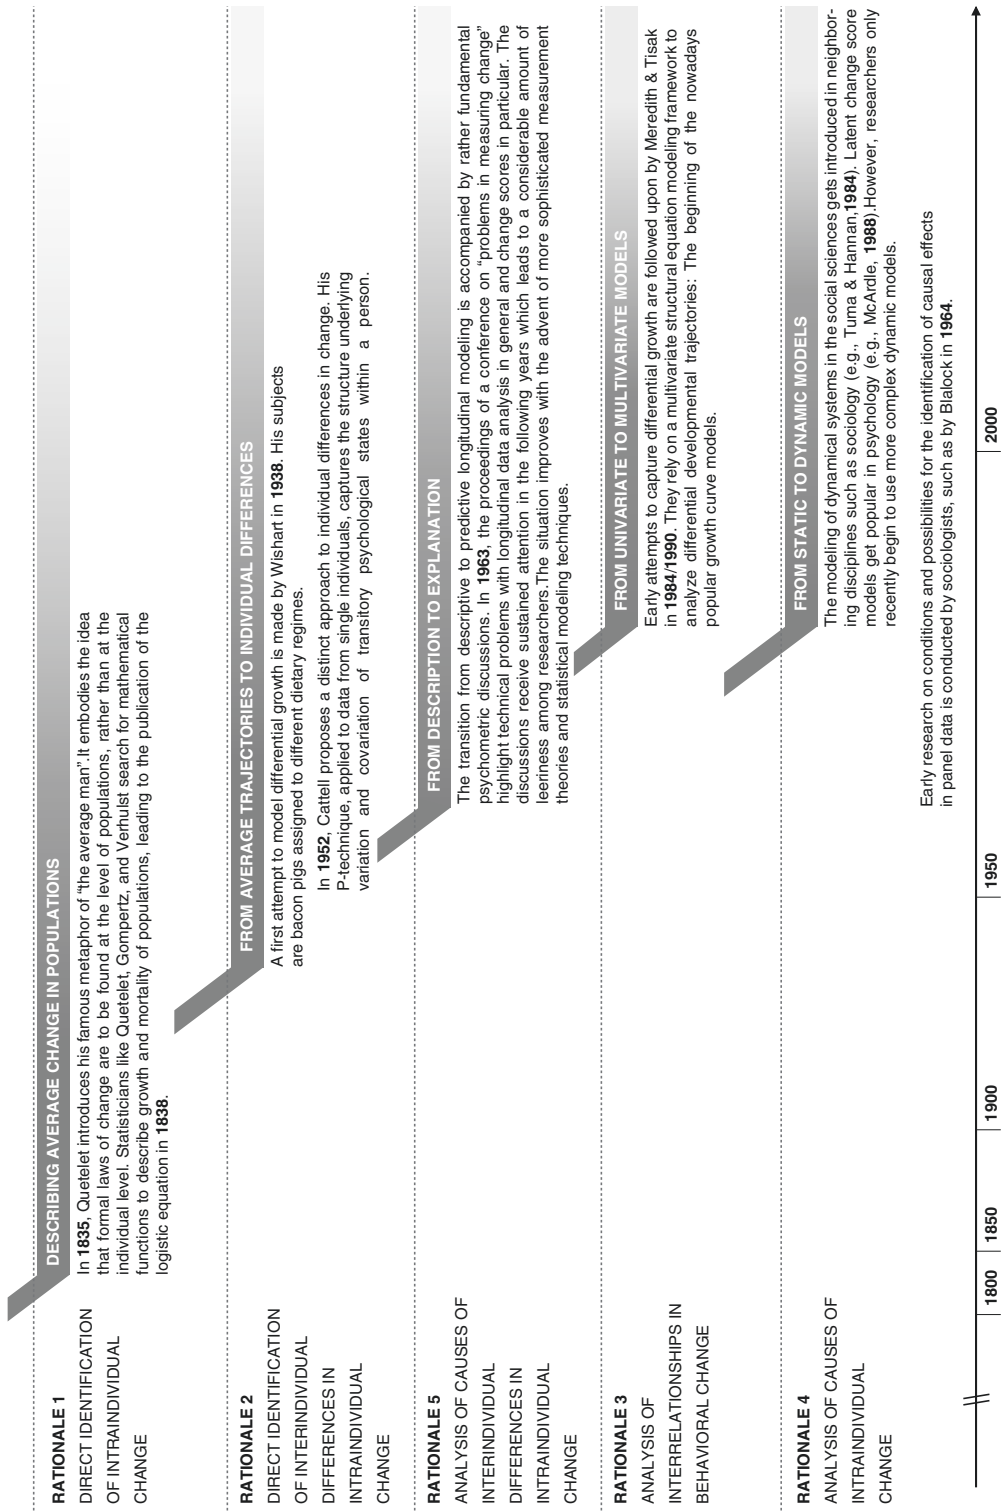

Longitudinal Research in Developmental Psychology and Geropsychology

Similarly, the origins of geropsychology can be traced back to the old Greco-Roman philosophers and beyond. It was not until about the mid-twentieth century, however, that geropsychology emerged as an organized field of research and education (Birren and Schroots 2000). Although the preceding historical developments were somewhat different in Europe and North America (Lindenberger 2007), geropsychology was always closely tied to developmental psychology (and vice versa) and, especially in the North American tradition, characterized by the quantitative empirical study of growth and decline. Accordingly, it is probably no coincidence that the birth of geropsychology as a field falls into the same time as the first attempts to explicate and resolve the conceptual and technical difficulties in the statistical analysis of change. A seminal 3-day conference on *problems in measuring change* in the year 1962, which brought together some of the most eminent

psychometricians in the field, is prototypical for these attempts (Harris 1963). The debates at that time were by no means confined to technical subtleties, but brought up rather fundamental psychometric issues, culminating a few years later in the well-known advice of the former president of the American Psychological Association Lee Cronbach that “investigators who ask questions regarding gain scores would ordinarily be better advised to frame their questions differently” (p. 80) (Cronbach and Furby 1970). Fortunately, most researchers did not follow this advice, and in subsequent years, measurement theories and statistical techniques got more refined and the rationales for longitudinal research were more clearly spelled out. Particularly influential in the field of geropsychology became the formulation of five different rationales for longitudinal research by Baltes and Nesselroade (1979), who distinguished between (1) *the direct identification of intraindividual change*, (2) *the direct identification of interindividual differences in intraindividual change*, (3) *the analysis of interrelationships in behavioral change*, (4) *the analysis of causes of intraindividual change*, and (5) *the analyses of causes of interindividual differences of intraindividual change*. Until today, this distinction has not only proven to be a useful taxonomy, but also reflects major trends in the history of longitudinal statistical analysis. For this reason, the remainder of this encyclopedia entry presents the attempt to reconstruct the history of longitudinal statistical analysis in developmental psychology and geropsychology along the lines of these five rationales. Figure 1 provides a graphical overview of the major trends in the history of longitudinal statistical analysis identified in this chapter and how they relate to the five rationales put forward by Baltes and Nesselroade (1979). The figure thus also serves as an outline of the encyclopedia entry.

Describing Average Change in Populations During the Nineteenth Century

Most writers date the beginning of the history of longitudinal statistical analysis to the early nineteenth century. For geropsychology, these early years were characterized by the pioneering work

History of Longitudinal Statistical Analyses, Fig. 1 Major trends in the history of longitudinal statistical analysis in geropsychology and their relation to the five rationales for longitudinal research put forward by Baltes and Nesselroade (1979)

of the Belgian scientist Adolphe Quetelet, who not only followed earlier work by Johannes Nikolaus Tetens in extending the scientific investigation of human development to the entire life span (“L’homme naît, se développe, et meurt d’après certains lois qui n’ont jamais été étudiées dans leur ensemble ne dans le mode de leurs réactions mutuelles”; p. 1, Quetelet 1835), but also made important contributions to longitudinal statistical analysis, such as the identification of research strategies that correspond to today’s schemes of cross-sectional and longitudinal research. At around the same time Quetelet studied the physical and social growth and decline in humans, his fellow countryman Pierre François Verhulst published the famous logistic equation in 1838. The equation was developed out of an attempt to better describe the growth of a population and after realizing that populations could not grow geometrically over a long period of time but that any increase is “limited by the size and the fertility of the country [. . . such that] the population gets closer and closer to a steady state” (p. 36) (Bacaër 2011). Finally, these early developments are closely associated with the name of Benjamin Gompertz, a British mathematician and actuary, who studied the laws of human mortality and proposed a sigmoid function to describe the mortality of a group of individuals which later became known as the Gompertz curve. The work by Gompertz, Quetelet, and Verhulst influenced (and was in part rediscovered by) renowned scientists in the early twentieth century, such as the biostatisticians Lowell Jacob Reed or Raymond Pearl, one of the founders of the new field of biogerontology. Indeed, the functional forms used to describe growth and predict mortality in the nineteenth century were quite sophisticated, even according to current standards, and continue to be used today. Inspired by developments in natural sciences, much work of this early period of longitudinal statistical analysis was concerned with detecting “natural laws” of human development or in the words of Baltes and Nesselrode with *the direct identification of intraindividual change* (rationale 1). Individual differences were acknowledged as early as the late 18th century, in the work of Tetens. However, such differences

were not incorporated in longitudinal statistical models as they were conceived of as either unpredictable or even erroneous. The latter view was taken to an extreme by Quetelet, who applied Gaussian error theory as developed for the quantification and control of observational error in astronomy to variations among humans. Rather than pertaining to confounding effects during the measurement process, his conception of error comprised what Quetelet considered inordinate and intractable idiosyncrasies and even deviations from physical and “moral” and eventually divine perfection (Porter 1986). This led to the metaphor of “the average man” (“l’homme moyen”) (Stigler 2002) which can, despite its somewhat ideological connotations, be considered programmatic for a period in which scientific effort to formalize and cast change in terms of mathematical laws centered around the population as the primary unit of analysis. As Porter (1986) notes: “The doctrine that order is to be found in large numbers is the leitmotif of nineteenth-century statistical thinking” (p. 6).

From Average Trajectories to Individual Differences During the First Half of the Twentieth Century

Following Quetelet’s venture into the analysis of genuine human variation, the interest in interindividual differences began to complement the interest in aggregate characteristics of populations. Francis Galton’s and Karl Pearson’s work on systematic covariation among members of the same population regarding, for instance, physiological appearance, are exemplary in this regard (Porter 1986). With respect to the study of change, John Wishart’s publication on “growth-rate determinations in nutrition studies with the bacon pig, and their analysis” in 1938 marked an explicit transition from merely describing the functional form of average trajectories towards quantifying individual differences in these trajectories (Bollen 2007). In this article, Wishart reanalyzed data from a total of 30 bacon pigs whose weights had been measured across 16 weeks and who had been exposed to three different levels of protein content in the food ration. After having plotted and manually fitted a

second degree parabola to each pig's growth curve, he studied the effect of the experimental conditions on individual differences in growth curve parameters by means of ANOVA and ANCOVA. As noted by Bollen and Curran (2006), this study is remarkable, because it was probably the first attempt at *the direct identification of interindividual differences in intraindividual change*, Baltes' and Nesselroade's second rationale for longitudinal research. The use of factor analysis for fitting longitudinal data and the resulting work on generalized learning curves by Tucker (1958, 1966), but also Rao (1958), followed in this tradition. The nowadays popular linear mixed effects and latent growth curve models for the analysis of interindividual differences in intraindividual change can be traced back to these early attempts.

A precursor for a complementary approach to differential longitudinal modeling may be seen in Raymond B. Cattell's (1952) proposal to analyze variation and covariation among psychological variables within single individuals by means of P-technique factor analysis. In contrast to standard (R-technique) factor analysis, Cattell's P-technique analyzes the relationship between variables intraindividually, over many time points. It thus targets instantiations of change as they can be expected for more transient psychological states that are likely to (co)fluctuate in a reversible manner over time. Requiring many repeated measurements per person, the modeling approach comes with a strong person-oriented flavor, a perspective that only in recent years received increasing attention in geropsychological research (Molenaar 2004). Although Cattell developed P-technique primarily to reduce a larger set of observed variables to an underlying structure of person-specific common latent variables, it clearly influenced later developments of longitudinal statistical models at the individual level that may subsequently be used to study interindividual differences in intraindividual (co)variation.

From Description to Explanation During the 1960s and 1970s

Once the interest in describing interindividual differences in intraindividual change was raised,

the desire to explain these differences came naturally. Already Wishart did not limit himself to identifying the best fitting trajectory for each individual pig, but was interested in the causes of interindividual differences of intraindividual change (Rationale 5). In this regard, the 1960s and 1970s can be considered a transition period. On the one hand, researchers got increasingly interested in longitudinal data analysis and the statistical techniques to carry out such analyses became more refined and more widely known. On the other hand, there was still a considerable amount of leering, with longitudinal studies often not only being considered inordinately expensive but also suffering from the image of being a "womb-to-tomb research plan, replete with inadequate design, inexact instruments of measurement, and low research product" (p. 987) (Sontag 1971). Furthermore, more advanced linear mixed effects models were not yet developed, and the by then popular methods of repeated measures ANOVA and MANOVA bound to several assumptions, such as sphericity, which were often not met in practice (Fitzmaurice and Molenberghs 2009). Even the conceptualization and operationalization of change itself were subject to discussions, which revolved around keywords such as "gain" or "change scores," "raw change," "true change," "base-free," or "residual change." Clearly, this time period was characterized by the most fundamental and controversial debates on longitudinal data analysis in (gero)psychological research. Exemplary for these were the proceedings of the above-mentioned conference on *problems in measuring change*, which were published in 1963 (Harris 1963). One focus of the conference was on problems that arise with certain measures of change, especially with fallible observed change scores. Bereiter's (1963) elaboration on "some persisting dilemmas in the measurement of change" – also the opening chapter of the book – is probably most prominent in this regard. This work influenced many researchers in subsequent years including David Rogosa's pointed chapter on "myths about longitudinal research" over 20 years later, which eventually demystified several beliefs about longitudinal statistical analysis that were formed

during those earlier years. Interestingly, the gradual shift from the pure description of change to the explanation of change manifested itself somewhat differently across disciplines. In the emerging field of geropsychology, the focus laid primarily on Rationale 5, that is, *the analyses of causes of interindividual differences of intraindividual change*, with the term “causes” being better replaced by the more neutral term predictors. Much of the interest was on how people differ in developmental trajectories and what characteristics such differences may be related to. True causation, that is, the study of causes of intraindividual change (Rationale 4), was not yet high on the agenda. This was different in sociology, where researchers increasingly realized the potential of panel data to infer cause-effect relationships, with the influential work by Blalock (1964) and Duncan (1969) being exemplary for these attempts. Also in this period falls the seminal work of sociologist James Coleman on the mathematical study of change (Coleman 1968). His distinction between change as a function of time, immanent change, and exogenously driven change, along with his considerations regarding multivariate dynamical systems, foreshadowed much of the later developments in longitudinal statistical analysis in the field of developmental psychology and geropsychology.

From Univariate to Multivariate Models During the Close of the Twentieth Century

The interest in longitudinal research continued, some of the earlier confusion was resolved as “myths” were separated apart from facts (Rogosa 1988), and longitudinal statistical analysis gained momentum in the 1980s. This was fueled by two closely related developments. On the one hand, there was the advancement of earlier mixed modeling approaches. The proposition of a flexible class of *random-effects models for longitudinal data* by Laird and Ware in 1982 (Laird and Ware 1982) is a citation classic and the basis of most current approaches to longitudinal data analysis in geropsychology. On the other hand, the earlier work on the use of factor analysis for longitudinal data continued. At that time, confirmatory factor analysis – as part of more general

structural equation models (SEM) – had become a powerful and increasingly popular approach to the analysis of cross-sectional data. This was facilitated by the availability of easily accessible software (Jöreskog and Thiilo 1972). Drawing upon earlier work by Rao and Tucker mentioned above, it was Meredith and Tisak who presented a paper on “*Tuckerizing*” curves at the annual meeting of the Psychometric Society in 1984 in which they showed how to implement the analysis of trajectories by factor analysis within a structural equation modeling framework. Because this opened up completely new modeling possibilities, the year 1984 can be considered another milestone in the history of longitudinal statistical analysis, even though the actual paper was not published until 1990 (Meredith and Tisak 1990). Most importantly, the embedding of longitudinal data analysis within an inherently multivariate SEM framework allowed the field to move beyond simple univariate models, toward the analysis of interrelationships in behavioral change (Rationale 3). Being an immanently multivariate field with multiple determinants and multiple outcomes, this development was particularly important for geropsychology, and the field saw a number of influential studies, for example on the differentiation-dedifferentiation of cognitive abilities, in the following years (Baltes et al. 1980; Schaie et al. 1998).

From Static to Dynamic Models During the Close of the Twentieth Century

Paralleling the trend from primarily univariate to multivariate models was an increasing reorientation from primarily static models to dynamic models. With better techniques for multivariate data analysis at hand, researchers got increasingly interested in not only describing interrelationships in behavioral change, but also in capturing the actual dynamics underlying such relationships. With the introduction of SEM-based latent change scores, it was primarily McArdle and colleagues who advanced the field in this direction, resulting in a number of important publications in geropsychology (McArdle 1988, 2001). Interestingly, the somewhat parallel trend in the development of longitudinal statistical analysis between otherwise closely related

disciplines continued during this time. For instance, the work by Tuma and Hannan (1984) on *social dynamics* was highly influential in sociology and can be considered a precursor of much of the most recent work on dynamical systems in (gero)psychology. The publication of the corresponding book in 1984 is another reason why this year can be regarded a milestone in the history of longitudinal statistical analysis. In contrast to the considerable degree of dispute and confusion that characterized the 1960s and 1970s, developments during the 1980s and 1990s were influenced by the insight that there simply is “no *best* way to study change” (p. 3) (Burr and Nesselroade 1990). In consequence, researchers became more and more aware of the freedom but also the responsibility they have when choosing from the methods “toolbox” of longitudinal statistical analysis.

Current Trends in Longitudinal Statistical Analysis in the New Millennium

Clearly, the history of longitudinal statistical analysis has not come to an end. Quite the opposite, with the beginning of the New Millennium, research activities involving longitudinal statistical analyses have increased tremendously. Unlike in the last century, today the need for longitudinal data and the value of longitudinal statistical analysis for psychological research are beyond dispute. Rather, with ever more longitudinal studies and an increasing number of different types of longitudinal data available, the discussion has taken a pragmatic turn, with most of today’s research focusing on different ways to improve the design and analysis of longitudinal studies. In this regard, the five historical trends associated with the five rationales for longitudinal research continue to exist, although the relative emphasis in their development may have changed over time.

Descriptive Models Accounting for Differential Change Are Well Established

Finding the best fitting function for a developmental process (Rationale 1) is still of core interest to

geropsychological research and may be best exemplified by the work on “the rise and fall in information processing rates over the life span” (Cerella and Hale 1994) and related research on intellectual development (Li et al. 2004), to give just one example. Being aware of the complex and multidetermined nature of human development, however, geropsychologists have largely dismissed the idea of reducing human development to a definite set of deterministic “natural laws” straightforwardly expressible in mathematical equations. Instead, the study of individual differences in change (Rationale 2) has become a major goal in geropsychology and so did the study of the determinants of such differences (Rationale 5). The search for predictors of the enormous interindividual differences in what may be generally called “successful aging” – best evidenced by the impressive behavioral and brain plasticity observed in recent years (Lindenberger 2014) – is in fact one of the most important goals in modern geropsychology. To this end, the application of methods of differential psychology to repeated measures, as called upon by John Nesselroade in his 2000 Presidential Address to the Society of Multivariate Experimental Psychology (Nesselroade 2002), has proven particularly useful and will likely continue to do so in the future. The numerous articles, chapters, and textbooks on SEM-based latent growth curve/multilevel modeling document this trend. With respect to the description of intraindividual change, the description of interindividual differences in intraindividual change, and their prediction, hence Rationales 1, 2, and 5, the field of longitudinal data analysis has clearly matured. Today, there will be few graduate students or researchers in geropsychology who have never been exposed to any variant of growth curve models.

Models of “Psychological Mechanics” Are Needed

In terms of multivariate causal models and thus in terms of Rationales 3 and 4, however, longitudinal statistical analysis in geropsychology is still in its infancy. Although there have been calls for taking holistic, experimental approaches to life span and

geropsychology as early as 40 years ago (Baltes and Nesselroade 1973), the number of studies that use multivariate longitudinal data with the explicit goal to identify cause-effect relationships in nonexperimental settings is limited and so is methodological research targeted on improving longitudinal (causal) analysis in gerontology. In recent years, however, there have been some exciting developments in neighboring disciplines, which may eventually spill over to geropsychology and accelerate the representation of multivariate change in conjunction with the investigation of (intraindividual) causes of change: first, the development and increasing use of dynamic causal modeling to analyze effective connectivity in functional neuroimaging data, which explicitly aims at a better understanding of the behavior of a dynamical multivariate system (i.e., Rationales 3 and 4) (Friston et al. 2003); second, the increasing use and continuing refinement of methods for panel data analysis in sociology and econometrics, with the goal of better identifying cause-effect relationships in non-experimental data (Rationale) (Halaby 2004); and, finally, a better theoretical understanding of causality and the conditions for its inference based on recent work in statistics and computer science (Rationale 4) (Pearl 2009; Rubin 2005).

Enriched and Ecologically Valid Intense Longitudinal Data

Another development that (gero)psychology has witnessed in recent years concerns the increasingly different types of longitudinal data (physiological, behavioral, experiential), which may be obtained at different timescales ranging from milliseconds to several decades – or even combinations of all of these timescales. This is a trend that is likely to continue, with studies that combine, for example, a real-time assessment of physiological functioning as part of a multiday measurement burst, within the context of a large-scale panel study with annual assessment waves, becoming less the exception but increasingly common. Obviously this not only permits completely new insights into geropsychological processes, but also poses new methodological challenges. In light of these developments – and

despite its long past – the actual history of longitudinal statistical analysis may only just be starting.

History of Longitudinal Studies of Psychological Aging

Andrea M. Piccinin and Jamie E. Knight
Department of Psychology, University of
Victoria, Victoria, BC, Canada

Definition

In a longitudinal study, the same individuals and characteristics are repeatedly measured sometimes over long periods of time. This type of design is used to study developmental trends across the lifespan, and because the same people are compared against themselves, the differences observed are less likely to be the result of generational differences. As a result, longitudinal studies can more accurately assess change and development than can cross-sectional studies, where individuals of different ages are compared against one another.

Early Longitudinal Studies

Longitudinal data collection can be traced back to the irregular collection of Israeli census data, circa 1491 BC. However, data collection with regular intervals is not seen until 1665 in New France (Canada) (Statistics Canada 2006). King Louis XIV was ahead of his time in recognizing the importance of collecting reliable population information with which to measure the growth and development of his colonies. Economic development and self-sufficiency were easily quantified from information gathered on age, sex, marital status, trade, and occupation as well as from livestock and cultivated land. These statistics were used to monitor the health and taxation of the growing colonies. One example of the utility of these early census data was identification of the nearly two to one male–female ratio within the young colony. This discovery prompted efforts to send more women, which led directly to an increased and more stable population due to the ensuing marriages and births. While these

repeated measurements did not make use of the within-person change information that differentiates longitudinal data from cross-sectional and is emphasized today, they did provide useful population level evidence.

Early longitudinal studies focused primarily on childhood growth: physical, cognitive, and emotional. The oldest reported longitudinal growth record is attributed to Count Philibert Gueneau de Montbeillard, who measured his son every 6 months (from 1759 to 1777) and published it in Buffon's *Histoire Naturelle* (Tanner 1989). A subset of more recent studies of child development are of particular interest with respect to aging. These have developed into studies of aging, either through data collection continuing for long enough or through new researchers re-contacting original participants so that measurement has continued into adulthood and old age.

The Terman Study of the Gifted is generally recognized as one of the first studies initiated in childhood that has continued throughout the participants' lives. Terman started recruiting children from schools in 1921. The initial average participant age was ten; however, the inclusion of siblings resulted in a sample with birth years ranging from 1900 to 1925 and an initial age range of 3–28. By 1928, the sample size had reached 1,528 and recruitment ended. By 2003, 200 participants remained.

The Berkeley Growth and Berkeley Guidance studies (initiated at birth in 1928–1929) and the Oakland Growth study (initiated 1932 from 1920 to 1921 birth cohort) were either continued or later re-contacted at several points in their lifespan and now proceed with consolidated data collection as the Intergenerational Studies of the Institute of Human Development. Similarly, the Harvard Growth Study (1922 school-aged) and the Harvard Cohort (graduates from 1939 to 1944) and Inner-City (“Glueck”) Cohort have also been extended from their original focus on child and young adulthood.

A series of birth cohort studies in the United Kingdom – Hertfordshire Aging (1920–1930 birth cohorts) and Hertfordshire Cohort (1931–1939 cohorts) Studies, National Study of

Health and Development (1946), National Child Development Study (1958), and the Boyd Orr study of families (1937–1939) – have also developed into studies of aging, by nature of their long follow-ups. These formed a formal collaboration as the Healthy Ageing across the Life course (cyon) Network in 2008, and several now interact with younger British cohort studies through the CLOSER initiative to promote excellence in longitudinal research.

Finally, several studies of aging have reached back in time to include administrative data. For example, the Aberdeen and Lothian 1921 and 1936 studies were begun between 1997 and 2004 when investigators contacted individuals who had completed national educational assessments at age 11 and followed them up starting in old age. In other words, the baseline data collected in these studies were initially one-time measurements not intended for research or longitudinal analysis, but have formed the basis of studies of aging that include information about childhood achievement.

History of Aging-Focused Research

Of studies with first measurements in adulthood, the Iowa State Study most closely mirrors the administrative baseline studies described above. While formally begun in 1950, the Iowa State Study sampled from men who had 1919 entrance exam scores, effectively extending the measurement of cognition to three occasions (the third in 1961) over 42 years from young to late adulthood. In 1946, the New York State Psychiatric Institute Study of Aging Twins began its long-term investigation of hereditary aspects of aging and longevity, following participants' cognitive performance for 30 years. The 1950s and 1960s saw a marked increase in studies focused on aging in the United States. The Duke Studies of Normal Aging (I, 1955, and II, 1968), AT&T longitudinal study of managers (1956), Baltimore Longitudinal Study of Aging (1958), and Seattle Longitudinal Study (1956) all followed closely in time the first American National Conference on Aging (1950) and development of the Federal Council on Aging

(1956). These are all described by Schaie (Schaie 1983). In Germany, the Bonn Longitudinal Study of Aging (1965) followed two 5-year birth cohorts for 15–19 years.

In contrast to cross-sectional research on aging, these large-scale longitudinal studies are often highly multidisciplinary – collecting observational data on psychological (cognition, personality, perceived stress, locus of control, self-concept, life event, etc.), psychiatric, medical, sociological, and other characteristics. Some, such as the Seattle Longitudinal Study, in which data collection for K. Warner Schaie's dissertation evolved into a pioneering career, developed from what was initially a cross-sectional study. While Seattle involved recruitment of specific cohorts of new participants at each wave, as part of Schaie's innovative cohort-sequential design, other studies used either a single recruitment period (e.g., Duke) or continuous enrolment (Baltimore).

Early reports from these longitudinal studies were not analyzed in the same ways as modern studies, since current methods had not yet been developed, but generally, results agreed with cross-sectional work regarding the finding of greater decline in fluid than in crystallized abilities. On the other hand, however, evidence was accumulating that, relative to cross-sectional findings, declines started later and, for most people, proceeded more slowly. This led to some very animated and contentious debates in the 1970s as well as great motivation to meet the challenges of studying development in later adulthood.

Debates and Challenges

Conventional and scientific observations going back centuries have consistently described age-related declines in cognitive function, beginning as early as the third decade of life. With the advent of longitudinal studies of aging in the 1950s and 1960s, new evidence surfaced suggesting that declines began four decades later than previously thought. This striking mismatch led to a great deal of thought about its source and prompted Schaie (Schaie and Strother 1968) to develop and implement a cross-sequential design

for the Seattle Longitudinal Study in order to try to separate the influence of age from the impact of generational or “birth cohort” differences (Kuhlen 1940). While this was a creative strategy and an excellent step forward, it did not fully resolve the fact that once any two of age, cohort, and time are known, the third is determined. As stated by Donaldson and Horn (Donaldson and Horn 1992), “You have to know the answer to get the answer.” Research, conducted because the answer is not known, must proceed by assuming that at least one of the three influences has no impact. There is good evidence that the debate over practice effects is at least in part associated with the age-cohort-time dilemma, as recent work has shown that differences in model assumptions can provide evidence for practice or cohort effects in the same data (Hoffman et al. 2011). Renewed interest in the age-cohort-time problem has led to a resurgence of work and publications in this area, but it appears that solutions still require making strong assumptions and placing constraints on one of the dimensions.

A concrete example of the impact of cohort differences (Schaie et al. 2005) can be seen in the work initiated by James Flynn. What is now known as the “Flynn” effect is the observation that like-aged and similarly sampled individuals (e.g., army recruits, elementary school children) in more recently born generations obtain higher scores on the same IQ tests than individuals in earlier generations. Often attributed to changes in the education system, though with specific causes not known, the existence of this consistent pattern requires careful consideration of cohort differences in research on aging.

Additional sources of variance that are likely to magnify differences in the conclusions drawn from cross-sectional versus longitudinal studies of aging are retest or practice effects, attrition, and mortality. While both cross-sectional and longitudinal samples are influenced by selection effects – for example, only the individuals from a particular generation who are still alive at the time of sampling can be included – only longitudinal studies include information regarding whom from a measured sample subsequently drops out or dies. Generally seen as a challenge of

longitudinal studies, it could equally be viewed as a strength – providing essential information about how the “population” changes with age and in time. While those who drop out or die tend to be individuals who are older, less healthy, and less educated, there is good evidence that once part of a longitudinal study, individuals of failing health and advancing age will be more likely to return for repeated assessment than they would be to agree to enter a study for the first time. In other words, the selection due to attrition is often smaller than that due to initial selection. Particularly in the oldest samples, therefore, faster declines may be seen in the longitudinal age changes than in the cross-sectional age differences (Desrosiers et al. 1998).

While retest effects have likely been most of concern in research on cognitive development, they appear in other psychological domains as well (e.g., mood, personality, mental health). Retest has been addressed by use of parallel forms or alternate measures at different occasions of measurement, but such extreme solutions undermine the longitudinal nature of the design and eliminate the ability to assess change at the within-individual level. Given (1) that practice is unlikely to occur equally in different individuals; (2) that it is operating at the same time as, for example, a dementing process in a subset of any sample; and (3) that learning and adapting is an essential characteristic of life, the assumptions required to implement the many approaches that attempt to “correct” for practice effects may introduce confounds that, again, confuse longitudinal changes with cross-sectional differences.

Methodology

The many challenges associated with analyzing and drawing inferences from longitudinal data require development of new methods for the analysis of change. Following an era of crisis, in which some asked “How we should measure “change” –or should we?” (Cronbach and Furby 1970), methods dealing with change have moved beyond struggles with change scores to comprehensive methods such as mixed effects models

(aka multilevel models, latent growth curve models) making use of multiple occasions, unbalanced designs, and a focus on individual “trajectories” rather than group occasion averages. Plenty of challenges remain for the stouthearted, however, as well as continued lack of consensus regarding how best to address them.

Particularly in studies of aging, there is a tendency to recruit age-heterogeneous samples – often ranging in age from 50 or 60 to 90 or higher. These 30- or 40-year age ranges are an attempt to capture the (potentially) long portion of the lifespan labeled “late life” as well, often, as the transition from middle age into this period. These samples, which would also be appropriate for a cross-sectional analysis, are then often followed for ten or so years. Given the age range for the cross-sectional (e.g., 40 years) relative to the longitudinal (e.g., 10 years) information, it is essential that the statistical models employed to analyze this type of data differentiate clearly between the two sources of variance. If longitudinal data are being collected, at great time and expense, because they are believed to contain superior developmental information, then the utmost diligence must be applied to ensure that results and conclusions are based on the longitudinal aspects of the data. Current priorities continue to include the hotly debated issues described above (Hofer and Piccinin 2010).

No doubt related to the challenges of mounting longitudinal studies and also to a system that rewards publication of new findings over subsequent supporting evidence and may initially ignore subsequent null findings (Pashler and Wagenmakers 2012), the longitudinal aging literature can be idiosyncratic and difficult to compare. It has not been uncommon for authors planning a meta-analysis to instead present a narrative review. The stated reasons for this change of plan have included the great variability in design and analysis features in longitudinal studies relative to cross-sectional research in general and relative to experimental research in particular. Indeed, if we are to combine or contrast results from longitudinal and cross-sectional designs, we must first acknowledge the fundamental differences between the meaning of (a) variance in the

changes that occur within individuals over time and (b) variance in the differences that exist between individuals of different ages at any one point in time. It is also essential to explicitly address whether each report from a longitudinal study made use of cross-sectional (e.g., baseline or other individual waves) or longitudinal (i.e., repeated measures) data. If longitudinal analysis, by definition, requires the analysis of repeatedly measured characteristics, then some of what has been called “longitudinal” in the past has not, technically, been longitudinal.

The Modern Era

The dark days regarding measurement of change were accompanied by some apparent reluctance to fund research specifically focused on aging. Initial bills met with resistance to the concept of separating aging from the biomedical purview to which it had belonged. In 1973, a bill was vetoed by US President Nixon based presumably in part on the sentiment expressed in a memo from the Office of Management and Budget claiming that it “could raise false expectations that the aging process can somehow be controlled and managed through biomedical research” (Lockett 1983). The bill was eventually passed in 1974 when Nixon signed legislation creating the National Institute on Aging (NIA) shortly before his resignation.

The late 1980s saw the beginning of a virtual explosion of new longitudinal studies of aging around the globe. Given the magnitude of this expansion, an enthusiastic response to earlier calls for longitudinal data fueled by improved funding and buoyed by significant advances in statistical methodology, it is difficult to neatly summarize this modern era of longitudinal studies addressing psychological aging. An important feature to highlight is the multidisciplinary nature of most longitudinal studies of aging, with aspects of psychological aging, among the components. As a result, opportunities abound for developing a more elaborated view of aging, one transcending traditional disciplinary boundaries. Geographically, longitudinal studies of aging now exist in

virtually all industrialized countries and are rapidly being initiated in many developing nations.

History of Collaborations

Based on their extensive infrastructure and funding needs, many longitudinal studies are inherently multidisciplinary and collaborative. Given the expense, the scarcity (relative to cross-sectional work) and the long delay until longitudinal results can be obtained, several attempts have been made to collaboratively bridge across studies. An early example of collaboration among longitudinal studies of aging is an effort, organized by the US Veterans Administration Normative Aging Study (Rose 1976) and funded by an NIA travel grant, which attempted to pool cardiovascular data across eight longitudinal studies. Words of caution from their report include the following statement regarding the appeal and promise of pooling: “The experience of the Cardiovascular Pooling Project, as well as preliminary data analysis in the present Longitudinal Interstudy Program, takes much of the magic out of the notion.” In the 1990s, Kaye Fillmore and colleagues from 25 studies pooled data related to drinking patterns. The Health and Retirement Study (HRS) family, including the English Longitudinal Study of Aging (ELSA) and the Survey of Health, Aging and Retirement in Europe (SHARE), and other multi-site studies such as the UK Cognitive Function and Ageing Study provide extensive opportunities for multi-sample analyses based on similar measures. Independently initiated (ca. 1984) Alzheimer’s Disease Research Centers across the United States created a minimum dataset in 1997 and formalized their collaboration with NIA funding in 1999 as the National Alzheimer’s Coordinating Center to facilitate collaborative research. In 2006, the National Institutes of Health (NIH) Cognitive and Emotional Health Project published evidence they reviewed from longitudinal studies regarding lifestyle and health behaviors related to maintenance of cognitive and emotional health. Much of this evidence, however, still relied on cross-sectional analysis of data.

Based on the realization that replication of some sort is needed to gauge consistency of findings and evidence that meta-analysis of published results is currently limited as a solution, a network was developed to encourage researchers leading longitudinal studies of psychological aging to participate in collaborative analyses that could be more directly compared (Hofer and Piccinin 2009). First funded in 2007, the Integrative Analysis of Longitudinal Studies of Aging (www.IALSA.org) network is an international collaboration focused on within-person analysis of psychological (particularly cognitive, personality, and well-being) and physical health. Acknowledging the high degree of variation in sampling, measurement, and design across studies, IALSA is emphasizing conceptual harmonization and harmonization of models over reliance on measurement harmonization. Several within-country networks (e.g., CLESA (Comparison of Longitudinal European Studies on Aging), Europe plus Israel; DYNOPTA (Dynamic Analyses to Optimize Ageing), Australia; Harmony, Sweden; HALCyon, UK) have also been developed.

Concurrent work in genetics and other fields requiring large sample sizes and greater statistical power simultaneously encouraged advances in harmonization, in order to permit pooling of data, and development of infrastructure to support federated analyses that avoid the need for data sharing. Motivated by these needs for replication and statistical power, there have been a growing number of efforts to combine forces on larger multi-study analyses and syntheses of research findings. In conjunction with IALSA, a publicly accessible platform for finding, matching and harmonizing metadata across longitudinal studies of aging from around the world is being developed and maintained by a research team known as Maelstrom Research (<https://www.maelstrom-research.org/>). In 2012, three associated projects, DataSHIELD, OBiBa, and DataSHaPER, joined together to create the Maelstrom Research program which has since been extending its infrastructure to accommodate longitudinal research. Maelstrom provides open source software for data cataloguing, harmonization, integration, and co-analysis of data and also actively conducts

research with the goal of reducing challenges surrounding data harmonization and data sharing (including data transformation, statistical modeling, federated data analysis).

Future Directions

Most existing longitudinal studies of aging involve age-heterogeneous samples measured at widely spaced intervals, some as often as annually, but others with irregular or wider spacing. From both psychometric and developmental perspectives, this presents numerous challenges, several of which have been articulated above. A further concern with such designs involves the reliance on single points in time to represent status or change over a longer period. In addition to ignoring day-to-day within-person variability in performance, these designs do not allow separation of retest effects from developmental changes. One method that addresses both of these is the measurement burst design, in which variables of interest are repeatedly collected from participants in a number of sessions during each measurement wave. One advantage of such a design is that measurement of each wave can be more reliable. Another, more powerful benefit is that retest effects (within burst) can be separated from potentially aging-related within-person changes (across burst) in order to at least partially separate short-term retest changes from long-term developmental ones. While the greater number of sessions adds to participant burden and to the complexity of the study, a variety of such intensive measurement designs show great promise for addressing some of the challenges associated with drawing firm conclusions from longitudinal studies. These methods also provide an additional window on understanding within-person change and variation.

A continuing challenge, which may soon be approachable with the current set of longitudinal studies of lifespan and aging, relates to study of the consistency of aging characteristics across generations and countries. How much of what we learn about current and past older generations will translate to those of the future? This

additional layer of inquiry will provide an exciting and essential dimension to our understanding of universal versus modifiable aspects of aging. It will likely require all and more of the collaborative skills and infrastructure that are currently being developed.

History of Sexual Orientation and Geropsychology

Douglas C. Kimmel
City College, City University of New York,
New York, NY, USA

Synonyms

Bisexual; Gay; Homosexual; Lesbian; Same-sex attraction; Transgender

Definition

Historical perspective on the study of the diversity in aging experiences reflecting sexual orientation and gender identity in the USA.

Introduction

Homosexuality was listed in the *Diagnostic and Statistical Manual of Mental Disorders* until 1973 when homosexuality per se was removed, and replaced with “ego-dystonic homosexuality,” by a vote of the Board of Directors of the American Psychiatric Association; the decision was later affirmed by a vote of the members (Bayer 1981). Same-sex sexual behavior between consenting adults was criminalized in all of the USA until 1970 when Illinois became the first state to remove it by legislative vote. Consenting same-sex sexual conduct in private was illegal in some

states until 1996 when the U.S. Supreme Court ([Lawrence v. Texas](#)) reversed an earlier decision in 1986 that upheld its criminality ([Bowers v. Hardwick](#)). Homosexuality remains criminalized in many countries, and the archaic laws in England were brought to attention in connection with a royal pardon granted to one of the heroes of World War II, Alan Turing, in 2013. Turing played a leading role in cracking the Nazi secret code but was forced to accept chemical castration after having admitted to the police in 1952 that he was a practicing homosexual (Hodges 1983).

In June of 1969, an uprising in New York City following the police raid on a popular gay and transsexual bar provoked a paradigm shift in the understanding of homosexual identity. What had previously been a personal condition (often thought to be a perversion of sexual attraction) became reconceptualized as a minority group identity (Hay 1990). This event is now celebrated around the world by “gay pride” celebrations. In time, mental and legal issues became reframed from pathology and criminality to matters of discrimination of an oppressed group of individuals who had little else in common except their sexual orientation.

Individuals also began to disclose their minority sexual orientation openly in public demonstrations against discrimination as well as in professional associations, including the American Psychiatric Association and the American Psychological Association. These self-affirming lesbian and gay protesters prompted resolutions designed to remove the stigma of pathology that had long been associated with homosexuality (e.g., Conger 1975). Researchers and academics likewise began to study and openly discuss issues of sexual orientation across the adult lifespan (e.g., Kimmel 1974).

Following the ruling of the state of Hawaii Supreme Court in 1996 ([Supreme Court of Hawaii](#)) that denial of same-sex marriages violated the nondiscrimination clause regarding sex, another paradigm shift emerged. Previously, legal issues regarding sexual orientation were concerned with discrimination based on sexual attraction and behavior. After that ruling, sexual orientation was reframed as a subcategory of

gender discrimination; that is, two individuals of the same sex were not entitled to the same marital rights and benefits as two individuals of differing genders. This paradigm shift linked sexual orientation and gender identity under the umbrella of gender discrimination and laid the groundwork for the coalition of lesbian, gay, bisexual, and transgender (LGBT) individuals opposing all forms of gender discrimination. A new program of education and research has now emerged known by the acronym SOGI (sexual orientation and gender identity; see <http://wwwp.oakland.edu/sogi/>).

Prevailing Views of Older Homosexuals in the 1960s

In our society there have always been older individuals who did not marry, who lived with someone of the same sex, or who were relatively open about their same-sex attraction (such as Walt Whitman or Gertrude Stein). It was not a positive status for the young LGBT person in the 1960s, however. Moreover, social gender distinctions were strongly held. Women focused on equal rights, and lesbians were often forced to choose between women's issues and gay issues. Gay men and lesbians were pushed into "butch" or "fem" roles. Bisexual men were felt to be hiding their homosexuality and not to be trusted. Transgender persons were limited to being a transvestite, cross-dresser, or drag queen.

Even after the paradigm shift at the Stonewall uprising, the belief was: being gay (LGBT was often collapsed into that single term) might be fun when you are young, but wait until you grow old; you will be lonely and depressed in isolation. A visit to any lesbian or gay bar at the time would have confirmed this belief, as there would be a few examples of such individuals in the bar at closing time.

Stern (1962) provided a description of being old and gay:

the ageing [sic] homosexual is an object of scorn and derision. Though his loneliness is often abject, he seldom arouses sympathy or interest, unless he has money or influence. . . .

Without money, the ageing homosexual may wind up in the Bowery, seeking oblivion in hand-outs and cheap wine. . . . For the most part, though, the ageing homosexual is usually his own worst problem, so desperately lonely and frightened at times that he frantically beats the walls in his anguish.

The homosexual does not appear to live as long, generally as heterosexuals. Some hold that a benevolent nature comes to the aid of the ageing deviate, shortening his term of life. (pp. 231, 232)

Allen (1961) presented a similar view of homosexual men and added,

The female homosexual often ends in the same way. Not all women homosexuals are the masculine, chain-smoking, short-haired dragons they are usually imagined to be, but a great many are. However, whereas the male homosexual often finds it hard to find someone, even another homosexual to live with, the female homosexual more often does find a partner.

One sees, then, two vigorous aggressive old women, sometimes sharing a small house, quarrelling, digging the garden, and trying to rule the neighborhood. Such examples, as everyone knows, have been the subject of innumerable novels. (p. 95)

Almvig (1982), in the introduction to her pioneering study of older lesbians, described the prevailing attitude for women: "Negative stereotyping of older lesbians in literature and film (such as *The Well of Loneliness*, *The Children's Hour*, *The Killing of Sister George*, and *The Fox*) have contributed towards further solidifying the general population's view that lesbians cannot lead satisfying and productive lives. Uneducated attitudes perpetuate the image of a lonely, pathetic and troubled group that just somehow missed having a relationship with a 'good man,' the 'right man,' or just 'any man'" (p. 4).

Adelman (1986) described what it was like to be lesbian in this period: "when marriage was the only socially and practically viable option for women; when few jobs were open to women; when moving about as a single woman was in itself both unacceptable and difficult" (p. 12). "The dominant view of gay people defined them as deviant and deficient. Because there was no visible or viable gay subculture to help offset this homophobic view, gay people were vulnerable to internalizing it: attributing these values to

ourselves and each other. Without benefit of mutual support, avoiding identification with other gay women was a way for lesbians to salvage their self-esteem. . . . For these elders, the struggle for self-acceptance was a painful and solitary process” (pp. 13–14).

As lesbian and gay individuals began to come out of the closet, bisexual and transgender individuals were largely invisible in the twentieth century in the USA. Nonetheless, Finocchio’s Club in San Francisco and similar female-impersonator or drag venues were popular. Ball culture, the house system, the ballroom community, and “Drag Balls” were major events in many communities; the film *Paris is Burning* (1990) portrayed some examples of this variety of LGBT culture.

Kinsey et al. (1948) found that “nearly half (46%) of the [male] population engages in both heterosexual and homosexual activities, or reacts to persons of both sexes, in the course of their adult lives (p. 656).” Their bisexuality was usually ignored as long as they were engaged in heterosexual relationships, and assumed to be homosexuality when arrested in a gay bar raid or caught in some other compromising situation. As Dworkin (2006) noted, “When a bisexual person falls in love he or she sometimes begins to identify (publicly or privately) as lesbian, gay, or heterosexual and thus becomes invisible as a bisexual aging person” (p. 36). Therefore, an aging bisexual person in the 1960s would typically have been regarded as either someone whose homosexuality had been cured by heterosexual marriage or someone who had become degenerate and fallen into homosexuality.

Transgender individuals have been noted in historical records. Katz (1976) reported several examples of “passing women” between 1782 and 1920 who appeared to be male in appearance and behavior. He also described many examples of males who dressed as women or performed in transvestite venues. Actual change of gender from sex of birth was not widely noted until Christine Jorgensen began sex reassignment surgery in the 1950s. Information about transgender options was very limited in the twentieth century and even today, “A substantial proportion of transgender

people do not transition until late middle age or later. . . . People who have struggled with gender questions all of their lives may not have realized until now, with the availability of the World Wide Web and more literature on gender variance, that there was a name for their feelings and courses of action they could take” (Cook-Daniels 2006, pp. 22–23).

Research on LGBT Aging

The field of geropsychology was only beginning to emerge in the 1960s; there were few studies on either sexuality or sexual orientation of older adults, and most studies focused on males.

Evelyn Hooker’s (1955) pioneering study of homosexual men matched on age with heterosexual men demonstrated that the stigma of mental illness placed on gay men was unsupported by projective tests popular at the time. The Kinsey Institute conducted a study of male homosexuals in the 1960s that found the “older” (over age 45) respondents were “no worse off than our younger homosexuals on various psychological dimensions, and are, on some dimensions, better off. . . . The stereotype which portrays the homosexual as decreasing in psychological well-being as he gets older results, we believe, from incorrectly attributing or overgeneralizing meanings to the sociosexual situation of the older homosexual which he himself does not experience” (Weinberg and Williams 1974, p. 220). The authors also suggested that the “identity crisis” faced by homosexuals earlier in life may in some way prepare them better than heterosexuals to weather the normal “role discontinuity” crisis of later life. Weinberg (1969, 1970) reported that older gay men in this study are no more depressed or lonely than their nongay peers and experienced improved adjustment as they age.

In the 1970s geropsychology was beginning to examine women’s issues, racial and cultural diversity, and a few openly gay gerontologists began studies relevant to their lives. A significant study was conducted by Jim Kelly (1977) as his doctoral dissertation and presented at the 1972 meeting of the Gerontological Society

of America in San Juan, Puerto Rico, where it was awarded the best student paper award. (At the opening reception the President of the Society announced Kelly's award for research on an "unmentionable topic.") This study included respondents up to age 69 and concluded that being gay does not cause problems for older men but that the social stigma of homosexuality may cause problems for older gay men.

Other early empirical studies of chronologically older gay men likewise focused on countering the stereotype of the lonely depressed old homosexual. Despite the unflattering title, "The menopausal queen: Adjustment to aging and the male homosexual," Francher and Hencken (1973) concluded, "In direct opposition to the popular mythology depicting the aging male homosexual as despairing and desolate, this paper proposes that homosexuality may be functional in adjusting to the aging process. Homosexuals commonly experience a 'life crisis' early in their development and are therefore less affected by the trauma of role loss that occurs for most men in later life" (p. 670).

The current author conducted an interview study of gay men between the ages of 55 and 81 (Kimmel 1977, 1979); he noted the diversity among this group, challenging stereotypes associated with aging homosexual men: "The wide diversity of their patterns of aging, the presence of positive aspects of gay aging, and high life satisfaction of many of the respondents contradicts the stereotype of the lonely, isolated old gay man" (Kimmel 1979, p. 239). He termed the phenomenon noted by others of the benefit of the earlier life crisis about identity as "crisis competence," which may be a coping skill that can help buffer against the usual concerns of growing older (Kimmel 1978).

Raymond Berger (1980) conducted a questionnaire study of 112 gay men over age 40 and found that "Few of the negative stereotypes that usually characterize descriptions of this group were supported. Most respondents were well adjusted and satisfied with their lives" (p. 161). He published a detailed account of this study in a significant book that included information about the emerging services for older gay

people and some policy recommendations (Berger 1982).

Berger's work was stimulated by Minnigerode's (1976) research on "accelerated aging" among older gay men, which is the idea that old age begins much earlier for homosexual men than for heterosexual men. In his later edition, Berger (1996) discussed this idea, as well as the critique by Lee (1987) that studies by liberated young researchers were presenting "too rosy" a picture of aging and ignored the "generation gap" between the researchers and the older men who valued secretive lives that allowed them to pass as heterosexual in the mainstream culture.

This debate continues about whether aging for gay men is characterized by sexual rejection (accelerated aging), positive resilience and diversity, or some combination of both and to what extent the aging experience for gay men is the result of cohort and the effects of personality, health, ethnic background, and social class.

Very little attention was given to research on older lesbians. An early exception was Marcy Adelman (1980), who codirected a National Institute of Mental Health grant-sponsored research project in the mid-1970s comparing homosexual and heterosexual men and women over the age of 60. It found that the same developmental challenges apply to gay and heterosexual white adults in the San Francisco Bay Area but there is a significant effect of stigma on the gay and lesbian respondents. She and her colleague, Fred Minnigerode, described the adaptations and problems of older homosexual women and men 60–77 years of age (Minnigerode and Adelman 1978). Her book, *Long-Time Passing: Lives of Older Lesbians*, based on interviews with lesbians 60–85 years old, described their current concerns and earlier life issues (Adelman 1986). Her study revealed an important reciprocal relationship among generations in the lesbian community that helps individuals prepare for their future.

Chris Almvig (1982) studied 74 lesbians over the age of 50: "this study explores respondents' self-perception of mental health, their thoughts about aging and ageism, what they value in relationships, their family relationships and support systems, their relationship to gay culture and to

straight culture and their preparation for the future” (p. 6). She found among the respondents little gender role-playing, that sexuality and affection continued to be a strong life-affirming force, that the struggle for identity in the face of discrimination created a better sense of self, and that being secret about her sexual orientation was the biggest factor determining how the lesbian was affected by aging. She also noted a potential benefit: “Apart from society and society’s expectations for women, perhaps older lesbians have had the advantage of living their own lifestyles without those constraints” (p. 154).

The emerging research in the 1980s prompted the formation of organizations to provide services and to promote further research in the geropsychology of LGBT aging. Almvig and Kimmel, both living in New York City, became cofounders of SAGE, a pioneer community organization providing services and advocacy for older lesbians and gay men, in 1978 (www.sageusa.org). Adelman was cofounder of Openhouse, an organization in San Francisco providing housing, services, and community for LGBT seniors (www.openhouse-sf.org).

Del Martin and Phyllis Lyon (1979) authored a significant article in *Positively Gay* titled “The Older Lesbian” that mentioned their cofounding of the Daughters of Bilitis (DOB), named for a woman who was thought to be Sappho’s contemporary (Cruikshank 1991, p. 68).

Sharon Raphael and Mina Robinson (1980) discussed intimacy and aging in lesbians age 50–73. They stressed love relationships and friendship patterns among the respondents and questioned the prevailing stereotypes of lonely isolated older lesbians who had no one to love or care about in old age. Sharon and Mina were cofounders of the National Association of Lesbian and Gay Gerontologists (NALGG). The history of NALGG and related organizations will be discussed later.

Soon after the beginning of modern LGBT geropsychology, the HIV/AIDS epidemic began, in 1981, and transformed the lives of the cohorts most affected. For infected gay men aging was no longer expected, and those who somehow survived with the virus long enough to benefit from

the antiretroviral therapies were confronted with actually growing old (Halkitis 2014). Lesbians, gay men, and supporters became caregivers and developed extraordinary organizations and effective protests to counter the stigma, ignorance, and discrimination about persons with HIV/AIDS. Research on growing older with HIV has become a major focus, both with regard to the psychosocial issues involved as well as the unknown effects of long-term use of the necessary medications (deVries and Herdt 2012).

Building on earlier research regarding the diversity within the small samples that disproved some negative stereotypes of LGBT aging, research in the 1990s focused on exploring racial and ethnic diversity (e.g., Adams and Kimmel 1997), women’s issues (e.g., Sang et al. 1991), and older couples (Quam and Whitford 1992).

As the stigma of mental illness and criminality was lifted by professional organizations – such as the American Psychological Association (APA) and legislation or judicial decisions supported by APA *amicus* briefs – partnership benefits and equality with respect to adoption, custody, and insurance benefits have been fought for and extended to same-sex couples. With the recent affirmation of legal marriage by the U.S. Supreme Court, and the recent ending of federal restrictions on same-sex and transgender benefits for veterans and Medicare recipients, aging LGBT individuals have benefited directly in countless ways. Research on LGBT grandparents, openly lesbian and gay aging veterans, and transgender issues in long-term care facilities are some examples of studies that became possible as a result of these recent changes.

A major focus of psychosocial research in this century has been on health disparities among lesbian, gay, bisexual, and transgender adults, especially as they affect the prognosis for aging (e.g., Fredriksen-Goldsen et al. 2013). Another major theme is providing affirmative services to LGBT elders in psychological and gerontological settings (e.g., Kimmel et al. 2015; Travis and Kimmel 2014). Perhaps the most challenging emerging area of geropsychological research and practice is the gender transitions of older adults and the aging of transgender adults (e.g., FORGE).

The appalling stereotypes and negative attitudes about aging lesbians and gay men have been challenged directly by the nationwide emergence of same-sex marriage. Unlike in the last century, the idea of gays and lesbians growing old does not come as a surprise to geropsychologists today. Although ageism continues to exist in the LGBT community (and widely in society), the fear of growing old can no longer be used as a threatening club to dissuade young people who are discovering their unconventional sexual orientation or gender identity.

Organizations Focused on Older Lesbians, Gay Men, and Bisexuals

The first national conference on Lesbian and Gay Aging was held at California State University, Dominguez Hills, in October 1981, sponsored by NALGG, with over 200 participants. Twenty-four sessions were audiotaped, including a workshop led by Jim Kelly, a program on Outreach Strategies by Sharon Raphael and some board members of SAGE, and a session titled “Black older lesbians & gay men share their history.”

NALGG was founded in 1978 and described itself as “The only group of professional gay gerontologists in the country. . . our membership includes professors, hospital administrators, writers, psychologists, medical doctors, teachers, clergy, students, and others, who are interested in pursuing the study of gay aging and its effects.” It published a newsletter, *Making a Difference*, from 1979 until 1994. It issued a mimeographed *Resource Guide: Lesbian and Gay Aging* in 1989. This resource guide contained an annotated partial bibliography, a list of films and videos, a list of the audio tapes from the 1981 conference, a list of newsletters and publications, and various organizations and services for lesbian and gay elders in the USA. Organizations listed were from San Francisco, San Diego, Long Beach, Berkeley, Los Angeles, Soquel, San Jose, and Hollywood, CA; Washington, DC; Philadelphia and Pittsburgh, PA; Seattle; New York City; Baltimore, Denver; and Columbus, OH.

A brief history of NALGG was provided in the Fall 1990 issue of *Making a Difference*. Sharon Raphael and Mina Meyer (1990) described the founding in Los Angeles by Raphael, Meyer, Jim Kelly, and Richard Southern, a graduate student, who coedited the first issue of the newsletter. Mina Meyer wrote *The Older Lesbian*, the first publication by NALGG. Raphael and Meyer organized the first lesbian symposium at the Gerontological Society of America (GSA) meeting in 1978.

The second national conference on lesbian and gay aging was held in June 1983, in San Francisco, drawing over 300 participants. Donald Catalano became chair of NALGG, and its office moved to San Francisco in 1984, where it held regular meetings and worked with local groups such as Gay and Lesbian Outreach to Elders (GLOE) and Gay and Lesbian Accommodations for the Experienced in Years (GALAXY) that was planning a retirement center in San Francisco.

The major national focus of NALGG during the 1980s was to hold membership meetings and present papers and symposia at each of the major gerontological meetings. The annual conferences of the GSA, the Western Gerontological Society, and the American Society on Aging (ASA) frequently included some content related to lesbian, gay, and also HIV/AIDS issues as a result of NALGG’s efforts. In the 1990 and 1991 meetings of the GSA, NALGG organized a formal “Interest Group” on lesbian and gay gerontology; these meetings were attended by 13 and 28 individuals, respectively (author’s notes).

In 1992 NALGG and the ASA cosponsored the first national conference on LGBT issues titled “Diversity With a Difference: Serving three Million Aging Gays and Lesbians.” It was held in conjunction with the ASA annual conference in San Francisco. Del Martin was the keynote speaker, and her talk drew an attendance of 250 (American Society on Aging 1992). Among the other speakers were Morris Kight, founder of the Gay and Lesbian Community Services Center in Los Angeles in 1971, and Shevy Healey, a founding member of the Old Lesbian Organizing Committee based in Houston. Audio cassettes of the 11 sessions were available at the time.

In the winter 1993/1994 issue of the NALGG newsletter, Sandra Zimmerman, president, reported that “the Board of Directors of the American Society on Aging approved a Task Force on Lesbian and Gay Aging Issues in 1992 and this group held its first open meeting at the ASA Annual Meeting in Chicago last March. . . . As a result of the development of the Task Force and in particular its network system, it becomes critical to ask whether NALGG has a mandate for a continued role in lesbian and gay aging issues?” (Zimmerman 1993). NALGG disbanded as a result of the response of the membership to her survey.

The Lesbian and Gay Aging Issues Network (LGAIN), affiliated with the ASA, carried on the work of NALGG and began publishing its newsletter, *OutWord*, in 1995; it is a standing Interest Network identified as LAIN ([American Society on Aging](#)). The Rainbow Research Group is a standing interest group in GSA: “The Rainbow Research Group helps facilitate connections between researchers interested in LGBT aging as well as researchers who identify as LGBT. Each year the Rainbow Research Group convenes a business meeting, group dinner, and symposium at the annual Gerontological Society of America meeting” ([Gerontological Society of America](#)). *OutWord* (2004) published a history of lesbian and gay gerontology based on interviews with Marcy Adelman, a cofounder of Openhouse in San Francisco; Raymond Berger, author of *Gay and Grey: The Older Homosexual Man* (Berger 1982); Margaret Cruikshank, one of the first educators in the USA to teach about gay and lesbian aging; and Douglas Kimmel, cofounder of SAGE in New York City.

The American Psychological Association Division 44, Society for the Psychological Study of Lesbian, Gay, Bisexual, and Transgender Issues, established a Task Force on aging, which resulted in an edited book, *Lesbian, Gay, Bisexual, and Transgender Aging* (Kimmel et al. 2006). It contained a bibliography of all relevant publications that could be located, which was updated in 2008 on the Division 44 website resource list ([American Psychological Association](#)).

With support from a federal grant, the National Resource Center on LGBT Aging was established in 2010 and became the leading repository of information and research about aging sexual and gender minorities for gerontologists ([National Resource Center on LGBT Aging](#)). This center is led by SAGE and 18 collaborating organizations; it has training resources and certified trainers throughout the USA.

This brief review of the historical changes in the geropsychology of nonconventional sexual orientation and gender identity has traced a remarkable evolution from mental illness, criminality, and sin to an inclusion within the broad array of diversities in aging within the lifetime of the author. Now attention needs to be paid to the diversities within the LGBT older population such as racial, cultural, or ethnic differences, disabilities, cognitive function, and social support.

Aging and HIV; HIV in older adults

Definition

The human immunodeficiency virus (HIV) affects the functioning of the immune system and can lead to a more severe form of immunodeficiency: acquired immunodeficiency syndrome (AIDS). Through compromise of the immune system, HIV often leads to secondary health problems, with young to middle-age patients experiencing increased risk for medical problems typically seen in an older population, such as cancer and cardiovascular disease. Further, advances in medication treatments result in more and more patients with HIV living into old age, leading to additional risks for cognitive symptoms, such as HIV-related dementia, and medical problems associated with aging.

Introduction

HIV compromises the immune system through preferential attacks on the CD4+ cells (“helper T-cells”) that are responsible for modulating and enhancing overall immune response, such as the direct function of other immune system cells (e.g., white blood cells) (Woods et al. 2009). The amount of CD4+ cells present in the body is used as a measure of the severity of HIV-related immunocompromise. Per the Centers for Disease Control and Prevention (CDC) definition, CD4+ counts below 200 cells/microliter are indicative of an AIDS diagnosis (Centers for Disease Control and Prevention 2016). The systemic effects of HIV may also lead to secondary health problems, as HIV infection increases the body’s susceptibility to other opportunistic infections. This can contribute to the same chronic health problems typically seen in the aging population. These secondary health problems led to the hypothesis that HIV infection is related to a condition resembling premature aging, and those who are HIV positive are considered at higher risk for medical and cognitive problems typically related to aging, such as cardiovascular disease, cancer, and changes in neurocognitive function (Deeks 2011).

Prior to the availability of effective medications for HIV, the expected life span of infected persons was significantly reduced relative to noninfected persons due to high HIV-/AIDS-related mortality rates (Valcour et al. 2004a). According to CDC census data collected between 1981 and 2008, HIV-/AIDS-related mortality rates climbed rapidly in the years before the release of effective antiretroviral treatments, with 451 reported deaths in 1981 increasing to 50,628 deaths in 1995 (Centers for Disease Control and Prevention 2016). However, with the advent of highly active antiretroviral therapy (HAART), also referred to as combination antiretroviral therapy (cART) due to the combined use of three or more antiretroviral drugs, the average lifespan of HIV-positive individuals has increased substantially and mortality rates have decreased. Per CDC census data, following the implementation of HAART treatments, corresponding declines were seen in HIV-/AIDS-related mortality rates.

Mortality rates then stabilized in 1999, and since that time CDC data indicates approximately 17,000 deaths per year (Centers for Disease Control and Prevention 2016). This stabilization of HIV-/AIDS-related mortalities is a direct result of cART's efficacy in establishing better control of overall viral load and stabilization of CD4+ cell counts, thereby enhancing the immune system's ability to respond to HIV and other infections (Centers for Disease Control and Prevention 2016; Gebo et al. 2010). As such, more and more individuals are living with HIV/AIDS for longer periods of time and into old age. According to 2013 CDC census data, current estimates indicate that of over 47,000 individuals in the United States diagnosed with HIV, approximately 21% are 50 years old or older (Centers for Disease Control and Prevention 2016). Therefore, the potential synergistic impact of HIV on the typical aging process is becoming an increasingly important area of study, as more people who have HIV enter the aging population.

As more HIV-positive individuals age, concurrent increases in the national medical cost of HIV infection are also expected. Before the introduction of cART, the annual cost of treating HIV-positive patients in 1998 was estimated at \$18,300 (Gebo et al. 2010). Using multisite data from 2006, Gebo and colleagues (2010) found that higher HIV-related care costs were associated with older age (\$16,541 to \$21,474) and more advanced HIV disease (\$30,415 to \$43,448 in patients with CD4+ cell counts of 50 or lower). HIV-related medical costs present a significant challenge, and the economic burden of these medical costs will likely continue to rise as more of the HIV-positive population transition into older age.

This encyclopedia entry provides a brief overview of the medical, neuropsychological, and psychological considerations associated with aging with HIV/AIDS. Furthermore, protective factors, which correlate with positive outcomes in the aging HIV-positive population, are also presented.

Biological Mechanism of HIV

Through HIV's primary effect on the immune system, the virus causes negative downstream

effects on the functioning of other organ systems within the body. The virus's primary mechanism of action – destroying CD4+ helper T-cells – reduces the body's ability to defend itself from other organisms by targeting the immune system. Through its effects on the immune system, the HIV virus also interferes with the body's ability to monitor its own cells, such as scanning for cancerous cell growth (Woods et al. 2009). A related finding to HIV immunocompromise is the co-occurrence of chronic systemic inflammation in persons who are HIV positive. In response to the virus's presence, the immune system triggers inflammation through proteins produced by immune cells that are important in cell signaling, called pro-inflammatory cytokines (Deeks 2011). Pro-inflammatory cytokines promote systemic inflammation in an effort to combat the virus and can persist over time in response to the virus's presence. This chronic inflammation is thought to underlie many of the other systemic problems seen in persons who are HIV positive, such as increased rates of cancer and cardiovascular disease (Deeks 2011). Lending support to this hypothesis is evidence that antiretroviral treatment decreases the levels of inflammatory markers in HIV-positive individuals, indicating a relationship between HIV and systemic inflammation (Deeks 2011). Nevertheless, even with successful antiretroviral treatment, inflammatory markers remain elevated in persons with HIV, relative to non-HIV-infected individuals, suggesting continued effects of the virus's presence even with good regulation of viral load (Deeks 2011; Wendelken and Valcour 2012). This chronic inflammation may explain the greater prevalence of comorbid medical problems seen in the HIV-positive population.

Chronic inflammation and other immune system changes experienced by individuals with HIV are similar to those found in the aging population. Studies show that as even healthy individuals age, they experience shrinkage of the thymus (the primary lymphoid organ of the immune system, which is involved in the production and training of helper T-cells), reduction of T-cell activity, and increases in systemic inflammation (Deeks 2011). These age-related changes in immune functioning

are collectively referred to as immunosenescence. Immunosenescence closely mirrors changes to the immune system seen as a result of HIV infection. As such, it is hypothesized that HIV's effects on the immune system likely result in premature aging of the systemic body (Deeks 2011). This condition of premature aging could then serve to explain the development of multiple medical problems and neurodegeneration typically associated with aging within the HIV-positive population.

Medical Implications of HIV and Aging

Medical problems such as cardiovascular disease and other comorbidities become increasingly prevalent as people age. In the HIV-positive population, similar increases in the prevalence of systemic diseases are seen, such as cardiovascular conditions and cancer (Valcour et al. 2004b).

Research demonstrates associations between HIV/AIDS and risk of developing cardiovascular disease and other cardiovascular risk factors like atherosclerosis (Hsue et al. 2004; Schouten et al. 2014). In a cross-sectional study, Schouten et al. (2014) found increased rates of hypertension in HIV-positive participants relative to HIV-negative controls (45.5% vs. 30.5%), as well as increased rates of myocardial infarction (MI; 3.9% in HIV vs. 1.5% in those without) and peripheral artery disease (2.6% in HIV vs. 0.6% in those without). In addition, HIV-positive individuals had significantly more age-associated noncommunicable comorbidities (AANCCs) than noninfected controls (Schouten et al. 2014). Dyslipidemia and abnormal fat distribution are other cardiovascular risk factors comorbid with both HIV infection and some antiretroviral treatments (Valcour et al. 2004b; Simone and Appelbaum 2008). Dyslipidemia is a well-established cardiovascular risk factor, which can lead to further cardiovascular complications such as coronary artery disease, MI, or stroke. Increased rates of atherosclerosis (hardening and narrowing of arteries due to the deposition of fatty plaques) are also seen in HIV-positive individuals relative to controls (mean carotid artery thickness:

0.91 mm in those with HIV vs. 0.74 mm in those without) (Hsue et al. 2004). As there exists a relationship between degree of atherosclerosis and risk of MI or stroke in the non-HIV-infected population, increased rates of atherosclerosis likely also contribute to the development of similar cardiovascular problems in HIV-positive individuals. Evidence indicates even greater risk of developing cardiovascular conditions or risk factors as the HIV-positive population progresses into older age (Valcour et al. 2004b).

The mechanism behind the development of these cardiovascular conditions is thought to be multifactorial, including aging, direct effects of the virus (e.g., CD4+ cell depletion) as well as indirect effects (e.g., chronic inflammation), and HIV/AIDS drug regimens. For example, findings from a large observational study demonstrated an association between combination antiretroviral treatment and increased risk of MI, noting an MI risk ratio of 1.6 per year of exposure to antiretroviral medication (The DAD Study Group 2007). This suggests that even the medications used to manage HIV/AIDS may exacerbate HIV-positive individuals' vulnerability to developing comorbid medical conditions. Additional problems can arise when medications routinely used to manage these cardiovascular conditions are contraindicated due to adverse interactions with HIV medications. For example, the use of either simvastatin or lovastatin is discouraged in individuals who are also being treated with protease inhibitors, a type of antiretroviral medication (Simone and Appelbaum 2008). Thus, cardiovascular risk factors become increasingly difficult to manage in individuals diagnosed with HIV/AIDS.

In addition to increased cardiovascular risk, persons infected with HIV display higher rates of cancer than the non-HIV-infected population. Prior to the advent of potent combination antiretroviral medication, individuals with HIV experienced increased rates of cancers such as Kaposi sarcoma and non-Hodgkin's lymphoma (termed "AIDS-defining cancers") (Simard et al. 2010). The commonality of these cancers in the HIV-positive population is thought to be due to HIV-related immunocompromise, a significant risk factor in the development of these cancer

types (Simard et al. 2010). Following the emergence of antiretrovirals, however, the incidence of these types of cancers has declined. This lends further support to the association between immunosuppression and the genesis of AIDS-defining cancers (Simard et al. 2010). Nevertheless, as the HIV-positive population ages, the risk of developing non-AIDS-related cancers also rises, particularly cancers associated with chronic infection (such as cervical cancer) or viral cause (such as liver cancer) (Simard et al. 2010; Grulich et al. 2007). The pattern of risk associated with cancer rates in HIV-positive individuals is similar to that of organ transplant patients, suggesting that immunodeficiency and decreased immunosurveillance in the body may directly contribute to increased cancer risk (Grulich et al. 2007). While antiretroviral medications do not often achieve normal CD4+ counts, early treatment is thought to be helpful in reducing the risk of developing cancer.

In sum, HIV infection is associated with chronic comorbid health problems, such as cancer and cardiovascular disease, through the virus's direct and indirect effects on the immune system. Additionally, some antiretroviral medications can add to cardiovascular risk, increasing the likelihood of cardiovascular disease. As cancer and cardiovascular disease are also typically seen in the aging population, HIV-positive individuals may be at increased risk for further health compromise as they age.

Neurobiology and Neuropsychiatric Considerations

In addition to increased risk of comorbid medical conditions, HIV infection is linked to changes in brain morphology and neuropsychological functioning. Many of the HIV-related structural and functional changes in the brain are similar to those changes seen in older adults and can lead to the development of HIV-associated neurocognitive disorder (HAND).

HIV impacts the brain by passing through the blood-brain barrier, a filtering mechanism of capillaries carrying blood to the brain and spinal cord

tissue. Once passing through this barrier into the central nervous system (CNS), HIV replicates in the brain through infiltrating both microglia and macrophage cells, which are responsible for consuming cellular debris and foreign substances in the CNS (Woods et al. 2009). The virus affects brain functioning in several ways, such as the formation of multinucleated giant cells which can cause multiple problems for the immune system, as well as the interference of neural function through the production of neurotoxic molecules, causing cell death and synaptodendritic injury (Woods et al. 2009). Chronic systemic inflammation due to HIV and comorbid cardiovascular conditions can also affect the function of the brain through their effect on the brain's blood vessels (e.g., by contributing to atherosclerosis and chronic small vessel ischemic disease) (Valcour et al. 2004b). Additionally, other comorbid medical factors and HIV-specific disease factors may contribute to impaired neuropsychological functioning (Valcour et al. 2004a). In particular, cardiovascular disease is independently associated with changes in cognition and may further compound HIV's effect on neuropsychological functioning. Overall, these direct and downstream effects of HIV on the CNS can lead to changes in the brain structure and thus impact neurocognitive functioning.

While the effects of HIV on the brain can be widespread, the virus more commonly affects the subcortical regions of the brain, such as structures within the fronto-striato-thalamo-cortical circuits (i.e., circuitry connecting the frontal lobe, striatum, thalamus, and other areas of the cortex) and white matter tracts connecting different areas of the cortex (e.g., the corpus callosum) (Ances et al. 2012). HIV may also be associated with volumetric changes in subcortical structures independent of aging and antiretroviral treatment, particularly in the corpus callosum, caudate nucleus (part of the basal ganglia), and amygdala (part of the limbic system) (Ances et al. 2012). These findings suggest that antiretroviral medications may not fully protect HIV-positive individuals from HIV-related brain changes. Additionally, diffusion tensor imaging, or imaging of white matter tracts which connect neurons within the brain,

suggests compromise of white matter tract integrity in the HIV-positive population (Woods et al. 2009). These changes in white matter integrity and gross brain structure occur particularly in the frontal cortex and striatum, which are regions thought to carry greater viral load (Woods et al. 2009). Overall, these structural changes in the gray and white matter of the brain likely underlie the varying levels of cognitive dysfunction seen in this population.

Individuals with HIV/AIDS demonstrate a subcortical pattern of impairment similar to the pattern associated with vascular etiologies of cognitive impairment. Slowed processing/psychomotor speed and impaired attentional processes are typically seen in both older adults and patients with HIV/AIDS (Woods et al. 2009; Wendelken and Valcour 2012). In older adults with HIV, these are thought to be an early indicator of neuropsychological difficulty (Wendelken and Valcour 2012). Bradykinesia (i.e., slowed movement) is also seen in HIV-positive individuals, particularly in later stages of disease due to the virus's effect on nigrostriatal function controlling motor movement (Woods et al. 2009). Executive dysfunction (problems with skills such as attentional control, inhibition, reasoning, and problem solving) and memory deficits are also commonly seen in the HIV-positive population. These difficulties may be mediated by the synergistic disruption of attention and processing speed described above. While this pattern of difficulties is commonly seen in those with HIV/AIDS, a great degree of heterogeneity of cognitive functioning remains. Individual differences in protective and risk factors for cognitive dysfunction likely contribute to this observed heterogeneity, including HIV disease severity, comorbid medical conditions, cognitive reserve, and psychological conditions such as depression or trauma (Wendelken and Valcour 2012).

The severity of HIV-related cognitive dysfunction ranges from "asymptomatic" neurocognitive impairment (i.e., no functional decline) to HIV-associated mild and major neurocognitive disorders (Woods et al. 2009). In a 2010 study, the CNS HIV Antiretroviral Therapy Effects Research study (CHARTER) demonstrated a 47% prevalence rate of HIV-related neurocognitive disorders

(mild and major) out of 1,555 patients receiving antiretroviral therapy (Heaton et al. 2010). Findings from this study also revealed decreased rates of HIV-associated dementia (HAD) relative to rates prior to the advent of antiretroviral medications, from approximately 10–15% prior to cART to just 2% (Heaton et al. 2010). The rates of HIV-associated mild neurocognitive disorder (approximately 44% of the study sample) were fairly similar to the pre-antiretroviral era, suggesting relative stability in the rates of mild neurocognitive disorder secondary to HIV (Heaton et al. 2010). However, Valcour and colleagues found that older age is a significant risk factor for the development of HAD, which could be a result of increased HIV infection duration, greater medical comorbidities, and the increased chance of developing other degenerative diseases in the aging population in general (Valcour et al. 2004a). This finding is suggestive of an increased vulnerability to CNS involvement, as evidenced by increased risk for changes in neurocognitive functioning, in older adults with HIV/AIDS (Valcour et al. 2004a).

In sum, HIV particularly targets fronto–striato–thalamo–cortical circuits, in addition to white matter tracts throughout the brain. Through its direct and indirect action on the CNS (e.g., directly interfering with cellular communication and indirectly affecting CNS function through atherosclerosis of cerebral vessels), HIV can result in cognitive impairment ranging from mild cognitive changes without significant impact on functional abilities to major cognitive decline with accompanying functional impairments. As individuals with HIV/AIDS age, they are not only at increased risk of developing dementia through the presence of HIV but also through comorbid medical conditions, such as cardiovascular disease or cancer metastases. It is important to consider both neurocognitive and functional abilities when tailoring treatment plans to the HIV-positive population in order to optimize their day-to-day functioning.

Medication Management

As in other causes of cognitive impairment, HIV-related mild and major neurocognitive

disorders are diagnosed based on the relative severity of declines in both cognition and functional completion of independent activities of daily living (IADLs) (Wendelken and Valcour 2012). IADLs include activities such as managing finances, driving, shopping, and cooking meals. An especially important IADL in the aging population is medication management. This is particularly critical for individuals who are HIV positive, as HIV disease and medical comorbidities lead to complicated medication regimens critical to managing and maintaining physical and neuropsychological health. Typically, older adults with more complicated medication regimens are considered at risk for medication nonadherence. Interestingly, in HIV-positive patients, studies demonstrate that older adults are at reduced risk of medication nonadherence, relative to younger individuals with HIV (Ettenhofer et al. 2009; Ghidei et al. 2013). Although older age is associated with improvements in medication adherence within the HIV-positive population, factors such as socioeconomic status and cognitive functioning can affect medication adherence (Ghidei et al. 2013). In particular, cognitive impairment frequently results in decreased medication adherence, particularly with complex regimens such as those seen in patients who have HIV/AIDS (Ettenhofer et al. 2009; Ghidei et al. 2013). Additionally, a cyclical relationship may develop where poor medical adherence further impacts cognitive function, resulting in worse adherence and exacerbating cognitive impairment in older adults with HIV (Ettenhofer et al. 2009). As antiretroviral medication is important for the control of viral load and immune function, medication adherence is crucial for the management of medical and neuropsychological functions. Strategies to enhance medication management in older adults with HIV, such as using alarms as medication reminders or employing a pill box to organize medications, may be valuable additions to treatment plans when working with this population.

Depression and Protective Factors

Depression is especially concerning for older individuals with HIV, as it can exacerbate the

progression of HIV to AIDS (Bouhnik et al. 2005). As these individuals experience functional declines related to normal aging and HIV, they may also be at risk for declines due to depression. One example of these functional declines is reduced physical functioning (e.g., difficulty walking), which can put older individuals at increased risk of falls, thus increasing their risk of injury or even mortality. Decreased activity, which is common in those with depression, may exacerbate this risk to physical functioning in individuals with HIV. Depression may also impact immunologic function, weakening an already compromised immune system in those diagnosed with HIV (Leserman et al. 2000). Thus, it is likely beneficial for individuals with HIV/AIDS to consider treatments addressing the management and care of depressive symptoms, as mood improvement may result in a better disease prognosis and improved physical health.

Research studies indicate several protective factors that may ameliorate the effects of depression in older individuals with HIV/AIDS, thus reducing the impact of mood on immune function. In particular, individual differences in personality traits may play a role in the relationship between mood and disease progression. Both general positive affect (Ickovics et al. 2006) and optimism (Segerstrom and Sephton 2010) are associated with reduced risk of immune system dysfunction in individuals with HIV. Other protective factors include acceptance of disease prognosis, which may be related to a slower progression to an AIDS diagnosis among gay and bisexual men (Thornton et al. 2000). Related individual factors that may play a positive role in slowing the progression of HIV include spirituality (Fitzpatrick et al. 2007), altruism (Ironson 2007), and self-efficacy (Ironson et al. 2005a). Older individuals with HIV/AIDS can increase the benefit of these protective factors via psychological interventions, thereby improving their disease prognosis.

In addition to individual protective factors resulting in a better prognosis for those with HIV, social support has a positive effect on overall well-being and may lead to fewer HIV-related symptoms (Ashton et al. 2005) and a slower progression to AIDS (Leserman et al. 2000).

Those with HIV in the aging population may lack adequate social support due to potentially diminishing social circles. Thus, it may be especially important for older individuals with HIV to seek out social support given its positive effect on HIV disease prognosis.

Research indicates that many of these protective factors are beneficial to individuals with HIV/AIDS through their effect on behavior. For example, personality factors such as optimism are associated with healthier behaviors, including more exercise, better coping mechanisms, and enhanced mood (Ironson et al. 2005b). In terms of increasing an individual's protective factors throughout treatment, therefore, it may be more beneficial for individuals to directly address these behavioral mechanisms rather than attempting to change other, more intrinsic characteristics such as optimism, as these may be more difficult for individuals to modify. Thus, it would be beneficial to encourage older individuals with HIV to incorporate healthy habits and coping mechanisms, as focusing on behavior change in treatment will be critical for these individuals to have the best disease prognosis possible.

Nevertheless, addressing behavioral changes in treatment may not be sufficient in improving mood. Therefore, treatment of individuals with HIV/AIDS who also suffer from depression should specifically target mood enhancement as well. Within the aging population, individuals with HIV should be encouraged to “remain engaged in living” in order to increase overall protective factors such as social support and healthy coping strategies (Ironson and Hayward 2008). Encouraging HIV-positive individuals to remain involved in their communities and maintain an active lifestyle may inherently increase healthy coping and social support, thus improving disease prognosis. Yet it is important to keep in mind that clinicians must be sensitive to the discussion of individuals' HIV diagnosis, particularly when encouraging them to enhance their own positive attitude (Ironson and Hayward 2008). Some individuals with HIV/AIDS could interpret efforts to increase their optimism as a suggestion that mood improvement is simply a

matter of “thinking positively,” which is disaffirming to the difficulties they may face due to their illness. Treatment providers must work to be sensitive to their clients' experience and aware of the influences of their own beliefs regarding both aging and HIV status in order to deliver culturally competent care.

Conclusion

HIV, a potentially devastating disease that puts individuals at risk for cognitive and physical difficulties, affects more individuals in the aging population than ever, even with the advent of more effective treatments such as cART. Biological changes seen in the progression of HIV are quite similar to those associated with aging, potentially resulting in premature aging in individuals with HIV. Thus, HIV-positive individuals are dually at risk for medical difficulties – those related to their HIV diagnosis and those related to aging. Older individuals with HIV/AIDS may also experience declines in neuropsychological functioning (e.g., executive dysfunction), which may lead to difficulties completing IADLs such as medication management and treatment adherence. Comorbid psychiatric disorders such as depression may further complicate the picture when considering their effect on immune functioning, disease prognosis, and quality of life. Therefore, treatment must address all of these risk factors while also promoting protective factors such as social support and adaptive coping strategies in order for older individuals with HIV/AIDS to have the best prognosis possible.

Definition

Home-based primary care is designed to provide comprehensive, longitudinal primary care services in the homes of individuals with complex, chronic disabling disease using an interdisciplinary team of skilled practitioners.

Several Headings (Free Choice)

As the world's population rapidly ages, the prevalence of individuals with multiple, complex medical conditions is rising. Within the United States, data suggest that 92% of older adults, aged 65 and over, have at least one chronic medical condition such as heart disease, hypertension, arthritis,

diabetes, chronic lung illness, or cancer. Seventy-seven percent of these older adults have at least two chronic medical conditions. Among the oldest old, individuals 85 and older, approximately 50% are dependent in at least one activity of daily living (ADL) such as feeding, dressing, mobility/transportation, bathing, or toileting. Additionally, nearly half of the oldest old group also may have a neurocognitive impairment such as Alzheimer disease and thus greater need for assistance with their daily care. This progressively older world population, with increasing prevalence of chronic illness and physical limitations, results in a growing population of older adults who are chronically, medically ill and homebound. Therefore, health care systems around the world must find ways to contend with this increasing demand for primary and long-term care services for the homebound aged.

Several variations of home health care programs have been developed internationally to meet the needs of the medically complex, homebound patient. One such program in the United States is the Medicare Skilled Home Care program (<http://www.medicare.gov/coverage/home-health-services.html>). This program serves patients with short-term conditions that require focused care. Examples of skilled health services provided include: intermittent skilled nursing care, physical therapy, speech-language pathology, and occupational therapy. These services utilize multiple providers and typically with little coordination/integration among them. In the United Kingdom and Europe, there are many outreach programs which provide multidimensional, home-based, geriatric assessments aimed to define needs and develop care plans for the homebound elderly (Stall et al. 2013). While these programs may provide some level of assistance to homebound older adults, they are not designed to provide ongoing primary care services to address acute and/or changing care needs. Without regular access to primary care services, these medically frail individuals must utilize alternative programs in times of health crises, such as emergency room visits and/or hospitalization (Stall et al. 2014). These alternative solutions can address the acute need, but there is no bridging

of care responsibilities such that the post-discharge care plan may become disjointed. Medically frail individuals who do not receive adequate follow-up services are further at risk for continued decline, readmission, or admission to a long-term care facility.

Home-based primary care programs (HBPC) have emerged through efforts to bridge these care services and better address the needs of the homebound older adult. These HBPC programs provide comprehensive, longitudinal primary care services in the homes of individuals with complex, chronic disabling disease using an interdisciplinary team of skilled practitioners. Many HBPC programs employ practitioners from a wide range of disciplines including but not limited to geriatricians, nurse practitioners, registered nurses, social workers, pharmacists, dietitians, occupational therapists, physical therapists, and dental assistants. A recent review program found that HBPC programs can reduce both hospitalizations and long-term care admissions while improving care recipient and caregiver quality of life and satisfaction with care (Stall et al. 2014).

One longstanding version of an HBPC program exists within the Veterans Health Administration (VHA), the healthcare component of the United States Department of Veterans Affairs. The VHA first established the hospital-based home care (HBHC) program with six sites in 1972 (Beales and Edes 2009). The program then expanded over the years, and the name was changed to home-based primary care (HBPC) in 1995. VHA HBPC now operates in more than 150 sites across the United States. The mission of VHA HBPC is to deliver longitudinal, comprehensive, and interdisciplinary primary care in the homes of veterans for whom routine clinic-based care is not effective due to complex and chronic medical, social, and behavioral conditions (Beales and Edes 2009; Edes 2010; Hicken and Plowhead 2010). Given this criteria for enrollment, it is natural that many of the Veterans Affairs HBPC patients are older adults. Data from 2009 described the VHA HBPC population as an older (76.5, mean age) and predominately male (96%) patient population with a high prevalence of chronic disease (Beales and Edes 2009).

VHA HBPC patients are seen in a variety of noninstitutionalized care settings ranging from their homes to large assisted care facilities to smaller registered care facilities for the elderly.

Using an interdisciplinary approach where the team collaborates in providing patient-centered care to address behavioral and mental health concerns, the primary goals of VHA HBPC programs are to maximize functioning, minimize hospitalization, and promote and maintain quality of life for aging patients with chronic disease. VA HBPC interdisciplinary teams are often headed by a physician medical director, while a nurse or social worker serves as the program manager. Additional allied health care professions such as pharmacy, nutrition services, and physical and occupational therapy round out the interdisciplinary team. Recognizing the high rate of concomitant mental health conditions among this particular medical population, VHA HBPC programs have also integrated full-time, doctoral-level mental health providers to support the team in meeting these goals (Hicken and Plowhead 2010; Karlin and Karel 2014). Mental health providers can be either a psychologist or psychiatrist, though the Veterans Health Administration (VHA) HBPC program typically employs more psychologists (Karlin and Karel 2014). Psychologists also support the overarching goals of VHA HBPC by providing better access to and improving the quality of mental health care among this population.

Most psychologists within VHA HBPC are working with older adults with comorbid medical illness and mental health concerns. As such, the remainder of this entry will focus on models of psychological assessment and clinical intervention for psychologists working in the home. While centered in the VHA HBPC practice model for psychologists, all mental health practitioners working in the home setting may find the information provided applicable to their practice. The entry ends with a discussion of the advantages and challenges of providing mental health care in home care settings.

A Model for Psychological Assessment in a Home-Based Primary Care Program

The VHA HBPC program utilizes an integrated care model to provide collaborative,

patient-centered care for managing enrolled veterans' care needs. Within this interdisciplinary model, the mental health provider assists the team in care management using a stepped care approach. This stepped care approach includes the entire interdisciplinary team in the assessment process for identifying, monitoring, and treating mental and behavioral health concerns.

Every veteran enrolled in VHA HBPC completes a series of medical and mental health screenings as part of an initial home visit, which is scheduled with the veteran, his or her family caregivers (or other care providers as relevant), and one or more VHA HBPC medical providers such as a nurse practitioner, nurse, and/or social worker. While there is some variability among HBPC programs in how these initial evaluations are conducted, all include VA-mandated screenings for conditions such as depression, PTSD, substance abuse, suicide and/or risk for self-injurious behavior, dementia warning signs, and caregiver strain (Gordon and Karel 2014). The evaluating team members also identify the veteran's (and caregiver's) medical treatment preferences and values, treatment issues associated with the environment of care, and any safety needs. Any abnormal finding may trigger a more comprehensive screening of presenting concerns (e.g., anxiety, cognitive functioning, chronic pain, suicide risk). This evaluation team then addresses any urgent care needs through phone consultation with other team members or by accessing appropriate community or VA care resources. The evaluating team then shares the findings during an interdisciplinary team meeting for discussion of treatment goals and to establish an interdisciplinary plan of care.

The role of the psychologist during these team meetings is to assist the team with identifying potential mental health concerns or any psychosocial barriers to receiving appropriate care as well as assisting with treatment planning for behavioral and mental health conditions. Some VHA HBPC teams prefer to use test scores on initial screening measures to identify those veterans in need of mental health care, while other teams prefer to utilize the initial findings as one aspect of the clinical picture, which is then

evaluated by all to determine if more specialized mental health assessment or treatment is needed. While it is beyond the purpose of this entry to cover all the elements of a comprehensive psychological assessment, the sections that follow will review some aspects of a psychological evaluation that are unique to VHA HBPC.

Psychological Assessment

Psychological assessment in HBPC is most effective and beneficial to the team when evaluations target patients with complex symptom profiles, when symptoms are of greater severity than can be managed with routine medical care, when a patient's clinical presentation and/or environment change dramatically, or when there is a need to clarify any concerns regarding patient risk or safety (e.g., suicide, neglect). In those areas, a psychological assessment enhances the team's understanding of the symptomology, person-environment interaction, and helps to clarify appropriate treatment goals and interventions.

HBPC psychological evaluations are different from those outside of an interdisciplinary setting in several ways. First, the VHA HBPC population is at high risk for mood and anxiety-related disorders due to the high prevalence of medical conditions, marked functional impairments, and often stressful environmental circumstances. Therefore, psychological evaluations must consider the medical conditions, treatments, and care environment as part of the entire clinical picture. Next, the consumers of these evaluation reports are from numerous other disciplines. Reports should be concise and clearly identify specific findings and recommendations that address the symptoms and/or treatment modifications requested of others. Finally, psychological evaluations not only assist with clarifying a differential diagnosis or in identifying behavioral and mental health treatment recommendations, but also help the team understand the patient's context. Evaluations include consideration of the adequateness and appropriateness of the care environment (e.g., social support systems, setting) as well as the patient's abilities and willingness to consent to and engage in medical or behavioral and mental health treatments.

Cognitive/Neuropsychological Assessment

Neurocognitive disorders are common among the VHA HBPC patient population, but cognitive change also may be associated with medical conditions or treatment effects (e.g., anticholinergic or electrolyte depletion effects of some medications). The psychologist assists the team by providing a more in-depth neurocognitive evaluation using tools appropriate for the patient. Objective data can help determine if the noted decline is secondary to medical concerns, is within acceptable limits for the individual, or is suggestive of abnormal cognitive aging such as mild cognitive impairment or a neurocognitive disorder. As not all psychologists will have experience/expertise in neuropsychological testing, some HBPC teams may find that a neuropsychological consult is needed for additional testing.

Neurocognitive assessment not only assists with clarifying diagnoses, but also informs the team regarding appropriate interventions. The HBPC psychologist utilizes test results to educate the team on a patient's strengths and limitations as some deficit patterns may impact both how medical care information is presented and what approach is needed to increase the likelihood of remaining compliant with recommended care. For example, assessment results may suggest the patient is experiencing symptoms of depression comorbid with a neurocognitive illness. However, the extent of patient's cognitive/memory impairment may be such that the patient will not benefit from a psychotherapeutic approach requiring self-initiating behaviors and/or higher order cognitive-focused interventions, as is common in evidence-based therapies. The psychologist might then work with the interdisciplinary team and/or caregiver to identify alternative strategies that have been shown to improve depressive symptomology (e.g., behavioral activation, problem solving).

Capacity. Providers meeting with patients and families in the home setting sometimes discover that a patient's situation has decompensated to the point that marked changes seem warranted to improve the patient's health, well-being, and/or safety. The HBPC psychologist then assists the team by performing an evaluation of the patient's

decisional and functional capacities in one or more areas. The areas most commonly evaluated in the VHA HBPC setting include the patient's ability to manage his or her own finances, reside independently, or make important medical decisions. Evaluations of this type assist the team in determining if a patient's choices should be honored or if alternative arrangements are needed.

Behavioral Medicine Assessment

The treatment and management of complex, chronic illness may at times result in the patient experiencing psychological or psychosocial stressors which medical interventions may not be able to alleviate. When this occurs, the HBPC psychologist can assist the team in the assessment and behavioral treatment of medically related conditions such as sleep disorders, chronic pain, smoking, weight management, sexual functioning, and medical/medication compliance. Assessment techniques are utilized to identify target behaviors and develop strategies that empower the patient to choose healthier alternatives and diminish the barriers impeding successful collaboration with the treatment team and or targeted interventions.

Caregiver Assessment

Previous data has found the VHA HBPC population averages eight or more chronic medical conditions, including dementia (Edes 2010). Given this, readers may anticipate that a large number of spouses and/or other care providers serve a significant caregiving function in assisting HBPC patients with management of medical care and ADLs. Over time, caregiver strain can lead to increased mental health problems, decreased health functioning, and marked caregiver burden. Caregiver strain impacts not only caregiver health but also the success of the HBPC model as it diminishes the ability of caregivers to provide adequate care and thus allowing the patient to remain in the home. Psychologists can use caregiver assessment tools to evaluate a caregiver's social support network, strengths and limitations, health, perceptions of caregiving, and overall well-being. The psychologist may then provide individual caregiver interventions or make recommendations to the team for appropriate strategies

to implement in the home to reduce caregiver distress.

Risk Assessment

Risk is evaluated by every VHA HBPC team member, but psychologists are typically called upon to provide comprehensive risk assessments and interventions services for patients at increased risk for suicide or other self-injurious behavior. Overall, the VHA HBPC patient population is considered among the high risk group due to the numerous risk factors frequently cited in the suicide literature (e.g., older, male, multiple medical conditions, new chronic conditions that limit functioning). Additional risk categories that VHA HBPC psychologists evaluate as part of a home-based assessment included firearm and driving safety. The focus is to identify those patients at increased risk for intentional and/or accidental harm to self or others when possessing a firearm and/or driving, if the patient has a significant mental health or neurocognitive impairment that would increase the risk. Psychologists then work with any patient and family to help decrease those risks by securing firearms or vehicle access, as appropriate. A final risk area is that of elder abuse and neglect. Psychologists can assist the team with completing an evaluation of abuse or neglect, in managing sensitive issues that may result in such discoveries, and in helping the team deal with any negative experiences associated with addressing the concerns. For example, many countries, including the United States, require mandated reporting of instances of abuse or neglect to law and social service agencies by health care providers; however, the requirements of what constitutes abuse and neglect and what professional disciplines are mandated reporters vary. Indeed, these requirements even vary by state within the United States. Psychologists can assist the team in determining if any concerns or reports meet criteria for reporting to an outside agency and how to best navigate these mandates from a patient-centered perspective.

A Model for Clinical Intervention in the Home-Based Primary Care Setting

VHA HBPC relies upon empirically based treatments in the provision of mental health

interventions for both patients and their families. Many VHA HBPC psychologists and teams use components of collocated, collaborative, and stepped-care approaches to effectively and efficiently identify those patients which may benefit from mental health interventions. Data on a nationwide VHA HBPC mental health provider survey indicated that only 10% of providers were seeing every patient in the program (Karlin and Karel 2014). These data suggest HBPC mental health providers deliver direct care services most often when they are alerted to a specialized need, which is based upon the screenings conducted by the larger interdisciplinary team. Approximately 53% of VHA HBPC mental health providers reported utilizing abbreviated interventions (1–3 sessions), while 79% reported often or frequently providing full interventions (10+ sessions) (Karlin and Karel 2014).

Individual psychotherapy functions similarly to that in clinic-based populations. Research consistently has shown that older adult populations respond as well as younger populations to targeted treatments, though minor modifications are needed at times to address sensory or medical needs. Among the most frequently presented mental health diagnosis in the VHA HBPC population are depression, coping with illness, anxiety, and adherence issues (Karlin and Karel 2014).

However, it should be noted that working in the home care setting can create additional logistical problems for scheduling interventions that is not likely to occur in the traditional clinic-based setting. Given the large geographic catchment areas that some VHA HBPC programs cover, HBPC mental health providers sometimes find it impossible to meet face-to-face with certain patients on a weekly basis. When this barrier occurs, mental health interventions may benefit from modifying the care plan to utilize face-to-face, telemedicine, and/or telephone technologies. Mental health providers also sometimes cluster appointments to a specific geographical area in order to maximize travel efficiency and thus increase the time spent with individual patients.

Couple/Family

VHA HBPC psychologists also are able to provide couples therapy focused on managing conflicts that stem from the strain on a relationship due to complex medical conditions, financial burdens, family issues involving care, or other concerns. Occasionally there is opportunity to address more complex relational dynamics, but usually the focus remains on the medical care and advocating for improvement in order to benefit the patient so that he/she may remain in the home as long as possible. This focus is different from caregiver support as it includes multiple parties in the intervention process.

Caregiver Support

As noted in the assessment section above, many chronically ill homebound patients will require the services of a caregiver for assistance with ADL/IADL care. The caregiving role can be challenging and potentially impact caregivers' physical and mental health, work, social relationships, and quality of life. When this occurs, the HBPC psychologist can provide caregiver support interventions to alleviate stress and better enable the caregiver to cope with the demands of caregiving. Caregiver support may take many forms, including but not limited to psychoeducation about the medical illness and/or cognitive impairment of the patient, traditional psychotherapy to address symptoms of depression and/or anxiety, or skills training using problem-solving and behavior management interventions to address specific problems. As with couples/family treatment, the primary focus is on reducing caregiver strain and prolonging the length of care in the home for the patient. Sometimes, the mental health care needs of the caregiver are greater than can be addressed by HBPC psychologist. In those instances, the psychologist works with the caregiver to identify and connect to a provider in the community that can emphasize the unique mental health needs of that caregiver.

Interdisciplinary Team and Program Support

The HBPC psychologist serves an important role on the team by using therapeutic skills to advocate for patients, promote an atmosphere of mutual

respect among providers, and facilitate positive communication and collaboration among staff. For example, psychologists can model appropriate professional behavior for the interdisciplinary team, both when communicating with other interdisciplinary professions and during collaborative discussions in interdisciplinary team meetings. Or, they may serve the larger HBPC program by educating the staff on clinical and professional topics. For example, psychologists can provide education and training on how to conduct brief cognitive or mood assessments, assess for risk, or communicate evaluation and treatment results to help improve overall care. The HBPC psychologist also can provide training on self-evaluation and self-care strategies to help providers deal with professional burnout and/or difficulties in managing patients with challenging conditions or behaviors.

Additionally, since psychologists have training in research and often in program development, some may serve in varying leadership capacities on the team. Psychologists can assist the team in addressing referral processes, monitoring and improving the quality of care of HBPC patients, and through collaboration with other hospital and community-based services, as appropriate. Psychologists also have advanced training in ethics and care standards and often may find ways to assist interdisciplinary team members in appreciating the unique boundaries and/or conflicts that occur within the provision of care in a home setting such as identifying issues associated with patient confidentiality, privacy, patient autonomy, or other ethical conflicts that may arise in the home setting.

Environment of Care

Psychologists assist the interdisciplinary team by evaluating the environment of care and aiding the team in determining what is acceptable, and in accord with a patient's values and preferences, versus what environmental factors are beyond the acceptable range for safety and optimal adaptive functioning. Input can assist the team in clarifying those environmental circumstances that need to be addressed as well as in developing targeted interventions also respect the unique needs and values of the patient. As indicated

above, a benefit of working within the home-based primary care environment is that doing so allows the psychologist to work directly with the patient and/or their family, in context, to address a specific issue of concern.

Advantages and Challenges of Mental Health Care Provision in Home-Based Primary Care

Working in the home setting provides several distinct advantages and disadvantages that the mental health provider must be ready to contend with. Below is a review of these, as well as suggestions for compensatory strategies that may be of benefit.

Advantages

Improved Access to Mental Health Care

A significant benefit of having a psychologist integrated into the HBPC team is increased access to mental health services for chronically ill older adults. The HBPC program improves access to mental health services for patients who: (a) are no longer able to easily access outpatient services and/or (b) may be reluctant to pursue specialty mental health services in traditional settings due to stigma. The provision of services in the patient's home overcomes a variety of logistical barriers for chronically ill older patients, such as physical limitations, a lack of transportation, and low energy. Offering in-home assessment and treatment also may increase the acceptance of services from a population that has historically found outpatient mental health services stigmatizing (Yang et al. 2009).

Through integration with a primary care team, the psychologist is better able to reach older adult patients, who have shown a preference for presenting mental health symptoms in a primary care setting (Areán et al. 2002). The psychologist's association with a trusted HBPC nurse case manager may increase the likelihood of a patient accepting a referral (Hicken and Plowhead 2010). Patients may feel more comfortable and in control in their own homes versus an office setting. Patients who have refused traditional outpatient mental health services in the past have been found to accept a home visit from an HBPC

psychologist and actively engage in psychotherapy in the comfort of their own home (Hicken and Plowhead 2010). The psychologist's role on the larger treatment team may also increase the chances of the patient staying engaged in treatment.

Enhanced Assessment and Treatment Planning

The home setting provides an abundance of information that is unavailable in a traditional outpatient or inpatient setting and can greatly enhance assessment and treatment planning. The HBPC psychologist can more easily evaluate the reliability of a patient's self-report on issues, such as medication compliance, ability to access emergency services, and ability to maintain sanitary conditions. For example, a 75-year-old man may present as capable during a 50-min outpatient session, but a home visit may reveal an excessively cluttered and unsanitary home with several safety concerns, which raises a red flag about the patient's ability to safely live independently. A more accurate assessment of the patient's functioning can be made during a home visit than in a traditional setting, which is particularly important if the psychologist has been referred for a capacity evaluation. In addition to being able to assess actual functioning within the patient's primary environment, the clinician can assess the patient's awareness of safety issues and his or her ability to respond to and manage unsafe environments (Hicken and Plowhead 2010).

Another significant benefit of providing services within a patient's home is increased access to people involved in the patient's life. This can be particularly helpful when working with cognitively impaired patients who may no longer be able to provide accurate historical information and self-reports. Family members, friends, home-health aides, and other health care providers are frequently encountered during visits. With client consent, valuable information can be gathered from these collateral sources, such as information about their history, and observations of the patient's mood, memory, sleep, daily activities, safety at home, and medication compliance.

With the patient's permission, a family member or home-health aide (HHA) can participate in aspects of treatment to help implement

interventions and monitor follow through (Yang et al. 2009). This can be particularly helpful with generalization of skills when the HBPC psychologist is not able to see patients weekly and when working with cognitively impaired patients. Conversely, home visits also allow for a closer examination of the caregiver's ability to assist in implementing a treatment plan (Hicken and Plowhead 2010). Family members may have their own medical or mental health concerns that make it difficult for them to assist patient's or unreliable. The presence of collateral significant others can also be a challenge as discussed further below.

Information gathered from observation of the patient's environment and discussion with collaterals can help the psychologist determine if a change in behavior can be supported, and at what level, in the current environment (Hicken and Plowhead 2010). For example, an HBPC psychologist, referred to provide treatment for insomnia, learned during the first visit that the patient's wife has dementia and inquired about her sleep patterns. This line of questioning revealed that his wife wanders at night causing the patient significant anxiety and stress. The patient reported that he was not willing to place her in a facility. The psychologist used this information to develop a treatment plan that included caregiver education and support and set realistic expectations around the patient's success given his caregiving responsibilities.

Challenges

Role Confusion and Establishing Professional Boundaries

With the many advantages of providing care in the home setting come a number of challenges. While the patient may feel more comfortable in their home, it can be difficult to establish a professional tone outside the controlled and predictable office setting. The physical signs that assist with role establishment, such as a standardized meeting space and a waiting room, are absent during home visits leading the patient to perceive the session as more of a social visit than a professional one (Yang et al. 2009).

The informal setting may increase the patient's perception of the psychologist as a friend or family member resulting in role confusion and more time spent engaging in small talk than in therapy (Knapp and Slattery 2004). The patient may request assistance with tasks that are outside the clinician's role or scope of practice such as transfers, explanation of bills, and assistance with cleaning. The clinician may be pulled to assist with these tasks and may experience feeling overwhelmed, burdened, or anxious when exposed to significant needs in the home or requests to function outside one's traditional scope. This can lead to the clinician actively fixing the problems, instead of empowering the patient (Yang et al. 2009). The home care psychologist must consistently weigh the pros and cons of assisting a patient with safety concerns versus supporting independence and autonomy.

Within the home setting there also are more opportunities to experience unusual or challenging behaviors, and boundary crossings are more likely to occur (Knapp and Slattery 2004). Clarifying the referral question prior to the visit, as well as explaining the psychologist's role and the purpose of the visit during the initial session, can help decrease role confusion and maintain professional boundaries (Hicken and Plowhead 2010). The psychologist may wish to reiterate the role of the psychologist throughout service delivery to help clarify roles (Knapp and Slattery 2004). If needed and appropriate, the HBPC psychologist can collaborate with and refer to other members of the interdisciplinary team to address those concerns outside the psychologist's role, such as seeking assistance from the social worker to connect the patient to needed resource or from the dietician to assist with nutritional concerns. At the same time, an HBPC psychologist might find a patient in a situation where ethical practice dictates that she complete a task outside of her defined role (Yang et al. 2009). For example, if a clinician arrives for a home visit and is informed that the patient, who lives alone and is at high risk for falls, has not set up his medical alert system due to physical limitations, the clinician may feel an ethical responsibility to assist the patient with that task prior to completing the home visit.

Privacy and Disruptions

Unexpected interruptions are common during home visits, including telephone calls, bathroom breaks, other visitors arriving, family pets, and television noise. Psychologists can help limit distractions by selecting a quiet area in the patient's home and arranging the seating, but often this is difficult due to small living spaces, limited seating options, and noise outside of the clinician's control. It is vital to review with the patient and their family, if present, the importance of a distraction free area for sessions early and often (Hicken and Plowhead 2010). This is particularly true when administering standardized assessment measures, such as brief cognitive assessments, whose validity can be threatened by interruptions. Asking the patient to turn off his or her cell phone and alerting others in the home that an assessment is being completed can limit threats to assessment validity.

Helpful information can be gathered from observing the patient's response to interruptions, such as how the patient interacts with others and if the patient utilizes interruptions to regulate the intensity and content of the therapy sessions (Yang et al. 2009). For example, when a patient who usually does not respond to family members who walk through the session area engages in a lengthy and unrelated conversation with his daughter one session, it may be helpful to discuss the purpose or function of the behavior as part of the therapeutic process.

Ethics

Challenging ethical dilemmas can arise during in-home service provision. Maintaining confidentiality, a primary tenet of the relationship between a mental health provider and patient, can be particularly hard in home care (Blass et al. 2006). There are many threats to confidentiality during a home visit starting with gaining access to the patient, who may reside in a facility or live in a home with multiple other people (Yang et al. 2009). For example, a fellow assisted living facility resident may request information about who the provider is and which resident is receiving services. This can be addressed by using nonspecific, but correct responses, such as stating

the provider's name and company, without stating the explicit reason for the visit. This is done both to maintain the privacy and confidentiality of the patient without impacting the psychologist's ability to access the patient.

Once in the patient's home, a caregiver or family member may feel reluctant to leave a provider alone with the patient as they may feel responsible for the patient or curious about the nature of the visit. Patients may at first consent to having a family member or caregiver present during the session without a full understanding of the personal topics discussed. Clinicians also must be aware of the "illusion of privacy" where sessions, thought to be private, are overheard intentionally or not by others in the home (Hicken and Plowhead 2010). A lack of privacy and fear of being overheard may result in patient avoidance of potentially important topics, such as family conflict, or the expression of negative emotion for fear of concerning a family member. The clinician must provide education on the rationale and importance of confidentiality early on and frequently throughout service delivery. The clinician can engage the patient in problem-solving ways to increase confidentiality (i.e., white noise maker, sit in the backyard, utilize available office space at an assisted living facility) (Hicken and Plowhead 2010).

Of particular importance when providing care in the home setting is a clear review of mandated reporting requirements. Observation of possible self-neglect, elder abuse, and child abuse are more likely to occur during home visits than in traditional settings. Depending on the clinical situation, the clinician may engage the patient in the reporting process to reduce anxiety and provide education on what to expect (Yang et al. 2009).

The nature of home visits, in which the provider goes to the patient, may make undue influence a greater concern (Yang et al. 2009). Without the option of "no showing," it is more difficult for patients to passively avoid sessions or terminate therapy. Patients may then continue with services that they are not actively interested in resulting in limited progression on treatment goals (Blass et al. 2006). Knowing that the psychologist is part of the larger primary care team also may

make it more difficult for the patient to refuse services or terminate. The clinician must remain mindful of these potential effects and address them within the therapeutic relationship.

The increased intimacy of the setting may lead to more frequent offerings of food and drinks and gift giving. The clinician must regularly weigh the pros and cons of accepting small gifts or food as a means to enhance rapport or refusing them as a means to establish and maintain professionalism (Yang et al. 2009). The cultural meaning of food and gift offerings must be considered when weighing the pros and cons of acceptance.

Safety

All professional homecare providers confront a number of safety concerns on a regular basis. Common concerns include weapons in the home, the presence of unknown family members or acquaintances, and intoxicated patients or caregivers. Beyond the potential safety concerns in a patient's home, the home care psychologist must also be mindful of safety concerns in the patient's building and neighborhood. HBPC policies and experienced home care psychologists recommend the following safety precautions when providing care in a home setting (Hicken and Plowhead 2010; Yang et al. 2009):

- Prior to a home visit, evaluate safety risks by reviewing the patient's chart for a history of violence.
- Call ahead to review program policies regarding weapons, substance use, and family pets.
- If the clinician senses a threat to safety at any time, leave immediately without fearing judgment from the treatment team.
- Position seating so the clinician is in between the patient and the exit.
- Conduct a joint visit with another team member if safety is a concern.
- Carry a cell phone with emergency numbers programmed in at all times.

- Provide a schedule of home visits to other team members so they are aware of the clinician's whereabouts.
- Discharge or refuse to admit patients who may be a danger to staff.

Competence

Since there are no published guidelines or standards of practice for home-based psychology, HBPC psychologists may wish to refer to the American Psychological Association guidelines for working with older adults and competencies for psychology practice in primary care (American Psychological Association 2004; McDaniel et al. 2014). Similarly to psychologists operating in rural settings, HBPC psychologists may come across patients whose treatment needs exceed the clinician's training (Hicken and Plowhead 2010). In these cases, it is vital that HBPC psychologists consult with colleagues, complete additional training when indicated, and/or assist patients with locating appropriate services either through the VA or in their community.

Summary and Conclusions

Due to the shifting demographics and increasing rate of chronic illness, health care delivery systems across the world must look for ways to meet the needs of medically complex, frail, homebound elders for whom traditional, office-based primary care does not serve well. This has led to the creation of home-based primary care (HBPC) programs. Interdisciplinary teams come together in HBPC to provide longitudinal, comprehensive primary care in the homes of their patients. While several variations of HBPC exist, the VHA HBPC model is unique in that it includes mental health practitioners, usually doctoral-level psychologists, as members of the interdisciplinary team to provide for the mental health needs of the aging veteran. The inclusion of psychologists in HBPC creates the opportunity for new ways to think about models of psychological assessment and clinical intervention,

as well as challenges and advantages to psychological practices in the home.

Definition

This chapter synthesizes the findings of the Hong Kong Centenarian Study (HKCS). Based on multidimensional models of successful aging, this chapter evaluates the levels of physical, functional, psychological, and social well-being of Chinese centenarians in Hong Kong. Extant models of successful aging were applied to the current dataset to estimate the percentages of successful agers among this group of exceptional survivors using different operational criteria.

Introduction

The growth in the proportion and number of elderly people has become a salient feature of population in many parts of the world (United Nations 2013). The rise is particularly prominent among the oldest-olds (i.e., individuals aged 80 or above). It is expected that by 2100, the world's population of oldest-olds will increase sevenfold, from 120 million in 2013 (14% of the total population) to 392 million in 2050 (19%) and to 830 million in 2100 (28%). China, in particular, is forecasted to have 90 million of oldest-olds by 2050 and become the country with the largest

oldest-old population. Meanwhile, the population of centenarians (i.e., individuals age 100 or older) will grow at an even faster rate, from 441,000 in 2013 to 3.4 million in 2050 and to 20.1 million in 2100, which is 45 times of the population of 2013.

Similar to the worldwide case, with a population of approximately 7.1 million, the segment of the oldest-olds is projected to grow from about 318,100 in 2014 (4.4% of the total population) to 1,144,300 in 2064 (14.7%) in Hong Kong (Census and Statistics Department, HKSAR 2015). The growth rate is more than twice of that of their younger counterparts (age 60–79). The population of centenarians (from 289 persons in 1981 to 1,890 persons in 2011) also increased quickly, such that by the near future these long-lived individuals will become a commonplace in Hong Kong society (Cheung et al. 2012).

Centenarians are of interest to gerontologists, geriatricians, physicians, and researchers of a wide repertoire of disciplines because they depict what life is like at the extreme of longevity. The health and well-being profiles of these exceptional survivors are valuable to the study of both successful and pathological aging processes (Gondo 2012; Rowe and Kahn 1997). The lives of these individuals can illustrate how the body, mind, and social networks adapt to the (almost) inevitable biological aging process; how early life experiences and habits affect quality of life at the end of the lifespan; as well as how important values such as life satisfaction, happiness, successes, and health are redefined and achieved in spite of waning socioeconomic resources and functional capacities. In all, centenarians are valuable to the study of multiple disciplines as they depict the “what” and “how” of successful aging and “why” they can survive to such an extreme old age (Arnold et al. 2010). In the light of the quickly aging population in Hong Kong and the Chinese population at large, the Hong Kong Centenarian Study (HKCS) sought to understand successful aging especially at the extreme of longevity. HKCS represents the first centenarian study in the territory (Cheung et al. 2012; Wong et al. 2014). This chapter reports the methodology of the study and provides a brief overview of the lives of Hong Kong centenarians based on their performance in

multiple dimensions of successful aging – physical health, functional health, psychological well-being, activities and health habits, and social well-being (Bowling and Dieppe 2005).

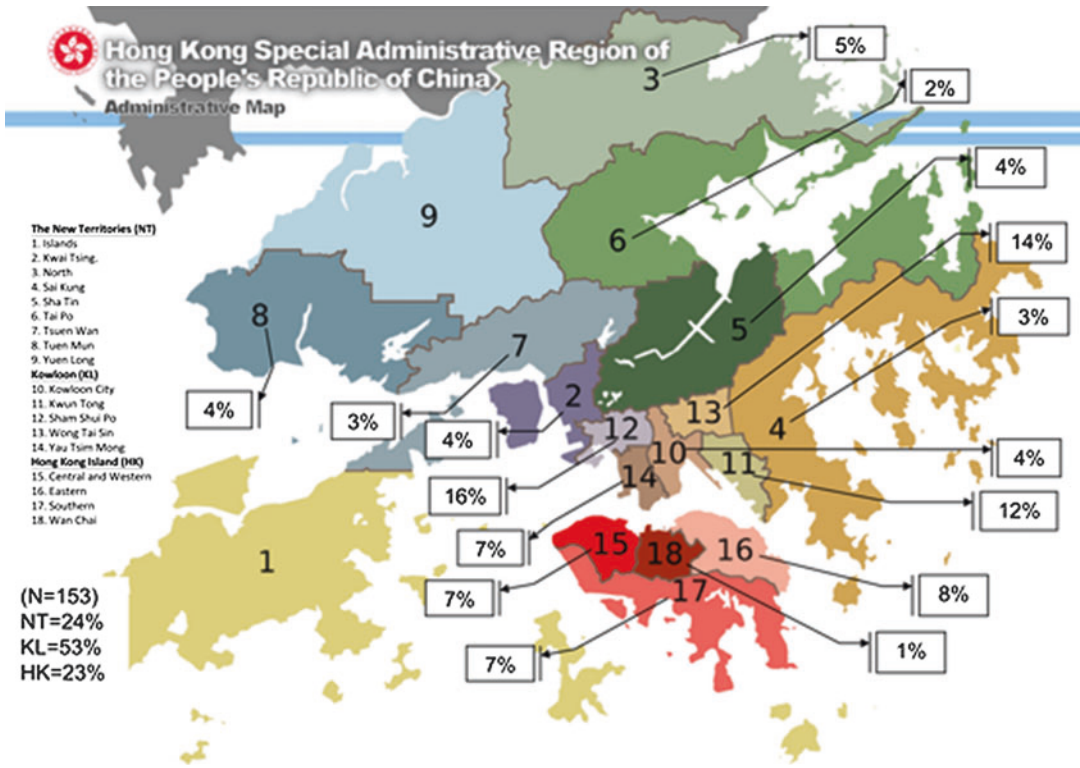

Methodology

Sampling

One hundred and fifty-three Cantonese-speaking Chinese near-centenarians and centenarians who were born between 1905 and 1915 were interviewed in April to September, 2011. In order to recruit a geographically representative sample, a quota sampling method was used according to the proportion of oldest-olds aged 85 or above in the 18 Geographical Constituency Areas (GCAs) of the territory (see supplementary Fig. 1). In the census data of Hong Kong, the oldest age group with geographical distribution information is 85 years old and above. No geographical distribution information about centenarians in specific is publicly available. Recruitment was conducted through two social and clinical networks. First, through the auspices of the Hong Kong Council of Social Service (HKCSS), 628 letters of invitation were sent to day care centers, district elderly community centers, neighborhood elderly centers, social centers for the elderly, home support team throughout the territory, and the University of the 3rd Age (U3A) centers. Two hundred near-centenarians and centenarians were reached. Among them, 56 elders participated (participation rate 28%) in the study. Second, based on the database of Elderly Health Clinics (EHC) of the Department of Health (DH) of the Hong Kong Special Administration Region Government, 210 letters of invitation were sent to eligible elders, and 97 of them (participation rate 46%) participated in the study.

Procedures

A face-to-face interview was arranged within 2 weeks after the participant had expressed interest in participating in the study. Prior to the any study procedures, a written informed consent was sought from the participant. In cases where the participant failed to exhibit sufficient cognitive

H

Hong Kong Centenarian Study, Fig. 1 Distribution of participants across the 18 geographical constituency areas (GCA) of Hong Kong

capacity to offer consent, proxy consent was sought. At least one family member and/or registered social worker were present and witnessed the signing of the consent form and the interview.

Each participant was interviewed once in their home or affiliated elderly service center/care facility. The interview was structured and took around 1.5–2 h. During the interview, a battery of questionnaires and a physical examination were conducted. The questionnaires were based on two validated instruments – the 2008 version of the Chinese Longitudinal Healthy Longevity Survey (Zeng 2008) and the Elderly Health Center questionnaire from the Department of Health, HKSAR Government) – and was piloted in 2010 (Cheung et al. 2012). The questionnaires covered questions on physical health, subjective health, functional health, psychological well-being, daily activities, social and healthcare needs and service utilization, and demographics. The

physical examination involved a handgrip strength test, a sit-to-stand test, and several other on-site tests of physical performances. After the administration of the questionnaires and the physical examination, participants were invited to participate in a blood test. Upon obtaining another written informed consent, 20 ml venous blood was taken by the phlebotomist. No proxy was allowed for blood taking. A total of 102 participants participated in the blood test. Analyses on the levels of 33 biomarkers (e.g., albumin, C-reactive protein, hemoglobin, glycated hemoglobin, high- and low-density lipoproteins) were conducted in the laboratory of the Queen Mary Hospital, Hong Kong. The Human Research Ethics Committee for Non-Clinical Faculties of the University of Hong Kong and the Ethics Committee of the Department of Health provided research ethics approval for all procedures.

Results

Demographic Characteristics

A scrutinized age cross-checking was performed based on at least one official document from the participants, such as the Hong Kong identity card (HKID), as well as their reported Chinese lunar zodiac year and the age of their children. Among the 153 cases, three females were found to have their self-reported ages (SRA) being notably inconsistent with their years of birth appeared on the HKID. The ages of another three cases were not verified successfully due to the absence of HKID and participants' total loss of cognitive capacity. For the latter three cases, the ages of the participants were reported by their proxy. Apart from these six cases, there were 33 cases (6 males and 27 females; 22.5% of 147 cases) with SRA being 1 year older, following the traditional Chinese culture to declare a year older than the actual age. The mean (SD) of SRA was 97.7 (2.4) years. 126 participants were between 95 and 99 years old. The remaining 27 participants were aged 100 or above, with the oldest being 108 years old.

Most of the participants were female (77.8%). The percentage of female participants among the age group of 95–99 was 78.6% (i.e., 99 participants), whereas the ratio among centenarians (aged 100 or above) was 74.1% (i.e., 20 participants). The majority of the sample was born in the rural area (63.4%) and in the Mainland China (83.7%). Half of the sample was coresiding with their family members or friends (50.3%), with the rest of them either living alone (30.7%) or in a care facility (19.0%). The median annual household income per head was HKD \$36,000 (USD \$4,643.51). About 42.1% participants fell into this category (HKD \$30,000 to HKD \$39,000). Less than 10% had an annual household income (per head) of HKD \$80,000 or more. 85.6% participants reported the socioeconomic status as “similar,” “wealthier,” or “much wealthier” compared to most local households. In terms of education attainment, slightly more than half of the sample did not attend any schooling (55.9%), 33.3% attended some primary education (equivalent to 1–6 years of schooling), while

only a minority attained more than 6 years of education (10.5%).

Subjective and Physical Health

Participants generally had favorable evaluations of their overall health despite their advanced age. In terms of the overall subjective health, 39.8% reported having “good” or “very good” health, while 39.2% evaluated their health as being “moderate.” More important, 47.0% reported their health as being “much better” or “better” than their same-aged peers, while 32.7% remarked their health being just similar to their peers. When asked to compare their health to the condition 1 year ago, a significant portion of participants did not perceive any significant differences (38.6%). A small proportion of participants (10.5%) even reported improvements in their health.

In fact, chronic diseases were common among the participants. Out of a list of 30 common elderly chronic diseases, the mean (SD, range) number of self-reported diagnosis was 2.9 (1.9, 0–9; see Table 1).

The most common diseases were cataract and hypertension. Other diseases such as diabetes, fractures, and gout were also common. Serious cerebrovascular/cardiovascular diseases such as strokes, congestive heart failure, and coronary heart disease were relatively uncommon; the same was the case for cancer (in the previous 5 years) and chronic obstructive pulmonary diseases among near-centenarians and centenarians. Only 3.9% and 1.3% were diagnosed as suffering from Alzheimer's disease and other psychiatric diseases, respectively. The average Charlson age-adjusted comorbidity index (Charlson et al. 1987), which covers serious health conditions including, among other diseases, coronary heart disease, congestive heart failure, stroke, dementia, chronic pulmonary diseases, stomach ulcer, moderate to severe renal failure, cancer, liver diseases, and diabetes, was 6.6 with a SD of 1.4.

Table 2 provides the results of the biomarker analysis. Based on the normal ranges for average adults (age 20–79) (Expert Panel on Detection, Evaluation, and Treatment of High Blood

Hong Kong Centenarian Study, Table 1 Distribution of self-reported diagnosis of 30 chronic diseases

Diseases	Diagnosis <i>n</i>	%
1. Cerebrovascular accident/stroke	11	7.2
2. Congestive heart failure	11	7.2
3. Coronary heart disease	19	12.4
4. Hypertension	99	64.7
5. Irregularly irregular pulse	13	8.5
6. Peripheral vascular disease	0	0.0
7. Alzheimer's disease	6	3.9
8. Dementia other than Alzheimer's disease	0	0.0
9. Head trauma	0	0.0
10. Hemiplegia/hemiparesis	1	0.7
11. Multiple sclerosis	2	1.3
12. Parkinsonism	0	0.0

28. Thyroid disease	4	2.6
29. Gout	20	13.1
30. Stomach ulcer	9	5.9

Cholesterol in Adults 2001), more than 80% participants had shown normal levels on white blood cell, neutrophil, monocyte, eosinophil, basophil, C-reactive protein, cholesterol, sodium, chloride, total protein, globulin, total bilirubin, alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase. A significant proportion of participants fell out of the normal range on

creatinine (percentage of participants outside normal range = 63.7%), red blood cell distribution width (48.0%), and platelet (48.0%). Nonetheless, it is noteworthy that the ranges considered as “normal” were derived from average adults aged between 20 and 79 years old. It is possible that some of these benchmarks have to be readjusted to cater for the advanced age of the sample.

Most participants reported no physical discomfort within the previous 2 weeks of data collection (73.9%) and experienced good quality of sleep (62.7%). The mean (SD) systolic and diastolic blood pressures were 137.9 (23.0) mmHg and 80.3 (13.8) mmHg. Most participants (86.3%) had regular pulse rates. Of particular note, 45.8% reported having had one or more episodes of illness or accident in the previous 2 years that required hospitalization. Days of hospitalization ranged from 0 to 365, with a median of 12 days. One in five participants (20.9%) had experienced a fall in the previous 6 months. Regarding their oral health, slightly more than half of the sample (58.8%) was completely edentulous. The range of remaining teeth was 1–24, with an average (SD) of 3.3 (5.4). Three participants (2.1%) had 20 remaining teeth or more. Nonetheless, 74.5% wore dentures to assist oral functions. 19.6% participants had a weight loss of more than 3 kg in the previous 6 months. However, most (61.4%) had maintained a normal body mass index (BMI) of 18.5–24.9 kg/m². The average (SD) BMI was 21.7 (3.5) kg/m². The mean (SD) handgrip strength of the right and the left hands were 13.1 (5.8) kg and 12.7 (5.6) kg, respectively.

Frailty, as a physiologic systematic vulnerability to resolve to homeostasis after a stressful event (e.g., a fall accident), is common among very old individuals (Morley et al. 2013). Based on the definition of the International Academy on Nutrition and Aging (IANA), frailty is measured as a phenotype reflected by the combination of feelings of Fatigue, diminished capacity for Resistant and Aerobic activities, presence of five or more chronic diseases (Illnesses), and substantial Loss of weight (IANA-Frail scale; see Table 3). Accordingly, most of the participants fell into the intermediate category of “pre-frail” (56.2%). The proportions of participants in the non-frail and

Hong Kong Centenarian Study, Table 2 Biomarkers levels ($N = 102$)

Biomarkers	Unit	Normal range ^a	Normal; n (%)	Mean	SD	Minimum	Maximum

Hong Kong Centenarian Study, Table 3 Distribution of frailty items and phenotypes

Frailty item	Question	Deficit, <i>n</i>	Deficit, %
Fatigue	Feeling full of energy?	38	24.8
Resistance	Able to crouch and stand for three times consecutively?	47	30.7
Aerobic	Able to walk continuously for 400 m at a time by yourself?	91	59.5
Illnesses	Having five or more chronic diseases?	14	9.2
Loss of weight	Lost 3 kg in the previous 6 months?	30	19.6
Frailty phenotypes		<i>n</i>	%
Non-frail (no deficit)		30	19.6
Pre-frail (1–2 deficits)		86	56.2
Frail (≥3 deficits)		37	24.2

frail categories were 19.6% and 24.2%, respectively.

According to the results of the physical examinations, most participants had intact mobility in

upper extremities (95.4% were able to touch the back of neck and waist by both hands, and raise both arms), were able to pick up a book on the floor from standing (71.9%), were able to stand up from sitting in a sturdy chair without supportive device (53.6%), and could complete a 360° turn within seven steps (62.1%). Very few participants had sensory impairment to the extent that had hindered their participation in the physical examination. Two participants (1.3%) were visually impaired such that their physical examination was hindered, but had intact (or corrected-to-normal) auditory functions. Six (3.9%) participants had auditory impairments that impeded the physical examination, but had intact (or corrected-to-normal) visual function. Another six participants (3.9%) had both visual and auditory impairments. 9.8% participants wore an assistive device to help with their hearing during the interview.

In sum, chronic diseases were found to be common among Hong Kong Chinese centenarians. Around half of the sample had experienced hospitalization in the previous 2 years when they were already nonagenarians or even centenarians. However, physical discomfort and sleep problems were not common. Most participants had fewer than three signs of frailty. 56.2% participants were

Hong Kong Centenarian Study, Table 4 Distribution of ADL and IADL independency

Independency in ADL	<i>n</i>	%
Bathing	113	73.9
Dressing	130	85.0
Toileting	138	90.2
Indoor transfer	137	89.5
Continence	110	71.9
Feeding	149	97.4
Number of dependent ADL	<i>n</i>	%
None	85	55.9
1–2	49	32.2
≥3	18	11.9
Independency in IADL		
Shopping	81	53.3
Prepare meals	89	58.2
Washing clothes	109	71.7
Using public transport	54	35.8
Telephoning	127	83.0
Handling finances	128	84.2
Number of dependent IADL		
None	54	35.3
1–2	35	24.9
≥3	64	41.8

categorized as pre-frail. In the light of the robust effect of subjective health on mortality and morbidity (Idler and Benyamini 1997), the most encouraging finding was that despite their advanced age, most participants had preserved a favorable evaluation of their physical health.

Functional Capacity

55.9% and 35.3% participants were respectively independent on all six activities of daily living (ADL; bathing, dressing, toileting, indoor transfer, continence, and feeding) (Katz et al. 1963) and six instrumental activities of daily living (IADL; shopping, preparing meals, washing clothes, using public transport, telephoning, and handling finances) (Lawton and Brody 1969) (See Table 4). The average (SD) number of dependent ADL and IADL were 0.9 (1.4) and 2.1 (2.1). The tasks which most participants required assistance were using public transport, shopping, and preparing meals.

The mean (SD) MMSE score from 140 participants who provided valid answers on more than

Hong Kong Centenarian Study, Table 5 Distribution of GDS-SF scores

Scores	<i>n</i>	%
0 (not depressed)	60	39.2
1–4 (slightly depressed)	57	37.3
5–9 (mildly depressed)	19	12.4
10–15 (moderately to heavily depressed)	11	7.2
Excluded cases (with less than 10 valid items)	6	3.9

ten items of the test was 24.0 (4.7). Out of these 140 participants, 73.6% obtained a MMSE score of 21.0 or more, which indicates intact cognitive capacity (Chiu et al. 1994).

Psychological Well-Being

Most participants enjoyed a high level of psychological well-being, indicated by a low level of depression, suicidal ideation, and negative psychological traits, as well as a high level of positive psychological traits. Depression was measured by the 15-item Geriatric Depression Scale – Short Form (GDS-SF) (Sheikh and Yesavage 1986). The mean (SD) GDS-SF score was 2.5 (3.6). A substantial percentage of participants scored 0 (i.e., no depressive symptoms), while 19.6% scored above 5.0 which indicates a depressive tendency (see Table 5).

Suicidal ideation was also rare, with only 3.3% participants answering “agree” or “strongly agree” to the items “want to end my life” and “have thought about suicide” at the time of the data collection. Negative psychological traits such as meaninglessness (“agree” and “strongly agree”: 3.3%), anxiety (“always” and “often”: 5.9%), and loneliness (“always” and “often”: 7.8%) were not commonly experienced. However, a much higher proportion of participants (34.6%) responded “always” and “often” on the item “feeling more useless as one gets older.” The pattern of responses implies that negative affect and meaninglessness were uncommon among the current sample. However, the perception of uselessness was relatively prevalent among this group of very old adults.

Participants tended to experience substantially more positive psychological traits than negative

psychological traits. 81.0% responded that they were “able” and “very much able” to “look on the bright sides of things (optimism).” 79.1% “liked” and “very much liked” to “maintain their belongings clean and tidy (conscientiousness).” 73.2% could often “make their own decisions (autonomy).” More importantly, 66.6% replied that they “often” or “always” felt they were “as happy as when (they were) young (happiness).”

Daily Activities and Health Habits

The majority of participants were nonsmoker (72.5%) and nondrinker (74.5%) even the past. Only 26.2% and 23.5% had a history of regular smoking and drinking, respectively. Most participants ate fruits (81.7%), vegetables (81.7%), meat (62.1%), and fish (79.1%) (almost) daily. 77.1% maintained a habit of regular exercises. In terms of daily activities, 82.4% watched television or listened to the radio, 50.3% had solitary outdoor activities (e.g., taking a walk in the parks), and 39.2% did household chores. Despite their advanced age, around one in seven (13.8%) participants had traveled abroad for leisure in the previous 2 years.

Social Well-Being

Reflecting the advanced age of the participants, only 9.2% were still married and living with their spouse. Most participants were bereaved (81.0%). Also, only about one-third (31.3%) of the sample still had one or more living siblings. Instead, most participants (77.8%) had more than one living children. The median number of living children was 3 (range = 1–8). Most participants (58.2%) reported to have a spouse or child to confide to when they need emotional support. Other common confidants include friends and neighbors, grandchildren and their spouses, and other relatives. However, it is noteworthy that 14.4% of the sample reported having no one to turn to when they need confidants.

Among the 77 (50.3% of the total sample) participants who lived with either family members or friends, 68.8% lived with their children or grandchildren only, 10.4% lived with their spouses only, and only 5.2% lived with both children/grandchildren and spouse. Domestic

helpers are common among Hong Kong households. Among those 77 participants, 26.0% coresided with a domestic helper. Among these households with domestic helpers, half of them were two-person households with only the elderly participant and his/her domestic helper. The domestic helpers tend to shoulder a substantial proportion of elderly care in these households.

In terms of social activities (e.g., visiting relatives, meeting friends at a restaurant, clubs and religious group gatherings, volunteerism), 28.1% of the sample attended social activities almost daily and 18.3% have weekly social gatherings. However, alarmingly, almost equally many participants (44.5%) reported having social activities at a frequency less than monthly. Some barriers including mobility and health issues, lack of company, transportation problems, and lack of toileting facilities may hinder participants' participation in social activities. Out of ten barriers of social activities, the average (SD) number of barriers participants were facing was 2.2 (1.8).

Successful Aging

There is little dispute that centenarians would have fulfilled “successful aging” if longevity alone is enough to define the elusive concept. However, as Havighurst (Havighurst 1961) proposed when the term was first coined, successful aging is to “add life to years” and should be about maximizing quality of life and happiness of the elderly. To investigate the phenomenon of successful aging among very old adults, previous studies have tested the utility of multidimensional models of successful aging on nonagenarians and centenarians (Cho et al. 2012; Nosraty et al. 2012).

Rowe and Kahn (Rowe and Kahn 1997) model of successful aging conceptualizes the condition as the combination of: (a) absence of diseases and disability, (b) intact cognitive and physical functioning, and (c) engagement with life. Based on this conceptual framework, Cho and associates (Cho et al. 2012) found that only 4.4% of their American centenarian sample achieved the criteria of intact cognitive and physical functioning. More remarkably, none of their centenarian

participants achieved all three criteria of the model. This model was subsequently applied to the current Hong Kong Chinese sample. The criteria for successful aging were operationalized as the combination of: (a) having none of the 30 chronic illnesses, (b) possessing a MMSE score of 21 or above, (c) independent in ADL, (d) having weekly social activities, and (e) not “often” or “always” feeling useless. Out of the 153 participants, only 2 (1.4%) were able to fulfill all the five criteria. However, the number of successful agers increased to 13 (8.5%) after the criterion for chronic illnesses was relaxed to only excluding those who have one or more serious health conditions covered by the Charlson age-adjusted comorbidity index.

Cho and associates (Cho et al. 2012) suggested an alternative model of successful aging which encompasses three criteria, namely good subjective health, perceived sufficiency of economic resources, and self-reported happiness. Compared to Rowe and Kahn’s model (Rowe and Kahn 1997), Cho and associates’ model places a greater emphasis on the role of subjective appraisals of coping resources (e.g., health, economic resources, and psychological resilience) over “actual” physical and cognitive capacity. The prevalence of successful agers in the current sample was therefore recalculated based on Cho and associates’ new model by operationalizing successful aging as the combination of: (a) “good” or “very good” overall subjective health, (b) evaluating one’s socioeconomic status as wealthier than most local households, and (c) “often” or “always” feeling “as happy as when (they were) young.” Sixteen participants (10.5%) attained successful aging. Compared to the model of Rowe and Kahn which places heavy emphasis on intact cognitive and physical functions as well as the absence of diseases, the model of Cho and associates renders a much larger proportion of the sample being included in the “successful ager” category.

Nosraty and colleagues (Nosraty et al. 2012) tested a multidimensional model of successful aging that has explicitly identified the biological, psychological, and social dimensions among an unselected sample of nonagenarians. Their results

neatly demonstrate that the proportion of successful agers depends heavily on the criteria one uses to define successful aging. Among the six models of different levels of difficulties they have tested, the most demanding model is similar to Rowe and Kahn (Rowe and Kahn 1997) and requires a successful ager to have no chronic diseases, no vision and hearing impairments, full independence in physical performance (indoor transfer, dressing, using stairs, getting out of bed, walking 400 m continuously), absence of depression, good subjective health, self-reported happiness, regular meeting with children, and phone calls with family members and friends. This demanding set of criteria rendered only 0.5% of their Finnish participants aged 94 or above being regarded as successful agers. However, the least stringent set of criteria, which involves no dementia, good vision and hearing, independence in physical performance, and regular meeting with children and phone calls with family members and friends, resulted in 7.8% of their older participants being categorized as successful agers.

The current sample was used to test the most and the least demanding models for successful aging of Nosraty et al. (2012) in order to illustrate how different repertoire of criteria will lead to disparate proportions of successful agers. In the attempt to reconstruct the most demanding model with a set of variables similar to the original study as possible, successful aging was measured based on the combination of: (a) the absence of coronary heart disease, congestive heart failure, cerebrovascular accident/ stroke, diabetes, arthritis, hip fracture, Parkinsonism, and Alzheimer’s disease; (b) absence of difficulties in indoor transfer, dressing, walking for 400 m continuously, sit-to-stand without supportive device, and crouch-to-stand for three times; (c) absence of vision and hearing impairments; (d) absence of depression indicated by a GDS-SF score of less than 5; (e) “good” or “very good” subjective health; (f) being “often” or “always” “as happy as when (they were) young”; (g) engaging in weekly or more often social activities; and (h) living with family members or friends. Only 3 out of the 153 (2.0%) participants in the current sample fulfilled all the criteria for successful aging. For the least demanding model

of Nosraty et al., the combination of criteria (b), (c), (g), and (h) was used, and the absence of multiple diseases (criteria (a)) was replaced with the absence of only Alzheimer's diseases. Similar to the original findings, 11 (7.2%) participants from the Hong Kong sample achieved all the criteria for successful aging.

In all, successful aging in multiple dimensions do not appear to be a common phenomenon among Hong Kong Chinese centenarians. Based on different sets of criteria for successful aging, the proportion of successful agers ranged from 1.4% to 10.5%. A successful aging model that stipulates more preserved functions and the absence of more chronic diseases tend to engender a lower proportion of successful agers than a model that is more heavily based on satisfaction on different dimensions of life.

Conclusion

Despite the value of successful aging and centenarian research, a number of areas are awaiting further investigation. First, a greater understanding on how very old adults *themselves* define concepts such as quality of life and happiness are needed to validate extant conceptual models on successful aging. The qualitative study by Wong and associates (Wong et al. 2014) with six successfully aged Chinese centenarians from Hong Kong shows that maintaining positive relationships with neighbors and family and possessing a collection of positive memories are important keys to happiness. However, a positive expectation for the future (i.e., hope) did not feature heavily in centenarians' happiness. In fact, many participants remarked that their "clocks are ticking." Hence, living 1 day at a time and "think less" about the future is the way to stay happy in the tenth decade of their lives. Second, because aging population is a worldwide phenomenon and the elderly's lives tend to exemplify cultural imperatives more so than those of their younger counterparts, a greater understanding is needed on how cultural imperatives influence "what is successful aging" and "how to achieve successful aging." Third, following the footsteps of many

frontiers of longevity research, further investigation on how nature (e.g., genes, diseases) and nurture (e.g., pollutants, family norms) interact to engender longevity is needed. Similarly, greater understanding on how different domains of lives weave together and interact to produce positive outcomes is needed for gerontologists and geriatricians. As a result of their waning self-care capabilities and physical functioning, very old adults may experience a diminishing sense of autonomy and increasing depressive symptoms. Future studies may therefore explore how very old adults use different cognitive restructuring strategies to cope with these challenges. Also, studies on how different personality traits facilitate adaptation to senescence, how spirituality and social support counter the effect of the reduction in active engagement in daily activities, and how to enhance age-friendliness in the social and physical environment will be essential.

The "graying" of population is haunting policy-makers of most countries in the world. Alongside the increase in the elderly population is the reduction in the proportion of active labor force (usually referred to individuals aged 15 to early 60s). In other words, aging population may imply a drastic increase in social and healthcare service demands. However, the World Population Ageing report published by the United Nations in 2013 remarked that "On the positive side (...) older persons can increasingly live independently" (pp. xii) (United Nations 2013). In framing a public health response to population aging, WHO has therefore released the first *World report on ageing and health* to redefine the term of "healthy aging" which focuses on the notion of functional ability and intrinsic capacity underlying physiological changes and psychosocial changes, relevant environmental characteristics, and the interactions between the individual and these characteristics (Beard et al. 2015).

In coping with the challenges of the aging population, enabling a greater proportion of the elderly to become "successful agers" are equally, if not more, important than adjusting social and healthcare policies to cater for the ever-expanding demand. The knowledge of how near-centenarians and centenarians thrive in a buzzing

cityscape like Hong Kong, especially for those who have maintained much functional independence and social engagement, is imperative to enriching the understanding on successful aging in general. Our team has begun this line of inquiry by investigating successful aging and frailty of these exceptional survivors (Cheung and Lau 2015; Kwan et al. 2015). The lived experiences of near-centenarians and centenarians will inform researchers and policy-makers what health conditions are reasonable (versus less reasonable) to expect and achieve at the end of lifespan, how to support the oldest-olds to capitalize their personal and interpersonal resources to cope with the physiological and cognitive declines, and how to prepare the future seniors for a more successful all-rounded aging process.

Davis 1997). However, individuals with the necessary therapeutic skills and knowledge of horticulture may also use horticulture as a therapeutic modality in other credentialed practice, such as occupational therapy or physical therapy. Programs in horticultural therapy offer older adults physical, emotional, social, spiritual, and cognitive benefits.

Background and History

Horticultural therapy is a relatively new discipline; however, recognition of the therapeutic effects of plants and horticulture dates back many centuries to 2000 BC and the lush agricultural landscapes of Mesopotamia and to Persian gardens, designed to please all of the senses, around 500 BC. During the Middle Ages, monastic gardens were used for growing medicinal plants and to provide places for the sick to dwell and recuperate. As well, in the late eighteenth and nineteenth centuries, hospitals and asylums encouraged patients into the gardens as a soothing distraction from their illnesses. In the 1940s, the US government established veterans' hospitals to care for wounded, returned servicemen. Working with plants in these hospital gardens, it was noted, resulted in remarkable improvements in their emotional, mental, and physical health.

The first formal training programs in horticultural therapy began in the United States in the early 1970s. However the term “horticultural therapy” was uncommon in the health sciences until the early 1980s, following the first systematic and empirical studies to examine the purposeful use of plants and gardening activities to improve or maximize an individual's social, cognitive, psychological, and physiological functioning (Kaplan 1973; Langer and Rodin 1976; Ulrich 1984). More recently, the use of horticultural therapy as a means of maintaining or improving the quality of life of older adults is gaining attention in the international literature. Studies have reported positive benefits of horticultural therapy for older adults that include relaxation and relief from stress (Kaplan 1973; Relf 1992; Scott et al. 2014), reduction in pain perception (Ulrich 1984),

Horticultural Therapy

Definition

Horticultural therapy describes a process, either active or passive, of purposefully using plants and gardens in therapeutic and rehabilitative activities designed to positively affect a set of defined health outcomes for individuals (e.g., improved mood, improved self-esteem, enhanced social interaction). Horticultural therapy can include hands-on activities, such as potting up plants, or passive involvement such as viewing a garden through an open window and listening to birdsong. The focus is on multisensory experiences and engaging all of the senses. Horticultural therapists are trained professionals who possess knowledge in plant science, human science, and horticultural therapy and are experienced in the application of horticultural therapy practice (American Horticultural Therapy Association (AHTA) 2015;

increased attention (Hartig et al. 1991), modulation of agitation (Whall et al. 1997), improved mood, enhanced social interaction (Kingsley and Townsend 2006; Yee Tse 2010), meaningful engagement, improved self-esteem (Scott et al. 2014), and enhanced physical well-being (Wannamethee et al. 2000).

Indoor gardening has been reported to be effective for improving sleep, agitation, and cognition (Epstein et al. 1991) and improving the quality of life (Yee Tse 2010) of persons with dementia. Memory can be stimulated by being exposed to the sights and smells of plants in planned horticultural therapy activities (Hartig et al. 1991). Outdoor gardens provide access to fresh air and sunshine and exercise, which helps regulate circadian rhythms that regulate sleep and appetite (Park et al. 2009). Preliminary studies suggest that a carefully designed and accessible horticultural therapy garden may reduce the need for high-dose psychotropic drugs to treat behavioral disturbances in older adults with dementia in long-term care facilities (Epstein et al. 1991; Detweiler et al. 2012), although as is common in studies with this vulnerable group, sample size has been limited and more controlled studies are needed.

Psychological Processes

Natural environments and their elements can act as a distraction, reducing stress and anxiety and promoting health and well-being. For example, prior research demonstrated that viewing nature through a window had physiological and psychological healing benefits postoperatively for patients who viewed the canopy of a large tree from their hospital beds, compared to those who viewed a brick wall (Ulrich 1984). Being in nature or viewing plants and gardens through a window or in pictures provides relaxation and restorative benefits. Using multiple modalities of measuring stress response – including blood pressure, pulse rate, electrodermal activity, electroencephalogram activity, salivary cortisol level, and self-reported mood states – numerous studies have reported that experiencing or being in view of nature, gardens, and plants helps regulate emotion, lowers stress levels, and fosters improved

mood (Detweiler et al. 2012; Relf 1992; Ulrich 1984; Ulrich et al. 1991).

One explanation for the stress-reducing effects of natural environments is that natural environments and their elements are less perceptually demanding than urban environments and require involuntary attention; they therefore provide restoration, a break from mental effort, and the capacity to recover from focused attention (Kaplan and Kaplan 1989). Furthermore, according to biophilia theory, people respond positively to natural environments and their elements because such a response is an evolved, adaptive one. From an evolutionary perspective, human beings are drawn to natural environmental features, such as plants, trees, and water, that are not only aesthetically appealing but would also have enhanced the survival of our species millions of years ago (Wilson 1984). According to the theory, humans have evolved with a capacity to prefer, and respond positively to, nature.

Applications

Increasingly horticultural therapy programs facilitated by trained therapists are located in a wide variety of care settings, including hospitals, rehabilitation centers, residential care facilities, psychiatric care facilities, institutions, prisons, and special education programs, to positively affect patient and resident well-being (AHTA 2015). In these settings, horticultural therapy can be an active or passive process, which occurs in the context of an established treatment plan. The process itself is considered the therapeutic activity, rather than the end result (AHTA 2015).

Older adult participants, especially those living in long-term care facilities, may vary in their physical abilities, social skills, intellectual and emotional needs, and values. Horticultural therapy activities can be modified to meet the needs and preferences of individuals and designed to improve or maximize the participant's psychological, physiological, social, and cognitive functioning. People with physical and cognitive limitations, bed- or wheelchair-bound residents, can take part in meaningful and motivating

plant-related activities as part of a recreational therapy program. Since the frequency of participation in many occupational and leisure pursuits often declines with increasing age – a decline most acutely experienced by frail older adults – horticultural therapy makes a significant contribution to recreational and rehabilitative therapy programs in residential care facilities.

Planned horticultural therapy activities should be person centered and result from an individual assessment of the participant's current and optimal level of functioning, their personal preferences, and personal goals. According to the American Horticultural Therapy Association's (2015) practice standards, the therapist should (1) conduct an assessment of the individual that acknowledges their abilities and limitations; (2) develop an individualized intervention plan; (3) develop observable, measureable, behavioral goals (with the client); (4) document progress; and (5) review the intervention plan if necessary.

Example Activities

Some example horticultural therapy activities include the following:

- Hands-on propagation of plants, plant cuttings, and seeds
- Potting up seedlings
- Observations of gardens, plants, and natural curiosities
- Flower arranging
- Smell-and-tell sessions, touch and identify familiar flowers, plants, fruits, and herbs
- Nature crafts, e.g., pressing foliage, making potpourri sachets
- Garden club discussion groups (e.g., recalling past gardens, seasons, learning Latin names of plants)
- Community outings (e.g., visiting public parks and gardens)

Settings

Horticultural therapy programs can include group or individual activities that are conducted indoors,

outdoors in a covered area, or a garden. Whether group or individual, the sessions are goal directed and individualized to the client and have documented progress. Treatment goals may include the needs of the individual, such as achieving a sense of purpose, as well as the common goals of the group, for example, to encourage or increase socialization. Planned horticultural therapy programs can be modified to provide accessible and cost-effective activities for residents of nursing homes. Horticultural therapy can provide a nonpharmacological alternative intervention to manage agitation and exit-seeking behaviors in people with dementia (Whall et al. 1997; Gigliotti et al. 2004). Furthermore, horticultural therapy activities are more engaging for people with dementia than traditional activities such as games (Gigliotti et al. 2004).

Therapeutic Gardens

Horticultural therapy can include activities in an outdoor garden or sitting and observing or wandering through a therapeutic garden. The term *therapeutic garden* describes outdoor gardens that include a variety of plants that are chosen for their aromatic and tactile qualities to attract biodiversity and to enhance sensory stimulation. Therapeutic gardens possess familiar features to promote reminiscence and enhance memory, and looping paths to encourage exercise. The importance of regular physical activity to maintaining functioning is widely recognized, and activities such as regular visits to outdoor gardens can be organized into the recreational program of residential care facilities, providing a means of improving physical functioning and reducing stress and anxiety.

Healing gardens describe a variety of pleasurable spaces that promote restoration, relaxation, and horticultural therapy objectives through an appreciation of the aesthetics of nature. *Healing* and *wandering gardens* are specially designed therapeutic gardens for people with dementia with the aim of stimulating the senses, encouraging positive memories, and providing a safe place to ambulate. An enclosed, outdoor garden that

excludes toxic plants and pesticides, where looping paths are built into the design, provides a safe place for people with Alzheimer's disease to wander or pace. Concern for residents' safety and potential for risk of falls may impede the installation or use of such gardens in dementia care facilities. However, as Detweiler and colleagues (Detweiler et al. 2012) found, the benefits of frequent use of a safe outdoor garden may reduce the rate of falls for frequent users, as compared to infrequent or nonusers.

For older adults residing in the community, exposure to the therapeutic benefits of horticulture can be promoted through visits to community gardens or working in their home garden. Gardening at home may be an important form of social and productive activity and exercise through which the health and well-being of older adults may be maintained or improved. People tend to take up gardening due to the many tangible benefits, such as to grow and harvest fresh fruits, vegetables, and flowers, and later in life for the intangible rewards, such as aesthetic pleasure, restoration, identity, and self-esteem (Kaplan 1973; Scott et al. 2014).

Social and therapeutic gardening programs are designed to offer group gardening for recreation; however, they also present opportunities for enhanced physical, psychological, and social well-being. Participation in group gardening programs provides isolated or lonely older adults with access to social partners and the impetus for social exchange around a shared identity and appreciation of the aesthetics of gardens. In addition community gardening programs encourage ongoing involvement and repeat interactions between participants and therefore increased social cohesion (Kingsley and Townsend 2006).

Future Directions

Horticultural therapy may be a cost-effective treatment modality to support cognitive, affective, psychomotor, and psychosocial functioning and to improve quality of life for older adults, in particular for those living in assisted living and

residential aged care facilities. Admission to a long-term care facility is often characterized by loneliness, a loss of identity, and independence; residents have considerable recreational hours available. Emerging evidence shows that the benefits of including horticultural therapy activities for residents encompass meaningful engagement, self-expression, mental stimulation, and socialization, as well as visual, olfactory, and auditory stimulation. For people with dementia, horticultural therapy may offer an alternative nonpharmacological intervention to manage agitation that, when delivered by a trained therapist, has no reported adverse treatment effects. Indoor gardening programs are affordable and relatively effortless to include. In particular, for older adults living in long-term care facilities, where the incidence of depression and anxiety is high, horticultural therapy may be a useful and cost-effective adjunctive treatment modality to other forms of psychotherapy, such as cognitive behavioral therapy, to enhance emotional well-being for residents.

While a growing body of theoretical and empirical evidence describes horticultural therapy as an appropriate and adjunctive therapy to treat a range of conditions and to improve overall well-being in older adults, to date there are few controlled clinical trials. More necessary funding, leading to more randomized controlled trials and other rigorous systematic analyses of the therapeutic benefits of horticultural therapy, and as compared to other therapies, is needed.

Housing Solutions for Older Adults

Built Environment, University of New South
Wales, Sydney, NSW, Australia

Synonyms

Aging in place; Downsizing; Seniors' housing

Definition

Housing is both a noun and a verb encompassing the physical nature of shelter for habitation (the individual dwelling), its physical organization and relationship to other dwellings (housing or settlement type), its geographical location (urban, regional, rural, or remote), the means whereby it is secured (tenure), and the attitudes and behavior of its residents regarding their living arrangements.

“Older adults” is a relative term but generally applies to those in or approaching retirement. Chronologically, aging varies considerably between individuals, cultures, and socioeconomic circumstances, but for policy and administrative convenience, retirement age is usually around 60–65 years of age for determining eligibility for pensions and other retirement benefits. The United Nations uses the age of 60 as the threshold for defining an older person for its aging index and 65 for calculating dependency ratios. However, the preretirement cohort from 50 or 55 years of

age is also often included in the definition of an “older” person and is therefore assumed for the purposes of this entry.

Housing solutions for older adults are enormously variable internationally. In traditional cultures with extended family structures, housing for the elderly family members has generally been accommodated within the family home, with three or more generations sharing the same dwelling and care and assistance for the oldest generation provided within the family. This has been both a cultural norm and a necessity where state welfare is nonexistent or extremely limited. In many immigrant communities, traditional intergenerational living arrangements can persist following migration. However, in developed welfare-state societies with nuclear family structures, the responsibility for aged care is generally subsidized to varying extents by the state, and care is less likely to be provided within the family. This has led to the development of specialized housing for older people in various forms including seniors’ housing developments, retirement villages, and various levels of institutional residential aged care. The majority, however, continue to live in the general community and prefer to do so for as long as possible. This entry will focus primarily on housing options for older people in the general community and age-specific independent-living environments.

Housing Problems of Older Adults

“Housing solutions” imply problems that need to be solved, and indeed a number of housing problems regarding older adults can be identified. Prominent among these is the global phenomenon of population aging resulting from the combination of decreasing fertility rates and increasing longevity, due largely to advancements in medical science and exacerbated by the arrival of the postwar baby boomers into older age. This is having a profound impact on national economies due to the increasing dependency ratio (those in the workforce to those not in the workforce), placing an increasing financial burden on a diminishing tax base to support increasing costs of pensions,

health, and aged care. While providing challenges broadly to economic and social policies, population aging is also driving a greater focus on appropriate housing provision for older people due to their sheer increase in numbers and growing political influence.

An almost universal response to population aging by governments has been to encourage aging in place and to increase the delivery of support and care services to the home, in order to reduce transitions into institutional aged care. Paradoxically, however, much of the existing (and new) housing stock is not suitable for aging in place due to its poor accessible design and high maintenance requirement. Moreover, there is a perception that older people underutilize their dwellings and that it is both in their interest and the efficiency of the housing market to encourage them to move to more appropriately sized and designed housing. While this view appears to be supported by the ratio of household size to number of bedrooms, it has been contested (Batten 1999; Wulff et al. 2004; Judd et al. 2010), yet remains a recurring theme in public policy debates.

The fact that many older people are on fixed (pension) incomes, which limits their housing options, is another problem. Most vulnerable are those in the private rental market who are much more likely to be in housing stress (i.e., spending more than 30% of income on housing costs) than homeowners and often with insecure tenure, unpredictable rental increases, and unfavorable landlord/tenant legislation. While homeowners are generally less vulnerable, an increasing percentage are reaching retirement age with a mortgage and may be asset rich but income poor. They may be reluctant to move from the familiar home and neighborhood or be constrained by moving costs and the availability and affordability of suitable housing and location alternatives.

The entry of the postwar baby boom generation (born 1946–1964) into older age also presents a problem. This cohort has lived through a very different set of circumstances than their parent’s generation. They have had better education and job opportunities and, as a result, have greater affluence and higher levels of consumption

including housing. Baby boomers are more likely to live longer, be more health conscious, and have fewer children. They are more likely to be divorced and live alone or in smaller more diverse households. They are more likely to have accumulated more wealth over the life cycle and to have superannuation to sustain their lifestyle into older age (Hugo 2003; Quine and Carter 2006). They are also more likely to be active in older age while expending their wealth on travel and other activities rather than transferring it as inheritance to their children. They have been found to be more likely to enter retirement years with a mortgage and to be more comfortable about relocating but less inclined toward age-segregated living (Quine and Carter 2006; Olsberg and Winters 2005). In short, they enter older age with very different set of attitudes, expectations, and behaviors toward housing than previous generations, which will impact on housing preferences and hence the housing market.

Housing, Aging, and Well-Being

The importance of the home environment to the health and well-being of older people has long been recognized in social gerontology. This has been the case since the emergence of environmental gerontology in the late 1950s and early 1960s drawing on Kurt Lewin's field theory and Roger Barker's ecological psychology and theory of behavior settings. The focus of these theories was the interdependence of person-environment relationships and particularly the notion of environment-behavior congruence or fit. This understanding was further developed in Lawton's seminal ecological theory of aging and notion of environmental press, a dynamic model relating level of competence to the demands (or press) of the environment. As competence declines with age, adaptation may involve increased performance in response to greater environmental press, modifications to the environment (including housing) to reduce press, or relocation to environments with less press (Lawton 1982).

The shift from disengagement theory to activity theory in social gerontology also had

significant implications for the housing of older adults. While disengagement theory had emphasized the inevitability of the mutual withdrawal from engagement of older people and society, activity theory posited that maintaining social and physical activity was important for successful aging (Rowe and Kahn 1997). Aging in place within the existing home and community was therefore seen as an important means of maintaining independence and participation. Environmental gerontology has also contributed to an understanding of the increasing importance of the subjective meaning of home and neighborhood as people age (Peace et al. 2006). Spatial behavior changes with age. People who have lived for long periods of time in particular locations develop strong attachment to the both physical and social aspects of place (Rowles 1978). The physical characteristics of the home, neighborhood, and transport infrastructure can all have an important bearing on the ability of older people to maintain independence and social participation.

Aging and Housing Policy

These developments in gerontological theory have also been reflected in changes in public policy on aging and housing, with a growing emphasis on active, positive, healthy, and productive aging to encourage independence, health, and well-being among the older population. In terms of housing, the most common and international policy response to population aging has been to encourage aging in place in order to reduce reliance on, and the cost of, residential aged care. This is seen as a win-win policy by governments seeking to combat projected increases in health and aged care expenditure and by older people themselves who overwhelmingly prefer to remain living in their home and familiar neighborhood for as long as possible.

But precisely what aging well in place means is less clear: in what kind of place? Does it mean remaining in the longstanding family home, moving to more appropriately designed and/or located housing in the private housing market, remaining within the general community, or moving into an

age-segregated seniors' housing development or retirement village? All of which fall short of moving to institutional aged care. The World Health Organization defines aging in place rather broadly as: "Meeting the desire and ability of people, through the provision of appropriate services and assistance, to remain living relatively independently in the community in his or her current home or an appropriate level of housing. Aging in place is designed to prevent or delay more traumatic moves to a dependent facility, such as a nursing home" (World Health Organization Centre for Health Development 2004). This could include age-segregated seniors' housing developments and retirement villages, but not institutional care, and may include a range of different dwelling types and tenure options.

To enable increased aging in place, it has also been necessary for governments to increase the level of support and care available in the home. This includes support for home modifications, assistance with day-to-day domestic activities and increasing the level of aged care services delivered to the home, more recently including those with dementia. However, the downside to aging in place can be loneliness and isolation within the community, the possibility that some may remain longer in the family home than they should, and the burden of care that can be placed upon family members, often an aging partner.

Urban planning policies often acknowledge that changing demographics due to population aging will require greater diversity of housing types for smaller and more diverse (including older) households but rarely translates these aspirations into tangible outcomes that increase the supply of age-friendly housing options. Attempts to improve the design of new dwellings to be more suitable for aging in place have also proved to be challenging. While accessibility standards for people with disabilities have long been applied by governments to civic and commercial buildings and public space, they are rarely broadly applied to new residential construction.

Age-Friendly Housing Design

There are various paradigms for inclusive design that can improve the suitability of housing design for older adults to age in place, including "visitable," "adaptable," and "universal" design. Visitable design aims to enable a person in a wheelchair to visit a dwelling by incorporating three basic features: a step-free entrance, appropriate width doors and circulation spaces providing a path of travel to the living area, and a toilet meeting the requirements of disability standards. For older people, visitable design can assist in maintaining social contact with family and friends and reduce the cost of home modifications in the future as some of the fundamental design elements are already in place.

Adaptable design is an approach where a dwelling is designed and constructed to facilitate easy and inexpensive modification at a future date when required. Adaptable design features include reinforcement of bathroom walls to enable installation of grab rails, extending kitchen flooring finishes under removable cupboards to enable wheelchair access and bathroom plumbing configurations to facilitate easy removal of a bath and replacement with an accessible shower. Standards for adaptable design have been developed in a number of countries and have been applied to age-specific housing, but are rarely required in the design and construction of all private housing. Adaptable design has also been demonstrated to reduce home modification costs and admissions into institutional care for older people while reducing the risk of falls and hence health and aged care costs.

Universal design is the most inclusive approach for age-friendly housing design, defined as "the design of products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialised design" (Center for Universal Design 1997). While not aimed at any specific age group or ability level, universal design offers the most comprehensive approach to the design of housing to facilitate aging in place. Universal design

embodies seven key principles articulated by the Center for Universal Design: equitable use, simple and intuitive use, perceptible information, tolerance for error, low physical effort, and size and space for approach and use (Center for Universal Design 1997). There have been numerous attempts to translate these principles into design guidelines, usually including features such as a step-free pathway to the home; good lines of sight, lighting, and visibility; appropriately wide doorways, openings, and corridors; reinforced walls for easy installation of grab rails; slip-resistant flooring; open planned kitchens with adjustable shelving, storage drawers, and lever handles; open planned bathrooms and toilets with level shower access and adjustable handheld showerheads; smart technology to enable fully electronic control and communication systems; and space for future installation of stair lifts or elevators (Department of Health and Ageing 2007).

However, age-friendly housing is not just about the dwelling, but also the neighborhood. Without a supportive neighborhood environment, the ability to age in place and remain socially engaged can be limited. Without access to and participation in the life of a local community, aging in place can result in loneliness and isolation. Since 2005, as part of the Aging and Life Course Program, the World Health Organization has recognized the importance of age-friendly environments to healthy aging. The project identified 11 elements of an age-friendly neighborhood: a pleasant and clean environment, importance of green spaces, somewhere to rest, age-friendly pavements, safe pedestrian crossings, accessibility, a secure environment, walkways and cycle paths, age-friendly buildings, adequate public toilets, and age-friendly customer service (World Health Organization 2007).

Close proximity and accessibility to local retail, health, and community services, as well as public transport and safe, age-friendly public spaces, are of particular importance for maintaining community/neighborhood participation, particularly in car-oriented low-density

suburban environments as driving can become difficult for older people or impossible due to loss of their driver's license. Paths of travel need to be continuous and step-free with low grades and level surfaces, unobstructed by objects or vegetation, and well lit at night. Public transport nodes need to provide shade, shelter, and seating as well as include easy-to-understand signage and route information (Judd et al. 2010) (refer to entry "► [Age-Friendly Communities](#)" for a more detailed discussion).

Factors Influencing Housing Choice

Older people are a diverse group and therefore will have diverse housing needs and preferences. Personal factors influencing choice include household size, wealth (in terms of both assets and income), housing history (including mobility and tenure), cultural background, and personal circumstances regarding relationship status, health and ability levels, and lifestyle preferences. Structural factors impinging on older people's housing choices include urban planning and development controls; the nature of local housing markets and their impact on housing costs, types, design, and availability; the provision of local infrastructure and services; housing-related taxation regimes; and government benefits available for housing assistance and support for older adults. Negotiating these can be a daunting task for older people when faced with housing decisions. Housing options available to older adults can include staying put, moving to more appropriate accommodation including downsizing into a smaller dwelling, or into age-segregated communities such as seniors' (55 and over) housing developments or retirement villages.

Staying Put

Staying put is by far the most preferred housing option for the majority of older adults. Contrary to arguments about underutilization, older people

often fully utilize their homes after retirement. Australian research (Judd et al. 2010) has indicated that the vast majority of older people regard the space in their mostly three or more bedroom homes as suitable for their household needs and use “spare” bedrooms for activities important to their health and well-being such as home office space, guest bedrooms for visiting family and friends, and hobbies. In some cases couples need to sleep apart for health reasons and for others, a bedroom is required to accommodate an overnight carer.

Where the design of the home is not supportive of staying put, home modifications will be necessary. Typical problems confronting older people are two-storey dwellings (stairs), steps at dwelling or building entrances, doors, and hallways that are too narrow for those requiring assistive devices such as wheelchairs and walkers, inadequate space in bathrooms and toilets, raised shower hobs, and confined space in shower recesses. For walk-up apartment dwellers, access is problematic other than on the ground floor. Home modifications typically involve changes to the dwelling including addition of ramps, wider doors, grab bars, and handrails to both interior and exterior and installation of stair lifts or elevators in two-storey dwellings. The aim is to tailor the dwelling modifications to fit the individual needs of residents thus enabling them to maintain independence and age in place. Home modifications have been found to assist in reducing the risk of falls and enabling recipients to live independently in the community for longer (Kochera 2002).

The cost of home modifications can vary enormously depending on the design of the dwelling, the degree of modification required, and the ability level of residents. They can also be esthetically unattractive and impact on the resale value of the dwelling. Often home modifications are necessary in response to a sudden health crisis making it difficult for older people to meet the costs. Home modifications may be fully or partially subsidized by government subject to an income and assets test or may be the responsibility of the older homeowner. Housing equity withdrawal products such as reverse mortgages may be useful in assisting with such costs for older home owners.

However, for private renters, home modification is difficult as landlords are usually reluctant to meet the costs, and landlord and tenant legislation is often lacking in facilitating modifications to improve accessibility.

House Sharing and Multigenerational Living

For those older adults who wish to stay put but do not fully utilize space in the home, house sharing or multigenerational living may be an option. House sharing refers to an arrangement whereby surplus space in the home is used to accommodate another older or younger person, or persons, resulting in a more efficient use of the dwelling, providing companionship, sharing of expenses, and assistance with domestic duties. For the secondary resident(s), this may be undertaken on a boarding or rental basis or through purchasing equity in the dwelling. In some countries there are not-for-profit agencies or private broking firms who assist in the “match-making” process.

Multigenerational living is another form of house sharing that can support aging in place. A multigenerational household is one where two or more generations of the same family (other than dependent children) occupy a particular dwelling. In 2011, one fifth of Australian households were multigenerational, many including financially independent adult children of older parents who are working or studying, having remained living at home or returned after living independently, or in some cases aged parents requiring care. Since housing is generally not designed with multigenerational living in mind, issues of control, privacy, and interference between generations can arise (Liu et al. 2015). Some home building companies market multigenerational housing designs with a semi-self-contained zone incorporating a bedroom, small living room, and bathroom facilities. Access may be via a common entry vestibule or separate entrances. The existence of such housing products suggests recognition of market demand for housing designed for multigenerational households, allowing optimization of privacy, independence, and social support

between generations, including opportunities for family care for the oldest generation.

Moving and Downsizing

While the majority of older people wish to stay put, moving is an option for those who find their existing dwelling unsuitable for their needs or wish to move for other reasons, some of whom downsize into smaller dwellings. While downsizing implies a reduction in physical dwelling size, the term often has broader connotations referring broadly to a reduction in housing consumption which may, or may not, involve a reduction in the actual size of the dwelling but may also refer to a reduction in the size of the property (garden) associated with the dwelling, the value of the dwelling (downpricing), household belongings (de-cluttering), or even simply moving to another home or location (Judd et al. 2014).

The extent of moving and downsizing in later life is often less than is assumed. Australian research has found that while 30% of Australians 50 years of age and over were considering downsizing (Adair et al. 2014), only a small proportion (18%) had moved within a 5-year period and an estimated half of these (9%) had downsized to dwellings with fewer bedrooms (Judd et al. 2014). For both groups lifestyle preference was the most common reason given for moving. Inability to maintain the house and/or garden and children leaving home were much more often cited by downsizers as circumstances leading to moving, along with relationship breakdown, death of partner, illness, and disability. When considering a replacement dwelling, low maintenance featured much more strongly among downsizers than other movers. However, lifestyle improvement and location to shops, transport, health services, children, and relatives and having a more accessible home were considered equally important by both groups. Most who had downsized did so within the private housing market in the general community and around one fifth into age-segregated retirement villages. Most had moved from three and four bedroom dwellings into two or three bedrooms dwellings, aptly

described as “smaller but not too small” (Judd et al. 2014).

A number of barriers to older people downsizing have been identified: firstly, financial barriers including the costs of moving (e.g., estate agents fees, removalist fees, stamp duty tax, and in some cases temporary accommodation and storage fees) and the potential impact on pension eligibility of capital gains from the sale of the home. A second barrier is a lack of supply of the kind of housing that potential older downsizers are looking for – smaller two or three bedroom, single-level dwellings with accessible design, and a small manageable amount of private open space. Apartments are often not attractive to older people who have lived their lives in low-density suburban environments because of the uncertainties around building management, noise, privacy, and the demographics of neighbors. Thirdly are the psychological and practical barriers to moving and downsizing. Important among these is not only the attachment to the family dwelling and neighborhood, but also the physical and psychological stress of the moving process including disposal of personal possessions, preparing the home for sale, packing and unpacking belongings, and having to reestablish social networks in a new location (Judd et al. 2014). Attempts have been made by governments to help reduce moving costs via stamp duty tax concessions, quarantining proceeds of sale from impacting on pension eligibility and grants to older home buyers, but these do not appear to have resulted in a significantly increased degree of moving or downsizing among older people.

Naturally Occurring Retirement Communities

A natural consequence of population aging and increasing aging in place is higher concentrations of older people in the community – but more so in some communities than others. For example, rural towns with limited employment opportunities for older people may age faster than the national norm, resulting in higher concentrations. Similarly, high concentrations may develop in popular

retirement areas such as coastal regions. When the point is reached that the majority of residents are older people, these areas have been termed naturally occurring retirement communities (NORCs). The term, which originated in New York with services aimed at concentrations of aging Jewish residents, has now become commonly used across the USA “to describe a community that was not intentionally built as housing for older adults, but has evolved to the point that it is comprised mostly of older residents” (Ginzler 2012). NORCs can vary considerably in scale from whole towns or suburbs to small precincts; in location from inner urban, suburban, or rural towns or regions; and in housing type from single-family housing to apartments, referred to, respectively, as “horizontal” and “vertical” NORCs.

Such concentrations of older adults provide the opportunity through economies of scale to target services to such areas to support aging in place while maintaining social networks and neighborhood attachment. In the USA, support services are typically provided by a combination of public and private agencies via NORC Supportive Services Programs (SSPs), including provision of federal funding in many states. The term NORCs is less used in countries outside the USA though examples of apartment blocks and residential areas with high concentrations of older people do exist, often attracting a higher level of age-specific services than surrounding areas with lower concentrations. The concept of NORCs is, however, likely to become increasingly prevalent as populations age and aging in place is increasingly favored over institutional and cohort living, both by governments and older people themselves.

Accessory Dwellings

Accessory dwellings, also referred to as granny flats, are usually smaller self-contained dwellings on the same property as a primary dwelling and may be subdivided within, attached to, or in some cases detached from the primary residence. Historically these have often been known as “granny flats” and, as the name suggests, were often

occupied by older parents of the primary residents. Accessory dwellings have not always been sanctioned under planning legislation, but recently there has been a resurgence of interest in some jurisdictions as they represent an affordable housing option in response to population aging and escalating housing costs. For older adults, an accessory dwelling can provide independent accommodation with family support or be an additional source of income if rented out.

Social Housing

Social housing options vary considerably internationally but are an affordable housing option for low-income older adults. Whether managed by public housing authorities, housing associations, or not-for-profit community housing organizations, social housing offers affordable and secure accommodation with access and rents determined according to income. Older adults in social housing can be in mixed-age communities or in age-specific developments. Social housing landlords are more likely to undertake modifications to improve accessibility for residents with physical impairments. Social housing may be in the form of large housing estates or scattered throughout the general community. However, reductions in supply of social housing by many governments have resulted in higher concentrations of tenants with high support needs in large public housing estates, leading to increased social problems including crime. Since older people are more vulnerable to crime, fear of crime can discourage their use of local community facilities and open space and hence impact adversely on their health and well-being. Despite this, older people in social housing have often been long-term residents who have developed strong social ties within their community.

Intentional Retirement Communities

Intentional retirement communities (also known as self-organized retirement communities (SORCs)) occur where a group of older people

privately fund, create, and manage their own mutually supportive community, providing housing, shared common facilities, and care services. This may be a small group of close friends or a group that is purposely formed around the desire to collectively create such a community. The housing may comprise purpose-built new buildings or adapted existing houses or apartment buildings with shared indoor common facilities and outdoor spaces.

Cohousing (also known as housing cooperatives or coops) is the most established form of intentional retirement community. The idea of cohousing originated in Denmark in the 1970s and was later promoted among older adults by the Danish government as part of its active aging strategy. While well accepted in Scandinavia and the Netherlands, the concept has also been adopted in North America (Durrett 2011). As a housing option for older people, cohousing can either be multigenerational or age restricted (usually 55+), though it is the latter that comprises an intentional retirement community. Cohousing communities are planned, designed, and managed collectively by their residents, often including a communal house with dining and other facilities. Coops are membership based with residency obtained either through purchase (equity coops) or leasehold agreements (non-equity coops), and members are actively involved in all decision-making.

The strength of intentional retirement communities is the mutual support and neighborliness that they offer older people who might otherwise be isolated, lonely, and unsupported. As for not-for-profit entities, they also can often offer more affordable housing options than in the private housing market and can be designed to be age friendly and accessible. However, they do require commitment to a more communal way of life and willingness to collaborate in the financing, planning, and the development process as well as participate in ongoing governance, which may explain why they have been taken up less in the more individualistic societies of North America and Australia than in European countries with a social-democratic tradition.

Manufactured Home Estates and Mobile Home Parks

A manufactured home estate is a form of low-cost housing where individual dwellings produced in a factory in transportable sections are assembled and connected to services on leased sites in a managed village. Often, depending on the target market, they will include communal facilities such as common rooms, recreational facilities, and space for traveling vehicles such as motor homes, camper trailers, and caravans. Dwellings are individually owned and a lease fee is paid for the site, common facilities, and management services. While most manufactured home estates are not age segregated, many are age concentrated and some are age restricted and therefore more akin to retirement villages. The major difference to a retirement village is that the dwellings can be sold either on-site or disassembled and relocated to another site. Manufactured home estates are favored by some older adults who wish to downsize or downprice into more affordable housing either in a low-cost area or in a high-amenity lifestyle (e.g., coastal or regional town) location. They offer lower maintenance than a conventional single dwelling due to the small site area and the proprietor's maintenance of common property and facilities. Since the manufactured housing products on the market are not necessarily targeted to seniors and are elevated about the ground, they are often not accessibly designed and therefore may require modification to accommodate older adults with impairments.

Mobile home parks (also known as caravan parks) serve the needs of older tourists (often referred to as gray nomads) for short-term accommodation and also function as low-cost housing for long-term residents as their principal place of residence. The itinerant lifestyle of gray nomads is particularly popular among the aging baby boomer generation who may, or may not, also have a permanent dwelling. Unlike manufactured home estates, mobile home parks usually have shared toilet, shower, and laundry amenities, though some of the more expensive mobile homes may have their own facilities. Mobile home parks have on-site management and daily,

short- or longer-term lease fees for use of the site and services provided.

Age-Specific Housing Options

In addition to the various housing options in the general community are a range of options in age-specific communities. Age-specific communities are housing enclaves available only to older adults, usually 55 or over who are able to live independently – also referred to as age-segregated or congregate housing. These are multi-unit developments comprised of small to large groups of detached, semidetached, attached, or apartment dwellings, aimed at the older, independent-living housing market, usually designed to be more accessible than general market housing and often including some kind of community facilities. In some cases, this may also include provision of some support services for independent living. At the most basic level, this could simply be a seniors-only commercial multi-unit housing development with a 55-year-old age threshold covenant without community facilities or services other than common access and open space. In such cases, ownership would be by freehold title with shared responsibility for maintenance and repairs of common property via monthly fees and some kind of body corporate or owners' association. Should assistance or care be required, this can be delivered to the home in a similar manner to those aging in place in the general community.

Managed retirement villages provide a higher level of on-site management, whether provided by a non-government, not-for-profit organization, or private company with greater provision of community facilities, sometimes including on-site support services to assist in maintaining independent living. At the high end of the market, privately developed retirement villages (also referred to as lifestyle villages), often located in resort areas, can have very elaborate communal and recreational facilities and support services. Retirement village dwellings may be occupied on a freehold, leasehold, or rental basis, all requiring a monthly fee for maintenance, repairs, and

management costs. Leasehold models normally include a substantial up-front loan to the provider, a monthly lease fee, and exit fees.

Retirement villages appeal more to the older-old age cohorts (75 and older) who are more likely to be frailer, single, and female and appreciate the companionship, safety, and security of age-restricted living environments. Where dissatisfaction with retirement villages is expressed, it is usually concerning unexpected costs (e.g., increases in monthly fees), maintenance, and management issues. There is some evidence that age-restricted living is less favored by the baby boomer generation who are more likely to want to age in place in the general community, but in the face of population aging, this sector is expected to continue to grow. See the “► [Retirement Villages](#)” entry in this encyclopedia for a more detailed discussion.

Conclusion

This entry has outlined the context, problems, and solutions of housing for older adults. While acknowledging the diversity of older people and their needs and the variety of housing responses internationally, it has emphasized the importance of appropriate and affordable housing for the health and well-being of older people including both their objective physical needs and subjective meanings of home and neighborhood. It has argued that changes in gerontological theory toward active and healthy aging, along with the demands of population aging, have seen a major shift away from reliance on institutional aged care to aging in place in the community, with support services increasingly delivered to the home. This, together with the pressures of population aging and the increasing political influence of older people, is placing greater importance on the provision of appropriate housing and neighborhood environments for older adults in the general community.

Human and Civil Rights of Older People

Aged; Elderly; Universal rights

Definitions and Historical Perspective

Older people with mental illness are among the most vulnerable in the community, due in part to discrimination, stigma, and denial of their basic rights. Equally people with cognitive impairment due to dementia or other neurological disorders are particularly at risk of having rights denied either unwittingly or consciously by their “carers.” Protection of the most vulnerable is acknowledged as a central tenet of human rights, and older people can be greatly supported by a human rights approach (Australian Human Rights Commission 2012; Broderick 2010).

Human rights are rights that everyone is entitled to regardless of their age, citizenship, nationality, race, ethnicity, gender, sexuality, religion,

language, abilities, or any other status (International 2010a, b). These were first promulgated in the Universal Declaration on Human Rights in 1948, which has since been recognized as customary law binding in all countries. The principles are embedded in other international laws, conventions, declarations, resolutions, and many individual country laws, including those guiding health professionals. Universal human rights are the cornerstone of international human rights law and form “a common standard of achievement for all peoples and all nations...” (United Nations 1948).

Civil rights are inherent rights of a citizen by virtue of their status as a citizen of their country. The concept of civil rights has been established since at least Roman times. In the United States (USA) and elsewhere, civil rights are protected by federal and many state constitutions, or their equivalent. In the United Kingdom (UK), some civil liberties were formally defined and proclaimed in the Magna Carta of 1215.

Human rights and civil liberties are interlinked. A right is demanded, while a liberty is the freedom to enact a right. The 1966 International Covenant on Civil and Political Rights and the International Covenant on Economic, Social, and Cultural Rights provided further recognition of, and support for, international human and civil rights which are inclusive of, but not only for, older people.

While basic human and civil rights have been articulated and continue to be refined in legal frameworks, their application to vulnerable older people and especially those with mental illness or cognitive impairment has been slower to establish. This is partly due to the fact that provision of health and social services for older people is a relatively recent addition to our support frameworks. Prior to World War II, older people who needed care were helped in their family homes, grouped with the poor in poor homes or work farms, or housed in asylums for the mentally ill. There were no special institutions for the long-term care of older people. In the 1940s, Marjorie Warren began her work in the UK that transformed care of older people as she advocated for careful assessment of older patients, special

training of medical students in the assessment and care of those patients, and for stronger links to hospitals. Nursing homes became an established form of care for older people unable to care for themselves in their own homes.

In the USA during the 1970s, there was increasing recognition of the role that aged care could provide in supporting older people who were discharged from acute hospitals to nursing homes. This marked the beginning of the teaching nursing home movement in that country. In Australia, the teaching nursing home model took much longer to eventuate, but the rights of older people to adequate health care were advanced because of subsidies in a national health system. In Australia, the Ronalds report (World Health Organization 2015) highlighted factors that affected residents’ ability to raise matters about their care. These included feeling isolated from family and friends, being unable to have a say in decisions about their care, having little knowledge about their rights as consumers, and fear of punishment if they spoke out. As a result, a residential aged care services advocacy and monitoring program was established. Today, federal aged care advocacy programs aim to assist older people to voice their concerns and to ensure that advocacy is delivered efficiently and effectively. The rise of the Alzheimer’s association greatly contributed to giving people living with dementia and their carers a voice in policy, practice, and research (Ronalds 1989). Similarly, advocacy organizations for older people with mental illness, such as *beyondblue*, have been instrumental in giving a voice to this group in the last decade (Hunter and Doyle 2014).

Key Principles

Two key human rights for older people are the right to adequate health care and the right to participate in decisions about their health regardless of physical or mental disability. Related to these rights, major human rights issues for older people include elder abuse, homelessness and barriers to accessing government services, and the opportunity to participate in

community and public life. Civil rights relevant to older people are age discrimination, the right to have a say in health care, and workplace discrimination.

Right to Adequate Health Care

According to the 1948 Universal Declaration of Human Rights, the right to adequate health is part of the right to an adequate standard of living that includes access to food, clothing, housing, medical care and social services, and security in the event of unemployment, sickness, disability, widowhood, old age, or other circumstances beyond one's control (United Nations 1948). The World Health Organization has defined "health" as "a state of complete physical, mental and social wellbeing, and not merely the absence of disease or infirmity" (World Health Organization 1946). This definition has relevance to the right of older people to access appropriate care to maximize their health status. In 1978, the Declaration of Alma-Ata further ratified the importance of access to primary health care for all, to help provide "(health promoting), preventive, curative and rehabilitative services accordingly" (World Health Organization 1978).

Right to Participate in Decisions About Health

Person-Centered Care

The concept of person-centered care has emerged as an articulation of the right to participate in decisions about health (The Health Foundation 2014). It is of special significance for older people who may be less able to exercise their rights to express their health and social care needs and to participate in decision making about that care due to ill health or other reasons. In person-centered care, the older person is a partner in his/her care rather than the recipient and maintains as much control in decision making regarding the care as possible. The person-centered care approach is now considered best practice in acute and long-term aged care.

The core approach advocated in person-centered care is engagement in a respectful, collaborative partnership between the person and his/her health and social care providers. This partnership will identify and provide health and social care that meets the needs of the person, and where applicable his/her family carers, based on personal and social circumstances. Person-centered care enables older people to become more health literate and enhances their ability to confidently articulate their needs to compassionate, responsive, and integrated service providers. A person-centered care approach actively supports the person to help identify and express their individual care needs and to participate as an equal partner in decision making about their care. The concept is extended to care of people living with dementia as well, ensuring that cognitive impairment does not preclude choice in care. Choice should be promoted, even for someone with severe cognitive impairment associated with late stage dementia.

Autonomy and Independence

A person-centered approach to care will promote and respect the autonomy and independence of the older person receiving care. Autonomy and independence may be interpreted and expressed in a variety of ways, dependent upon a person's world view, and are influenced by a person's culture and values. For some older people, exercising autonomy and independence may involve delegating a trusted other to make decisions on their behalf. How a person wishes to make decisions about their care, and with whom, should be established as early as possible and reviewed regularly by their care professionals.

Older people have the right to participate in decision making about treatments, including the right to choose whether they want particular medical treatment, and they also have right to be protected from cruel, inhuman, or degrading treatment or punishment. This has special relevance to older vulnerable people living in the community, in nursing homes, or those who are hospitalized.

Many older people are unaware of their rights, and it is incumbent upon practitioners, governments, and policy makers to uphold and support these rights through the prudent development of

law and policy and for service providers and health professionals to inform all people of their right to access treatment and to provide appropriate access and care that respect these rights. There is also a right to prevention, treatment and control of diseases, and access to essential medicines (Office of the United Nations High Commissioner for Human Rights 2015).

Rights of People with Dementia

People with dementia sometimes have their rights to full participation in health-care decisions impeded by their cognitive impairment because of presumption on the part of their health-care practitioner. There can be an assumption that a diagnosis of dementia means that the individual cannot make decisions at all. Even in mental health research, people living with dementia experience barriers to participation in research (Doyle et al. 2013). There are often multiple gatekeepers for people living with dementia. Unless an advance directive regarding participation in research or health-care decisions has been completed, those seeking to protect people with dementia may unwittingly remove their freedom and right to participate in an activity that could give extra meaning to their life. Participation in research may enable them to make a contribution to society at a time when their contribution is otherwise considered by some to be less meaningful. In Australia, the National Statement (NHMRC et al. 2007) indicates that fair participation in research also includes fair distribution of the benefits of participation.

People with dementia may also experience barriers to accessing adequate mental health services. In Australia, federally funded mental health plans are not available to those living in residential aged care, which means that services from psychologists are more expensive and potentially out of reach for financially disadvantaged older adults (Davison et al. 2016).

The voices of people living with dementia and their families have been slowly getting louder. Consumer participation has increased internationally in recent years for people with dementia as a

result of Alzheimer's associations encouraging people with dementia to engage in assignment of research priorities, to participate in public forums, and to meet regularly with politicians (Department of Parliamentary Services 2010). Parliamentary Friends of Dementia meet regularly to allow interchanges at a political level about dementia. The aims of the group are to provide opportunities for stakeholders, practitioners, researchers, and peak bodies working on dementia treatment, research, or awareness to share their work and discuss policy issues with senators and members of parliament, to provide a forum to discuss issues of importance to politicians and their constituents, and to exchange information about dementia issues (Department of Parliamentary Services 2010).

Advance Care Planning

Advance care planning is one way of supporting the rights of older people to exercise their autonomy and to preserve preferences in health care for those who have lost their capacity to participate in health-care decision making. It originated in the USA in the early 1990's and its practice is supported internationally although mostly in western countries. While its adoption is not yet widespread, its prominence is growing. Relatively few older people have an advance care plan due to a number of complex factors. These include individual and family beliefs and values, perceived relevance, access to opportunity, and the reliance of plans on their clarity and relevance to presenting circumstances. Fragmented health communication systems also mitigate against the effective recognition and use of advance care plans.

Advance care planning is a process of ongoing discussion between a person, his/her family, and significant others, including health-care professionals, and it can be used to guide the future health and social care of the person. The process can occur in the community or other health-care settings although it is most commonly available for people moving into residential aged care. The planning process may help facilitate autonomous

decision making and can assist proxy decision makers and health professionals to make decisions that accord with the older person's values and stated preferences at a future time when the person no longer has the capacity to make such decisions. A person's preferred process for health and social care decision making can also be ascertained by advance care planning (Berger 2010).

Advance care plans can take different forms. It may be one or a combination of the following: a verbal understanding of the person's wishes among family members and the treating health-care team, a written statement or description of the person's wishes, a legally binding written refusal of particular medical or other health-care treatments (an advance directive), or the legally binding appointment of a substitute decision maker (also a type of advance directive). Older people with episodic mental illness may use advance care plans to assist with their care during mental illness.

The implementation of advance care plans for people living with dementia may hold special challenges. Crucially, an early diagnosis of dementia, where it is determined that the person still has capacity, is usually required to make formal legal arrangements about future decision making, such as appointment of a proxy decision maker and completion of other forms of advance directives such as a limitation or refusal of medical treatment.

Freedom of Choice when Living in Residential Aged Care and the Role of Control in Mental Health

Basic rights to outcomes from a minimum required standard of care are outlined in Australia's outcome standards monitored by an independent accreditation agency (Australian Aged Care Quality Agency 2015). These standards highlight access to emotional support, treatments, recreational therapy, rehabilitation support, assistance in obtaining health practitioner services including psychiatric support, assistance in obtaining access to specialist therapy services,

support for care recipients with cognitive impairment, provision of services to manage "challenging behavior," and assistance to enable the care recipient to exercise choice and control over his/her lifestyle. Standards relating to the provision of services within a client's own home are less prescriptive in ensuring that clients with mental illness have their rights protected.

Consumer-Directed Care

The concept of consumer-directed care (CDC) has been adopted in the care of older people to promote their autonomy in choosing and directing their own health care. It has its roots in the disability rights and independent living movements beginning over 30 years ago. With the success of deinstitutionalization, the disability rights movement began to conceptualize independent living as an issue of autonomy instead of simple self-sufficiency and required that people with disabilities were viewed as consumers. Therefore, the CDC model was tightly aligned with fulfillment of civil or disability rights (Ruggiano 2012).

Consumer (or self)-directed care, also known as "cash for care," is a model of health and social care delivery designed to provide a flexible, "person-centered" approach to care choices and service delivery for a range of people, including older people and their carers. CDC can help uphold the right of older people to participate in decision making about their health, by enabling them to manage their own care, rather than only having the choice of the involvement of an external "case manager." There is, however, recognition that many older people may prefer or even require a case manager to assist with their decision making and choice in health and social care and the providers of that care. Government-funded consumer-directed care "packages" have been implemented in the aged care sector in many European countries including the UK, Austria, France, Italy, the Netherlands, Sweden, and Germany and in the USA since the 1990s. More recently, it has also been introduced into home care for older adults in Australia. Different CDC models exist in different contexts such as complete consumer direction, where consumers hold and manage the budgets, and a mix of consumer

direction and case management where case managers and consumers share responsibilities for the budget management (Taylor and Donoghue 2015). Consumers' preferences for different CDC models are varying and there is no one-size-fits-all model (Ottmann et al. 2013).

Age Discrimination and Ageism

Although older people are not explicitly identified in existing international human rights laws that protect the rights of all, the implied rights of older people are nevertheless acknowledged in some of the laws in countries that strive to uphold and respect the Universal Declaration of Human Rights. The need for a specific International Convention on the rights of older people is gaining momentum, fuelled in part by the changing age profile of western countries where the proportion of the population over 65 years is increasing.

The social construction of aging has been especially negative in western countries, where age discrimination can lead to older people not being afforded their full rights. Older people with mental health problems face discrimination in health policy, practice, and research (England 2007). Negative attitudes and perceptions about aging are the result of ageism, which leads to older people not receiving services that are afforded to younger people. Having the "double jeopardy" of psychiatric stigma and old age leads to the mental health of older people being neglected. The stigma of working with older adults with mental illness has led to psychogeriatrics being viewed as one of the least desirable specialties among health professional graduates (England 2007) and psychologists being largely absent from residential aged care in Australia (Davison et al. 2016). In order to protect the rights of older adults with mental illness, it is necessary to remove age barriers to accessing services, make sure that specialist services for older adults are resourced adequately, work to reduce stigma attached to mental health issues, and pay more attention to older people without strong advocates, such as those with alcohol and drug abuse and those growing older with lifelong severe mental illness (England 2007).

Many people believe that mental health problems such as dementia and depression are an inevitable part of growing older and that living in residential aged care is inevitably a depressing lifestyle. Some public health campaigns have been instigated to reduce such negativity and raise awareness of the efforts that can improve the quality of life of older adults with mental health issues, such as the *beyondblue* public health campaigns (beyondblue 2015) and Dementia Awareness Month (Australia 2015), but more needs to be done to promote residential aged care services as desirable places to live and work. Programs to reduce isolation and strengthen social support among older people with mental health problems will assist to prevent depression symptoms (England 2007). Media guidelines on reporting about mental illness have improved the way in which news outlets portray people with mental illness, including people with dementia (Doyle et al. 2012), but reports about residential aged care continue to feed stigma associated with the negative lifestyle associated with living in nursing homes.

Older people with a history of mental illness can also experience discrimination by insurance companies when traveling or seeking health insurance. The Burdekin Report in the 1990s (Human Rights and Equal Opportunity Commission 1993) identified considerable discrimination against people with mental illness in the insurance industry, and 20 years later, the situation had not greatly improved. A survey by the Mental Health Council of Australia in 2011 showed that people with a history of mental illness experienced considerable difficulty in obtaining insurance products. Consumers with mental health conditions sometimes face higher premiums or outright refusal of insurance if they reveal their mental health history to the insurer. This in turn results in difficulty in accessing mental health services that are offered at a subsidized rate by health insurance companies (Mental Health Council of Australia 2011).

Workplace Discrimination

The right to work, free from discrimination on any basis, is another fundamental human right. Limiting older persons' access to the workforce is a

breach of this right. In 1991 UN Principles for Older Persons reiterated support for the health, dignity, independence, and financial security of older persons. The UN Principles, while not binding, encourage all states to provide support and adequate social systems for older people to have the opportunity to work or have access to other income-generating opportunities and to be able to participate in determining when to retire. The link between work, income generation, and health is well established and has particular resonance for societies where ageism can exclude or marginalize older people who wish to continue working or to find work. Older people with disabilities or dementia can be particularly disadvantaged in their efforts to find and maintain work, at great social and economic costs to the community. Those with cognitive impairment due to dementia or mental illness are particularly vulnerable to workplace discrimination and may hide their conditions in order to maintain their positions at work.

Elder Abuse

Older people are vulnerable to abuse, and the growing number of older people worldwide indicates a potential increase in the incidence of elder abuse.

The World Health Organization has defined elder abuse as:

“a single, or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person”. Elder abuse can take various forms such as physical, psychological or emotional, sexual and financial abuse. It can also be the result of intentional or unintentional neglect. (World Health Organization 2002a)

Health professionals and others who come into contact with older people can play an important role in identifying potential or actual elder abuse and protecting elders from abuse. Many countries have enacted laws aimed to protect their elders from abuse; some countries have enacted legislation that requires mandatory reporting of suspected elder abuse by some professionals.

Other approaches designed to protect the rights of older people not to be abused include aged care and health-care standards, special services, consumer telephone “hotlines” and organizations, state statutory bodies including ombudsmen, and education and training for some professionals, including health professionals and some professionals in the legal and financial sectors. Elder abuse is a violation of basic human rights that must be addressed by a team approach across many levels of society (World Health Organization 2002b).

Conclusion

Psychologists and other mental health professionals can take a broad advocacy role as well as promoting equity and the protection of human rights, legal rights, and moral rights for their older clients (Australian Psychological Society 2007). The continuing development of human and civil rights for older people requires the degradation of stigma, continuing sensitivity to discrimination, and building strong social, legal, and political frameworks.

Human Resource Management and Aging

Dorien Kooij
Department of Human Resource Studies, Tilburg University, Tilburg, Netherlands

Older workers

Definition

Human resource management refers to the management of work and people, for example, by offering HR practices, such as training and compensation, to employees. HR practices lead to

positive worker outcomes, such as engagement and performance. However, employee motives and abilities change with aging, affecting the utility of HR practices for employees. Therefore, research on aging at work focuses on how the influence of HR practices on worker outcomes might change with aging and on HR practices particularly tailored to older workers.

Human resource management (HRM) refers to all activities associated with the management of work and people within organizations (Boxall and Purcell 2011). This broad definition implies that many different concepts at different levels are part of HRM and that different actors are involved in HRM. At the organizational level, researchers distinguish HR principles or philosophies and intended HR policies (Wright and Nishii 2013), which refer to the vision and intentions of key decision makers in the company (e.g., board of directors) with respect to managing people. These intended HR policies are implemented by lower-level managers and HR professionals, which are referred to as actual HR practices. At the individual level, these objective actual HR practices are perceived, interpreted, and experienced subjectively by employees. It is important to make this distinction between intended HR policies, actual implemented HR practices, and employee perceptions of HR practices, because they are found to differ significantly and they are differently related to employee outcomes, such as attitudes, performance, and health. It is known that particularly HR practices as perceived by employees (referred to as perceived HR practices) lead to positive employee outcomes (Wright and Nishii 2013).

Different theories are relevant in explaining why HR practices lead to employee outcomes (Kooij and Van De Voorde 2015). An important theory explaining why HR practices increase positive employee *attitudes* is social exchange theory (Blau 1964). Based on the norm of reciprocity, this theory argues that individual employees view HR practices as a personalized commitment toward them, as an investment in them, and as a recognition of their contribution, which they will reciprocate through corresponding positive attitudes and behavior toward the organization. This line of reasoning is supported by many (mostly

cross-sectional) employee survey studies in HR research (Wright and Nishii 2013).

The most important framework relating HR practices to employee *performance* is the ability, motivation, and opportunity (AMO) model, which argues that HR practices positively influence employee performance by enhancing employee knowledge, skills, and abilities (A), by stimulating employee motivation and commitment (M), and by providing skilled and motivated employees with the opportunity to perform (O). For example, a recent meta-analysis on 120 studies at the organizational level (Jiang et al. 2012) found that skills-enhancing (e.g., training and selection), motivation-enhancing (e.g., compensation and promotion), and opportunity-enhancing (e.g., job design and employee involvement) HR practices were related to financial outcomes both directly and indirectly by influencing human capital (i.e., ability) and employee motivation and subsequently voluntary turnover and operational outcomes. This study also reflects an important trend in HR research to focus on bundles of HR practices instead of on HR practices in isolation. Bundles of HR practices are sets of interrelated and internally consistent HR practices, which are aimed toward the same goal (e.g., enhancing skills).

Finally, researchers increasingly use the job demands-resources (JDR) model (Demerouti et al. 2001) to link HR practices to *health* outcomes. The JDR model proposes that job demands (i.e., physical, social, or organizational aspects of the job that require sustained physical or mental effort and are therefore associated with certain physiological and psychological costs) lead to continuous overtaxing and hence to exhaustion. Following the JDR model, HR practices can lead to higher job demands, such as time pressure and role overload, which activate a health impairment process and will thus decrease employee health. For example, a recent multilevel employee survey study among government workers (Jensen et al. 2013) found that employee perceptions of high-performance work systems (i.e., HR practices aimed at increased organization performance, such as incentive-based compensation and performance management) lead to role

overload and anxiety. In sum, HR research shows that HR practices influence employee outcomes. However, since workforces are aging in many developed countries (Hedge and Borman 2012) and aging involves changes in biological, psychological, and social functioning (Kanfer and Ackerman 2004), it is important to look at HRM from an aging perspective.

The Role of Aging

The most important changes that are part of the aging process involve abilities and motives. It is known that physical abilities and fluid intelligence, such as working memory and speed of processing information, deteriorate with age and that crystallized intelligence, such as general knowledge and verbal comprehension, improves with age (Kanfer and Ackerman 2004). Although these changes in abilities are important in itself, they also lead to changes in goals and motives; since losses (e.g., in physical health) start to outnumber gains (e.g., in general knowledge) in older age, older people will think more carefully about how to allocate their resources, such as time, energy, and effort, resulting in a shift in their goals and motives. This is explained by lifespan theories, such as the selection, optimization, and compensation (SOC) model (Baltes and Baltes 1990).

The SOC model, which is a metatheory on lifespan development, proposes that older people will engage in three strategies to deal with changing abilities that are part of the aging process. These strategies are selecting fewer goals or outcomes (e.g., delegating lower priority responsibilities to others), optimizing resources to reach these goals or outcomes (e.g., keep up work skills and abilities), and compensating for losses in outcome-relevant means (e.g., use external aids). These strategies are aimed at achieving four lifespan goals: (i) growth, which refers to reaching higher levels of functioning; (ii) maintenance, which refers to maintaining current levels of functioning in the face of new challenges; (iii) recovery, which refers to recovering to previous levels of functioning after a loss; and (iv) regulation of

loss, which refers to functioning adequately at lower levels when maintenance and recovery are no longer possible.

As employees age, they experience losses in their abilities, and they will allocate fewer resources to the growth goal and more resources to the maintenance, recovery, and regulation of loss goals. These changes in the allocation of resources across the lifespan are supported by evidence on age-related changes in work-related goals and motives (i.e., the importance employees attach to job characteristics and work outcomes). A recent meta-analysis on 86 studies and survey study among university and health-care employees (Kooij et al. 2011, 2013), for example, found that work motives pertaining to challenging work, career advancement, working with people, recognition, and compensation (so-called growth and extrinsic motives) were lower among older workers than younger workers, while motives pertaining to interesting work and use of skills, accomplishment, autonomy, helping and teaching others, and job security (so-called intrinsic, security, and generativity motives) were higher among older workers in comparison with their younger counterparts. In other words, intrinsic, security, and generativity motives appear to increase in strength with age, while growth and extrinsic motives appear to decrease in strength with age.

Because of these changes, the utility and thus the influence of HR practices on employee outcomes also change with age (Kooij et al. 2010). In addition, researchers have questioned whether universally applied HR practices are suitable for older workers at all and have thus focused their attention on HR practices specifically tailored to older workers.

At the organizational level, two HR philosophies on older workers can be distinguished: depreciation and conservation (Kooij and Van De Voorde 2015). According to the depreciation HR philosophy, the value of individual employees peaks early in their career, reaches a plateau in their midcareer, and then steadily declines as the employee approaches retirement. According to the conservation HR philosophy, all employees, regardless of their age, can continue to add value over a long period provided they are adequately

educated, trained, and managed. Research demonstrates that employers adopt both philosophies and implement HR policies that are in line with a depreciation philosophy (e.g., early retirement schemes) and HR policies that are in line with a conservation philosophy (e.g., flexible working hours, ergonomic measures, reduction of working hours, and training programs for older workers; Knies et al. 2015). Similarly, different bundles of HR policies for older workers are distinguished by employers (Van Dalen et al. 2014). These are exit HR practices (e.g., part-time retirement), related to a depreciation HR philosophy, and development (e.g., continuous career development) and accommodation HR practices (e.g., decreasing workload for older workers), both related to a conservation model.

Line managers or lower-level managers play an important role in implementing these intended HR policies as they are increasingly responsible for the implementation of HR practices (Knies et al. 2015). Hence, these managers are crucial for ensuring that HR policies are implemented as intended, either among all employees or among specific groups of employees, but also for making tailor-made arrangements for individual employees (i.e., idiosyncratic deals). However, line managers may hold negative stereotypes about older workers which impact their attitudes toward and decisions on these older workers. They may thus decide not to implement certain HR practices (universal or specifically tailored to older workers) among older workers. Fortunately, more recent studies (e.g., vignette studies) among managers demonstrate that stereotypical views of line managers do not influence their decisions when more information is available on the individual attributes of older workers (Knies et al. 2015).

At the individual level, there are a number of studies examining HR practices specifically tailored to and as perceived by older workers. These HR practices tailored to older workers particularly include training opportunities adapted to older workers' needs; flexible work conditions, such as flexible work schedules; and new work roles, such as internal consultant or mentors. From the studies examining these HR practices, we know

that particularly training opportunities adapted to older workers' needs helping older workers to update and develop their skills have positive effects on older worker commitment, perceived organizational support, and intention to continue working (Kooij and Van De Voorde 2015). For example, building on social exchange theory, a survey study among older nurses and professionals found that training and development HR practices tailored to these older workers influenced intention to remain via perceived organizational support, while flexible HR practices did not affect perceived organizational support and intention to remain (Armstrong-Stassen and Ursel 2009). Although HR practices specifically tailored to older workers have positive effects on older worker attitudes, they can also have perverted effects. For example, offering older workers specific training programs or workload reductions might contribute to age prejudice (Schalk and Desmette 2015).

Besides these types of HR practices specifically targeting older workers, organizations offer universal HR practices, such as universal training, performance appraisal, and rewards, to all their employees. Because motives and abilities change with age, researchers found that some of these universal or general HR practices are less and some of these universal HR practices are more appropriate to motivate and retain older workers (De Lange et al. 2015). Four bundles of HR practices for aging workers are distinguished based on the goals of these HR practices as perceived by employees (Kooij et al. 2014). Using the lifespan goals as proposed by the selection, optimization, and compensation model as an organizing scheme, four broad bundles of HR practices for aging workers can be distinguished:

1. Development HR practices, such as training and development on the job, which may help workers to reach higher levels of functioning (growth goal)
2. Maintenance HR practices, such as job security and flexible work hours, which may help workers to maintain current levels of functioning in the face of new challenges (maintenance goal)

3. Utilization HR practices, such as horizontal job movement, task enrichment, and participation in decision-making, which may help workers to recover to previous levels of functioning after a loss by removing job demands that have become unachievable for an employee from the job and replacing them with other demands that *utilize* already existing, but not yet necessarily applied, skills and personal resources (recovery goal)
4. Accommodative HR practices, such as reduced workload and working part-time, which may help workers to function adequately at lower levels when maintenance and recovery are no longer possible by protecting or sparing them (regulation of loss goal)

The influence of these HR bundles is found to change with age. Since motives change with age, the utility of HR practices changes with age as well. According to social exchange theory (Blau 1964), the utility or value of specific HR practices determines to what extent employees reciprocate through corresponding positive attitudes and behavior toward the organization. Therefore, the influence of HR practices on employee attitudes and behaviors can be expected to change with age as well. As mentioned, previous research found that growth motives decrease and that security motives increase with age (Kooij et al. 2011, 2013). In line with these findings, meta-analytic and survey studies found that development HR practices, such as training and development on the job, are less important in eliciting positive worker attitudes of aging workers, but that maintenance HR practices, such as job security and flexible work hours, are more important in eliciting positive worker attitudes of aging workers. Accommodative HR practices, such as reduced workload and working part-time, are found not to change with age, but to be more important in eliciting positive worker attitudes of workers engaging in selection, optimization, and compensation strategies (Bal et al. 2013).

Besides influencing the relation between HR practices and employee attitudes, aging might also influence relations of HR practices with performance and health (Kooij and Van De

Voorde 2015). For example, because of skill obsolescence and constriction, HR practices aimed at development are particularly important for the performance of older workers. In line with this reasoning, the relation between development HR practices and performance has been found to strengthen with age. In addition, aging might influence the relation between demanding HR practices, such as high-performance work systems (HPWS), and employee health. On the one hand, HPWS might be worse for older workers' health compared to younger workers, because of deteriorating abilities and loss of personal resources needed to offset demands related to HPWS. On the other hand, this relation might be attenuated, because older workers are better at regulating their emotions than younger workers, and might thus be better able to deal with these demands. To date, no research has been done on the moderating role of aging in relations between HR practices and health. Nevertheless, it is known that granting older workers higher levels of autonomy helps them to deal with job demands (Kooij and Van De Voorde 2015).

Future Research Directions

There are three fruitful areas for future research in HRM and aging. First, more (longitudinal) studies are needed that examine which HR practices (besides training programs tailored to older workers and maintenance HR practices) will elicit positive outcomes among aging workers. These studies should also examine the mediating mechanisms (e.g., perceived organizational support, human capital, person-environment fit, or job crafting behavior; De Lange et al. 2015) through which these HR practices have a positive effect. Since many of the studies on aging workers focus on employee attitudes, such as commitment or satisfaction, these studies should also include other employee outcomes, such as performance, productivity, employability, work ability, or health (Kooij and Van De Voorde 2015). For example, HR practices aimed at empowering employees (i.e., high-involvement work practices) might stimulate job crafting behavior,

allowing aging workers to continuously adjust their job to changing abilities and motives that are part of the aging process, resulting in positive attitudes, performance, and health of these aging workers. Second, the role of lower-level or line managers in implementing HR practices among older workers deserves more research attention. Line managers are crucial in implementing and potentially tailoring HR practices to aging workers, but research on the role of line managers in managing aging workers is scarce (Knies et al. 2015). Third, future studies should focus on the context and examine when specific HR practices have a positive influence on aging worker outcomes. Important moderators are age-related factors, such as physical abilities, tenure, and future time perspective, but also type of occupation, line manager support, and organization climate could play an important role (Kooij and Van De Voorde 2015). For example, it might be that the influence of specific HR practices on employee attitudes, performance, and health only increases with age when the company has an age-supportive climate.

Definition

Ikaria Island has been acknowledged as a place with high prevalence of nonagenarians, around the world. The aim of this prospective survey was to evaluate all those clinical, lifestyle, anthropometric, behavioral, social, and nutritional characteristics and gene–environmental interaction that can be related with longevity in a cohort of 1500 individuals, permanent inhabitants of Ikaria Island, above the age of 40 years. Furthermore, a secondary aim was to fulfill a prospective long follow-up of this elderly and middle-aged population. Additionally, the results of this study can be linked to the results of other similar surveys in order to create the profile of long-living populations worldwide.

Introduction

Demographic analyses throughout the developed world suggest that the oldest old (i.e., people of age 80 years and older) are the fastest growing portion of the population. Due to these changes, the United Nations' Global Population Pyramid is undertaking a shift, from the classical shape of a pyramid to a cube. The resultant change in the age distribution of the world's population has been partially attributed to the medical advancements in recent years, a reduction in maternal and infant mortality, as well as in improved nutrition (Cohen 2003). Beyond these global considerations, it is of interest that there are places around the world where people live longer, and, most importantly, they are active beyond the age of 100 years. Specifically, in the past years anthropologists observed that people living in Sardinia (Italy), Okinawa (Japan), Loma Linda (California), and Nicoya Peninsula (Costa Rica) have very high life expectancy, with the percentage of individuals over the age of 90 being at amazing rates as compared to the developed world's average rate of nonagenarians. These places have been defined as the "Blue Zones" and are a part of a large anthropologic and demographic project of the Quest Network, Inc. funded by the National Institute on Aging and National Geographic ([The Blue Zones](#)). It has been observed that people living in these areas share common behavioral and lifestyle characteristics, despite the different race, nationality, and regional characteristics they have.

Clearly, longevity is a complex attribute, determined by factors such as exposure to disease, variability in sleeping patterns, smoking, physical activity, and diet, in addition to the indirect emotional and cognitive influence on physiological pathways. Recently it was reported that people in Ikaria Island, Greece, have also one of the highest life expectancies in the world and, therefore, joined the “Blue Zones.” Ikaria Island is located in the central–eastern part of the Aegean Sea and the total population of the Island is 8,312 (census 2001), and the vast majority of them follows a traditional way of living (i.e., traditional dietary habits that included plant foods, daily physical activities, daily naps, mountain living, low stress). Moreover, Ikaria has eight super-hot, radioactive, saline springs, which flow at various points on the Island’s shores.

This survey aims at examining the existence of gene mutations related to longevity with the amount of cell surface lipids and oxidation stress in respect of lifestyle habits and biological, clinical, and genetic characteristics of people living on Ikaria Island, in order to gain insight on factors related to exceptional survival. Specifically, the purpose of this survey is to correlate dietary habits, lifestyle patterns, and behaviors with clinical and genetic characteristics and with the overall cardiovascular risk in middle-aged (i.e., 40–65 years) and elderly (i.e., 65–107 years) residents of Ikaria. Furthermore, the study will conduct epidemiological 5- and 10-year follow-up assessments to investigate cardiovascular and overall mortality and morbidity in both populations. For this purpose face-to-face interview with surviving participants and public data records from the National Statistical Service for the causes of deaths will be used.

Design and Study Population

The baseline assessment of IKARIA Study is a cross-sectional survey that has been carried out in the Province of Ikaria Island, Greece, from June 2009 to October 2009. During this period, 673 elderly men and women (328 men, mean age 75 ± 7 years, and 339 women, mean age

75 ± 6 years) and 650 individuals (aged 40–64), all permanent inhabitants of the island, were voluntarily enrolled (the participation rate was high and included 673 out of the 800 elderly individuals). All participants were interviewed by trained personnel (i.e., cardiologists, general practitioners, and nurses) who used a standard questionnaire developed for the purposes of the study. Dietary assessment was based on a validated food frequency questionnaire (FFQ) (Tyrovolas et al. 2010). Physical activity was evaluated using the shortened version of the self-reported International Physical Activity Questionnaire (IPAQ) for the elderly (Craig et al. 2003). The survey also included basic demographic items, such as age, gender, financial status (average annual income during the past 3 years), educational level (years of school), and various clinical characteristics. Weight and height were measured to assess body mass index (BMI) scores (kg/m^2). Resting arterial blood pressure was measured three times using the right arm, at the end of the physical examination, while participants were sitting. Fasting blood samples were collected in the morning between 08:00 and 10:00 AM, before physical examination. All the biochemical evaluation was carried out in the same laboratory that followed the criteria of the World Health Organization Reference Laboratories. Depressive symptomatology in the middle-aged individuals was assessed using a translated and validated version of the Zung Self-Rating Depression Scale (ZDRS), while in individuals above the age of 65, Geriatric Depression Scale (GDS) was used (Fountoulakis et al. 1999). Complete ECG measurements at rest were available for all participants, for whom a standard 12-lead ECG was recorded for a duration of 5 min. Echocardiographic assessment was performed for all participants during the initial examination, using standard procedures.

Demographic Characteristics

The majority of the oldest old (above the age of 80 years old) men were married, whereas the majority of women were widowed, a fact that could be explained by an old Greek tradition for men to marry much younger women (i.e., usually

5–15 years younger). It is of interest that almost half of the oldest old participants of the IKARIA Study reported low income (i.e., below their annual average needs). There was also a large proportion of individuals, especially women, without any pension. Moreover, majority of people were found living together with other members of their families (i.e., children, relatives, etc.), in relatively small but owned houses. In addition, 3.3% of men and 4.1% of women of these oldest old individuals were still working (mainly self-employed). Furthermore, 3.4% of men and 27.6% of women were doing works in their houses (i.e., gardening). The education status of these oldest old was very low, with an average of 7.4 ± 3.4 years of school; 20.3% of them had not completed primary school, and the illiteracy rate was 10.1%.

Lifestyle Habits

Men compared to women were more physically active: about nine out of ten men and seven out of ten women reported daily (mainly occupational) activities. A large majority followed a traditional Mediterranean diet (i.e., average score was 38/55 or 69% adherence to the pattern), with no differences between genders (Lazaros et al. 2014; Siasos et al. 2013; Oikonomou et al. 2011; Tsiachris et al. 2011; Panagiotakos et al. 2011). Depressive symptomatology as assessed by the GDS was much higher in women as compared with men. Nevertheless, the average scores were very low (i.e., <5), suggesting low rates of depression in this advanced age group. According to mental health status, findings revealed that in these elderly individuals, cognitive function seems to be related with aortic elastic properties. In particular, increased aortic distensibility, as evaluated by echocardiographic measurement, was associated with increased likelihood of having a good mental function in advanced age. This was the case for both males and females, and the effect remained stable after various adjustments were made for the presence of cardiovascular disease, renal dysfunction, and other cardiovascular risk factors (Chrysohoou et al. 2013a, 2013b). Depressive symptoms constitute a frequent condition in aged people. N-3 polyunsaturated fatty

acids provide a promising approach in the treatment of depression. In the IKARIA Study we found a relationship between fish consumption and depression in the elderly population; thus, more frequent fish consumption seems to have beneficial effect on depressive mood in elderly individuals. This association remained significant even after various adjustments were made, including obesity, diabetes, lipidemia, smoking habits, hypertension, physical activity, sex, age, Mediterranean diet score, and cardiovascular disease. In particular, consumption of 300 g of fish on weekly basis was associated with about 66% lower likelihood of having depression levels above the median value of the GDS score for this population (Chrysohoou et al. 2010). Additionally, fish consumption was associated with improved kidney function among older adults, independent of other biochemical, lifestyle, and CVD risk factors, as well as the level of adherence to the traditional Mediterranean dietary pattern. This is the first study that evaluated the aforementioned association in a Mediterranean population. Moreover, the beneficial effects of long-term fish intake on kidney function were observed in elders suffering from several other comorbidities, extending the current scientific knowledge about the benefits of polyunsaturated fatty acids (PUFA) consumption on populations with chronic health problems (Chrysohoou et al. 2013c). The prevalence of hyperuricemia in the elderly population of the IKARIA Study was 34% in males and 25% in females. Similar to previous studies, it was observed that serum uric acid (UA) levels were higher in males than in females, a fact that has been attributed to the influence of sexual hormones. Among other therapeutic modalities, diet has been associated with the prevention of hyperuricemia, as consumption with purified purines increases serum UA levels in animal and humans. Purine-rich foods include animal meats (i.e., beef, pork, lamb, organ meats, and meat extracts); seafood (i.e., fish fillets, tuna, shrimp, lobster, clams, etc.); and plants (i.e., yeast extracts, peas, beans, lentils, asparagus, and mushrooms). By contrast, dairy products (i.e., milk, cheese, yogurt, ice cream), grains and their products (i.e., bread, pasta, cereals), vegetables, fruits, nuts, sugars,

and sweets are low in purines. Although the effects of a Mediterranean type of diet on the incidence of hyperuricemia have not been studied thoroughly up to now, there is experimental evidence indicating that diets enriched in both gamma-linolenic acid in plant seed oil and eicosapentaenoic acid in fish oil significantly suppress urate crystal-induced inflammation in animal models. Our findings revealed that long-term adherence to a Mediterranean type of diet decreases UA levels, in elderly population, without known cardiovascular disease, irrespectively of other traditional risk factors (Chrysohoou et al. 2011). This relationship was more evident in males. As elderly individuals show increased vulnerability for expressing hyperuricemia and gout, which is often related to other pathological conditions, it is essential to find alternative therapeutic solutions. Dietary interventions promoting consumption of patterns enriched with fruits, legumes, and vegetables and poor in animal protein, with moderate alcohol consumption, may be useful in lowering the burden of morbidity related to high levels of UA in elderly population.

Testosterone Levels and Atherosclerosis

In other studies, the metabolic syndrome (MetS) has been found to increase in prevalence among elderly individuals and seems associated with pathophysiological conditions that involve increased inflammation and oxidation process and mitochondrial and endothelium dysfunction. In previous studies testosterone levels have been found to be linked with cardiovascular health, as low testosterone levels seem to accompany aging-related diseases, like vascular dysfunction and atherosclerotic disease. In the IKARIA Study, the prevalence of MetS was associated with serum testosterone levels, only in men; at the same time, such relationship was not observed in women. Furthermore, serum testosterone levels were inversely associated with components of the MetS in both genders. When categories of lipids, hs-CRP, BMI, and insulin resistance levels were taken into account, testosterone lost its significance in predicting MetS, suggesting a mediating effect of these markers on the relationship

between testosterone and the syndrome (Chrysohoou et al. 2013d).

Environmental Radiation

Another issue that the IKARIA Study evaluated is the impact of environmental radiation on longevity. The island of Ikaria is located in the eastern Aegean Sea. It is dominated by a mountainous area divided, from the geological point of view, into two petrologically distinct equal parts: (a) the eastern part consisting of largely metamorphosed sedimentary formations and (b) the western part mainly consisting of granitic formations. The Laboratory of Archaeometry of the National Center for Scientific Research “Democritus” has measured the natural radioactivity at the surface of Ikaria Island. Following their findings, Ikaria Island can be separated in three major radioactive areas, with extremely different levels of gamma radiation: the western and west–north part with medium to high levels of radioactivity and the eastern part with low radioactivity levels, with the nuclide ^{226}Ra as the main contributor to these dose rates. The annual dose equivalent ranged between 0.20 and 3.31 mSv per year, revealing the higher exposure in the west–north part of the Island. Based on the demographic information from the National Statistical Service of Greece (NSSG), significant differences were observed in the rate of persons aged 90+, as well as in the survival between the aforementioned areas. In particular in Ikaria, the rate of the permanent inhabitants, men above the age of 90 years old living in the higher radioactivity area, was twofold as compared with the nonagenarian living in low radioactive areas, while the respective percent of women was higher by one third. The biological effects of low-dose radiation have been found to be similar to that of moderate exercise in animal studies, as they stimulate the production of antioxidants and enhance the immune system. Low-dose radiation (<0.1 Gy) seems to induce anti-inflammation by hampering leukocyte adhesion to endothelial cells and induction of apoptosis, by reducing the activity of the inducible nitric oxide synthase, and by lowering the oxidative burst in macrophages, reducing the endogenous DNA damage and increasing DNA

repair capacity. It seems that the U- or J-shaped dose–response curve of radiation to human health represents hormesis or a hormetic effect, which has been described as an evolutionary adaptation of human or animal models to environmental levels of toxins and other hazards such as radiation (Chrysohoou et al. 2013e; Stefanadis 2013; Trabidou and Florou 2010). Although, the maximum value of the dose rate observed in the case of sediment in Ikaria (26.8 mGy d^{-1}) did not reach the threshold reported for metabolic malfunctions in the exposed organisms, this report can be used as a perspective for further research on the effects of chronic exposure in nonintervention environmental radiation levels.

Four-Year Follow-up

During June–July 2013, the IKARIA Study’s investigators performed the 4-year follow-up. Vital status was recorded for all $n = 676$ participants. In order to participate in the follow-up, all participants were appointed through telephone calls and then had face-to-face medical examination with the study’s investigators. During 2009–2013, 53 deaths were occurred in the study’s sample; i.e., the all-cause mortality rate was 790 deaths per 10,000 inhabitants. The gender-specific all-cause mortality rates were 580 per 10,000 women and 100 per 10,000 men inhabitants ($p = 0.04$). Causes of death were acute myocardial infarction (21%), stroke (15%), cancer (21%), infection (10%), renal failure (4%), respiratory (2%), and the rest 27% from other causes (e.g., accidents, suicides). The 4-year incidence of hypertension was 900 new cases out of 10,000 inhabitants, the 4-year incidence of hypercholesterolemia was 650 new cases out of 10,000 inhabitants, and the 4-year incidence of diabetes was 690 new cases out of 10,000 inhabitants; no gender-specific differences were observed. A strongly significant trend was observed between baseline age of the participants and all-cause mortality (p for trend < 0.001). In particular, men who were over 80 years at baseline examination had an about two times higher mortality risk compared to those aged between 65 and 80 years (2.07, 95% CI 1.04, 4.12). Women who were over 80 years at baseline examination had an

about eight times higher mortality risk compared to those aged between 65 and 80 years (8.27, 95% CI 3.00, 22.77). The probability of surviving after the age of 80 years increased, whereas the aforementioned probability showed a progressive reduction up to the middle of the eighth decade of life. This study illustrated that among individuals of mean age 75 years old, age, male gender, blood urea measurement, increased heart rate, decreased left ventricular performance, thyroid abnormalities, and pulse pressure were the most significant clinical predictors for mortality. Among lifestyle habits, nutritional aspects of daily olive oil consumption, less daily energy intake with smaller food portions, and moderate coffee intake were also associated with increased survival (Chrysohoou et al. 2015). Those lifestyle habits have been also described in other high longevity communities nowadays, but Hippocrates (400 BC) had first referred to behaviors promoting healthy aging: “*All parts of the body which have a function if used in moderation and exercised in labors in which each is accustomed, become thereby healthy, well developed and age more slowly; but if unused and left idle they become liable to disease, defective in growth and age quickly.*”

Conclusions

The IKARIA Study helped us to record and identify the clinical factors, lifestyle, dietary habits, genetic and biochemical markers and environmental factors associated with longevity and quality of life, morbidity, and mortality. This study illustrated the beneficial role of Mediterranean type of diet on several health aspects even in elderly individuals and the role of physical activity and long-term lifestyle habits in preserving quality of life in advanced age. Based on 4 years of observation in older individuals in Ikaria Island, age, depression, left ventricular hypertrophy, volume of left atrium, left ventricular ejection fraction, red blood cell distribution, olive oil consumption, and thyroid stimulating hormone were statistically significant predictors for all-cause death. Also, age, male gender, heart rate, serum urea levels, pulse pressure, plasma insulin levels, left

atrial volume, and coffee consumption were found significant predictors for CVD mortality. Moreover, the long-term adoption of a nutritional pattern close to the Mediterranean diet, the presence of physical activity, and the optimistic behavior seem to characterize the very old men and women who were alive at the 4-year follow-up.

 Minneapolis, MN, USA

Synonyms

For urinary incontinence: Urine leakage; Involuntary urination; Enuresis; Bedwetting; Nocturnal enuresis; Diurnal enuresis

For fecal incontinence: Accidental bowel leakage; Encopresis; Anal incontinence; Bowel incontinence

Definition

The International Continence Society defines urinary incontinence as “the complaint of any involuntary leakage of urine” (Abrams et al. 2002). The International Consultation on Incontinence defines fecal incontinence as “the involuntary loss of liquid or solid stool that is a social or hygienic problem” (Norton et al. 2005). The term “incontinence” is used in this entry to refer to urinary incontinence (UI) and fecal incontinence (FI).

Overview

Incontinence is a prevalent and costly health condition in older adults that contributes to significant

psychosocial morbidity including impaired quality of life. The annual cost of managing incontinence exceeds \$16 billion, with the majority of expenditures (70%) targeting the use of incontinence pads. Less than 10% of expenditures are for treatment (Wilson et al. 2001). The inability to control the bladder or bowel creates psychological distress and emotional burden and leads to social isolation and disability and, in some situations, institutionalization (Ory et al. 1986). The double stigma of being “old” and “incontinent” carries negative consequences that can affect overall well-being and influence the decision not to seek treatment. Many individuals who are affected with UI or FI do not report their incontinence to a health-care provider (Wagg et al. 2013). Along with demographic characteristics, incontinence type, and severity, the lack of reporting incontinence is strongly influenced by embarrassment, shame, and other psychological factors, lack of knowledge and erroneous beliefs about available treatments, and low expectation of treatment benefit. Some older adults may try to hide their incontinence for fear of nursing home placement. Although knowledge, awareness, and treatments have improved in recent years, incontinence continues to be underreported, under-detected, and undertreated in older adults.

This entry will provide an overview on urinary and fecal incontinence, their prevalence, and major types. The literature on whether psychological factors are a risk factor or consequence of incontinence is summarized, along with a brief discussion of the management of incontinence.

Epidemiology and Subtypes of Incontinence

Urinary incontinence (UI) is more common than fecal incontinence (FI) or the combination of both UI and FI (known as dual incontinence) (Gorina et al. 2014). Prevalence estimates vary widely depending on the definition and type of incontinence, methodology used, and population studied. In general, the prevalence and severity of incontinence increases with aging, especially in older age

groups (75+ years), and varies by type of population (community vs. long-term care).

Prevalence rates from a representative sample of noninstitutionalized adults aged 65 years and over from the National Health and Nutrition Examination Survey (NHANES) found that 43.8% reported UI and 17.3% reported FI (Gorina et al. 2014). In this sample, older women were more likely to report UI than men (54.4% compared to 29.9%, respectively). UI severity increased with advancing age, with adults aged 75 years and over having higher UI severity scores than those in the 65–75-year-old age category. These same prevalence patterns are observed in older noninstitutionalized medically complex and vulnerable adults and in those living in long-term care settings (Gorina et al. 2014). Based on data from the 2009 Long-Term Care Minimum Data Set (MDS), 70.3% of long-stay nursing home residents had UI and 60.0% had FI (Gorina et al. 2014). A higher proportion of female nursing home residents had UI than men (73.5% vs. 64.9%, respectively), whereas there were no sex differences noted with FI. The 2010 National Survey of Residential Care Facilities indicated that 36.6% of older adults living in residential care facilities have UI. Women were 1.2 times more likely to have UI than men in this setting (39.4% vs. 32.7%); however, the prevalence of FI was similar between genders at 20.4% (Gorina et al. 2014).

Incontinence prevalence and its severity may also vary by racial and ethnic background. For example, in community-dwelling populations, non-Hispanic older white women have a 1.8 times higher rate of UI than non-Hispanic older black women (Gorina et al. 2014). In contrast, non-Hispanic black long-term nursing home residents have a higher rate of both UI and FI (73.1% UI, 66.9% FI) than non-Hispanic white (69.8% UI, 58.5% FI) or Hispanic (69.1% UI, 62.8% FI) residents. However, in residential care settings, no racial or ethnic disparities in UI prevalence were found (Gorina et al. 2014).

Although incontinence exerts a toll on psychosocial functioning, these effects vary based on incontinence subtypes. UI has several subtypes: (a) stress UI which refers to leakage on effort,

exertion, sneezing, or coughing; (b) urgency UI which refers to leakage accompanied by a sudden, intense desire to urinate; and (c) mixed UI which refers to symptoms of both stress and urgency UI (Abrams et al. 2002). The prevalence of the UI subtypes varies by age and sex. Typically, urgency and mixed UI are seen more frequently in older women and men (age 65+) compared to younger adults. In addition, a constellation of lower urinary tract symptoms (urgency, frequency, nocturia, with or without urgency UI) known as overactive bladder (OAB) syndrome is also quite distressing and debilitating.

FI and anal incontinence, while they share similar characteristics, are not completely synonymous. As most studies have focused on FI, this term will be used. FI can consist of gas, liquid, or solid stool. The characteristics of FI have sometimes been identified as: (a) passive incontinence or the involuntary soiling or leakage of stool without forewarning of the patient, (b) flatus incontinence or the inability to control flatus, and (c) urge incontinence or the inability to defer defecation once the urge is perceived, for long enough to find a toilet (Norton et al. 2005).

Incontinence in older adults is associated with multiple interacting factors, including age-related changes in the lower urinary tract and brain; lifestyle choices in diet and physical activity; chronic conditions such as diabetes, arthritis, stroke, and constipation; trauma with resulting damage to the muscles and nerves associated with bowel and bladder function; and certain medications (Wagg et al. 2013). In addition, functional deficits in cognition and mobility play a significant role in the development and exacerbation of incontinence as they can impair the individual's ability to perceive and respond appropriately to the awareness of bladder or bowel fullness and/or to reach the toilet in time before the loss of urine or stool occurs (Wagg et al. 2013).

A strong association between UI and FI has been documented in epidemiological studies (Halland et al. 2013) suggesting that one type of incontinence is a risk factor for the other. However, the complex physiology of urinary and gastrointestinal function is interrelated, and most likely the association between UI and FI reflects

a common neurophysiological etiologic pathway rather than either being a risk factor for the other.

Psychological Risk Factors for Incontinence

The linkage between the brain and the bladder was first described in the late 1970s by Frewen, a British urologist, who identified that psychogenic factors in women were associated with bladder overactivity confirmed by cystometry and that a simple behavioral intervention, bladder retraining, was effective in resolving UI (Ory et al. 1986). Psychological variables such as anxiety, depression, and cognitive impairment have been correlated with incident incontinence, especially UI. However, studies have been limited by age, sex, and incontinence type, making it difficult to extrapolate to the entire incontinent older population, especially older men.

Case-control, cross-sectional, and longitudinal studies have identified a strong association between anxiety, depression, and incontinence in older women and men (Halland et al. 2013; Luo et al. 2015; Tenunissen et al. 2006; Lobchuk and Rosenberg 2014; Coyne et al. 2012; Heinrich and Wells 2004; Dugan et al. 2000; Melville et al. 2009; Perry et al. 2006; Xu and Kane 2013; Nygaard et al. 2003; Bogner et al. 2002; Asoglu et al. 2014; Lussier et al. 2013). Effects of anxiety on UI have been noted in older adults of both sexes (Tenunissen et al. 2006). When the effects of UI are severe enough to cause functional impairment, the prevalence of anxiety disorders increases fourfold (Bogner et al. 2002). Higher anxiety as measured by the Beck Anxiety Inventory was associated with urgency incontinence and mixed UI in women but not with stress UI (Asoglu et al. 2014). Depression raised the risk of developing incident UI in several studies (Heinrich and Wells 2004; Melville et al. 2009).

The association between depression and incontinence might be bidirectional; e.g., depression is a consequence as well as a cause of incontinence. In one large prospective study of women aged 40 years and over, incident cases of anxiety and depression were predicted by urgency UI at

baseline. In this study, 56.6% of respondents reported substantial and frequent anxiety, while 37.6% reported significant depression (Perry et al. 2006). In contrast, in a large longitudinal study of female participants (mean age 59.3 ± 0.5 years) from the Health and Retirement Study, major depression predicted the onset of UI over a 6-year period (adjusted odds ratio, 1.46; 95% confidence interval, 1.08–1.97). However, incontinence did not predict the onset of depression (Melville et al. 2009). A separate 6-year longitudinal study of women with an average age of 73.3 years who were incontinent at baseline as well as developed UI over time found that both groups had lower levels of psychosocial functioning (Heinrich and Wells 2004).

A neurophysiological mechanism might explain how mood contributes to incontinence. Depression is associated with abnormalities in serotonin, an important neurotransmitter that affects bladder function (Wagg et al. 2013). Also, increased sympathetic nervous system activity associated with depression can increase circulating levels of cortisol and catecholamines and consequently lead to physical changes in the bladder and UI (Melville et al. 2009).

There has been increasing attention to the role of brain processes in voiding dysfunction. Previous research comparing incontinent to continent older adults has demonstrated changes in cognitive processing. In one study, women aged 60 years and over with mixed UI had poorer performance on measures of executive function than those who had stress UI or continent controls (Lussier et al. 2013). These findings were specific to the neurocognitive test performed and involved only those that had involuntary switching and sharing/dividing attention between two tasks. Recent studies on brain imaging in cognitively intact older adults have more clearly mapped out a model of brain-bladder control and the neural circuits that are associated with bladder sensation and voiding suppression. Functional magnetic brain imaging suggests that damage to the cortical pathways serving the frontal, midcingulate, and subcortical circuits, e.g., white matter hyperintensities, increases with age and is linked to voiding dysfunction, especially the severity of

urgency UI (Smith et al. 2015). Studies of brain processing in older women with and without urgency UI suggest that disordered brain processes are contributing more to lower urinary tract symptoms and incontinence than end-organ changes (Smith et al. 2015).

UI and FI and their severity are highly associated with dementia. In a recent systematic review of the association of dementia and lower urinary tract symptoms, UI was found to be related to the type of dementia and its disease progression. For example, UI occurs in late-stage Alzheimer’s disease, but lower urinary tract symptoms precede cognitive impairment in Lewy body disease and in vascular dementia (Averbeck et al. 2015).

In long-term care facilities, staff attitudes and expectations may reinforce incontinent over continent behavior or have disincentives to remain or regain continence (Ory et al. 1986). The physical labor of caring for an incontinent resident with frequent leakage is time consuming, stressful, and frustrating and can lead to negative staff behaviors and a poor relationship with the incontinent resident.

Psychosocial Consequences of Incontinence

Incontinence results in profound psychosocial consequences that have been well documented in quantitative and qualitative studies (see Table 1) (Halland et al. 2013; Luo et al. 2015; Tenunissen et al. 2006; Lobchuk and Rosenberg 2014; Coyne et al. 2012; Heinrich and Wells 2004; Dugan et al. 2000; Melville et al. 2009; Perry et al. 2006; Xu and Kane 2013; Nygaard et al. 2003; Bogner et al. 2002; Asoglu et al. 2014). The majority of studies have been conducted in women with UI; less is known about the psychosocial consequences in men.

How individuals perceive and respond to incontinence is influenced by attitudes about self, aging, and their general life situation (Ory et al. 1986). Many older adults deny they are incontinent in an attempt to preserve their self-respect and dignity. One-third to one-half of older adults experience feelings of embarrassment, frustration, and anxiety and limit or adjust their social activities because of the “fear of an accident.”

Incontinence and Aging,

Table 1 Psychosocial consequences of incontinence in older adults and family caregivers

Older adult	Family caregiver
Embarrassment	Embarrassment
Shame	Frustration
Worry about having an accident	Anger
Feeling of worthlessness	Revulsion (especially fecal incontinence)
Feeling out of control	Resentment
Anger	Caregiver burden and stress
Hopelessness/futility	Depression
Anxiety	Social isolation
Depression	Role change
Impaired relationships	Decreased physical activities
Decreased life satisfaction and purpose	Sleep disruptions/fatigue
Loss of self-esteem/self-confidence	Decreased intimacy/sexual activity
Burden of always taking precautions to prevent or manage incontinence	Impaired relationships
Restriction of physical activities	Potential for abuse or neglect
Sexual difficulties/decreased intimacy	Decision to institutionalize
Decreased travel	
Social isolation	
Potential for institutionalization	

Constant worry about the possibility of the loss of bladder or bowel control in public causes psychological distress, leads to activity restriction, and impairs social functioning. Sufferers can experience loss of self-esteem and confidence, as well as have sexual difficulties (Coyne et al. 2012; Asoglu et al. 2014). Even older nursing home residents with UI experience decreased quality of life scores in mood, dignity, and autonomy (Xu and Kane 2013).

Some studies suggest that incontinence has a major impact on well-being, although most studies report a more modest impact, with only a subsample experiencing significant distress. These inconsistent results might be explained, in part, by different definitions of incontinence, incontinence severity and subtypes, and use of different instruments to measure well-being and psychosocial impact. Men tend to report greater social impact than women and may experience more emotional burden including anxiety and depression (Tenunissen et al. 2006; Coyne et al. 2012).

Psychosocial consequences tend to vary based on the type of incontinence and its severity, although studies are not consistent. In a large population-based study of women aged 50–59 years, women with severe UI were 80% more likely to experience significant depression, whereas women with mild to moderate UI were 40% more likely to experience depression (Nygaard et al. 2003). In some studies, the presence of more than one type of UI compared to one type alone was associated with significantly higher psychological burden in both men and women (Coyne et al. 2012). Urgency and mixed UI tend to have a greater impact affecting social, psychological, and sexual function (Tenunissen et al. 2006; Coyne et al. 2012). One explanation for why individuals with urgency UI may experience greater impact on psychosocial functioning is that it is associated with bothersome lower urinary tract symptoms such as urgency (sudden, compelling urge to urinate), urinary frequency (increased urination), and nocturia (awakening at night to empty the bladder). Although there are fewer studies on the consequences of FI, its impact is believed to be greater

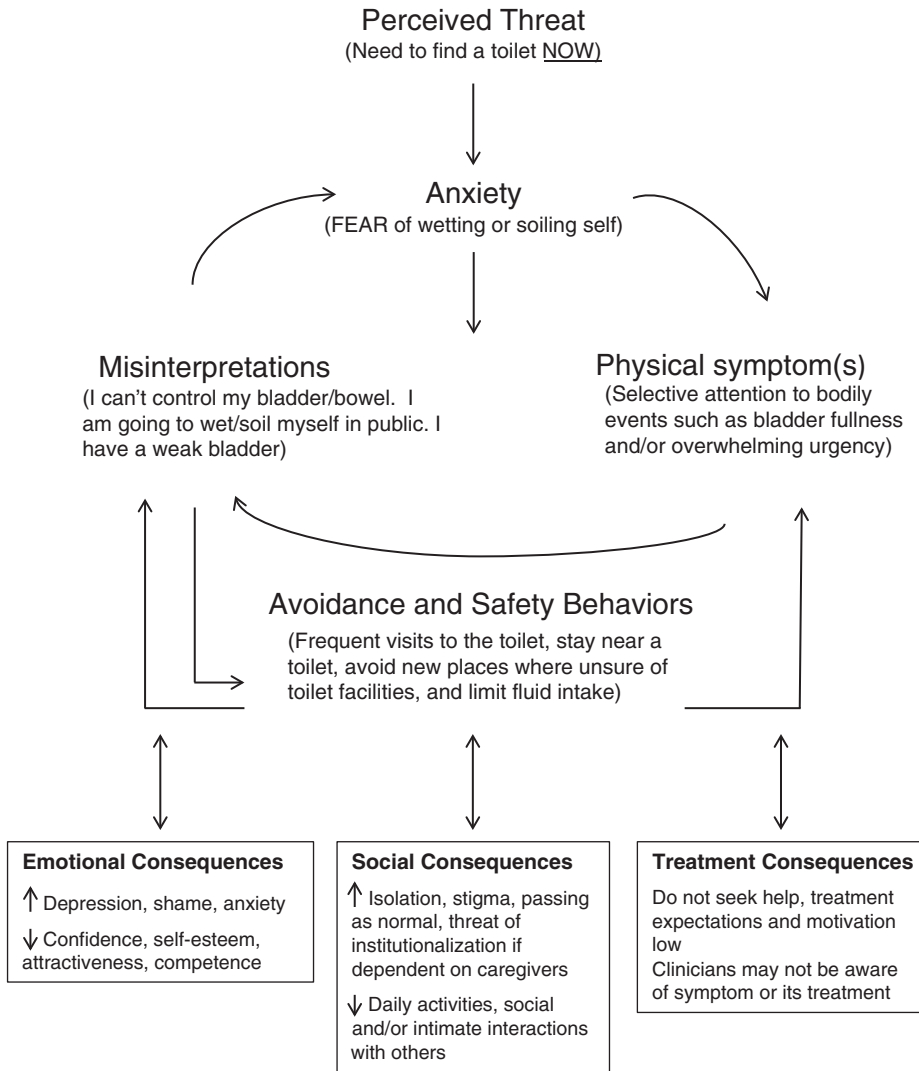

than UI (Norton et al. 2005; Wagg et al. 2013; Halland et al. 2013).

Perry and colleagues (Perry et al. 2006) proposed a model which integrates behavioral, cognitive, emotional, and social aspects of incontinence. While initially proposed for women with urgency UI, it has applicability to FI as well. In Fig. 1, an adapted psychological model for both UI and FI highlights how differences in perceptions, feelings, and behaviors lead to emotional and social consequences as well as decisions on treatment-seeking, expectations, and adherence. Interventions that provide active problem-oriented coping strategies may help individuals feel more “in control” of their bladder or bowel function and decrease the emotional and social consequences.

Family caregivers of affected individuals experience significant negative effects on their overall well-being and functioning (Ory et al. 1986; Wagg et al. 2013; Lobchuk and Rosenberg 2014). Feelings of embarrassment, frustration, anger, and revulsion are commonly reported. Consequences of caring for an incontinent individual, especially if there is cognitive impairment, can lead to psychological stress, sleep disruptions, fatigue, depression, and social isolation. Over time, sexual activity decreases, and intimate relationships become impaired. In families with preexisting poor relationships, the potential for abuse or neglect exists. The decision for nursing home placement is more likely if the individual cared for has frequent incontinence.

Management of Incontinence

The goals for effective management of incontinence in older adults involves reducing or eliminating incontinent episodes, improving quality of life, preventing complications (negative psychosocial consequences, pressure ulcers, nursing home placement), and minimizing adverse treatment consequences and cost. A comprehensive evaluation should be conducted initially to exclude chronic diseases and local pathology that might be contributing to the incontinence (Wagg et al. 2013).

Incontinence and Aging, Fig. 1 Psychological model for incontinence (Adapted with permission from Perry et al. (2006). John Wiley and Sons License)

Nonpharmacological, nonsurgical intervention, preferably behavioral intervention, is the first-line treatment for incontinence in patients with and without dementia. This approach is ideal for the older adult who is at higher risk for adverse effects from more invasive interventions such as drugs and surgery. Nonpharmacological treatment options for UI are summarized in Table 2. These include behavioral interventions (lifestyle modifications, scheduled toileting regimens, pelvic floor muscle rehabilitation,

and complementary therapies), external neuromodulation, anti-incontinence devices, and supportive interventions. Nonpharmacological treatment options are similar for FI. They include establishing a regular bowel regimen, dietary modifications to include a high-fiber diet, use of bulking agents using methylcellulose or psyllium, pelvic floor muscle exercises, and biofeedback.

Pharmacological therapy may be considered for patients whose incontinence is not adequately controlled by behavioral intervention and who

Incontinence and Aging, Table 2 Nonpharmacological management of urinary incontinence in older adults

Intervention	Description	Patient characteristics
Lifestyle modifications		
Behavioral changes (e.g., fluid and caffeine modifications, smoking cessation, weight loss, constipation prevention)	Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate UI	Used as first-line therapies or in combination with other treatments
Scheduled toileting regimens		
Timed voiding	Toileting on a fixed schedule where interval does not change, typically every 2 h during waking hours	Used for patients with cognitive or physical impairments
Habit retraining	Scheduled toilettings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern	Used for institutionalized or homebound patients with cognitive or physical impairments
Prompted voiding	Scheduled toilettings that require prompts to void from a caregiver, typically every 2 h; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting	Used for patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver
Combined toileting and exercise therapy	Prompted voiding combined with functionally oriented, low-intensity endurance and strength exercises	Used for frail, inactive, or deconditioned nursing home residents. Nursing staff implement during toileting care routine
Bladder training	Scheduled toilettings with progressive voiding intervals; includes teaching urgency suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy	Used for stress, urgency, and mixed UI in patients who are cognitively intact, able to toilet, and motivated to comply with training program
Pelvic floor muscle rehabilitation		
Pelvic floor muscle exercises (e.g., Kegel exercises)	Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition	Used for stress, urgency, and mixed UI in patients who can isolate and correctly contract pelvic floor muscles; requires cognitively intact and highly motivated patient
Biofeedback	Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction or urge inhibition; home trainers available	Used for stress, urgency, and mixed UI in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises
Vaginal weight training	Active retention of increasingly heavy vaginal cone weights; typically used in combination with pelvic floor muscle exercises at least twice per day	Women with stress UI who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse

(continued)

Incontinence and Aging, Table 2 (continued)

Intervention	Description	Patient characteristics
External neuromodulation		
Nonimplantable electrical stimulation	Application of electrical current through vaginal, anal, surface, or fine-needle electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficacy of pelvic floor muscle contraction; handheld stimulators for home use are available	Used for stress, urgency, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception; urinary retention, history of cardiac arrhythmia, cardiac pacemakers, implantable defibrillators, pregnant or attempting pregnancy; vaginal or anal electrodes are contraindicated in moderate or severe pelvic organ prolapse
Percutaneous tibial nerve stimulation	Application of a pulsed electrical current through a fine-needle electrode placed externally near the tibial nerve	Used for treatment of overactive bladder with urinary urgency, frequency, and urgency incontinence; contraindicated in patients with pacemakers or implantable defibrillators, prone to excessive bleeding, or women who are pregnant
Complementary therapies		
Acupuncture	Involves insertion of disposable sterile fine stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra	Used for stress, urgency, and mixed UI and UI due to spinal cord injury
Mindfulness-based therapy	Combines meditation with more traditional aspects of cognitive behavioral therapy; preliminary evidence suggests benefit	Used for stress, urgency, or mixed UI in women and incontinence associated with depression and anxiety
Yoga	Combines body movements (yoga postures), breathing techniques, and meditation; preliminary evidence suggests benefit	Used for stress, urgency, and mixed UI in women
Anti-incontinence devices		
Bed or pant alarms	Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism	Can monitor incontinence in home care and institutional environments
Pessaries	Intravaginal devices designed to support the bladder neck, relieve minor to moderate pelvic organ prolapse, and change pressure transmission to the urethra	Used for female stress UI and mild to moderate pelvic organ prolapse; in postmenopausal women
Urethral or intravaginal device (women only)	Nonabsorbent, removable products inserted within urethra or vagina to prevent leakage	Used in female stress UI who are cognitively intact and have good manual dexterity
Urethral compression device (men only)	Penile clamp	Used in men patients with stress UI who are cognitively intact and have good manual dexterity
External collection devices (men only)	Condom catheter with leg bag	Used in men with functional impairments

(continued)

Incontinence and Aging, Table 2 (continued)

Intervention	Description	Patient characteristics
Catheters	Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters	Used for patients with urinary retention and overflow UI and patients who are bed-bound or with significant mobility impairments, with terminal illness, or with sacral pressure ulcers until healing occurs
Supportive interventions		
Toileting substitutes and other environmental modifications	Female and male urinals, bedside commodes, elevated toilet seats, grab bars	Used for patients with mobility impairments that make reaching toilet in timely fashion difficult
Absorbent products	Variety of reusable and disposable liners, pads, male drip collectors, male guard, collector undergarment, fitted brief, and pant systems; some products contain a polymer that absorbs and wicks urine away from the body	Used for all types of incontinence
Physical and occupational therapy	Gait and/or strength training, toileting skills training	Used for older patients with mobility impairments that make reaching a toilet in timely fashion difficult

have no major contradictions to drug treatment. In general, pharmacological therapy provides a better response when combined with behavioral interventions. Surgery is considered a third-line intervention and is considered when the degree of bother or lifestyle impairment is sufficient and other nonsurgical interventions are undesired by the patient or ineffective.

Future Directions for Practice and Research

Practice. The psychosocial impact of incontinence, while relatively minor for many older adults, can impose a significant emotional and social burden and affect treatment-seeking. This suggests the need to implement regular screening programs for incontinence in patients seen in primary care or long-term care settings. Brief screening instruments are available that can help facilitate the detection of incontinence. If detected, health-care providers should use a focused history and physical examination to diagnose incontinence subtype. Further evaluation of how incontinence is affecting the patient’s quality

of life and mental health should be conducted using interview questions or standardized condition-specific quality of life questionnaires. Men, in particular, may need to be questioned about possible feelings of shame and frustration to provide psychological support during treatment. Patients with complex symptomatology or who have failed empirical treatments should be referred to an incontinence specialist (e.g., urologist, urogynecologist, or gastroenterologist continence nurse specialist). For patients with family caregivers, attention should be given to assessing the impact of the incontinence on the caregiver, along with their needs for information about appropriate methods of management. The treatment decision-making process must take into consideration not only the bothersomeness of symptoms but also their impact on psychosocial functioning (Ory et al. 1986).

Treatment should be patient centered, involving the patient’s preferences and goals, and be targeted to the particular type of incontinence (Ory et al. 1986). If appropriate and preferred, first-line therapies such as behavioral interventions that carry the lowest risk of adverse side effects should be used initially. Multicomponent

therapies may be more effective than any single treatment focused on the bladder or bowel. For frail older adults with functional impairments or who are dependent upon caregivers, combining scheduled toileting regimens with functional exercise may reduce UI severity and caregiver burden associated with toileting. The key to success with behavioral intervention for incontinence is motivation of patients or caregivers. Regular follow-up is needed to help motivate patients and caregivers, provide reassurance and support, and monitor treatment outcomes, including impact on psychosocial functioning and quality of life.

Research. There is relatively limited research on the psychosocial consequences of incontinence and the role of psychosocial factors in the development and exacerbation of both UI and FI, especially FI and their effect on treatment-seeking. Longitudinal studies using multivariate analyses are needed to explore how psychological factors such as anxiety, depression, and cognitive processing are associated with the incidence of incontinence. Further study of how psychological factors influence treatment-seeking and moderate the success of behavioral and pharmacological treatments is needed. In addition, quantitative studies are needed to explore the effects of incontinence in family caregivers, including the decision to institutionalize the incontinent individual. The impact of incontinence on health-care staff, especially those working in long-term care facilities, is known to be especially frustrating but warrants further investigation. Attitudes, expectations, and care processes need improvement, and staff interventions directed toward helping staff cope with the heavy demands of caring for incontinent patients and residents might help to improving the quality of incontinent care. Clinical trials are also needed to explore promising interventions such as mindfulness-based therapy and yoga for their effect on psychosocial functioning, as well as tailoring multicomponent interventions most effectively to those individuals who have significant anxiety and depression in combination with incontinence or those with varying types and stages of dementia.

Individual Differences in Adult Cognition and Cognitive Development

Christopher Hertzog

School of Psychology, Georgia Institute of Technology, Atlanta, GA, USA

Definition

Individual differences refer to differences between persons in level or organization of cognition. With regard to aging, it also can entail between-person differences in rates of age-related cognitive change. Developmental differences can be due to normal aging, environmental context and lifestyle, or age-related disease and pathology.

Introduction

A key question regarding aging and cognition is whether individuals differ in their patterns of growth, maintenance, and/or decline across the adult life span. Implicitly, the concept of “successful aging,” with its emphasis on preservation of cognitive function in old age (e.g., Martin et al. 2015), builds on the assumption that there are individual differences in the extent to which cognition remains functionally intact into old age.

One can view adult individual differences in cognition and performance from several different vantage points (Hertzog 2008). A major theme in cognitive aging has been the differing approaches and interpretations encountered in studies emphasizing differential approaches to cognition as opposed to experimental approaches to cognition. The latter approach often uses sophisticated techniques from cognitive psychology to measure multiple cognitive processes relevant to a particular type of cognitive function. The former approach may use complex sampling designs to evaluate age differences in performance on standardized or widely accepted tests, emphasizing the importance of obtaining measures of individual differences. Arguably, both approaches have strengths and weaknesses, and integrative approaches that capture the strengths of both traditions are needed to understand individual differences in cognitive aging.

A focus on individual differences in cognitive and adult cognitive development has generated a large literature that enables several inferences about aging.

First, individual differences are a hallmark of human behavior at every stage of the human life span. Since the work by Galton in the nineteenth century, it is well established that elemental and complex aspects of the human thought show substantial variability in the general population.

Second, individual differences at different points in the adult life span provide a means of framing individual differences in rates of aging. To a large extent, individual differences in cognitive abilities are well preserved across much of the adult life span, with high test-retest stability of cognitive variables over long time spans (Gow, ► [Intelligence and Aging](#)). Longitudinal studies of intelligence and other cognitive abilities paint a very clear picture of individual differences across the adult life span. Whenever correlations of a variable with itself can be computed over some span of years, from relatively short to extremely long, there is an impressive degree of stability of individual differences in the sample. Simple correlations of a variable with itself are attenuated by measurement error. Corrected for measurement error, the stability of individual differences in psychometrically

measured intellectual abilities is on the order of 0.9 over a span of 10–20 years (Schaie 2013) and remains high over longer age epochs. Some reviewers contend that the degree of stability is so high as to merit the inference that change in adulthood is predominantly about rates of decline that are relatively uniform or what might be termed preserved differentiation (Salthouse 2006). This is an overstatement; longitudinal studies detect individual differences in change at the construct level (e.g., Tucker-Drob 2011).

Nevertheless, the impressive degree of stability based on dozens of longitudinal studies is that individual differences in cognitive changes are, on average, relatively small in magnitude until the sixth decade of life. Normatively speaking, mean changes are probably most pronounced in perceptual speed but stronger in fluid intelligence, executive function, and episodic memory tasks than in tests of crystallized intelligence (Nilsson and Lövdén, ► [Normative Cognitive Aging](#); Rönnlund et al. 2005; Schaie 2013). These changes are small, however, in relation to the magnitude of preexisting individual differences, as are individual differences in rates of cognitive change. An inference that can be drawn, then, is that cognitive aging is a slow and subtle process, such that cognitively able persons in early adulthood are likely to be cognitively able older adults, relative to their same-age peers.

Third, even in the face of stability of individual differences, longitudinal studies of age changes in cognition in adulthood have detected individual differences in rates of cognitive and intellectual change in midlife and old age (e.g., Schaie 2013; Hultsch et al. 1998). A critical question is whether a decline in one domain of cognition implies changes in most if not all other domains. The answer appears to be that changes are often correlated across abilities but that there are reliable construct-specific individual differences in change as well. This pattern indicates that general or overall changes in rates of age-related change can be observed but that cognitive aging effects must involve multiple processes (see Salthouse 2006 for a different perspective). Furthermore, individual differences in rates of cognitive aging do emerge as a function of individual differences in health (and disease; see Anstey, this volume), lifestyle, and other factors.

Fourth, variability in human cognition can be seen in long and short time scales, with individuals differing both in long-term change and in short-term fluctuations (intraindividual variability, Nesselrode 1991). Individual differences in mood states, stress reactions, and physiological variables like the circadian rhythm can both affect cognitive performance and be a marker variable signifying future aging-related changes. An excellent example of the importance of this issue comes from a work by Sliwinski et al. (2006), who showed that within-person fluctuation in stress and stress-related effect was coupled with within-person fluctuation in working memory capacity.

Fifth, individual differences in cognitive performance across different constructs can be leveraged to evaluate whether there is a qualitative functional reorganization of cognition with aging and how it is structured or organized. Instances of qualitative reorganization are rare and are typically more likely in the presence of major neuronal pathology (e.g., macular degeneration (Alzheimer's disease)). Such findings suggest that aging effects in the main are more about altering level of cognitive performance than about generating a wholesale shifting of the underlying psychological and neurobiological bases of cognition. Developmental differences in patterns of correlations among variables are more likely to be discovered in domains like the creation of new complex skills (where (1) the mode of processing qualitatively changes from one of novice discoveries to automated skills and (2) adults of different ages differ in how and whether automated skills develop; see Rogers et al. 2000) than in fundamental aspects of cognition like working memory or divided attention that appear to change in level but not the structure of performance.

Sixth, qualitative differences in the mechanisms and processes applied to solve cognitive problems may generate different patterns of correlations among cognitive tests. Variation in the strategic approaches taken to achieve cognitive outcomes can occur within or between persons, depending on factors such as motivation, task demand, and availability of relevant knowledge and expertise (Lemaire 2010; this volume).

Developmentally, shifts in strategies used to solve cognitive problems can reflect learning and experience, or they can signify compensation for age-related changes in underlying cognitive mechanisms that necessitate functional reorganization of behavior.

Seventh, psychologists develop empirical measures of cognition in the form of psychometric tests, cognitive tasks, and scales taken from questionnaire and interviews. Individual differences in these empirical measures may stem from individual differences in the target constructs of interest, but they may also arise from variability that is specific to how performance is measured (or captured) by the task at hand. Multiple studies in different cognitive domains have demonstrated that individual differences are influenced by test- and task-related behaviors that are not actually generated by the cognitive construct of interest. In developmental science, such violations of measurement equivalence (equivalent measurement properties at different parts of the life span or for different groups of persons) can generate incorrect conclusions about why adults differ in cognitive performance.

Eighth, there is an important distinction between cognition as measured in experimental tasks or psychometric tests and the extent to which individual differences in such measures predict problems in cognition in everyday life. On the one hand, individuals who are experiencing cognitive challenges related to aging may be more likely to engage in effective compensatory behaviors that offset the changes (e.g., Bäckman 1989). On the other hand, it is an open question as to how much everyday tasks draw on the kinds of cognitive mechanics (Baltes et al. 1999) emphasized in cognitive research. To a great degree, people select themselves into behavioral niches in which knowledge, expertise, and habitual behavioral routines may matter far more for success in cognitively demanding tasks than fluid intelligence per se. One should not generalize from evidence about, say, age differences in a laboratory task measuring a construct like prospective memory (e.g., Kliegel, ▶ [Prospective Memory, New Perspectives for Geropsychological Research](#)) to presume age deficits in everyday prospective memory, such as remembering to take medications

(e.g., Park et al. 1999). In real life, successful goal pursuit is influenced by many variables, including motivation and personality, that are separable from the relevant cognitive processes. Furthermore, cognitive demands may not exceed an individual's cognitive capacity, even if that individual has experienced cognitive decline from early adulthood.

Methodology and Individual Differences

A critical issue for assessing individual differences in cognitive aging is how applied developmental research design and multivariate statistics can be employed to scale individual differences in adult cognition and cognitive change across the adult life span. In the 1960s and 1970s, the life-span developmental psychology movement championed the application of quasi-experimental design principles to the study of adult development, to good effect (Baltes et al. 1988). This approach and parallel efforts in gerontological science led to a focus on a number of critical methodological issues, including (1) differentiating cohort differences from age changes, (2) how population definition, sample selection, and sampling practices affect inferences about aging, (3) the importance of longitudinal data for capturing individual differences in cognitive change, (4) influences of practice effects in longitudinal studies, and (5) the consequences of selective mortality and attrition in biasing estimates of individual differences in change. More recently, the field has emphasized applications of advanced statistical models for scaling individual differences in change, including structural equation models, growth curve models, and growth mixture models (e.g., Ferrer and McArdle 2010). Indeed, one might claim that advances in statistical applications have papered over problems of developmental design. It is also the case that methodological sophistication and attention to rival explanations for age-related effects are more predominant in longitudinal studies of cognitive change than it is in typical cognitive aging

studies deriving from an experimental cognitive psychology perspective, where scientists are likely to treat age differences in cognitive dependent variables as unambiguous indications of the effects of development and aging (Hertzog 1996). With respect to statistical applications, interesting new developments in growth mixture models and related approaches have the potential to invigorate the search for subtypes of persons showing qualitatively different developmental patterns.

Historically, an important methodological concern has been to address the question of measurement equivalence, the idea that cognitive tests or tasks measure the same underlying constructs with the same measurement properties for people of different ages (e.g., Labouvie 1980). Confirmatory factor analysis is often used to test the idea of equivalence and to evaluate whether there are interpretable changes in phenomena such as the correlations among latent cognitive ability factors (e.g., Brickley et al. 1995). A common finding is that factor correlations increase in old age samples, although this inference can be biased by including wide age ranges in samples drawn from different parts of the life span (e.g., Hofer et al. 2006). For instance, using a 20-year span to define young (20–40), middle-aged (40–60), and old (60–80) subgroups might inflate correlations in the older group because there are greater individual differences in cognitive change after age 60. Aggregating the data across wide age intervals would risk an artifactual increase in correlations.

Individual Differences Arising from Performance-Specific Confounds

There are multiple strands of evidence that age comparisons of cognitive task performance are complicated by age differences in task-related behavior that can be misunderstood as age differences in the construct the research was attempting to study.

Sensory and perceptual deficits can create performance deficits in older adults that can be misattributed to other constructs (e.g., Davis

et al. 2002; see Schneider and Pichora-Fuller 2000). It is also well known that the speed of behavior slows with advancing age (Verhaeghen, ► [Age-Related Slowing in Response Times, Causes and Consequences](#)). Slowing of cognitive task performance can occur because of fundamental changes in information transmission rates or because of response conservatism in the decision stages in a speeded discrimination task or both. As a consequence, slowing in speed of processing can impact older adults' intelligence test performance. Many intelligence tests are heavily influenced by the speed of response, and slowing in response speed will result in fewer items solved correctly in a fixed time limit. Hertzog (1989) showed that slowing in the marking of old-style answer sheets accounted for substantial proportions of variance in the tests used by Schaie (2013) in his longitudinal study. It appears that similar longitudinal gradients in Schaie's (2013) study could be in part due to contributions of speed to different tests (in particular, the speeded nature of the vocabulary test probably overestimated the degree of decline in test performance between ages 60 and 75 on this test). Furthermore, the correlations of these components across multiple tests accounted for a large part of the increase in correlations among ability factors in old age (Hertzog and Bleckley 2001). However, performance speed confounds cannot account for all of the age changes in intelligence, nor can they be a sufficient explanation of dedifferentiation in intellectual ability factors observed in old age (deFries et al. 2007).

Likewise, gerontologists have studied age differences in learning-related shifts in some skill-based tasks, for example, changing from numeric computation to memory retrieval when calculation problems are repeatedly presented. The repetition of items allows for responses based on remembering the correct answers without the need to compute the solution. However, a number of studies have demonstrated that delayed shift to memory retrieval by older adults is also influenced by a reluctance to rely on memory, in part because of a distrust of memory as a function of lower memory self-efficacy (Touron 2015). For

instance, monetary incentives to respond quickly, forcing the use of memory retrieval strategy, substantially alter the shift to memory strategy used by older adults. One therefore cannot estimate age differences in the rate of performance improvements and then treat the estimated slopes as unbiased measures of the cost of associative learning deficits on rates of skill acquisition. The work by Ratcliff and colleagues (e.g., Ratcliff et al. 2011), applying the diffusion model for response times and response accuracy, similarly suggests that age differences in a response time task are also influenced by age differences in decision criteria (how much evidence is needed to respond), for some tasks (e.g., item recognition memory) to a greater extent than age differences in how rapidly information is accumulated (drift rate).

Such findings emphasize that it is hazardous to interpret age differences in cognitive tasks as necessarily reflecting age differences in the cognitive processes the task was designed to measure without a more complete understanding of the cognitive processes evoked by the task. Sadly, more careful measurement and construct validity work are required than is the norm in the field.

Conclusions

The work on individual differences in adult cognitive development has produced a rich set of findings that implicate heterogeneity in cognition that is well preserved across the human life span. There is also evidence that people vary in the nature and magnitude of cognitive changes in old age. The next decades are likely to witness major advances in our understanding of who ages more gracefully and why.

Wakefulness

Definition

Broadly speaking, insomnia is defined as a person's dissatisfaction with the quality or quantity of their sleep. Specifically, the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (5th edition; DSM-5; APA 2013) describe the characteristics of insomnia as including one or more of the following over three or more nights per week for a period of at least 3 months: difficulty falling asleep, frequent and extended nighttime awakenings or waking up earlier than planned. These symptoms occur despite the opportunity for adequate sleep and cause the individual distress and/or other symptoms of impairment, such as feelings of fatigue, excessive daytime sleepiness, and decreased motivation to keep up normally planned activities.

Prevalence and Magnitude

With advancing age, both men and women experience higher rates of insomnia. Disturbed sleep is frequently associated with a range of medical and mental health problems. Insomnia symptoms negatively impact one's quality of life but also, in turn, put the individual at increased risk of declining health and psychiatric functioning over time, such as heart disease and depression. Over 50% of

older adults over the age of 65 report that they have problems sleeping (Foley et al. 1995). In particular, women and individuals with other medical or psychiatric conditions are at a significant risk of developing problematic sleep patterns. Age-related changes in sleep architecture include increased time to fall asleep, an increase in the amount of time spent awake after falling asleep, and a lower percent of the total time spent actually asleep while in bed (i.e., sleep efficiency). In addition, older adults are likely to spend less time in deep or slow-wave sleep, which contributes to a greater sleep fragmentation and the lack of feeling restored upon waking, which is even further complicated by, medical, psychological, environmental, and behavioral factors.

Nonpharmacological treatments, such as a multicomponent cognitive behavioral therapy for insomnia (CBT-I), are an effective primary treatment or adjunct therapy to sleep medication. CBT-I has also been shown to positively impact other psychiatric and social factors in addition to improving sleep. It can be implemented individually or in groups by sleep specialists or other trained interventionists. Furthermore, there is growing evidence that treatments, such as CBT-I, adapted for older adults in residential settings or those with mild levels of cognitive impairment are also effective in improving other aspects of functioning in addition to the symptoms of insomnia. Insomnia is an ideal target for change in older populations given its high prevalence, impact on functioning, and the availability of effective treatments that do not put the older individuals at risk of other complications, such as the side effects experienced from prescription medication.

Sleep and Residential Settings

Across the continuum of long term care, from home-based care, to assisted and independent living facilities and onto skilled nursing settings, sleep problems are an incredibly common complaint of older adults. Due to declining health, acute and chronic stressors (e.g., loss of loved ones, moving into new residence, logistics

involved in the management of health conditions), as well as the characteristics of the settings themselves (e.g., lighting, noise, scheduling), insomnia is one of the first signs of such change and stress. One of the most frequent strategies employed by those with sleep difficulties is to spend more time in bed trying to make up for a bad night's sleep. In addition, many individuals worry intensely about the consequences of their sleep problems and its potential impact on their health. There are many messages transmitted through media and word of mouth about how much sleep one "should" be getting. Unfortunately, all of these efforts, pressure and messaging only serve to further exacerbate the difficulties of getting a better quantity and quality of sleep.

One of the most detrimental consequences of impaired sleep is the increase in reports of daytime sleepiness. This issue is exacerbated in the residential setting and affects one's ability to engage in daytime social activities (Martin et al. 2006). When individuals become less socially engaged, less physically active and more prone to planned and unplanned napping, their sleep becomes even more disrupted across the entire 24-h day. In addition, there are other consequences fueled by disengagement, such as increased rates of comorbid medical illnesses and additional prescription medication added onto an already complicated clinical picture. Other primary sleep disorders, such as sleep apnea and restless leg syndrome are diagnosed at much higher rates in older adults and also compound the risk of experiencing an overall decline in functioning. Unfortunately, even though it is recognized that older adults in residential settings have high rates of fragmented sleep, appropriate treatment options are not yet commonly available (Ancoli-Israel et al. 1989).

Sleep and Cognitive Impairment

Cognitive impairment resulting from various, progressive neurological conditions, such as Alzheimer's or Lewy Bodies Dementia, increase in prevalence with age. Sleep disruption is a troublesome and common symptom associated with such conditions. In addition to being one of the

consequences of neurological disorders, research has also revealed that sleep problems may precede the identification of the neurological disorder. Pursuing efforts to support and improve the quality of life of those with cognitive impairment is critical and efforts to improve their sleep are one path to do so. An example of a successful intervention includes the work of McCurry et al. (2005) in which Alzheimer's patients exhibited improvements in their sleep as a result of a behavioral intervention that has been effective in other nondemented, noninstitutionalized populations. Another study by Alessi and colleagues (2005) illustrated the benefits of a similar nonpharmacological, behavioral intervention focused on sleep at decreasing daytime sleep and improving social functioning.

Evaluation

When an older adult presents with sleep difficulties, a comprehensive assessment approach that determines the presence of other medical and psychiatric causes is advised. Because it is common for sleep problems to co-occur with other disorders, such as depression or post-traumatic stress disorder, the historical approach was to focus the initial clinical treatment on the "primary" disorder and assume that the sleep problems will resolve during the course of this intervention. Current scientific knowledge and experience has revealed that such an approach often leaves the individual improved, but still experiencing symptoms of problematic sleep and with a higher chance of relapse for the "primary" disorder (e.g., depression). As such, the current recommended approach is to treat both conditions simultaneously unless there are reasons not to, such as the patient is experiencing an acute medical crisis, lack of available treatment providers, or avoidance of over scheduling a medically fragile patient, patient preference.

When evaluating and treating older adults, it is also important to investigate the possible presence of other sleep disorders, such as sleep apnea and RLS, which increase greatly with age. Also, the shifts in sleep patterns, common with advancing

age and often related to changes in circadian rhythms are important to ask about. Such shifts often manifest as feeling sleepy earlier in the evening and rising earlier in the morning, as known as an “advanced sleep phase.” Shifts in sleep schedules aren’t necessary disruptive or pathological, and questions about the problems caused in an individual’s schedule or social calendar will reveal whether such shifts are having a negative impact on their maintenance of health or quality of life. Assessment of the older adult’s environment can also reveal causes of sleep disruption that may reveal more simplified intervention target. As mentioned earlier, the timing of light exposure, time spent in bed, irregular sleep schedules across the course of the 24 h day, tendencies towards being a morning or an evening person, changes in their circadian rhythm and their coping styles (e.g., levels of worry) with advancing age can impact one’s ability to sleep well. Finally, it is important to rule out other medical conditions that could be at the core of the sleep problems, such as thyroid problems leading to daytime fatigue, medication side-effects or the possibility that another primary sleep disorder, such as sleep apnea or restless leg syndrome are present.

Sleep measures include easy to administer self-report instruments to more complicated, objective, and computer scored tools, such as wrist actigraphy. One of the simplest measures is also the probably the most powerful: a sleep diary. This straight forward recording of various sleep parameters, such as time in bed, time spent awake, recording of alcohol intake can be incredibly useful in identifying the specific patterns and struggles that an individual has during their “sleep window.” Individuals can use these tools independently in order to track and better understand the ebbs and flows of their sleep functioning. When possible, a review of this information by someone familiar with the principles of behavioral sleep medicine can result quickly in an understanding the presenting concerns. Employing the use of other assessment tools, such as polysomnography, is particularly useful if another primary sleep disorder, such as sleep apnea or restless leg syndrome, is suspected. There are several popular

scales that can be used to rate the nature and severity of sleep problems, such as the Insomnia Severity Index (Morin 1993), which also parallels the questions that you would ask to verify diagnostic classification. Questions regarding the consequences of sleep loss, such as symptoms of daytime sleepiness, avoidance of planned daily activities, and time spent worrying, are useful elements to fill out the clinical picture. Sleep evaluations can be supplemented by the use of actigraphs. These wearable devices are accelerometers typically attached to one’s wrist or ankle to estimate sleep patterns as measured by the body’s position and amount of physical movement. Although use of these devices are most common in research studies, less sophisticated versions of these devices (e.g., commercially available devices worn on wrists that compute estimated time spend sleeping) are becoming increasingly popular as individuals become interested in their sleep functioning. Professionally administered and scored actigraphs provide an objective estimate of several sleep parameters, such as time in bed, number and length of nighttime awakenings and sleep efficiency (proportion of sleep time relative to intended sleep time). Using actigraphy in combination with a standardized version of a sleep diary (Carney et al. 2012) can be a powerful combination to assess sleep across the lifespan.

Treatment Options

Insomnia represents a modifiable source of disability in older adults. Multicomponent CBT-I and hypnotic medications (e.g., benzodiazepines, such as Halcion, and nonbenzodiazepines, such as Ambien) are the only treatments with sufficient evidence of treatment efficacy (NIH state of the science 2005). Due to the risks associated with the use of hypnotic medications in the elderly, such as confusion, increased fall risk, and polypharmacy concerns, alternative treatments are in great demand. Morin and colleagues (1993) have studied nonpharmacological sleep interventions focused on an older adult population extensively and have found treatments, such as CBT-I, are

incredibly efficacious in this older age group. Identifying new ways to further the dissemination of CBT-I, and variations thereof, is a crucial next step. For one, CBT-I is cost-effective and fairly straightforward to administer given the multiple treatment protocols currently available. It can also be implemented by frontline staff, such as advanced practice nurses, if given adequate training. Therapy can target individuals, groups, or the caregivers of more impaired older adults. The different components commonly included in a CBT-I package, include providing the theoretical basis for sleep-related recommendations, general information about sleep, and may also include education about the age-related changes in sleep. Suggestions for creating sleep promoting practices, such as minimizing alcohol consumption, exercising at an optimal time, or keeping the room at a cool temperature, is typically clustered under the recommendations associated with “Sleep Hygiene”; a necessary but not sufficient approach to improving sleep that is frequently included in standard sleep treatment. In addition, there are components with considerable empirical support, such as the behavioral approaches of stimulus control and sleep restriction. These include using procedures like setting a consistent wake time and sleep opportunity window as well as recommending that the individual get out of bed if unable to sleep, in addition to other instructions. For those who spend a significant amount of time worrying about the consequences of lost sleep or their ability to achieve a good night’s sleep, there is also a component of therapy which focuses exclusively on challenging and replacing these dysfunctional cognitions with ones that are more conducive to bringing on sleep. Morin and colleagues (1993) have described older insomniacs as succumbing to a vicious cycle that perpetuates insomnia, with emotional distress fueling dysfunctional beliefs and attitudes that serve to worsen and extend their sleep problems.

In summary, effective treatments are available for insomnia in older patients. Recognizing, assessing, and effectively treating sleep problems in older adults have the potential to reduce the burden of a significant public health problem. Sleep is an ideal intervention target due to the

potential influence one’s sleep has on a wide range of common disorders experienced in old age. Increasing the awareness of this disorder and furthering the dissemination of treatment approaches is a crucial part of maintaining high levels of medical and psychiatric functioning and preventing premature disability and declining health of older adults.

variance remains. There are characteristic age-related changes in intelligence, such that performance on tests of cognitive ability generally decline with age. However, longitudinal research suggests cognitive abilities show marked stability across midlife, with some aspects of intelligence being less susceptible to age-related declines; verbal abilities, for example, may continue to develop through midlife and be maintained into old age, while declines in processing speed-type abilities may be observed many decades earlier. Furthermore, there are marked individual differences in the timing and degree of decline experienced. A focus of research on intelligence and aging is therefore to define the content and structure of the broad domains underlying general intelligence; to characterize how and when those general and more specific domains decline on average; to examine individual differences in both the level of, and change in, intelligence across the lifecourse; and to identify the determinants of both level and change.

Intelligence and Aging

University, Edinburgh, UK

Synonyms

General cognitive ability; General intelligence (g); General mental ability; Intelligence

Definition

Intelligence has been described as a “very general mental capability that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience” (Gottfredson 1997, p. 13). This “general intelligence” is conceptualized as the peak of a hierarchy describing the positive associations that exist among all cognitive abilities; it is the common variance among broad cognitive domains – for example memory, executive function, processing speed – though important domain-specific

Intelligence and aging

What is intelligence, and how does it change with age? Most people would likely provide overlapping or at least complementary definitions of what makes a person intelligent. It is likely there would also be a consistency of opinion in the expected course of age-related changes in intelligence, with inevitable decline perhaps being the overarching theme. The loss of thinking and memory skills, or cognitive aging, is one of the greatest fears people have about growing older. Researchers have therefore sought to better understand intelligence and how it changes with age, so that it might be possible to identify the factors that underlie those changes, explain why some individuals experience greater decline than others, and ultimately translate that knowledge into interventions that might reduce, delay, halt, or even reverse age-related declines in intelligence.

The current entry will explore intelligence and aging by focussing on how we define intelligence

and how it changes with age, before touching on a series of key questions, including:

- How stable are individual differences in intelligence across the lifecourse?
- When it goes, does it all go together?
- What role do genes play in age-related changes in intelligence?
- Is age kinder to the initially more able?
- Can we alter the course of age-related changes in intelligence?

In exploring these questions, a general overview of intelligence and aging will be provided with examples to highlight and illustrate specific concepts or findings. By no means an exhaustive series of questions in the field of intelligence and aging (the overview will not detail neuroscientific explanations for what might account for the development of, or age-related changes in, intelligence, for example), the intention is to briefly introduce selected topics, many of which can be explored in greater depth elsewhere in the *Encyclopedia of Geropsychology*.

What Is Intelligence?

In order to clarify misunderstandings and potentially misleading claims about the “knowns and unknowns” of intelligence, in the mid-1990s the American Psychological Association assembled a task force to report on the fundamental issues, whose aim was to clearly articulate what was understood scientifically by the term intelligence (Neisser et al. 1996). The report stated:

individuals differ from one another in their ability to understand complex ideas, to adapt effectively to the environment, to learn from experience, to engage in various forms of reasoning, to overcome obstacles by taking thought. (p. 77)

This general characterization covers both what a lay and expert conception of intelligence might amount to; beyond this, however, it is important to understand the way in which these observed differences in intelligence might be structured and determined. “Because there are many ways to be

intelligent, there are also many conceptualizations of intelligence” (Neisser et al. 1996, p. 95).

For present purposes, the psychometric approach will be taken, being the prevailing form of research in the area of intelligence, bringing with it over 100 years of research and development (Neisser et al. 1996). This approach to intelligence attempts to rank individuals according to their performance on a number of psychometric tests (Deary 2000). These can assess a specific ability using one form of item (such as verbal or numerical) or may be structured in a larger battery of many tests to form a composite measure of overall test performance. These general scores are traditionally, though not always, reported as IQ (intelligence quotient) scores using a standardized scale with a mean of 100 and a standard deviation of 15. People can differ on their scores for both the numerous specific tests and on their overall level of performance. Throughout, when the terms intelligence, cognitive ability, or mental ability (or combinations thereof) are used, they refer only to psychometric intelligence as assessed by psychometric measures. This methodology necessarily involves interpreting these scores on standardized tests as reflecting underlying differences in some actual intellectual capacity, though no direct correspondence to brain structure or function is implied (Deary 2000).

One of the most important initial findings across research with these varied tests was the discovery of a “positive manifold” (Spearman 1904): an individual’s score on one test is positively associated with their performance on a range of other, often disparate measures. This ever-present positive interrelatedness led many, most notably Spearman (1904), to propose the existence of a general factor of intelligence (conventionally annotated *g*, with synonyms including general ability, general mental ability, general cognitive ability, and similar). Performance on each measure of mental ability can be accounted for to varying degrees by *g* (Neisser et al. 1996). Thus, one way to view cognitive function is as *g*: the shared variance across a number of abilities. This paradigm was not, however, universally accepted (although, as will be

discussed, it now sits within the most widely accepted models of cognitive ability) and initiated research leading to conceptions of intelligence which highlighted varying numbers of specific factors or abilities, often to the exclusion of a superordinate *g* factor. Models of intelligence often favored different levels of description, consequently making them appear seemingly incongruent or contradictory. Such competing models were, in fact, in far greater agreement than was often manifestly apparent (Deary 2000). J. B. Carroll is frequently cited as the consensus maker, providing empirical support to effectively place this general factor at the apex of a hierarchy of ability: *g* forms the peak, below which are found more specific abilities (Carroll 1993).

Carroll's (1993) efforts were based on reanalyzing the corpus of data that had amassed concerning the structure of intellectual abilities as a necessary "review and critique of the extant literature on the identification, characteristics, and interpretation of cognitive abilities" (Carroll 1993, p. 73). This included surveying the available factor analytic and correlational studies of mental ability over the previous half century. From his initial list of around 1500 references – containing all or virtually all the important and classic factor analytic studies – 477 datasets were selected for reanalysis. Just over 460 led to satisfactory solutions. The complex procedure utilized exploratory factor analysis in order to determine the number of common factors present within each dataset, resulting in the production of simple-structure first-order factors, which were subsequently analyzed for the presence of higher-order factors, at the second, and sometimes, the third order. The 2850 factors produced across the different datasets reanalyzed by this process were inspected and given appropriate names. This allowed an examination across the datasets to "determine how many different factors [were] represented among them, preparatory to interpreting them as basic dimensions of individual differences in cognitive abilities" (Carroll 1993, p. 135).

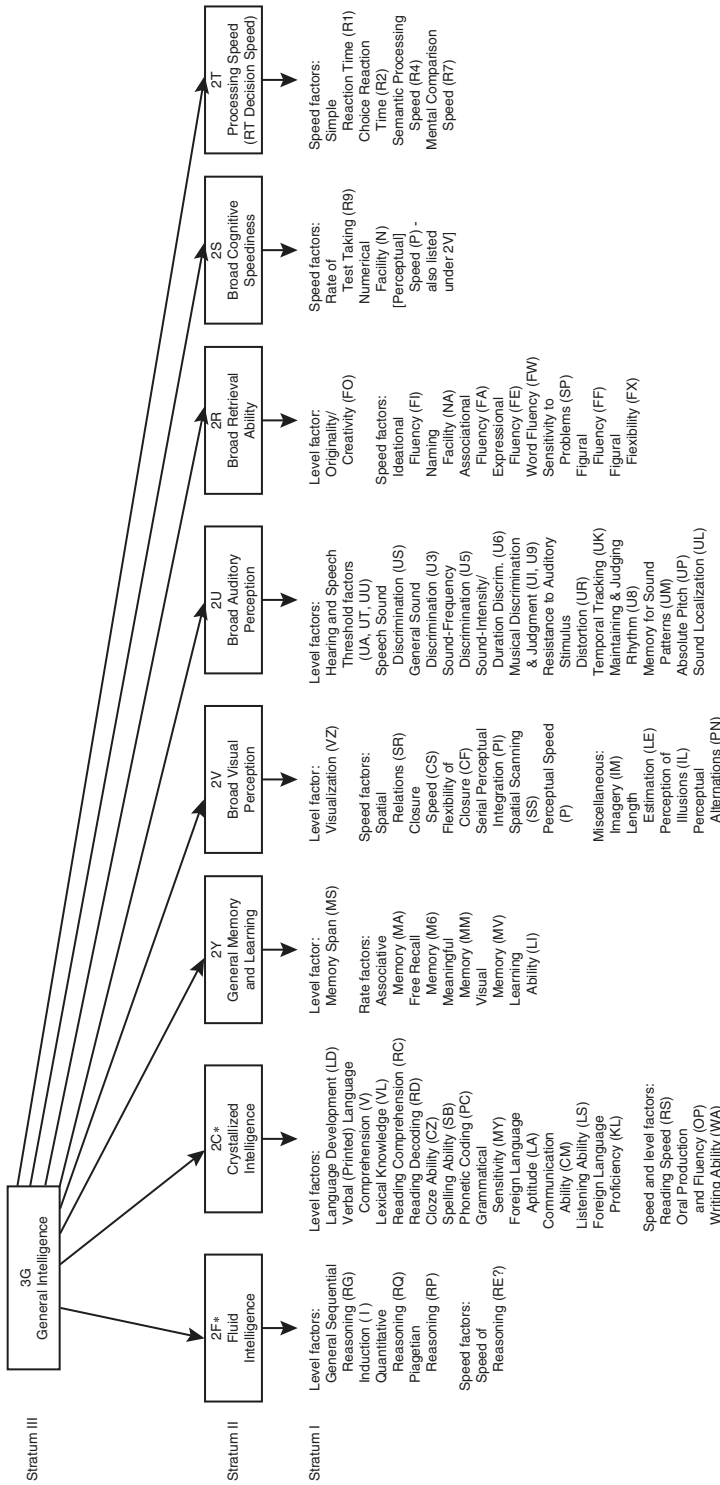

Carroll (1993) suggested that mental abilities could be described by a three-strata hierarchical model (Carroll's model is reproduced in Fig. 1). It was an essentially syncretic model, fusing the

"opposing" blocs of previous intelligence theory and research. At the highest level, stratum III was situated, a general intelligence factor (much like Spearman's *g*, although labeled *G* in Carroll's analysis). Below this, a number of distinct broad ability factors (stratum II) were located, including fluid intelligence, crystallized intelligence, general memory ability, broad visual perception, broad auditory perception, broad retrieval ability, broad cognitive speediness, and processing speed. Finally, stratum I consisted of the narrower, more specific lower-order factors underlying appropriate stratum II factors. For example, induction and quantitative reasoning factors would lie below fluid intelligence; memory span and free recall memory factors would fall under general memory (Fig. 1). While general intelligence is placed firmly at the peak of the cognitive ability hierarchy, the "possible importance of more specialized abilities cannot and should not be ignored" (Carroll 1993, p. 27).

Due in no small part to the comprehensive efforts of Carroll (1993), the *g*-centric, hierarchical concept of intelligence came to be described as "the most widely accepted current view of the structure of abilities" (Neisser et al. 1996, p. 81). A broad consensus has emerged around this hierarchical structure; however, it is imperative to distinguish between this as a description of the structure of psychometric test performance and an explanation of why people differ in intelligence (Deary 2000). That said, as the "job of mapping the structure of psychometric intelligence differences is done to a sufficient degree" (Deary 2000, p. 32), it is possible to begin asking how age affects intelligence.

How Does Intelligence Change with Age?

On the whole, older people do less well on some tests of cognitive ability compared with younger adults (Deary 2000; Salthouse 2010; Hedden and Gabrieli 2004; Schaie 2013; Hertzog et al. 2009); that is, with age, cognitive decline is apparent. This general trend towards poorer psychometric test performance with increasing age has been

* In many analyses, factors 2F and 2C cannot be distinguished; they are represented, however, by a factor designated 2H, a combination of 2F and 2C.

reported by a number of international research teams cross-sectionally and by following a diverse range of cohorts longitudinally. Longitudinal studies are rarer, relative to cross-sectional designs, due to the logistics involved in following a large enough sample over time and the length of follow-up required to observe changes in cognitive ability. Cognitive aging studies also vary greatly in their design, in the nature of the tests employed or in the characteristics of the actual individuals tested (Hertzog et al. 2009). Nevertheless, to illustrate the nature of the changes in cognitive ability that can be expected with increased age, results from one major study, the Seattle Longitudinal Study (SLS), are discussed in detail. Descriptions of a number of other longitudinal studies can be found in the *Encyclopedia of Geropsychology*.

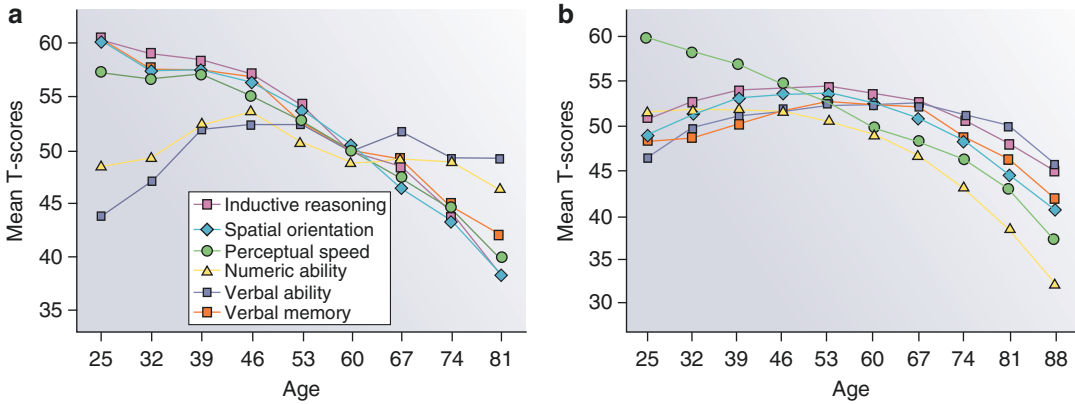

In 1956, the Seattle Longitudinal Study (SLS) was initiated by K. W. Schaie (constituting his doctoral dissertation), a study which has since become a key reference in the domain of cognitive aging research. The study consisted of seven further waves of testing and remains a significant source of information regarding the changes in cognitive ability across almost the full human adult lifecourse (Schaie 2013). The purpose of the study was to explain not only differences in the actual level of ability at a given age but also the differences observed in the rates of change with increasing age. The latter aim could potentially suggest interventions whereby it may be possible to reduce or reverse cognitive aging.

The design of the study was complex. At the first wave in 1956, 500 participants were recruited for baseline cognitive examination from the Seattle area. They were randomly selected from a potential pool of 18,000 individuals registered at a Health Maintenance Organization (HMO) stratified by sex and age such that there were 25 men and 25 women born in each year from 1889 to 1939 (aged 21–70 at baseline). Seven years later, these participants were recalled for repeat cognitive testing. At the same time, a new sample numbering 996 individuals was also recruited. This process of retesting the survivors of previous waves and recruiting a new sample was repeated

every 7 years, resulting in 9476 complete records for 4857 participants. The cross-sequential design of the SLS allowed a simultaneous investigation of cohort and cross-sectional differences in cognitive aging, and importantly, a comparison between individual paths of change in cognitive function longitudinally. Over the waves of the SLS, participants completed measures of verbal meaning, space, reasoning, number and word fluency (based on Thurstone's primary mental abilities), and in the fifth cycle (1984), multiple markers for different abilities were added (Schaie 2013). Analyzing these data allowed Schaie and colleagues to investigate some of the most fundamental questions in cognitive aging research.

Differences noted across cohorts varied by the particular ability under investigation; for instance, word fluency appeared to be poorer in the more recent, and hence younger, samples, although these participants generally possessed better inductive reasoning ability. Schaie and colleagues therefore cautioned fellow researchers: If abilities in which performance is generally improving in younger cohorts are only considered cross-sectionally, these abilities may be described as being more susceptible to age-related decline than is actually the case (Schaie 2013). That is, at a single time point, older people would be observed performing poorly relative to younger individuals on the particular measures. This difference, however, is partly attributable to the improved performance in the younger group rather than wholly being the result of any cognitive decline in the older individuals. Likewise, those abilities exhibiting a performance bias for older cohorts would be characterized as showing less change with age than is the case. Longitudinal studies allow the analysis of actual changes with age, and reduce the potential for misinterpretation of results as a consequence of possible generational changes in ability, though other methodological considerations mean longitudinal studies present their own issues in interpreting age-related changes (Salthouse 2010).

To illustrate this, consider Fig. 2. In the first graph (a), cross-sectional data are shown from the SLS and would appear to show steady, linear

Intelligence and Aging, Fig. 2 (a) Cross-sectional data from the Seattle Longitudinal Study. Declines are evident in all domains, with the exception of preserved verbal and numeric ability. (b) Seven-year longitudinal data from the same study. Declines are evident in all domains after age

55, with only processing speed displaying declines before 55 (Reproduced by permission from Macmillan Publishers Ltd (*Nature Reviews Neuroscience* (Hedden and Gabrieli 2004), copyright 2004); reproduced with permission from Cambridge University Press)

declines in inductive reasoning, spatial orientation, perceptual speed, and verbal memory across the lifespan (numeric and verbal abilities show relative stability). Contrast this with longitudinal data gathered over 7-year periods (b). The patterns observed here would suggest that abilities are relatively stable in young and mid-adulthood, with declines becoming apparent from around 60 years of age (Schaie 2013). Examining cognitive abilities either cross-sectionally or longitudinally can therefore produce quite different models of change. Cross-sectional studies may overestimate changes associated with increasing age due to cohort effects. Longitudinal studies, however, are not immune from bias, and may underestimate cognitive changes due to nonrandom attrition, or practice and retest effects over numerous testing sessions (Salthouse 2010; Hedden and Gabrieli 2004; Tucker-Drob and Salthouse 2011). Bearing in mind such methodological caveats, it appears in general that certain cognitive abilities may be relatively preserved up to, and in some cases into, old age before declining from that point onward. Different abilities begin to show marked decline at different ages, and this decline occurs at different rates, though debate continues in the field on the precise timing of such changes (Tucker-Drob and Salthouse 2011). As a result, any study with only a general

measure of ability may be insufficient for exploring the totality of age-related changes in cognitive ability.

Fluid abilities, “concerned with basic processes of reasoning and other mental activities that depend only minimally on learning and acculturation” (Carroll 1993, p. 624), are seen to decline at an earlier age than crystallized abilities, “concerned with mental processes that reflect not only the operation of fluid intelligence but also the effects of experience, learning, and acculturation” (p. 624), although the latter may show more rapid decline after about 70 years of age. Returning to the SLS example, noticeable declines were generally apparent across the range of diverse abilities tested when individuals reached 50–60 years old, and by the mid-70s, declines in all abilities were evident. Perceptual speed exhibited almost linear decline from young adulthood onwards (Schaie 2013). Data from another study, the Kungsholmen Project (a population-based study with individuals aged 75 years and over comprising assessments on five occasions over 13 years) indicated “a clear age-related deterioration from the mid 70s through the mid 90s for tasks in which performance [is] contingent on new learning, speed, and flexible adjustment to new situational demands. . .small or non-existent age-related differences were observed in tasks that draw on

pre-experimental experience, have limited speed demands, and are highly automated” (Backman et al. 2004, p. 217).

In summary, the illustrative examples highlight key findings in intelligence and cognitive aging research. Cognitive changes observed cross-sectionally and longitudinally may differ, with longitudinal studies suggesting many cognitive abilities may be sustained into old age. When marked decrements become apparent in later life, the rate of change is greater with increasing age. In addition, “ageing...influences certain cognitive functions disproportionately” (Hedden and Gabrieli 2004, p. 88); distinct domains (for example, memory, reasoning, or verbal ability) exhibit unique patterns of change, with deterioration beginning at different ages and occurring at different rates. As suggested, however, longitudinal studies may overestimate the stability of intelligence for a number of reasons, including differential attrition and practice effects with repeated test administration (Tucker-Drob and Salthouse 2011).

How Stable Are Individual Differences in Intelligence Across the Lifecourse?

When discussed above, both change and stability referred to “mean level” change or stability. Cognitive ability scores from individuals of different ages, or from repeat measures in individuals followed over time, are interpreted to indicate when different cognitive abilities might begin to show reliable decline on average. However, it is also possible to consider individual differences in the stability of intelligence (Deary 2014). In terms of the stability of individual differences, it is a person’s ranking relative to others that is of interest: If a person performs well on one occasion, how likely are they to perform as well on future occasions relative to the others tested? Given that intelligence across the lifecourse may be characterized by both stability and change, studies of individuals who have completed the same measure or measures of cognitive ability over long periods of time have been able to estimate the stability of individual differences in intelligence.

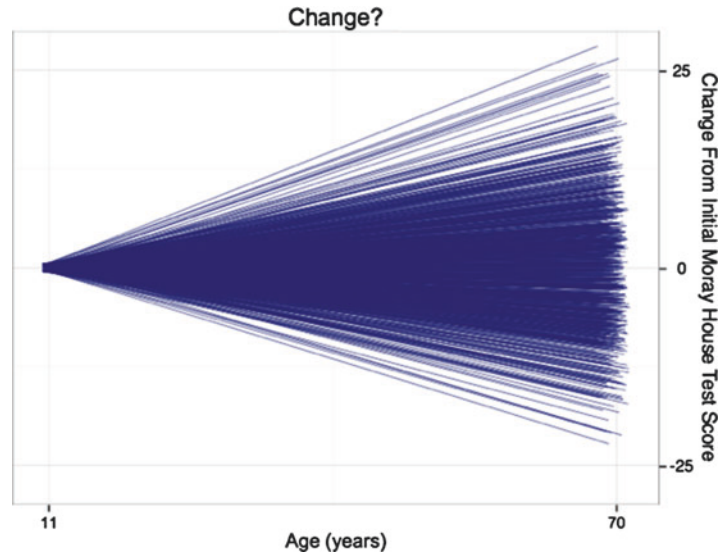

For example, participants in the Lothian Birth Cohort studies (Deary 2014) completed a test of cognitive ability when aged 11 and repeated the same test when aged 70 or 79 years old. The older cohort (recruited in later life at age 79) took the test a further twice, at ages 87 and 90. The latter follow-up – from age 11 to 90 – is believed to be the longest test-retest period in the field and produced a correlation of 0.45 from a sample of 99 participants (before the exclusion of seven participants with dementia or possible dementia, the correlation was 0.54).

With any cohort study, there is likely to be a restriction in the range of possible scores compared with the larger population from which they were drawn (Salthouse 2010; Hertzog et al. 2009; Deary 2014). That is, they are unlikely to be truly representative. In the Lothian Birth Cohort studies, the cognitive ability scores at age 11 were drawn from larger population-wide surveys, and so it was possible to correct the childhood to old age correlations for the observed restriction of range. In the younger of the cohorts (with a sample of over 1000), the raw test score correlation between ages 11 and 70 increased from 0.67 to 0.78 after this correction. As correlations can be squared to estimate shared variance, it was suggested that “about half of the differences in intelligence at age 70 can be traced back to age 11, and about a third of the differences in intelligence at age 90 can be traced back to age 11” (Deary 2014, p. 243). With data on intelligence across the lifecourse, it has also been possible to visualize the individual differences in lifetime change in intelligence. Figure 3 shows the test scores from the cohort standardized at age 11. The scores at age 70 therefore reflect the relative change from that point. Of particular interest was the normal distribution of relative lifetime change in intelligence.

Other studies including repeat cognitive assessments across many decades have provided similar results on the stability of intelligence; two independent samples with about four decades of follow-up both produced correlations of 0.78, for example (Deary 2014). Understanding the stability of intelligence is important as this “gives a baseline from which to reckon the amount of

Intelligence and Aging,

Fig. 3 Individual differences in change in intelligence from age 11 to 70 in the Lothian Birth Cohort 1936 (Reproduced with permission of the copyright holders Ian Deary and Stuart Ritchie)

change, and then to start the process of finding the contributors to that change” (Deary 2014, p. 243).

When It Goes, Does It All Go Together?

Considerations of the stability of individual differences in intelligence across the lifespan, while of interest, are perhaps of more importance in quantifying the portion that might be open to change (and therefore perhaps to intervention). Regarding change, a key area of interest is whether change in one domain of cognitive ability is associated with changes in other domains. If changes are found to be related, researchers would therefore be seeking to identify a common cause or causes; if the changes across domains are largely unrelated, it would suggest more specific developmental processes (Tucker-Drob and Salthouse 2011).

As another illustrative example, the Religious Orders Study, conducted by Wilson and colleagues (2004), has been following older Catholic nuns, priests, and brothers, with the aim of examining the aging process (and specifically Alzheimer’s disease) in a group believed to be relatively homogenous with respect to lifestyle and living conditions from early adulthood (Wilson et al. 2004). The participating individuals underwent an annual clinical examination (and

agreed to a brain autopsy after death), allowing the level and change in cognitive ability to be assessed. The study began in 1994, and by the end of 2002, there were 958 participants, with a mean age at baseline of 75.3 years. As part of the annual evaluation, each participant completed 21 cognitive tests, the scores from which were summed to give a global score. The tests were also scored according to the main domain they assessed (episodic memory, semantic memory, working memory, perceptual speed, and visuospatial ability).

With increasing age, the rate of decline in performance recorded across each of these domains was greater. Interestingly, the results further suggested that “part of the age-related cognitive decline is global in nature but another specific proportion appears to be domain specific” (Wilson et al. 2004, p. 287); about 30% of the variance in the rate of change was shared across cognitive domains.

The Religious Orders Study investigated a group who showed potentially limited variation in their lifestyles but was not intended to be representative of older people in general. Yet similar results have been reported in community-dwelling samples, suggesting that part of age-related decline is specific to a given domain, while part is global and shared across all domains (Hedden and Gabrieli 2004; Tucker-Drob and

Salthouse 2011; Backman et al. 2004; Wilson et al. 2004). In summarizing the findings from a number of independent studies, Tucker-Drob and Salthouse (2011) suggest the data are consistent with “a single common factor accounting for between approximately 35–60% of individual differences in cognitive change” (pp. 250–251). Thus, while cognitive abilities display unique and independent changes with increasing age they also decline partly in concert due to some common process or processes.

What Role Do Genes Play in Age-Related Changes in Intelligence?

Understanding the genetic determinants of intelligence, or the age-related changes experienced in this, may increase both our understanding of the structural and functional mechanisms underlying complex and diverse cognitive processes, and indeed, identify targets for either pharmacological or lifestyle based interventions designed to reduce or delay any decline. Heritability estimates for intelligence appear to vary across the lifecourse, rising from about 20% in early childhood to 60% by adulthood (Plomin and Deary 2015). However, studies indicate the same genes are associated with intelligence across the lifecourse. This “apparently contradictory finding” may be the outcome of a developmental pathway in “which small genetic differences are magnified as children select, modify and create environments correlated with their genetic propensities” (Plomin and Deary 2015, p. 100). Increasingly sophisticated techniques, for example, genome-wide scans, have also suggested that there are unlikely to be any single genes with large effects on intelligence, but rather that many thousands of genes are likely to each contribute very small effect sizes (Plomin and Deary 2015).

In exploring the genetics of intelligence, an important objective has been to quantify the extent of the genetic and environmental contributions to change across time. In analyses utilizing data from the cohorts tested in childhood and again in later life described above, genome-wide data on almost 600,000 common single nucleotide

polymorphisms (SNPs) accounted for about 0.24 of the variation in relative cognitive change across the lifespan (Deary et al. 2012). That is, about one quarter of the variation appeared to be accounted for by genetic factors, suggesting lifestyle and environmental factors may have a larger influence on individual differences in relative lifetime change in intelligence. While in need of replication – the analyses were based on just under 2000 participants – these initial estimates provide an impetus to identify what those environmental determinants might be.

Is Age Kinder to the Initially More Able?

Before briefly concluding by considering some potentially malleable determinants of later life intelligence and change, it is necessary to take into account a predictor which, by later adulthood, cannot be altered: prior intelligence. This is a central issue in research on intelligence and aging and is related to the stability of intelligence discussed above. Consider the Nun Study, a research project examining members of the School Sisters of Notre Dame (Midwestern, Eastern, and Southern United States). Six hundred and seventy-eight sisters were examined at baseline in 1991–1993, with annual evaluations and brain autopsy upon death. Importantly within this group, 180 individuals had written autobiographies at a mean age of 22. From these, it was possible to derive a measure labeled idea density, defined as “the average number of ideas expressed per ten words, computed for the last ten sentences of each autobiography” (Riley et al. 2005, p. 342). An average of 58 years elapsed from the sisters writing their autobiographies to being enrolled in the Nun Study, when they completed a battery of cognitive tests. The mean age at baseline was 80 years old and at the seventh follow-up examination was 86.

The percentage prevalence of low idea density was greater in the more cognitively impaired groups. For the sisters with a memory impairment at the first exam, those showing mild cognitive impairment were 5.3 times more likely to have written autobiographies scoring poorly on idea

density (with those having intact cognition as the reference group). The results suggested that lower idea density displayed in an autobiography written in young adulthood was associated with poorer cognitive function in later life, supporting “a strong inverse relationship between early-life linguistic ability and late life cognitive function, including mild cognitive impairments” in those groups showing memory impairments (Riley et al. 2005, p. 345).

Within the sample, participants covered the complete continuum of cognitive functioning, from intact, through mild impairment, to global impairment and dementia. The authors therefore stated that the “relative homogeneity of the sisters’ adult lifestyles and environments suggests that those with low linguistic ability [as assessed by idea density, related to vocabulary and general knowledge] in early life brought risk factors with them when they joined the religious congregation at an early age” (Riley et al. 2005, p. 346). A measure of early ability was therefore shown to be a major predictor of later life ability, consistent with the stability of intelligence discussed above. The Nun Study results might suggest that those of higher initial ability experience less decline in later life and are therefore less likely to become cognitively impaired. This would be consistent with the concept of cognitive and brain reserve capacity, whereby those of higher ability have a higher tolerance for “the amount of damage that can be sustained before reaching a threshold for clinical expression” (Stern 2002, p. 449). This reserve could be expressed as some brain parameter, such as overall size or the number and density of synapses for example, or via the use of alternative cognitive processes or structures after damage to “normal” pathways. The latter model of reserve is often defined as active as alternative routes or networks need to be sought in order to cope with some insult or decline, compared with the former passive models (Stern 2002). Individuals who develop a greater “reserve” might therefore be spared the process of cognitive aging until a later age compared with their peers who developed less reserve across the lifespan.

Another possibility, however, is that those of higher initial ability experience later life decline at

the same rate as those of lower initial ability, but simply have a greater distance to fall before reaching any “impairment threshold,” however that is defined. In this explanation, the concept of reserve may still be relevant. In the studies that have asked the question, “Is age kinder to the initially more able?,” the results appear to be inconsistent; some suggest individuals with higher initial ability experience less decline across time, while others show no association between initial ability and subsequent trajectories of change, and others still have reported greater decline in those initially at a higher level (Deary 2014). While there are clear individual differences in level, rates of change in intelligence may exhibit far smaller or according to some studies no differences according to initial level (Salthouse 2010).

Can We Alter the Course of Age-Related Changes in Intelligence?

While initial ability may or may not account for individual differences in change, as the cognitive trajectories recorded across persons are variable, it is likely that a number of other factors are responsible. As described above, perhaps up to three quarters of the variance in lifetime change in intelligence could be accounted for by environmental factors (Deary et al. 2012). A key goal would be to determine if mutable factors accounting for this change could be identified, such that these could be promoted or discouraged as appropriate, or manipulated as part of delivered interventions, to delay, reduce, or indeed reverse this decline.

Before highlighting some candidates, consider the conceptual model illustrated in Fig. 4. Here a hypothetical individual’s level of cognitive function is shown by the white dots, with stability across midlife and decline in old age. However, the shaded area highlights the range of their possible functioning, that is, the individual could do both better or worse than their current level given the influence of protective and detrimental factors respectively (Hertzog et al. 2009). Indeed, the search for determinants of cognitive aging relies

Intelligence and Aging, Fig. 4 Depiction of the zone of possible cognitive development across adult life for a given individual (Reproduced with permission of the authors (Hertzog et al. 2009))

on the possibility of plasticity across the lifespan and within old age, and while supported by intervention studies, the boundaries of this are yet to be fully defined.

Factors associated with differences in level and change in cognitive ability would first be identified from observational studies (by exploring what factors are associated with better or worse performance either cross-sectionally or longitudinally), before their influence could be directly tested in more controlled intervention studies. The potentially cognitively beneficial effect of activity participation – in the intellectual, social, and physical domains – has been a key focus for research and, indeed, has been summarized as favoring “the hypothesis that maintaining an intellectually engaged and physically active lifestyle promotes successful cognitive aging” (Hertzog et al. 2009, p. 1).

For many, the intellectual stimulation resulting from increased activity is intuitively central to the protective effect of activity. That is, activities which are specifically cognitive, or those from other domains also necessitating some level of cognitive engagement, may act through a shared pathway. These suggest that the beneficial effects of intellectually stimulating activity may be the result of a “use it or lose it” scenario (Tucker-Drob and Salthouse 2011). An engagement model of

cognitive level and decline has therefore emerged, whereby those who show a greater degree of engagement with their environment are less likely to suffer the adverse effects of cognitive aging or at least delay the onset of such age-related cognitive decline. Use or disuse of mental abilities (via engagement in activities) may therefore lead to actual structural or functional changes in the brain (number of synapses, speed of dendrites, etc.) which will then determine an individual’s future engagement with their environment (Hertzog et al. 2009). If disuse is a major predictor of cognitive decline, the suggestion would be that cognitive aging may be reversible, to a degree (Schaie 2013).

However, there are issues of causality which can rarely be addressed in longitudinal research whereby those of higher ability are also more likely to be active in, and engaged with, their environment (Tucker-Drob and Salthouse 2011; Gow et al. 2012). Less cognitive decline in these individuals may not be due to some greater buildup of reserve but rather due to their initial ability. Evaluating this, Salthouse (2006) stated:

the relation [between mental exercise and mental ageing] could occur because, as proposed by the mental-exercise hypothesis, the amount of mental activity throughout one’s life contributes to the level of mental ability at later periods in life, but

the relation could also originate because the amount of mental activity at any age is at least partially determined by one's prior, and current, level of mental ability. More generally, although it is tempting to attribute some of the variability in cognitive performance apparent at any given age to individual differences in prior rates of age-related change in cognitive abilities, it is important to consider the possibility that much of that variability was present at earlier ages, and may have little or nothing to do with differential aging. (p. 70)

While a number of psychosocial, behavioral, and environmental factors have been associated with age-related changes in intelligence, this important caveat remains. Are those associations evidence of differential preservation, or are they rather the result of preserved differentiation (Tucker-Drob and Salthouse 2011; Gow et al. 2012)? Even in studies with assessments of cognitive ability across years or decades, distinguishing between the two remains difficult. It is, however, an important endeavor as many lifestyle or behavioral factors are confounded by reverse causation, that is, many factors of interest (education, occupational complexity, activity participation) are strongly associated with earlier intelligence. It is necessary to better understand how the association between any given factor and cognitive aging might be attenuated once the stability of intelligence has been accounted for. While efforts to address this remain somewhat limited (Gow et al. 2012), intervention studies where participants are randomly assigned to groups remain the clearest test of whether specific factors can alter the course of age-related changes in intelligence. It has been suggested that relatively consistent benefits have been reported from physical activity interventions, for example, though by no means universal (Salthouse 2010; Hertzog et al. 2009).

While the preserved differentiation-differential preservation debate needs to be more fully accounted for, the most recent review of those factors likely to affect cognitive decline suggested that the strongest evidence for cognitively protective factors included a higher number of years of

education and physical activity, while brain injury, obesity and hypertension in midlife, smoking, and diabetes appear to be detrimental (Baumgart et al. 2015). The conclusion to that report is a fitting conclusion here also:

“it is clear that there are still many unanswered questions and significant uncertainty with respect to the relationship between individual risk factors and dementia [cognitive decline was also considered] (for example, to what degree there is a causal relationship). There is a clear need for more research on risk reduction, prevention, and brain health – both more longitudinal, population-based cohort studies and randomized controlled trials on the effectiveness of specific interventions that address modifiable risk factors. . . The evidence has now reached a point that it can no longer remain simply an exercise in academic discussion. The public should know what the science concludes: certain healthy behaviors known to be effective for diabetes, cardiovascular disease, and cancer are also good for brain health and for reducing the risk of cognitive decline.

Definition

The Interdisciplinary Longitudinal Study of Adult Development and Aging (ILSE) is characterized

by a multidisciplinary longitudinal study design investigating the aging process of two German birth cohorts born between 1930–32 (C30) and 1950–52 (C50), respectively.

Overview

The main objective of the Interdisciplinary Longitudinal Study on Adult Development and Aging (ILSE) is to investigate individual, societal, and sociostructural preconditions for aging well. Aging well is seen as achieving the best physical and mental health as well as the highest autonomy and well-being possible. ILSE is designed as a multidisciplinary longitudinal study investigating the aging process of German birth cohorts born in 1930–1932 (C30) and 1950–1952 (C50), respectively. This cohort design offers the opportunity to explore the potential impact of different childhood conditions (before and after World War II) on lifespan development. Moreover, the study sample includes participants from the former Western (Heidelberg region, HD) as well as Eastern (Leipzig region, LE) parts of Germany, allowing for the analysis of East/West Germany differences in developmental trajectories and outcomes. Given its first measurement wave at the beginning of the 1990s and its fourth measurement wave, initiated in 2013, ILSE is now also able to contrast development in mid versus late adulthood. At the applied level, ILSE also strives to contribute to the promotion of health and well-being, as well as to the prevention of disease and functional loss as people age.

Guiding Conceptual Ideas of ILSE

ILSE was initiated at the beginning of the 1990s by two key figures of German developmental and aging research: Ursula Lehr and Hans Thomae. Given the special emphasis these scholars put on the critical role of subjective appraisal of life situations for human development (“biographical approach”; Lehr and Thomae 1987; Thomae 1979) as well as their ambition to include the established psychometric approach in

longitudinal aging research, ILSE is rather unique in its striving to combine and reconcile these different world views in developmental and lifespan research. A major conceptual step toward this goal has been the introduction of the model of developmental adaptation by two scholars affiliated with ILSE at the end of the 1990s/early 2000s, i.e., Peter Martin (now Iowa State University) and Mike Martin (now University of Zurich; see (Martin and Martin 2002)).

The biographical approach, as used in ILSE, emphasizes the importance of considering the full life course of individuals in order to understand their current motivations, concerns, and behaviors. In this context, recent events as well as past experiences (e.g., adverse childhood experiences) are taken into account. According to Thomae (1998), biographical approaches are well grounded in various developmental theories that argue for a causal relationship between early and more recent life events on late-life outcomes, particularly in the area of mental health. Emphasis is also put in accordance with acknowledged life-course research (e.g., Settersten 2003) on the impact of subjective turning points in individual biographies, as well as driven by the *cohort flow argument*: the significance of political and societal circumstances as constantly changing, driving forces of lifespan development.

The model of developmental adaptation (Martin and Martin 2002) purports six developmental factors, which are all assumed to be related to core developmental outcomes (e.g., health and well-being), i.e., past life events and biography, family of origin, individual resources, social and economic resources, and individual coping strategies (Fig. 1).

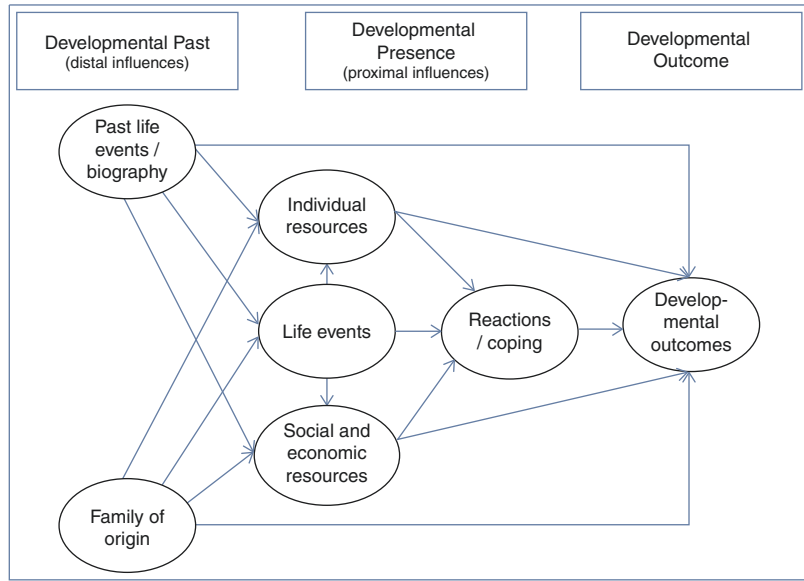

In addition to these fundamental conceptual cornerstones, ILSE also relies on core assumptions now widely accepted as essential for productive longitudinal aging research:

- *Combining mid- and late adulthood and focusing on the transitions from mid-adulthood to young old age and from young old age to old-old age*

With few exceptions, middle adulthood has often been neglected in studies focusing on development later in life. Due to its research

Interdisciplinary Longitudinal Study on Adult Development and Aging (ILSE),

Fig. 1 Model of developmental adaptation across the lifespan (Adapted from Martin and Martin 2002)

design (see below), ILSE allows for in-depth analyses concerning developmental trajectories of key constructs and variables, such as cognitive performance, dementia, well-being, personality, and social relationships from middle to late adulthood. Given longer observation intervals conducted (which now approach 20 years in ILSE), ILSE also makes it possible to focus on trajectories from middle adulthood into early old age (Willis and Martin 2005) and from early old age into what has been labeled the fourth age (Baltes and Smith 1999); these two transitions have been described as highly significant for development in the second half of life.

- *Theory-driven cohort approach*

The consideration of birth cohorts allows for an in-depth examination of long-term effects on adult development and aging with respect to socialization and historic events. ILSE examines the aging development of two birth cohorts, which grew up under very different historical, economic, and political conditions. The elder birth cohort (born 1930–32: C30) experienced childhood and adolescence in National Socialist Germany. After the World War II, members of C30 spent their early and mid-adulthood within different political systems (German Democratic Republic [GDR] vs Federal Republic of Germany [FRG]);

when Germany was reunified, the members of this cohort were already in their 60s. By contrast, the younger birth cohort (born 1950–52: C50) experienced their childhood and adolescence in divided Germany (GDR vs. FRG) and were only middle-aged adults when Germany was reunified. Additionally, the consideration of two regions (HD vs. LE) offers the opportunity to examine potential long-term effects of heterogeneous ideological, societal, and economic circumstances on various developmental outcomes, e.g., life expectancy, health, and quality of life. ILSE assumes that such East/West comparisons provide unique empirical insights concerning the potential impact of severe economic, political, and social changes on individual (longitudinal) adjustment and well-being from middle to old age.

- *Interdisciplinary approach to aging*

ILSE follows an interdisciplinary approach in order to answer a variety of scientific questions related to aging and development. Questions about the processes and outcomes of successful aging can thus be addressed from different disciplinary angles. The set of disciplines considered in ILSE includes (developmental and gero-) psychology, sociology, psychiatry, dentistry, nutritional science, and sports science.

Consistent with these conceptual and methodological metaideas, ILSE's assessment protocol covers a wide range of domains of functioning and includes biographical data, critical life events, person-related resources and environmental resources, attitudes, physical and mental health, and various indicators of subjective and objective well-being (see below for a more detailed description of ILSE's main data areas). In addition to semistructured procedures to assess biographical development and subjective appraisal processes, a multidimensional package of established cognitive and neuropsychological test procedures and self-report instruments has been completed by participants at each measurement wave. In addition, a clinical assessment regarding physical and mental health conducted by study psychogeriatricians is part of ILSE's assessment package.

Methodology

Study Design

ILSE is based on a 2 (cohort) \times 2 (region) \times 2 (measurement point) study design. ILSE participants have been followed since 1993 for an average time period of 12 years and assessed at three measurement waves (t1: 1993–1996; t2: 1997–2000; t3: 2005–2008). After completion of the ongoing fourth examination wave in 2016, ILSE will cover a total observational period of about 20 years in each cohort. This measurement wave is particularly important because the younger cohort (C50) will have reached the age of the older birth cohort (C30) at the beginning of the study, allowing us to begin disentangling the effects of age and cohort on processes and outcomes of successful development. The first three examination waves of the ILSE study were funded by the Federal Ministry for Family, Senior Citizen, Women, and Youth, Germany (Bundesministerium für Familie, Senioren, Frauen und Jugend - BMBFSJ) and the Ministry of Sciences, Research, and Arts Baden-Württemberg, Germany (Ministerium für Wissenschaft, Forschung und Kunst, Baden-Württemberg - MWK). Additional financial support was provided by the Mar-silius Kolleg (center of advanced studies),

Heidelberg University, Germany. The currently conducted fourth examination wave is funded by the Dietmar Hopp Foundation, Germany (Dietmar Hopp Stiftung).

Recruitment and Sample Characteristics

Participants were randomly selected and recruited on the basis of city registers, which comprise data on all inhabitants of German communities. A random address sample ($N = 4000$) was drawn for each study center (HD vs. LE). This sample was stratified by gender and birth cohort in order to assure an approximately equal distribution of male and female participants, as well as participants from the older (C30) and younger (C50) birth cohort. Potential participants were invited to take part in the ILSE study via a respective invitation letter sent by mail, followed by a short telephone interview concerning relevant sociodemographic data. Those who agreed to come to the study center located at the universities of Heidelberg and Leipzig first received a comprehensive description of the study and then underwent a written informed consent procedure. Each of ILSE's data waves was approved by the ethics committee of Heidelberg University's medical faculty.

Assessment of the random address sample continued until the envisaged sample size of 500 per birth cohort was reached. Recruitment efforts finally resulted in a sample of 1002 participants. This initial study sample was equally distributed in terms of birth cohort (C30: $N = 500$; C50: $N = 502$) and research center location (HD: 49.9%; LE: 50.1%). According to ILSE's stratification procedure, men were initially overrepresented (Male: 52%; Female: 48%). Apart from a slightly higher educational level, comparative analyses revealed that the respective birth cohorts were adequately represented in terms of relevant sociodemographic data (e.g., marital status, household net income).

At the first examination wave (t1), 500 subjects from Heidelberg and 502 subjects from Leipzig participated in the ILSE study. At the second measurement point (t2), 896 subjects (89.4%) were re-examined. The third examination wave (t3) was completed by a total number of

Interdisciplinary Longitudinal Study on Adult Development and Aging (ILSE), Fig. 2 Development of ILSE sample from t1 to t3

789 participants, resulting in a high longitudinal response rate of 78.7% of the initial sample (see Fig. 2).

Seen in more detail for each cohort, t1 included 500 subjects from C30. Half of the study participants were located in HD and LE, respectively. At t2, 449 subjects (89.8%) were reinvestigated (HD: N = 222; LE: N = 227), resulting in 51 dropouts between t1 and t2. A total number of 23 subjects died (HD: N = 10; LE: N = 13), while 28 subjects refused their participation for various reasons (see dropout analysis given below). Finally, the third examination wave (t3) was completed by a total number of 381 subjects, resulting in 68 dropouts between t2 and t3. During this time period, 37 participants died (HD: N = 23; LE: N = 14). Moreover, 38 subjects who took part at t2 refused to participate at the third examination wave. However, 7 subjects who had not participated at t2 were rerecruited for the examinations at t3. In summary 119 subjects of the older birth cohort dropped out between t1 and t3. Out of these dropouts, 60 participants died. Other dropout reasons were relocation (N = 13), health problems (N = 19), lack of time or interest (N = 15), and other reasons (N = 12; e.g., nursing care of spouse). Subjects that dropped out were significantly less educated than those who finished t3. However, participants who left the study did not differ concerning other

sociodemographic characteristics (e.g., gender, age, socioeconomic status).

Of the younger birth cohort (C50) 502 subjects were recruited for the ILSE study at t1. Altogether, 250 subjects were located in HD and 252 subjects in LE, respectively. At t2, 447 subjects were reinvestigated, resulting in a high response rate of 89% of the initial sample. Between t1 and t2, 5 subjects died. Another 50 subjects decided not to take part in the investigations for various reasons (see dropout analysis given below). At t3, 408 subjects were re-examined (81.3% of the initial sample). Between t2 and t3, 8 subjects died. Another 45 participants refused to take part in the investigations for several reasons. However, 14 subjects who had not participated at t2 were rerecruited for the third examination wave. In summary, 94 participants of the younger birth cohort dropped out between t1 and t3. Out of these dropouts, 13 participants died. Other main reasons included relocation (N = 20), health problems (N = 10), lack of time due to professional obligations (N = 15), and loss of interest (N = 7). Another 29 participants mentioned other reasons for their nonparticipation (e.g., personal reasons).

Overall, as to be expected, the number of participants who died during the 12-year period was significantly higher for the older as compared to the younger birth cohort (C30: N = 60; C50: N = 13).

Assessment Program

ILSE’s comprehensive data collection has been accompanied by an interdisciplinary research team at all measurement occasions. In light of ILSE’s conceptual fundament, main assessment areas included a semistandardized biographical interview as well as medical/dental and psychogeriatric examinations (see Table 1).

Moreover, in psychometric terms, participants underwent a multidimensional cognitive testing procedure, as well as were asked to complete a wide range of questionnaires addressing a broad range of demographic, educational, social, psychological, and medical variables (e.g., personality traits, values, attitudes, personal lifestyle, oral quality of life). Examination also included a state-of-the-art assessment of neuropsychological status (e.g., MMSE, *Trail Making*

Test) and physical health and functioning. Moreover, neuroimaging-based assessments (MRI of the brain (t2, t3), as well as genotype analyses (Apo-E, COMT), were performed for a subsample of ILSE.

Biographical Exploration by Means of Semistandardized Interviewing

The main objective of the semistandardized interviews has been to obtain a comprehensive understanding of the participants’ appraisal of their past and present life situation and their future expectations. The first examination wave included a detailed set of in-depth questions on the participants’ biographical development in all major life domains (see Table 1), ranging from early childhood to present; the interview questions at t2 and t3 then focused on experienced changes since the last measurement point in these life domains. Interviews were all audiotaped and are in the process of being digitalized for long-term preservation and forthcoming analysis (e.g., linguistically). Also, part of the interview material found a state-of-the-art transcription for qualitative data analyses.

Medical and Psychogeriatric Assessment

Medical and psychogeriatric assessments were performed by professional psychiatrists. Assessments included a thorough medical history, physical assessment, and blood sampling. Moreover, psychiatric disorders were assessed clinically as well as based on the Structured Clinical Interview for *DSM-III-R* (SKID).

Structured Questionnaires/Self-Report Data

ILSE’s structured and psychometrically driven assessment focused on *sociodemographic characteristics* (e.g., education, socioeconomic status), *attitudes* and *values* (e.g., toward the aging process, religion, politics), *personality* (e.g., Big Five assessment via NEO-FFI, control beliefs), indicators of subjective well-being (e.g., aging satisfaction, positive affect), and *social relationships* (e.g., social support). Additional questionnaires refer to *leisure activities* (e.g., physical

activity involvement), *volunteer work, nutrition, perceived home and neighborhood, and media use.*

Examination of Normal Cognitive Aging and Neuropsychological Assessment

ILSE's cognitively oriented and neuropsychological test battery was administered by professional psychologists. Tests able to assess normative cognitive aging were mainly derived from the "Nürnberger-Alters-Inventar" and the "Leistungsprüfungssystem," which are commonly used test batteries in Germany with high similarity to the Wechsler scales. Sample subtests include *visuospatial functioning* (spatial orientation, block design), *verbal comprehension, abstract thinking, speed* (number-connection test, digital-symbol test), *attention/concentration* (D2), and *memory* (immediate word list recall, delayed word list recognition). Severity of cognitive deficits was assessed by the *Mini Mental State Examination* (MMSE). The *Wechsler Memory Scale* (WMS) and the *Trail Making Test* (TMT) were applied to address memory and learning, as well as attention and cognitive flexibility. A depression screening (Zung scale) is also part of the neuropsychological assessment program.

As is usually the case in longitudinal studies, part of the assessment battery was adjusted and changed over the years. In particular, the fourth measurement wave covers, in addition to the core measures of ILSE, a performance and film-based test of empathy (Wieck and Kunzmann 2015), a workplace-related assessment, and an assessment of awareness of age-related change.

A Selection of ILSE Results

Due to the high number of disciplinary as well as interdisciplinary research activities (publications and presentations) that took place within ILSE during the last 20 years (www.psychologie.uni-heidelberg.de/ae/apa/forschung/ilse.html), we can only selectively present a few of the major findings.

Cognitive Development, Cognitive Health, and Disease Processes

The maintenance of cognitive performance and the prediction and possibly prevention of cognitive deficits play a decisive role with respect to quality of life in old age as well as respective intervention efforts. The huge amount of cross-sectional data in this area worldwide is valuable but obviously comes with a number of serious limitations, when maintenance and prevention issues are the target of analysis. Therefore, it was clear from the start that cognitive development and detailed analyses of cognitive health and disease processes must be a major focus of ILSE. In this context, age-related cognitive disorders – such as mild cognitive impairment (MCI) and Alzheimer's disease (AD) – were of special interest. We consider in what follows only the older cohort (C30) and its so far three measurement waves. Participants from the younger cohort (C50) are not considered because the prevalence and incidence of cognitive disorders was, as to be expected, very low for this cohort due to their low calendar age.

Prevalence of cognitive disorders significantly increased over time. At t1, 13.4% of the C30 participants were diagnosed with MCI, while 5.8% received a diagnosis of mild cognitive disorder (MCD). According to the relatively low mean calendar age of the sample ($M = 62.9$; $SD = 0.9$), dementias were not prevalent at this measurement point. Four years later, at t2, the prevalence of MCI and MCD increased to 23.6% and 7.8%, respectively. Dementias in considerable magnitude were not diagnosed until t3, when participants had reached a mean calendar age of 74.3 years ($SD = 1.2$). At this measurement point, 6.8% of participants were diagnosed with Alzheimer's Disease (AD), and 1.1% fulfilled criteria for vascular dementia (VD). Prevalence of MCI increased to 28.6%, while the proportion of MCD remained relatively stable (7.6%).

Additional analyses showed that the risk of developing AD at t3 was significantly higher for those subjects who already exhibited cognitive deficits at t2. More than 80% of AD patients were previously diagnosed with MCI (73.1%) or

MCD (7.7%). In other words, only 19.2% of AD patients at t3 did not exhibit any cognitive deficits 8 years prior to diagnosis (t2). Overall, ILSE's findings support that cognitive disorders show a rather high prevalence rate, affecting about one-third of the older population in community dwellings. Moreover, results clearly underscore a significant association between MCI and an increased risk of developing subsequent AD.

From the vantage point of prevention, an important body of work targeting protective factors able to counteract cognitive disorders refers to the concept of "cognitive reserve." The concept states that cognitive impairments do not directly result from neurobiological changes but are modified by a full set of heterogeneous risk and protective factors. ILSE offers the opportunity to investigate the immediate and longer-term effects of such risk factors and resources using longitudinal data from different assessment waves. Respective longitudinal analyses of ILSE's older birth cohort revealed the following major findings: participants who engaged in a high number of cognitively demanding leisure activities (e.g., investment in educational activities, solving crossword puzzles) at t1 showed a 62% reduced risk of developing MCI or AD at t3. Furthermore, cognitively active participants at t1 exhibited better neuropsychological test results over time (t1, t2, t3). Protective effects concerning MCI/AD development were also detected for high levels of education (85%), socioeconomic status (69%), and physical fitness (65%) (Sattler et al. 2011, 2012).

In summary, the longitudinal analyses of ILSE data concerned with cognitive development support the existence of several protective factors with respect to cognitive impairments in older adults. Results also point to important practical implications concerning prevention and as-early-as-possible intervention strategies. For example, in accordance with the established evidence in this area worldwide (Hertzog et al. 2009), intensive promotion of physical fitness as well as cognitively challenging leisure activities might result in successful behavioral prevention measures, able to reduce and delay cognitive disease processes to a remarkable extent.

Findings from Additional Domains of Functioning

Due to its large number, we only provide here (without any aspiration of being comprehensive) a highly selective overview of additional ILSE findings. In addition to what has been described above, a number of publications addressed measurement invariance of cognitive assessment as well as the detection of stability and change of cognitive development in both cohorts across 12 years (Martin and Zimprich 2005). Similar analyses were also performed with respect to personality in both cohorts (Allemand et al. 2008). With the lifespan-oriented developmental adaptation model as a background, research questions regarding connections among early life and more distal experiences and developmental outcomes such as subjective well-being (e.g., Heyl and Schmitt 2007; Jopp and Schmitt 2010) were also examined in a set of papers. Predictors of oral quality of life in old age were identified in a joint effort of dental medicine and geropsychology (Hassel et al. 2011). Recently, attitudes toward own aging were analyzed in terms of measurement invariance issues as well as predictors; this analysis again, similar to cognitive findings of ILSE, supported the need to start interventions toward more positive views on aging early in life (Miche et al. 2014).

Outlook and Future Potential of ILSE

As already mentioned, the fourth examination wave of ILSE started in 2013 and will be completed by 2016. At this point, ILSE will cover a longitudinal investigation period of 20 years, which will bring the analysis of all of the abovementioned domains to a new dimension. For example, data of the fourth examination wave will provide the opportunity to investigate the concept of cognitive reserve in still more detail and long-term dynamics. In particular, analyses of C30 data (t1-t3) suggest a protective effect of high education concerning MCI/AD development in old age. It will be interesting to examine if similar effects can be confirmed for the younger birth cohort (C50), which enjoyed enhanced

educational opportunities. In fact, participants of C30 reported 12.9 years of education, while participants of C50 enjoyed 14.0 years of education on average ($t = -6.88, p < .001$). According to cognitive reserve theory, a higher level of education leads to a more effective compensation of cognitive deficits associated with neurodegenerative disorders. Consequently, participants of the younger birth cohort (C50) should exhibit a lower prevalence rate of cognitive disorders at the beginning of their 60s (t_4), compared to the older birth cohort (C30) at the same age (t_1). We also generally expect that the observational interval available with the fourth measurement wave will considerably increase ILSE's empirical potential to inform preventive measures in different domains (e.g., cognitive, educational, physical activity, views of aging). Finally, new research designs are planned to be added to ILSE's long-term, intraindividual change design, such as a short-term, intraindividual variability measurement burst design.

Acknowledgments The first three examination waves of the ILSE study were funded by the Federal Ministry for Family, Senior Citizen, Women, and Youth, Germany (Bundesministerium für Familie, Senioren, Frauen und Jugend – BMBFSJ) and the Ministry of Sciences, Research, and Arts Baden-Württemberg, Germany (Ministerium für Wissenschaft, Forschung und Kunst, Baden-Württemberg – MWK). Additional financial support was provided by the Marsilius Kolleg (center of advanced studies), Heidelberg University, Germany. The currently conducted fourth examination wave is funded by the Dietmar Hopp Foundation, Germany (Dietmar Hopp Stiftung).

Intergenerational relations; Parent–child relationships; Parent–child ties

Definition

Intergenerational relationships are ties between adult family members in different generational positions within the family of which the parent–child relationship is the most widely studied.

Introduction

Intergenerational relationships have played a central role in families throughout history and across cultures. Nonetheless, these ties have risen to heightened importance over the past few decades, both to the people who experience these ties and to the scholars who study them. Scholars point to many demographic and social shifts related to the growing significance of intergenerational relations, three of which dominate the literature in the area: (a) delayed marriage and increasing divorce rates, (b) declining birthrates, and (c) increased longevity and active life expectancy. These trends create opportunities for interaction and dependence across generations, in particular, between parents and their adult children. In fact, intergenerational relationships may be just as, if not more, important to individuals than nuclear family relationships (Bengtson 2001). Throughout adulthood, these relationships serve different functions, though the strength of the tie is evident from early adulthood to late life.

Throughout the twenty-first century, young adults have become increasingly close to and dependent on their parents. The transition to adulthood has become prolonged, with young adults completing education and finding serious romantic partners and/or marrying later (Fingerman et al. 2012a; Schwartz 2009). Cell phones and computer technologies make communication easy, nearly instantaneous, and relatively cheap. As such, most young adults are in contact with their parents several times a week. Moreover, parents provide a wide range of support to grown children – from advice to providing a listening ear or giving money – more often than was the case in the twentieth century. A small, but meaningful, proportion of young adults lack contact with one parent (most often a father), due to divorce, parental incarceration, parents' never marrying or, in rare instances, death. But most young adults in the USA maintain ties to parents involving greater intimacy and support than was the case 20 or 30 years ago (Fingerman et al. 2012a).

Increases in longevity allow for sustained interaction between parents and children well

beyond early adulthood, and the relationships that are forged with parents in young adulthood continue to be central as adult children make transitions in employment, marriage, and parenthood. Not only are parents living longer, but parents maintain high levels of activity and low levels of disability much longer as well. This increased active life expectancy allows for noncaregiving based interactions between older adults and their middle age children that extend for several decades and greatly influence the lives of both generations. In fact, older parents and adult children remain in frequent contact; many speaking on the phone or seeing each other every week (Fingerman et al. 2012a). Further, despite the increased mobility of individuals, many children remain in proximity to parents (Schwartz 2009). This proximity and frequent contact fosters intimacy between the parties and provides opportunities for the parties to help one another. Thus, the focus of this entry centers on the emotional ties and support exchanges between generations.

Emotional Ties of Parents and Adult Children

For over four decades, scholars have studied emotional aspects of the parent–child tie, focusing first on closeness and then on conflict and ambivalence within these relationships. Not only do the emotional ties of parents and children influence the well-being of both generations, but these factors are associated with other aspects of the relationship including contact and support.

Generational Stake and Intergenerational Solidarity

In the late 1960s and early 1970s, scholars examining the family observed an interesting phenomenon in which older generations and younger generations reported different attitudes. For example, Bengtson and Kuypers (1971), studied college-aged children and found that, compared to their parents, young adult children perceived larger differences between the generations with regard to political, religious, and family values.

Further, children reported lower levels of closeness to their parents than their parents did to them. Bengtson and Kuypers termed this phenomenon the *generational stake*. The generational stake pertains to the idea that both generations are invested in the relationship, but their level of investment is different. The older generations are invested in the intergenerational bond to foster continuity and stability. Therefore, parents view greater similarity in values and report high levels of closeness with grown children. On the other hand, the younger generations seek to establish independence from their families of origin, thus emphasizing differences in values and reporting slightly less closeness to the older generation. Based on the dynamics of the intergenerational relationships observed in this study, Bengtson went on to develop one of the most widely used frameworks for the study of intergenerational relations, the Intergenerational Solidarity Model (Bengtson 2002).

Much of the literature on intergenerational relations, particularly during the 1980s and 1990s, was shaped by the Intergenerational Solidary Model (Bengtson 2002; Suito et al. 2011). This model emphasizes cohesion between a parent and an adult child as captured through six dimensions: emotional closeness, frequency of contact, similarity of values, exchange of support, and shared expectations for familial behavior. These dimensions are associated with factors such as number of children within the family and geographic proximity between the parties. Although this theoretical framework focuses on several dimensions of the intergenerational relationship, the affective component, which centers on the degree to which a parent or adult child feels intimate to or distant from the other, receives a great deal of attention in the literature.

Consistent with the generational stake hypothesis, many studies over the past three decades have confirmed that, although both parents and adult children rate relationships with each other as close, parents tend to rate their relationships with adult children as closer than do adult children (Schwartz 2009; Suito et al. 2011; Sechrist et al. 2012). In addition to generational position, children and parents alike indicate that mothers

have closer relationships with their children in comparison to fathers. Likewise, daughters have greater closeness with their parents in comparison to sons. The only other factor related to closeness in the parent–child relationship as consistent as generation and gender is value similarity. Both parents and adult children report greater closeness in relationships when they also perceive greater similarity in their values.

The Intergenerational Solidarity Model received considerable attention, but also suffered a great deal of criticism. Critics of the model highlighted the lack of attention to negative aspects of intergenerational relations, particularly conflict and disagreement between generations. Proponents of the theory explain that the model recognizes variation in level of closeness, but scholars argue that emotional distance in a relationship is not the same as conflict in a relationship (Bengtson 2002; Lowenstein 2007). Thus, the model was revisited with these issues in mind (Bengtson 2002). Yet, these critiques inspired a new line of investigation in the late 1990s focusing on the presence of both positive and negative emotions experienced in the parent–child relationship.

Conflict and Intergenerational Ambivalence

Although ties between adults and parents are typically characterized by affection and warm regard, parents and grown children also may experience irritation, annoyance, worry, and overt conflict in their tie. Scholars have examined the conflict perspective to assess tensions and negative experiences in this tie (Birditt et al. 2009). Researchers also have referred to mixed experiences in the parent/child tie as “intergenerational ambivalence.” This construct is premised on the idea that people can experience both positive and negative feelings towards the same partner (Lowenstein 2007).

Researchers who study intergenerational ambivalence measure it in a variety of ways; each type of measurement taps a distinct type of ambivalence. Some researchers measure parents’ and children’s positive and negative feelings about one another in separate indices. These measures can be mathematically combined to give an index of “ambivalence,” whereby reports of

considerable positive and considerable negative feelings together constitute greater ambivalence. Other researchers categorize relationships as absent (i.e., the parties have little contact or feelings for the other), mostly positive, mostly negative, or ambivalent. Finally, researchers sometimes ask parents and grown children to report whether they feel subjectively torn or conflicted in their relationships. These different approaches to assessing ambivalence yield a continuous sense of mixed feelings, a distinct categorization of different types of relationships, or a sense of whether parents and grown children are themselves aware of their own ambivalence (Fingerman et al. 2012a).

Ambivalent feelings may arise for a variety of reasons. At a societal level, relationships between adults and their parents have unclear “norms” – that is a lack of clarity regarding what each party is supposed to do for the other party. Is it OK and normal for grown children to live in their parents’ basement? Are grown children supposed to take off from an important work meeting when their parent needs a ride to the doctor? These types of issues can give rise to conflicted feelings when parents and grown children are unsure what they are supposed to be doing and feeling.

From an individual perspective, parents and grown children may experience positive and negative feelings when the other party is dependent on them or they have to turn to the other party for help. Americans typically value independence and autonomy. Parents may experience ambivalence when their grown children turn to them due to problems in their lives (e.g., the grown child has lost a job or is going through a divorce). This ambivalence reflects love and affection and a sense that the child has not succeeded in adult roles. The parent may partially blame him or herself and also empathize with the child’s distress. Similarly, grown children incur ambivalence when their parents’ health fails in part due to shared distress and in part, due to the sense of loss that comes with watching a parent age.

Within-Family Differences

The vast majority of the work examining relationships between parents and grown children has

focused on a single relationship, focusing on affection between one parent and one child. Clearly, these studies have provided important understanding of intergenerational relationships. However, a focus on just one relationship fails to take into account the complexities of family ties. Thus, recent studies of intergenerational relations emphasize the importance of viewing these ties in the context of other family relationships. Within-family differences studies that have grown in prominence in the last decade focus on the variations in relationship quality between parents and children within the same family, and how each relationship is influenced by relationships with other family members (Suitor et al. 2008).

Findings in these studies indicate that parents do not have the same level of intimacy with all children in the family. Despite a belief that parents should love all their children equally, most mothers and fathers studied can identify one child in the family with whom they feel the closest (Suitor et al. 2008). Parents typically choose daughters and children who share the parent's outlook on life. Child age also plays a role, in that younger children are most frequently named as the closest child to parents. Interestingly, children are likely to concur that parents have a child to whom they feel most close, but are less likely to be able to decipher accurately which child in the family it is. The variation in closeness between parents and children within a single family influences other family relationships including other parent-child ties as well as relationships among siblings (Suitor et al. 2011; Sechrist et al. 2012).

Emotional Ties and Well-Being

Given the life long, involuntary nature of the relationship between parents and children, it is no surprise that the emotional aspects of the intergenerational relationship have been tied to the well-being of both parents and children. Distant, highly conflictual and ambivalent relationships are related to lower psychological well-being of parents and adult children (Carr and Moorman 2011; Fingerman et al. 2008). Further, parental well-being is also tied to children's experiences of problems such as divorce, physical or mental illness, and drug and alcohol problems.

The effects of children's problems on parents' well-being may be in part due to parents feeling disappointment or failure, but may also be due to empathy for a child. Similarly, parents react to their grown children's successes with positive feelings and pride; though parents' tend to be more sensitive to their children's troubles than they are to their children's triumphs (Fingerman et al. 2012b). Thus both intimacy and distance in a parent-child relationship has important psychological consequences for parents and children.

Exchanges of Support Between Parents and Children

Another aspect of intergenerational relations that has received considerable attention is the exchange of support between generations. Early investigations of support focused on caregiving that adult children provided to an ill or disabled parent in later life. However, as noted earlier, the increase in life expectancy, in particular active life expectancy, has extended the period in which older parents do not require intensive caregiving and are active in the lives of their adult children. Thus, the flow of support both up and down the generational ladder outside of caregiving has received a great deal of attention.

Exchanges of support are complex and scholars have focused on several aspects of these exchanges including: (a) types of support parents and adult children exchange, (b) the flow of support to parents or to grown children, and (c) the factors that predict when and why parents and grown children give and receive support. Though the terms for different types of support vary to some extent in the literature, researchers commonly examine the following dimensions of support: emotional or expressive support; instrumental support; and financial support (Schwartz 2009; Davey et al. 2005). Emotional support includes listening to a problem or offering empathy when someone is distressed. Researchers have also examined confiding or listening, advice, and companionship under the general rubric of expressive support (Fingerman et al. 2009). Instrumental support includes practical help with

housework, home maintenance, transportation, shopping, cleaning and child care. Financial support includes monetary and other material transfers across generations. Recently, researchers also have examined technical support between generations; that is, assistance with electronic devices, software, and apps (Fingerman et al. 2009). Parents and grown children often provide and experience emotional support which, in most cases, is given to a high degree and sustained throughout the course of the relationship. Although most parents and children can turn to each other for help, the provision of instrumental, technical, and financial support tends to be more sporadic (Schwartz 2009). Indeed, as discussed later, these latter types of support typically reflect need more than affection.

Support Exchanges Between Adults and Parents

The flow of support across generations has been of widespread interest. Despite the fact that the preponderance of literature prior to the 1980s focused on children providing care to aging parents, it is now widely accepted that in Western countries, parents disproportionately provide many types of support to their children throughout adulthood (Fingerman et al. 2012a; Schwartz 2009; Suito et al. 2011).

The Multidimensional Intergenerational Support Model elaborates several mechanisms that help account for the support that parents provide to grown children (Fingerman et al. 2012a). This model suggests that structural factors such as children's needs and parental resources shape the provision of support, as do psychological factors such as the parties' beliefs about support and their affection for one another. Structural factors may include family structures and life course events. Similarly, beliefs about support may vary by culture and ethnicity.

According to this model, family members' needs evoke support. For example, parents respond to life course transitions and their children's everyday needs with several types of support including advice, money, housing, and practical help (Fingerman et al. 2009). As mentioned in the introduction, educational, economic,

and marital transitions in young adult children's lives create greater dependency on parents into adulthood. Extended education and delays in marriage lead many parents to provide direct financial support and housing for their grown offspring, particularly for young adult offspring (Schwartz 2009; Suito et al. 2011). Once adult children begin to have children of their own, parents, and mothers in particular, are likely to provide childcare, which can mean occasional babysitting to caring for grandchildren full time with or without a parent present. This assistance qualifies as financial assistance (as well as practical support), given that grandparents' providing childcare saves adult children money on formal childcare services (Schwartz 2009; Suito et al. 2011). Parents are likely to respond to children's problems with instrumental and financial support as well. Parents are more likely to support children who experience divorce, unemployment, physical or mental health problems, or engage in deviant behavior such as drugs (Suito et al. 2011; Sechrist et al. 2012; Fingerman et al. 2009).

Other factors associated with the child also tend to evoke support. Younger grown children are more likely to receive parental support than older grown children. Parents respond to a variety of needs as young adults finish education, start jobs, and search for permanent romantic partners (Sechrist et al. 2012; Fingerman et al. 2009). Parents also give more support to grown children when they feel greater affection for those children, perhaps because they spend more time with them and enjoy helping them more (Davey et al. 2005; Fingerman et al. 2009).

Cultural factors play a role in the level and types of support parents give to children. In general, White parents provide financial and material support to their children, whereas ethnic and racial minority parents tend to provide more housing and practical support to their children (Fingerman et al. 2012a; Suito et al. 2011; Sechrist et al. 2012). Moreover, the flow of support may differ in White and ethnic or racial minority families. For example, studies find that Black families tend to provide greater support to aging parents, whereas non-Hispanic White families tend to provide greater support to their grown

children. Similarly, Asian families tend to place greater value on support to aging parents than do families outside of Asia.

Nonetheless, studies point to the greater importance of economic resources than ethnicity in determining the support older parents give (Suitor et al. 2011). Clearly, parent's material and nonmaterial resources or socioeconomic status (SES) play a role in the extent to which they can provide practical and monetary support to their adult children. Not surprisingly, parents with higher income levels tend to provide greater financial support and parents in poverty provide less financial support (Davey et al. 2005). Recent research shows that there are nuances in these patterns, however. Grown children whose parents have more income and higher education typically receive more emotional and financial support. Yet, with the exception of money, lower SES parents provide more total support across all of their children. That is, families where the parents have less education and lower income suffer two disadvantages: (a) grown children, on average, receive less support and (b) resources are stretched trying to meet more needs from a greater number of children (Fingerman et al. 2015).

Family structures also play a role in exchanges of support. Divorced parents, both mothers and fathers, tend to provide less financial and practical assistance to their grown children. Yet, because divorced fathers often experience infrequent contact and more distant relationships with their adult children, they are the least likely to provide support to adult children when compared with married fathers, married mothers and divorced mothers (Schwartz 2009). Divorced fathers also receive less practical support from their adult children than do divorced mothers. Fathers who divorced early in their child's life and noncustodial fathers receive the least support from their children; likely due to less frequent contact and more distant relationships over the life course (Suitor et al. 2011; Davey et al. 2005). Similarly, widowhood appears to negatively affect the provision of support from parents to grown children, whether mothers or fathers are widowed (Davey et al. 2005). Yet, studies suggest widowhood may increase the likelihood that adult children provide

practical support to parents, and also the likelihood that mothers will live with an adult child (Davey et al. 2005).

In late life, when parents experience health declines, the flow of support may reverse. In general, as parents age, children's support increases, particularly in response to the needs of the parents. When parents' health begins to decline, the balance of support tends to shift toward parents receiving more support than they provide. Only a few grown children provide financial support to parents (Schwartz 2009). Yet, children often provide instrumental support or emotional support in response to parents' needs. As those parental needs increase, grown children may gradually increase support, even becoming full time caregivers if the parents incur disability due to extreme physical or cognitive declines.

Exchange of Support Across the Life Course and in a Family Context

It is important to consider support in the context of the relationship across time as well as in the context of the family. Theorists have discussed the idea of a support "bank" in the parent-child tie that carries over time (Antonucci 1990). That is, exchanges of support are often reciprocal in nature across time. When a parent provides support to a young adult child, it is common and often expected that the child will provide support to the parent in late life. Thus, another factor in predicting receipt of support at any given time is whether the respondent *provided* support in the past. Reciprocity can be an exchange of the same type of support within a relatively short time period such as when a middle-aged parent helps a young adult child move and the child reciprocates by helping the parent paint a room in his house a few weeks later. More often, however, reciprocal exchanges occur across the duration of the relationship. Thus, the emotional, financial, and practical help parents provide in a child's young adulthood and midlife results in practical support and caregiving in the parent's later years (Schwartz 2009; Suitor et al. 2011).

Just as with emotional aspects of intergenerational relations, examining support within the family is important as well, though evidence

regarding within family support is limited. In examining support provided by parents within families, studies reveal that in larger families, parents provide more support to children than parents in smaller families. Yet, each child in a larger family receives less support in comparison to children from smaller families. In other words, a parent with many children tends to give some support to each child, but because that parent's resources are spread out over more children, children in that family do not receive as much support as their counterparts in smaller families. Further, children who experience greater need, who have closer relationships with their parents or who provide support to their parents receive more support than their siblings (Fingerman et al. 2012a; Davey et al. 2005; Silverstein and Giarrusso 2010).

On the other hand, parents may benefit from having more children. Parents who have more children or at least one daughter have a higher likelihood of receiving support from a child. Despite this, a child with a greater number of siblings is less likely to provide support to a parent than a child with few siblings (Davey et al. 2005), perhaps because the siblings are filling the parents' needs. Though research is still limited, these within family studies indicate that exchange relationships between parents and adult children vary within a family.

Exchange and Well-Being

The interplay between support exchanges and well-being is complex. It is logical to assume that support is costly for the provider and beneficial for the recipient, but this is not always the case. In general, providing support to adult children is not detrimental to parent's well-being unless that support is required because of problems in an adult child's life, the parent views the child as too needy, or the parent is experiencing a stressful situation like retirement or widowhood (Suitor et al. 2011; Fingerman et al. 2012b). In contrast, children who provide intensive support or caregiving for a parent often experience stress, but also report positive outcomes as well (Suitor et al. 2011).

Yet, parents in Western cultures who receive support from adult children may experience lower levels of psychological well-being due to beliefs that parents should provide for their children, rather than the reverse (Suitor et al. 2011). Thus, exchanges of support in the parent-child relationship have a complex association with well-being that researchers continue to explore.

Conclusion

Intergenerational ties continue to be a central relationship for parents and children alike. Over the past half century, knowledge regarding this important relationship has flourished identifying the important patterns in relationships between parents and adult children. It is clear that both parents and children enjoy close and supportive relationships with each other over the life course; relationships which influence the well-being of each generation. However, social, economic, and demographic shifts continue to create new contexts in which to study these relationships. Continued advances in theory and methodological techniques will allow scholars to examine these relationships in an ever increasing depth and complexity.

Evidence-based treatment

Definition

Interpersonal psychotherapy (IPT) is an evidence-based, time-limited psychotherapy originally developed for the treatment of depression. IPT focuses on interpersonally relevant issues that are the apparent precipitant or consequence of depression. These include role transitions, interpersonal role disputes, grief, and interpersonal deficits. In the treatment of depression, IPT is typically delivered in 16 sessions over three phases of treatment: the initial sessions, intermediate sessions, and termination. IPT requires relatively little adaptation for older adults.

History and Overview

IPT was developed in the 1970s by Gerald Klerman, Myrna Weissman and their colleagues (Weissman 2006). Its development was informed by research on attachment behavior, the adverse emotional consequences of life stresses, and the negative consequences of depression on interpersonal relationships. Theoretically, IPT was

influenced by the work of the interpersonal school of psychiatry (best known by the writings of Harry Stack Sullivan) and the field of social psychiatry. IPT was first developed as an individual psychotherapeutic treatment for depression. In the 40 years since its development IPT has been adapted for mental health problems other than depression, varied age groups, nonwestern cultures, and treatment formats different from its original design as a 16-week individual psychotherapy (Weissman et al. 2000).

Numerous research studies have demonstrated the efficacy of IPT. IPT or an adaptation of it has been found efficacious in the treatment of depression, bipolar disorder, eating disorders; adolescents, adults, and older adults; mental health and medical settings; individual, conjoint, and group formats; brief or sessions extended beyond the original 16 sessions; and different countries and cultures (Weissman et al. 2000). In the treatment of depression, IPT is recommended in depression treatment guidelines in the United States, UK, and New Zealand/Australia (Hinrichsen and Iselin 2014). IPT along with other evidence-based psychotherapies has been disseminated within national health care delivery systems including the UK National Health Service and the U.S. Department of Veterans Affairs (Stewart et al. 2014). Members of the International Society for Interpersonal Psychotherapy include researchers and practitioners throughout the world.

Structure and Goals of IPT

As originally developed, IPT is delivered in three phases of treatment: The initial sessions (sessions 1–3), intermediate sessions (4–13), and termination (14–16). One or two interpersonally relevant problem areas are the focus of IPT treatment. These include role transitions (a change in life circumstances), interpersonal role disputes (conflict with another), grief (death of an important person), and interpersonal deficits (individuals who lack skills to initiate or sustain relationships). Therapeutic goals and strategies are outlined for each of the four problem areas. Therapeutic techniques are used in IPT to help the patient achieve goals and strategies relevant

to the identified problem area(s). Commonly used techniques include communication analysis (engagement in a detailed review of a recent interaction), decision analysis (engagement in a process for taking action to address an issue of concern), role-play (enactment of a planned conversation), interpersonal skill building (enhancement of ability to successfully interact with others), and work-at-home (encouragement to make efforts to address problems between therapy sessions).

In the initial sessions, the therapist engages the patient in a discussion of his or her symptoms of depression, administers a depression rating scale (and at later points in therapy), provides psychoeducational information about depression and its treatment, and encourages the patient to be hopeful that depression will likely improve during the course of treatment. Apparent precipitants and consequences of the current episode of depression are identified. Through use of IPT's interpersonal inventory the patient's current and past important relationships are broadly reviewed. One or at most two interpersonal problem areas are identified and will be the focus of treatment. The patient is provided with an interpersonal formulation, which is a succinct statement of the therapist's understanding of the likely precipitant(s) of the patient's depression and interpersonal problems that may have resulted from the depression. A therapeutic contract is discussed with the patient that includes a statement of therapeutic goals, review of the format and duration of treatment, conveyance of expectations about attendance at sessions, and practical matters such as fees.

In the intermediate sessions, goals and strategies for the identified problem area(s) are implemented. As noted, techniques are used to facilitate achievement of goals and strategies. Throughout the intermediate sessions, the status of the patient's depression is monitored. The link between changes in the patient's symptoms and events from the prior week is discussed. Briefly, the goals of each of the four problem areas are the following: For role transitions, the therapist works with the patient to come to emotional terms with how life has changed and facilitates the development of new skills to better manage new life circumstances. In the treatment of interpersonal

role disputes, the therapist aids the patient to better understand issues in the dispute, clarifies expectations about what he or she would like to change, and then helps the patient to change expectations and/or improve capacity to deal with the dispute. For grief, the therapist engages the patient to mourn the loss of the deceased and find ways to establish or reestablish activities and relationships with others that are sustaining. For those with interpersonal deficits, the therapist helps the patient to develop skills to enlarge the scope of interpersonal involvements. Achievement or partial achievement of goals for each of the problem areas is typically associated with reduction in depressive symptoms. Improvement in depression will likely make it easier for the patient to better manage issues associated with the IPT problem area. Throughout the intermediate sessions, the patient is periodically reminded of the remaining number of sessions.

In the termination phase of IPT, the ending of therapy is discussed including feelings that the patient may have about its ending. Changes in depressive symptoms over the course of IPT are reviewed with the patient as well as changes in the identified problem area(s). Therapeutic gains are attributed to efforts that the patient has made. For patients who have not made gains, other treatment options are reviewed. For some patients, less frequent (“maintenance”) sessions may be recommended. Possible future triggers of depressive symptoms are discussed, and the patient is engaged in a review of what efforts might be made to effectively respond to them. The overall therapeutic ethos of IPT includes active collaboration, encouragement, conveyance of hope, and facilitation of problem solving. The IPT treatment manual for depression is *Comprehensive Guide to Interpersonal Psychotherapy* (Weissman et al. 2000). Other IPT treatment manuals exist for other mental health problems, populations, and treatment formats.

IPT in the Treatment of Late Life Depression

Early in the history of IPT, researchers commented that IPT seemed especially well suited to

the problems confronted in later life (Sholomskas et al. 1983). A series of research studies has generally supported the efficacy of IPT in the treatment of late life depression (Hinrichsen and Iselin 2014). IPT is one of the recommended evidence-based treatments for older adults with depression by the Substance Abuse and Mental Health Services Administration (2011). Two published clinical treatment manuals for IPT with older adults exist: *Interpersonal psychotherapy for depressed older adults* (Hinrichsen and Clougherty 2006) and *Clinician’s guide to interpersonal psychotherapy in late life: Helping cognitively impaired or depressed elders and their caregivers* (Miller 2009).

Clinical reports on the use of IPT with older adults have appeared over the last 15 years (e.g., Hinrichsen 2008; Hinrichsen and Iselin 2014; Miller and Silberman 1996). For cognitively intact older adults, IPT can be used without substantive adaptation from its original formulation as an individual psychotherapy for depressed younger adults. However, IPT should be more broadly informed by knowledge and skills recommended for those providing clinical services to older adults (American Psychological Association 2014). The four IPT problem areas encompass many of the issues seen among older adults who seek treatment for depression. The collaborative, problem-focused approach of IPT is consistent with general guidance in the provision of psychotherapy with older adults (Knight 2004). IPT, in the treatment of late life depression, can be taught successfully to psychology trainees and postlicensure mental health care professionals. Older adults treated with IPT appear to have clinical outcomes similar with those found in research studies (Hinrichsen and Clougherty 2006). Consistent with this observation is a recent report from the U.S. Department of Veterans Affairs (VA) national dissemination of IPT to mental health clinicians (Stewart et al. 2014). Large and significant decreases in depressive symptoms were evident among veterans treated with IPT, almost half of whom were older adults.

Clinical and research reports indicate that the following are common issues treated within each of IPT’s four problem areas. The most frequent

problem area is role transitions for older adults. Examples of role transitions for older people include assumption of care for a relative with health or cognitive problems or care for a grandchild; onset or exacerbation of health problems in self; retirement or loss of employment; and residential transition. The second most common problem area is interpersonal role disputes which include onset or exacerbation of longstanding conflict with a spouse or partner; adult child; in-law; sibling; or institution (hospital, service delivery system). Grief typically includes loss of spouse/partner, adult child, sibling, or grandchild. Among the four problem areas, interpersonal deficits are least frequently the focus of IPT among older adults seen in outpatient clinical practice. Interpersonal deficits may include individuals with longstanding problems in making interpersonal connections as well as those who confront new life circumstances for which they do not possess needed skills.

Illustrative Examples of IPT with Older Adults

Role Transitions. Mrs. Washington is a 70-year-old African American woman with a 1-year history of severe depression (Note: All names are fictitious and identifying information has been changed in this and other examples). Her primary care physician had repeatedly asked her to take an antidepressant medication or to see a psychotherapist. Mrs. Washington refused since she had never had mental health problems in the past and felt that seeing a mental health professional would be stigmatizing. Finally she agreed to see a therapist. In the last few years the patient had been diagnosed with several medical problems that increasingly limited her mobility. Prior to the onset of her depression she had reluctantly agreed to have a medical procedure, which did not go as she had hoped and which left her with functional limitations she had not anticipated. She told the therapist she did not believe psychotherapy would help but agreed to do it because of the persistence of her physician. The problem area was role transitions – a transition from an individual who

was in relatively good health to someone with health problems and associated physical limitations. The goal of therapy was to help her to come to emotional terms with how her life had changed and find ways to make her current life more meaningful.

Therapy involved ongoing discussion of depression and depressive symptoms. She attributed depressive symptoms to a lack of will and failure of character. Ongoing monitoring of depression helped clarify that her depressive symptoms fluctuated with issues tied to her health problems, how she managed them, and efforts she made to expand the range of meaningful activities. During the course of the intermediate sessions, the patient expressed regret that she had not cared for her health in younger years and felt that she was to blame for her current health problems. Even when she began to have significant health problems, initially she did not comply with medical recommendations. As noted, reluctantly she had agreed to undergo a medical procedure that had unexpected side effects and which further impaired her ability to function. It was at this point Mrs. Washington became depressed. During therapy she began to make small efforts to complete neglected household tasks, see friends, and resume some social activities. Her physician recommended another medical procedure. The therapist facilitated a discussion about what she needed to know about the procedure. She decided to speak with her physician about both the potentially favorable and unfavorable outcomes of the procedure – in a way she hadn't done previously. Finally she agreed to undergo the procedure but negotiated with the physician how, when, and where the procedure would be completed. The procedure had a favorable outcome. She felt empowered that she had been an active participant in her medical care and was less depressed. She continued to increase involvement with friends and activities, which further decreased her depression.

Interpersonal Role Disputes. Mr. Fort is an 85-year-old widowed European American man with multiple health problems. He sought treatment because of depression and associated conflict with his daughter. Mr. Fort was encouraged by his daughter to live with her and her family

following the death of Mr. Fort's wife. He had moved in with his daughter 2 years prior to seeing the therapist. At first things went well with his daughter and her family. Increasingly, however, he felt disappointed that he was not "really part of the family," that his daughter did not spend enough time with him, and that his grandson seemed disinterested in him. He grew increasingly depressed and intermittently expressed anger and disappointment toward family members that he felt made them even more distant from him. The identified problem area was interpersonal role disputes, and the goal of therapy was to help him to clarify the issues in the dispute, his expectations of his daughter and her family, and options to improve the dispute.

At the beginning of the intermediate sessions, Mr. Fort expressed criticism, anger, and disappointment toward his daughter. The therapist engaged him in a detailed discussion of what transpired before, during, and after conflicts with his daughter or her family members. It became evident that he had different expectations than his daughter about what it would be like to live together. He expected his daughter to make him an integral member of her household in the same way that he felt he did with his aged mother when she moved in with him. The therapist asked Mr. Fort to think of different options to deal with the unsatisfactory and conflictual living arrangement. He made efforts to try to get his daughter to change her family routines so that they would spend more time with each other. This effort did not work to his satisfaction. In the end, Mr. Fort decided that because of his declining health, there were advantages to living with his daughter's family. He remarked, "I'll just have to change my expectations." He did change his expectations and accepted that he would not have the living arrangement he had first envisioned. The result was reduced frustration and depression and more congenial relations with his daughter and her family.

Grief. Mr. Garcia is a 78-year-old Hispanic American man whose wife died about 10 years prior to starting therapy. He remarried shortly after his wife died. He had had depressive symptoms since the death of his wife, and in the last year his

symptoms grew worse. He was referred by his primary care physician for since he did not show substantive reduction in depression after being prescribed several antidepressants. Mr. Garcia did not feel that he ever fully grieved the death of his wife. Although he and his wife had a congenial relationship, he felt distant from her. Further, he had recurrent thoughts about his deceased wife and actively missed her. Notably he retained his deceased wife's ashes in his home. The identified problem area was grief with the goal of facilitating the mourning process and helping the patient to more fully engage in his current life. Many of the intermediate sessions focused on recollections of his deceased wife and their relationship. At first, the patient resisted discussion of his deceased wife, and it was apparent that it was painful for him to talk about her. He was encouraged to bring in pictures of his wife and other memorabilia. The therapist persisted in facilitating discussion of both positive and negative aspects of his relationship. Mr. Garcia talked about the early years of his marriage during which he said he was unfaithful, insensitive, and, at times, cruel toward his wife – actions which he deeply regretted. The therapist pressed the patient to talk in detail about specific incidents that he found most difficult to discuss. He said that he did not feel that he deserved someone as caring as his wife. He recounted the circumstances surrounding his wife's illness and the pain of seeing her physically deteriorate. He acknowledged that despite regrettable behavior during the early years of their marriage, he provided reliable help to her at the end of her life. As therapy was ending, Mr. Garcia said that he wanted to bury his wife's ashes since "Now I can release her." He arranged a ceremony with family members at which they buried his wife's ashes. By the end of psychotherapy, the patient's depression was significantly improved, and he felt closer with his current wife.

Interpersonal Deficits. Mr. Carl is a 78-year-old European American man who had been widowed for about 1 year. His primary care physician referred him because he appeared depressed, lonely, and evidenced difficulties adjusting to the loss of his wife. In the initial sessions, he reported that his grief lessened over

the past year and he appeared to have come to emotional terms with the loss of his wife. However, he complained of social isolation and depression. He had four children, three of whom lived in another part of the country. One son lived near him, but he never felt close to him and they had little contact. A review of his social history revealed that Mr. Carl heavily depended on his wife to arrange social engagements with friends and family. During her lengthy illness, both he and she became more socially isolated as she was less capable of reaching out to others. During the months following his wife's death, family and friends paid condolence calls, but those visits lessened in frequency. A year after his wife's death, he felt he had little to do and limited contact with others despite a desire for social contact. He appeared to lack knowledge and skills of how to initiate, sustain, and respond to social invitations with others. Interpersonal deficits were the IPT problem area, and goal of therapy was to reduce Mr. Carl's social isolation.

During the intermediate sessions the therapist worked with Mr. Carl to clarify past efforts on his part – independent of those initiated by his wife – to socially connect with others. He had some work friends, but after he retired contact with them lessened especially when his wife became sick. He casually mentioned that after his wife's death his work friends had called and invited him out a number of times. He said he refused the invitations because he was grieving and did not want to be with people. He had received other invitations. Couples with whom he and his wife had previously socialized repeatedly asked him for dinner, but he did not respond to their messages on his answering machine. He said he was not comfortable socializing with couples without his wife. His children had invited him for visits to their homes, but he did not feel up to traveling after his wife's death. He understood that people stopped calling him because he repeatedly said no to their invitations. Now he was feeling lonely and wanted contact but did not know how to initiate it. "My wife always did that." Most of the intermediate sessions were

devoted to engagement of Mr. Carl in reviewing options for increasing social contact, building skills around how to connect with others, discussing the unwritten rules of social protocol, rehearsing conversational skills, role playing anticipated conversations with others, and reviewing his experience of being with others. By the end of treatment, Mr. Carl had rekindled a work relationship, responded to an invitation by a couple to come to their home for dinner, and agreed to a visit with an out-of-town child. He was less depressed and felt more confident of his ability to further rebuild his social world.

Future Directions

The rapid growth of numbers of older adults will mean that many mental health providers will be seeing older people in clinical practice. Depression is a common presenting clinical problem of older people seeking treatment and interpersonally relevant issues are often a precipitant of depression. IPT is useful and well suited for depression in older adults and can be effectively taught to graduate students and postlicensure professionals. The challenge for mental health care providers is that many did not learn IPT or other evidence-based psychotherapies in their training. Even today, they are not substantively taught in graduate education or in internship or practicum placements (Weissman et al. 2006). The US Department of Veterans Affairs Healthcare System (VHA) is a model of how to train postlicensure clinicians in evidence-based treatments and integrate them into practice (Stewart et al. 2014). Sustained efforts for accountability in health care will likely create incentives for graduate programs to substantively teach and for practitioners to deliver evidence-based psychotherapies since better clinical outcomes are tied to reduced health care costs. IPT researchers will continue to adapt and test this psychotherapy's utility for additional problems and population including subpopulations of older adults such as those with cognitive impairment and in long-term care (Miller 2009).

Collaborative care; Interdisciplinary; Multidisciplinary; Transdisciplinary; Treatment teams

Definition

Interprofessional care consists of the ways in which providers across multiple disciplines collaborate to provide comprehensive care and care planning for patients. This method of care management provides an opportunity for more holistic care as the treatment team is able to address the biopsychosocial needs of the patients in a more efficient and effective manner.

Population Aging and the Need for an Interdisciplinary Care

In developed nations over the past century, we have seen an increase in life expectancy and the number of adults aged 65 and older. It is believed that this increase in life expectancy has a great deal to do with improved sanitation and more efficacious treatment of infectious disease. Therefore, people are simply living longer. In the USA, for example, it is estimated that by the year 2020 older adults will account for more than 20% of the entire population. Nevertheless, this increase in life-span brings along an increased likelihood of developing chronic medical conditions. Over the

life-span, people in developed nations are seeing increasing rates of hypertension and diabetes, which are chronic conditions that also pose as risk factors for a number of more serious illnesses. Also, as the likelihood of having multiple medical conditions increases, so does debility. For minority and immigrant older adult populations, the rates of multiple chronic conditions are even greater. Minority and immigrant elders are thought to be at much greater risk due to experienced health disparities related to access, race and ethnicity, and quality of healthcare (Wegner et al. 2003; Gauthier and Serber 2005).

With multiple comorbidities, debility, and accompanying functional decline, management of one's healthcare becomes more complex. Older adults, who are no longer able to manage their complex care, need additional support from a caregiver and in some cases institutionalization. All of these factors combine to create very complicated profiles for the geriatric patient population. From a biopsychosocial perspective, the interrelationship between physiological, psychological, and social statuses must be addressed in older adults to provide adequate care in these complex cases. Therefore, older adults require more comprehensive and holistic care from multiple providers. The method identified to address the many issues faced by those with complex medical issues is interprofessional care. Interprofessional care requires professionals to come together across disciplines to collaborate in assessment, treatment planning, and interventions. These treatment teams not only provide more efficient care but more efficacious treatment. Numerous gerontological and other professional organizations have identified interprofessional care as the recommended method of care delivery for older adults due their complex care needs (Partnership for Health in Aging 2014). Nevertheless, the structure of the current healthcare system does not always facilitate interdisciplinary management, and more often than not if there are interdisciplinary teams, psychology is not involved. Therefore, this chapter looks to explore the need for interdisciplinary care, the structure of care teams, the role psychologists play on interprofessional teams,

training needs, policy, and barriers to care provision.

The current healthcare system is characterized as fragmented and disconnected, with providers across multiple settings. This requires those already burdened with illness, and their caregivers, to manage and navigate a fractured system often with little support. In addition, prevention is the most powerful tool in healthcare, yet our healthcare system remains primarily focused on treatment of disease. This focus on treatment often is not inclusive of palliative care options or patient-focused care. The provision of value based care with a focus on improving quality of life throughout and not simply at the end of life. In many instances the majority of patient care is managed in primary care. Unfortunately, with the low numbers of practicing geriatricians, this poses numerous problems for many older adults as they tend to rely on primary care to not only address their physical issues but also their mental healthcare needs (American Psychological Association and Presidential Task Force on Integrated Health Care for an Aging Population 2008). Often primary care providers lack adequate training in geriatric issues and may make ageist assumptions about disability, chronic illness, and cognitive impairments. Therefore, geropsychologists must join with other providers to address the unique issues facing the geriatric population across treatment settings by becoming members of interdisciplinary teams.

Integrated Care

Ideally, integrated care would focus on a single setting for the provision of care in a clinic, a home care team, or a consultation team working in a hospital. Next, the idea of looking at care in a holistic manner where there are multiple aspects of the patient is considered and each patient is approached as a unique individual. Therefore, integrated care focuses on providing holistic care that is patient centered. With integrated care the team has a broader reach and can therefore assess, intervene, and manage a much broader range of problems. There are a number of team models, but

ideally the team will work toward developing a comprehensive and cohesive plan of care. This is probably the most important aspect of integrated care and why it is the preferred method for managing complex patients and specifically older adults. In order to develop this plan, all individuals must collaborate and continually work together to manage and modify the plan of care with ongoing assessment. Such collaboration requires fluid communication and information sharing across disciplines.

In order to truly note the benefits of collaborative integrated care, the focus of treatment must be seen through a biopsychosocial framework. There must be respect for and understanding of the usefulness of the work done by all disciplines. Members of a treatment team must understand that there is not only value in the work done by others, but that there is multidirectional influence from one area to the next. There should be clear understanding by all members of the team that physiological changes can influence a person's psychological state which in turn will change their social situation and vice versa. Although patient care often takes place in primarily traditional medical-focused settings, all members of the team must understand that each aspect of care is of great significance. Older adults tend to present with physiological symptoms that are rooted in psychological distress and/or resulting from a lack of resources and adequate social support (American Psychological Association and Presidential Task Force on Integrated Health Care for an Aging Population 2008). For this reason, all members of interprofessional teams must be involved in assessment and ongoing intervention and management.

Benefits of Integrated Care

So what are the benefits of integrated care, and why has there been such a focus on changing the system? One major benefit of integrated care is the ability to address the fragmented healthcare system (American Psychological Association and Presidential Task Force on Integrated Health Care for an Aging Population 2008). Collaborative care

often eliminates the need for multiple appointments in a variety of locations resulting in increased access and more fluid care. Collaborative care also allows for improved screening and monitoring through information sharing. Assessments are completed in combination, which allows the team to address a range of issues at once. Moreover, integrated care allows the team to simultaneously address mind-body issues and reinforces the importance of mind-body relationships to patients and caregivers (Karel et al. 2012). The care team addresses more comprehensively modifiable risks by implementing services and providing additional support to the patient, caregiver, and families when needed. In addition, when consults are needed, teams are able to more efficiently make use of specialty clinics and other teams as they have a broader picture and can more accurately assess the patient's specific needs. Often interprofessional team management increases communication as well. Due to the numerous benefits, there is increased patient satisfaction as well as provider satisfaction in integrated care settings. The increased satisfaction is not simply perceived by patients and providers, but there is evidence that outcomes for patients are greatly improved (Hirth et al. 2009; Famadas et al. 2008). The resulting improvements in patient outcomes have resulted in numerous national and international organizations with a focus on geriatrics, aging, and complex care management including the Gerontological Society of America (GSA), the American Geriatrics Society, the National Institute for Care of the Elderly (NICE), and the International Federation on Ageing, to name a few, to highly recommend the provision of integrated care (Partnership for Health in Aging 2014).

How to Begin

Many practitioners are interested in implementing integrated care and forming interdisciplinary teams. Nevertheless, they are faced with questions of how to implement this care within the current structure. Many professionals practice independently or within organizations where disciplines

practice in silos. How does a provider, a unit, and/or an organization come together to form an integrated care team? First, the team must begin where they are. Often organizations need proof or outcomes in order to fund a new initiative. Therefore, many teams must begin with a few providers working together to form a team. The new team likely has members under the direction of numerous departments. The team should come together to meet an identified need within the organization or a specific need for an identified population. The team must be savvy and understand the language and culture of the organization so that they can build within the structure of the organization. Also, the team can work to reach their goals within a specified clinic or group experience from which they can build. Therefore, it may be necessary to start small and then gradually expand. As an example, many times there is a need to address dementia assessment, diagnosis, and treatment in primary care. In a primary care setting, there often is not enough time to comprehensively address patient and family needs in this area. Therefore, providers may decide to offer an interdisciplinary memory clinic that specifically assesses patients referred from primary care for dementia and related disorders. In addition, this clinic could go a step further to provide the patient and caregiver with resources and guidance for future care. All of this information would be integrated into an individual treatment plan made available to the primary care provider addressing the patient's current needs. This memory clinic although very specific and small initially fills a need for the organization, provides comprehensive dementia assessment and care planning that could not be accomplished by one provider, and identifies and meets the needs of those patients and family members assessed. The interdisciplinary memory clinic has therefore met the needs of the organization and the patients. In addition, if the clinic has measurable outcomes, this would allow for improvement in the future and identification of both strengths and weaknesses of the project. If the clinic is successful, the organization and providers are very likely to support continuation and expansion if necessary. Again, the team can start small with a specific goal and expand

accordingly. Teams as with other providers must act as one and provide services as well as feedback in a timely manner. If a provider or another team cannot reach the provider or they are not provided with the resulting assessment and treatment plan, then many others will not want to use the services in the future. This conceptualization and model was used in developing the Memphis Dementia Clinic model (Jacobson et al. 2012).

Team Models

There are differing team models. The ideal function of a team would be to have fully integrated care in one location. However, due to the structure of most current medical systems and limitations on space, time, and reimbursement, establishing fully integrated care poses a challenge for providers. Therefore there are numerous ways in which teams operate. Here three different team models are described: multidisciplinary, interdisciplinary, and transdisciplinary. The models of care are dependent on the setting, communication style of the team, and the provider roles (Partnership for Health in Aging Workgroup on Multidisciplinary Competencies in Geriatrics 2010). Many collaborative care teams are set up as multidisciplinary teams. In these teams, the care is collaborative; however, the members contributions are additive as they tend to practice independently but in parallel. Oftentimes the teams are colocated, but each individual member performs their own assessment. The disciplines although working together have independent discipline-specific goals. The roles of the providers are often more clearly defined as the providers are focused on their discipline-specific treatment plans. In addition, there tends to be a hierarchy as the team shares information but one discipline takes on primary management, which oftentimes is medicine. Many times this manner of care is confused for interdisciplinary due to the fact that other disciplines are present. However, this is not the case as the care is collaborative but not integrated. For example, in this team type, another provider may consult the psychologist. The psychologist performs their own

discipline-specific intake and develops goals of care and recommendations. The results of this assessment and intervention can be brought to the team in a treatment team meeting or the providers could be notified about the results electronically or through traditional records. The team does not have one integrated treatment plan in this scenario but numerous plans being implemented simultaneously.

The second type of team is the interdisciplinary team. This is the treatment style that is clearly identified as the useful model of care in geriatrics. The care is fully collaborative unlike the multidisciplinary team that is simply colocated and shares information. The highlight of this treatment style is the fully integrated treatment plan. Each discipline is working toward united goals of care and they often have overlapping roles and skills that allow for the team to perform as one. In addition, there is no hierarchy as the team works together to make all care decisions. On interdisciplinary teams psychologists usually receive information about new patients at the time of consultation or initial intake. The members of the team can perform the initial intake in combination or they all provide initial assessment individually and come together in regular treatment team meetings to develop a unified plan of care for the patient. The team usually communicates their findings to address the biopsychosocial issues with each member contributing to the treatment plan and all members being involved with intervention and maintenance as needed. Often the needs of the patient may dictate the continued level of involvement in the intervention, but all team members remain available reviewing the case in treatment team as long as the team is managing the patient's care. In this team structure, psychologists may provide cognitive assessment and initial mood management. Results of assessment would be shared with the team, which could lead to continued psychotherapy for the patient. Psychotherapy could assist the patient in adjusting to and coping with a new chronic medical condition. Psychology could also assist the patient in determining goals of care and continue to assist with communication with the team and other professionals for the duration of their care.

The third type of team is the transdisciplinary team. This type of treatment team is the ultimate in collaboration. The providers on this type of team are able to provide more holistic care for their patients. There is a single treatment plan that has been developed for the patient by all members. The team not only understands the roles of other providers, but this collaboration has allowed for the expansion of their roles. As the members work together, they learn more about their teammates and the other discipline's roles. This allows for more seamless information sharing and integration. The team also trains together to learn skills specific to their care provision, and therefore multiple if not all providers are able to perform certain tasks equally. In this team style, the team members share leadership responsibilities, as again they are working toward the same goals. Palliative care and hospice are modeled after this style of care team. These teams work to provide values based on patient-centered care, so assessment and treatment are focused on the patient's goals of care for all providers. In this treatment team structure, psychologists may work with the other team members to devise a team initial assessment measure, which gathers pertinent information for all members. The psychologist will use this information to determine if further evaluation is necessary and make treatment or other recommendations along with the team members. Also, due to the nature of the team and the overlap in roles, the psychologist and other members of the team may share responsibilities in assessment, in documentation, and on some interventions as the roles can expand to include specialty-specific assessment. As in palliative care, most members of the treatment team are able to assess symptoms and goals of care and are well versed on end-of-life planning. This information is then taken back to the team to develop the integrated treatment plan.

Interprofessional Training/ Multidisciplinary Competencies

As healthcare moves toward more interprofessional team care, healthcare providers must learn to work together across multiple settings.

Therefore, learning to work on a high-functioning interdisciplinary team should be incorporated into the training of all healthcare professionals so that they are able to provide optimal care to older adults (Karel et al. 2012; Fulmer et al. 2005). Although healthcare is moving in the direction of integrated care, most disciplines continue to train students in silos with very limited opportunities for collaboration and even fewer opportunities for integrated practice (Partnership for Health in Aging 2014). Trainees across disciplines are missing opportunities to gain reciprocal knowledge. Due to the highly beneficial nature of integrated care, it is recommended that across the learning spectrum opportunities there would be opportunities to engage in interdisciplinary training (Partnership for Health in Aging 2014). This training should consist of understanding the need for integrated care, learning to work collaboratively, and the unique aspects of collaborative care across numerous settings including acute care, clinical care, long-term care, and care within the home (Leipzig et al. 2002).

Presently, there are several geropsychology training programs that have moved toward incorporating integrated care into the curriculum (Leipzig et al. 2002). Internationally, many geropsychology programs are using the Pikes Peak model as a tool for developing graduate and postdoctoral curriculum and didactics, which is inclusive of interdisciplinary training as a competency (Pachana et al. 2010). The University of Alabama, for instance, has worked extensively to develop a comprehensive graduate geropsychology training program, and they have included interdisciplinary clinical practice as well as classroom experience within the program. Specifically, they have developed an interdisciplinary Health and Aging course, which includes faculty from disciplines outside of psychology (Warton et al. 2013). In addition, there are a growing number of interprofessional training programs, which work to provide shared learning experiences for trainees across disciplines. Within these programs, the didactics, rotations, and many projects involve collaboration; participants are often at similar developmental levels in their professional training so that they are working with

others at similar expected competency levels (Partnership for Health in Aging Workgroup on Multidisciplinary Competencies in Geriatrics 2010).

Interprofessional programs must have primary faculty across disciplines to provide guidance and support to the trainees and appropriately modeled collaborative care and to ensure that discipline-specific competencies are appropriately evaluated in order to be successful. Overall, numerous professional organizations, accrediting bodies, credentialing, and licensing boards are recommending and supporting interprofessional training programs (Partnership for Health in Aging 2014; American Psychological Association and Presidential Task Force on Integrated Health Care for an Aging Population 2008).

Barriers and Difficulties Associated with Interprofessional Teams

The numerous benefits of collaborative interprofessional care have been stated, but as with any manner of care there are a number of barriers to implementation. First, there are institutional difficulties. The structure of the healthcare system is such that many providers are under the management of discipline-specific departments. This often means that providers have variations in professional/department expectations, time and availability to the team, space allocation, different direct supervisors, and various other discipline-specific professional requirements. These differences can pose as challenges for the team. The team may have varying levels of support across departments, which can lead to unequal workload. Documentation and coding of appointments becomes more complex when working in team settings, so teams must ensure that all members are accumulating adequate and accurate workload. Scheduling of team meetings and treatment planning can also be very difficult, especially if providers do not have time fully dedicated to the team or there are differences across disciplines in availability. Therefore, providers must work together to form a team plan. It is helpful for the team to define their purpose and goals for

provision of care. The purpose of the team should be clearly defined and patient centered. In using the Memphis memory clinic example mentioned previously, the purpose of the team would be to provide comprehensive assessment, treatment planning, and resources for patients and their caregivers (Jacobson et al. 2012). Therefore, the team must decide what patients are appropriate and what the shared responsibilities would be for each discipline. In this example, the memory clinic team determined that they will take referrals from primary care of outpatients over 85 years of age and those exhibiting likely cognitive impairment. This specificity allows multiple disciplines to clearly understand the usefulness of the clinic and assists in developing an understanding of roles of the contributing healthcare providers. Psychology will provide the neurocognitive assessment, the geriatrician will provide the physical and neurological evaluation, the geriatric pharmacy will perform medication reconciliation, and social work would provide the family with necessary resource recommendation and advance care planning. With clear goals and discipline-specific tasks, the team comes together to create an integrated treatment plan. Without this prior planning, the goal of the clinic and roles on the team could be interpreted very differently by members of the team resulting in conflict and loss of efficiency and effectiveness, as well as providers feeling as though their skills are being utilized inappropriately. Taken together, this can ultimately lead to conflict. Planning can often decrease the likelihood of role-based conflict.

In addition to systemic issues, the team must also understand and learn to work with one another. Enhanced communication is the ultimate benefit of collaborative care; however, poor communication is often the greatest barrier to implementation of team care (Leipzig et al. 2002). Teams therefore must learn to work together. Of the utmost importance is mutual respect for the role and value of each team member. All disciplines must take the time to learn and understand the competencies and roles of the treatment team members. Often many disciplines have overlapping abilities, which is often expected and appreciated. Nevertheless, many teams have great difficulty when providers

are unclear about their role on the team and feel threatened or defensive about their area of practice (Leipzig et al. 2002). Bearing this in mind, teams must work to better understand one another by developing trust and expressing appreciation. Teams should meet consistently to not only discuss patient care but treatment team management. Team members should work to foster positive relationships with their fellow team members and provide support as appropriate in the professional environment. Providers who are happy and satisfied with their work provide better care overall (Leipzig et al. 2002). Again, members of teams have the benefit of shared experience and can process difficulties together as well as celebrate triumphs.

Policy Issues

As healthcare adopts interprofessional care as a preferred method of care, policy change must follow to make room for the implementation and maintenance of these teams. This includes improving reimbursement across disciplines for interdisciplinary encounters. For instance, in the USA, there are now Current Procedural Terminology (CPT) codes (medical codes maintained by the American Medical Association (AMA) that describe the medical diagnosis services similar to the ICD-10 coding but speak to the service or procedure and not necessarily the diagnosis) for team conferences as well as health and behavior codes that can be used when providing care to patients whose primary issue is a medical condition and who may not have a psychiatric diagnosis (Karel et al. 2012). These new codes are great improvements that will assist in interdisciplinary care provision. Nevertheless, there is great need for additional support, as these nontraditional roles for healthcare providers will call for changes in workload. Due to the increased need for collaboration across disciplines, many providers spend a great deal of time outside treatment team meetings consulting with team members about patient care. Also, institutional support for interprofessional care is of great importance as it dictates the sustainability of care teams and again can eliminate some of the discussed barriers to implementation.

Supplementary financial support is also of great importance due to the changes in coding; the collaborative care settings are often not as profitable for individual providers as traditional clinics (Partnership for Health in Aging 2014).

Psychologists' Unique Contribution

Psychologists have a great deal to offer interprofessional teams. They have the ability to perform cognitive assessments, mood assessment, and capacity evaluations. Psychologists have the ability to intervene using non-pharmacological behavior management (especially important for those patients with dementia), evidence-based therapies, supportive therapies, relaxation, and enhanced communication. In addition, psychologists are helpful in providing caregiver support and bereavement services for the patient and family. Geropsychologists also have the unique skill set of understanding the geriatric population and how to modify assessment and intervention methods to address the specific needs of the population. Geropsychologists are adept to understanding the impact of sensory loss, functional decline, and debility. Furthermore, conceptualizing patients from the biopsychosocial perspective gives insight into the influence and interactions between physiological change, social change, and psychological change. Geropsychologists should be familiar with delirium, dementias, the neurocognitive effects of certain medications, methods for non-pharmacological symptom management, and the influence of environmental change, family dynamics, and changing social roles. Geropsychology board certification now provides a method to identify as an expert provider with these geriatric-specific competencies (for more information on this, see the entry on Training Psychologists in Aging) (Karel et al. 2012).

Advocacy

Many times psychologists' skills are overlooked, and they are not always included as healthcare

providers on interprofessional teams (American Psychological Association and Presidential Task Force on Integrated Health Care for an Aging Population 2008). Psychologists therefore must advocate for inclusion. Patients, caregivers, families, and other providers can greatly benefit from the skills that psychologists bring to the table. Psychologists also benefit from working within these team structures as they are able to improve communication and often intervene much earlier than if they were consulted separately. Psychologists and other providers who work on interdisciplinary teams learn a great deal more about their patients, which in turn informs future practice. Psychologists must advocate by speaking to the unique contributions that they bring to the interprofessional table. Psychologists, however, must first be seated at the table. Psychologists should therefore become more informed about policy issues and legislation that influence research and practice, with specific attention paid to policies that support psychologists' participation in treatment teams as well as support appropriate reimbursement. As stated previously, more often than not, other disciplines do not understand the education, training, and competencies of psychologists and more specifically geropsychologists. Psychologists need to inform other providers of the services that can be offered, with a focus on how these services and skills when provided in collaboration improve overall patient care. Advocacy on a national level begins with collaboration between professional psychological organizations and other national professional organizations to expand the reach of the message. The Partnership for Health in Aging is a coalition of 35 member professional organizations that has continued to detail the necessity of integrated care as well as training. This work can also take place within interdisciplinary national organizations such as The Gerontological Society of America (GSA), which advocates and promotes improved care for older adults and all professionals with a geriatric focus in the USA, as well as international organizations such as the International Federation on Ageing, NICE, and the International Association of Gerontology and Geriatrics (IAGG) which advocate globally for aging issues in

research, training, and care provision through collaborative intergovernmental and multinational organization collaboration. Individual psychologists can also advocate in their individual workplace by offering to work with providers from multiple disciplines to not only demonstrate the services provided, but to importantly demonstrate an interest in others' work as well and how collaboration is overall beneficial in daily practice.

Summary

Overall, interprofessional treatment teams are thought to provide the most comprehensive care for the complex care needs of the geriatric population. Integrated care shows numerous benefits for the patients in providing improved access, more holistic care, and more efficacious management. As for providers, interprofessional care allows them to have access to more information and develop a more integrated treatment plan. Providers of integrated care, when performed appropriately, are more satisfied with their jobs and their patients have more positive outcomes. There are three types of interprofessional teams, with interdisciplinary teams being the standard and transdisciplinary team care provision being an ultimate goal. There can be numerous barriers to the provision of team care at the institutional as well as individual provider level. Communication is thought to be one of the most beneficial aspects of collaborative care for providers, but lack of communication can be devastating to the implementation of team processes. Getting a team started requires some initial planning, but once started the outcomes are mostly positive. With the focus on increasing the number of interprofessional teams, it is important to incorporate interprofessional collaboration in training across the training continuum. For psychologists it is very important to understand the role they can serve on the team. All too often psychology is not at the table when it comes to integrated teams. Therefore, psychologists must advocate for team participation as the development of policy that will support the implementation of integrated care teams across settings for sustained comprehensive geriatric care.

Brain training; Cognitive stimulation; Non-pharmacological interventions

Definition

Interventions or techniques designed to prevent cognitive impairment, slow cognitive decline, or enhance cognitive function.

Introduction

In 2015, the number of people living with dementia worldwide was estimated at 47.47 million, and this number is projected to triple by 2050. The total estimated worldwide costs of dementia were \$604 billion in 2010, which is equivalent to 1% of the world's gross domestic product. Moreover, dementia is a significant contributor to the disability and dependency experienced in late-life. Currently, there are no effective pharmacological interventions that slow or stop this progressive

cognitive decline. In recognition of the global prevalence of dementia and its costly economic impact, the World Health Organization and Alzheimer's Disease International declared dementia an international public health crisis and urged the global community to mobilize their resources for immediate action (World Health Organization 2012). In conjunction with the continual efforts to develop effective pharmacological treatments, efforts to identify modifiable risk factors for dementia and effective nonpharmacological interventions have steadily grown. These promising areas of research may serve as important components in risk-reduction strategies that can minimize the number of affected individuals worldwide.

Dementia is a nonspecific umbrella term that describes the clinical syndrome of cognitive and functional impairment, yet the term "dementia" does not assume a particular etiology. The two most common causes of dementia are Alzheimer's disease (AD) (accounting for 60–80%) and cerebrovascular disease (10–20%), though on autopsy most patients with AD also have concomitant cerebrovascular disease. Given that AD and cerebrovascular disease account for a preponderance of cases of mild cognitive impairment (MCI) and dementia, the bulk of research on nonpharmacological interventions has focused on these etiologies. Thusly, information presented henceforward will focus on MCI and dementia presumed due to AD and/or the cerebrovascular disease.

Modifiable Risk Factors

In the absence of treatments that cure or slow the progressive decline, the World Dementia Council (WDC) has emphasized prevention as a key element to counteract the international dementia public health crisis (Baumgart et al. 2015). Much of the prevention efforts have focused on the identification of modifiable risk factors as they represent opportunities for intervention to reduce late-life cognitive impairment. It has been suggested that delaying symptom onset by 1 year may lower AD prevalence by more than

nine million cases over the next 40 years (Barnes and Yaffe 2011).

Hypertension. The relationship between hypertension and cognitive function appears to change with age. At midlife, but not late-life, hypertension is associated with an increased risk of AD and dementia, with a weighted Odds Ratio (OR) of 1.61 (95% CI: 1.16, 2.24). The authors calculated the population attributable risk (PAR) of hypertension (in addition to other dementia risk factors described below); PAR refers to the proportion of cases of a disease in a population that can be attributed to a given risk factor, assuming that there is a causal relationship. This estimate takes into account the strength of the association between the risk factor and the outcome, in addition to the prevalence of the risk factor. Based on this equation, approximately 5% (1.7 million) of AD cases worldwide are potentially attributable to midlife hypertension. If the prevalence of midlife hypertension was reduced by 10%, there could be more than 160,000 fewer AD cases; a 25% reduction in midlife hypertension would be associated with more than 400,000 fewer AD cases worldwide (Barnes and Yaffe 2011).

Hyperlipidemia. The relationship between cholesterol levels and cognition appears to be complex and nonlinear. Cholesterol levels appear to decline before the onset of dementia with a greater decline in cholesterol from mid- to late-life is associated with more severe cognitive impairment in late-life (Rusanen et al. 2011).

Smoking. It is well recognized that smoking augments oxidative stress and inflammation, which are believed to be important pathophysiologic mechanisms in AD. Although the conferred risk of smoking has differed in the literature, the most comprehensive meta-analysis reported a relative risk (RR) of 1.59 for AD, or put another way, smoking increased the average risk of developing dementia by around 50% (Barnes and Yaffe 2011). Yet it is not clear if a linear dose-relationship exists between smoking and cognitive impairment. Persons smoking more than two packs per day were almost twice as likely to develop AD (HR, 2.57; 95% CI, 1.63–4.03) yet there was no statistically significant increased risk in those smoking under two packs per day.

When compared to nonsmokers, those smoking more than two packs per day in midlife were almost three times (HR, 2.72; 95% CI, 1.20–6.18) more likely to develop vascular dementia in late-life. It is estimated that nearly 14% (4.7 million) of AD cases worldwide and 11% (575,000) in the USA are attributable to smoking (Hughes and Ganguli 2009). A 10% reduction in smoking prevalence could potentially reduce the number of AD cases by 400,000 cases globally and 50,000 in the USA (Barnes and Yaffe 2011).

Obesity. Similar to hypertension, the association between weight and AD appears to change with age. In a 36-year follow-up study of 136 adults aged 40–45 years, compared with normal weight, those who were overweight had a twofold increased risk of AD and vascular dementia, while obesity was associated with three times and five times higher risk of AD and vascular dementia, respectively (Whitmer et al. 2007), yet obesity in late-life has been shown to possibly be protective against dementia (Fitzpatrick et al. 2009). Furthermore, midlife obesity and dementia risk have a RR estimate of 1.60 (95% CI: 1.34, 1.92), or put another way, midlife obesity conferred a 60% excess risk of developing dementia. Approximately 2% of (677,000) AD cases worldwide are potentially attributable to midlife obesity. In the USA, the PAR is higher – 7.3% (386,000 cases) – due to the higher prevalence of midlife obesity. A 10% reduction in midlife obesity prevalence could potentially prevent more than 66,000 AD cases worldwide and 36,000 cases in the USA (Barnes and Yaffe 2011).

Diabetes Mellitus. Diabetes mellitus is frequently associated with changes in cognition. A number of studies have implicated a relationship between insulin resistance and the pathogenesis of plaque formation and impaired neuronal signaling in AD. A recent meta-analysis showed that diabetic patients had a 73% increased risk of all type dementia, 56% increase of AD and 127% increase of VaD (Gudala et al. 2013). Approximately 2% (825,000) of AD cases worldwide are currently attributable to diabetes, including 3% (nearly 175,000) in the USA. A 10% reduction in diabetes prevalence could prevent more than 80,000 AD cases worldwide and nearly 17,000

cases in the USA could; a 25% reduction in diabetes prevalence could potentially prevent more than 200,000 cases worldwide and 40,000 cases in the USA (Barnes and Yaffe 2011).

Alcohol. Numerous studies have reported the beneficial effect of moderate alcohol consumption on cognitive function. The relationship between alcohol consumption and dementia and MCI risk appears to be U-shaped, with the greatest benefit garnered by those who drink in moderation. Consistent with this, abstainers and heavy drinkers appeared to be at higher risk of dementia, a recent systematic review reported moderate alcohol consumption significantly reduced overall risk of incident dementia by 38% and AD by 32%, but did not find a significant association with vascular dementia (Peters et al. 2008).

Sedentary Lifestyle. There is mounting support for the association between physical activity and dementia. In reviewing the extant physical activity literature, a systematic reviewed reported a RR of 1.39 (95% CI: 1.16, 1.67) for all-cause dementia and 1.82 (95% CI: 1.19, 2.78) for AD. Thus physical inactivity is associated with an almost 40% excess risk for all-cause dementia and an 80% excess risk for AD.

It has been estimated that approximately 13% (nearly 4.3 million) of AD cases worldwide may be attributable to physical inactivity, including 21% of the AD cases (>1.1 million) in the USA. A 10% reduction in the prevalence of physical inactivity could potentially prevent more than 380,000 AD cases globally and nearly 90,000 cases in the USA (Barnes and Yaffe 2011).

Diet. Observational studies on the relationship between diet and cognition have found that certain dietary practices and nutrient intake are predictive of cognitive decline and dementia. However, essentially all RCTs that have focused on specific nutrient components, including dietary fatty acids, fish oil, vitamins E and C, B6, B12, and folate, have generally produced negative or mixed results (Smith and Blumenthal 2010). Thus recent studies have moved from an individual nutrient approach to a whole diet approach. The Mediterranean diet, which is the most widely researched whole-diet approach, consists of a high consumption of vegetables, moderate consumption of fish

and wine, low consumption of dairy products and meat, and almost exclusive use of olive oil as the primary fat source. A recent review of the existing literature reported growing evidence of the beneficial cognitive effects of the Mediterranean diet (van de Rest et al. 2015).

To date, there has been one clinical trial that had baseline and follow-up neuropsychological testing. This study utilized a subcohort from the *Prevencion con Dieta Mediterranea* (PREDIMED) trial (Valls-Pedret et al. 2015). In this study, participants were randomized into one of three intervention groups: a Mediterranean diet supplemented with extra virgin olive oil, a Mediterranean diet supplemented with mixed nuts, or a control diet (advised to reduce all dietary fat) with a median follow-up up to 4.1 years. Results revealed that participants allocated to the Mediterranean diet plus nuts had improvement in memory compared to those in the control group. Similarly, participants in the Mediterranean diet plus olive oil had improved executive function and global cognition relative to the control group. However, there were no group differences in incidence of MCI or dementia.

The Dietary Approach to Stop Hypertension (DASH diet) is another diet that has been supported by emerging research in the cardiovascular disease literature. The DASH diet has been shown to protect against hypertension, obesity, cardiovascular disease, and diabetes – all of which are known to impact cognitive function. Like the Mediterranean diet, the DASH diet emphasizes plant-based foods, whole grains, low-fat dairy, and moderate amounts of lean meat and fish. The DASH diet differs from the Mediterranean diet as it includes more lean meat (the Mediterranean diet encourages less meat and more fish intake) and has more variety of fat source (the Mediterranean diet almost exclusively relies on olive oil as the primary fat). The DASH diet also specifies low consumption of saturated fat and sweets and higher consumption of dairy than the Mediterranean diet. The two diets also differ in respect to recommended amounts of alcohol consumption as the DASH diet allows for one to two drinks per day for women and men, respectively, whereas the Mediterranean

diet incorporates moderate consumption of wine. While there is less research on the DASH diet and cognition, observational studies do suggest that adherence to the DASH diet may be associated with slower rates of cognitive decline (Tangney et al. 2014).

Social Engagement. A systematic review of 29 longitudinal cohort studies reported that low social participation, less frequent social contact, and more loneliness were significantly associated with incident dementia. Low social participation [RR: 1.41 (95% CI: 1.13–1.75)], less frequent social contact [RR: 1.57 (95% CI: 1.32–1.85)], and more loneliness [RR: 1.58 (95% CI: 1.19–2.09)] were each independently significantly associated with incident dementia (Kuiper et al. 2015).

Depression. Late-life depression is associated with poorer general health and, in particular, has a strong association with greater burden of cardiovascular and cerebrovascular disease. Furthermore, depression is consistently an independent risk factor for AD, vascular dementia, and all-cause dementia. There continues to be debate as to whether late-life depression is a risk factor for or prodrome of dementia. The relationships between depressive symptoms and cerebrovascular disease appear to be bidirectional, giving rise to the term “vascular depression” (Butters et al. 2008). It may be that depression and dementia share common etiological factors as inflammation, vascular changes, and vascular risk factors have each been implicated in both disorders. A meta-analysis of 13 studies found that a history of depression was associated with an approximate twofold increase in risk of dementia, with pooled relative risk estimates of 2.01 (95% CI: 1.16, 3.50) for 7 case-control studies and 1.87 (95% CI: 1.09, 3.20) for 6 prospective studies (Barnes and Yaffe 2011). More than 10% (nearly 3.6 million) AD cases worldwide and almost 15% (>780,000) in the USA may be attributable to depression. A 10% reduction in depression prevalence could potentially result in more than 325,000 fewer AD cases worldwide and 67,000 fewer cases in the USA.

Cognitive Reserve. “Cognitive reserve” refers generally to the capacity of the brain to recruit

alternative neurological pathways to process tasks in a more efficient manner. As a result, brains with greater cognitive reserve can tolerate more damage or disease than brains with less cognitive reserve. The idea of reserve against brain damage emerged from the observation that there does not appear to be a clear relationship between the degree of brain neuropathology and extent of clinical symptomatology. Furthermore, it has been suggested that education or occupational attainment may protect one against the development of AD. In a meta-analysis that included 21,456 individuals, the risk of dementia was significantly lower for those with higher education (OR, 0.53; 95% CI: 0.45, 0.62), occupational attainment (OR, 0.56; 95% CI: 0.49, 0.65), intelligence/IQ (OR, 0.58; 95% CI: 0.44, 0.77), and mentally stimulating leisure activities (OR, 0.50; 95% CI: 0.42, 0.61) (Valenzuela 2008). When all of these cognitive reserve markers were combined, the pooled OR was 0.54 (95% CI: 0.49, 0.59). This can also be expressed as its inverse: the odds of dementia were significantly increased in those with low cognitive reserve (OR, 1.85; 95% CI: 1.69, 2.04). Worldwide, approximately 19% (6.5 million) of AD cases are potentially attributable to low education, including 7% (>385,000) cases in the USA. A 10% reduction in the prevalence of low educational attainment could potentially lower AD prevalence by more than 500,000 cases globally and 36,000 cases in the USA (Barnes and Yaffe 2011).

Summation of Risk Factors

While aforementioned risk factors is not exhaustive, it has been suggested that the seven potentially modifiable risk factors addressed in their study (e.g., hypertension, diabetes, smoking, physical inactivity, cognitive reserve, obesity, and depression) contribute to up to half of AD cases globally (17.2 million) and in the USA (2.9 million). If the prevalence of all seven risk factors were reduced by 10%, there would be as many as 1.1 million fewer AD cases globally and 184,000 fewer cases in the USA; if the prevalence of these risk factors were reduced by 25%, AD prevalence

could potentially be reduced by up to 3.0 million cases globally and 492,000 in the USA (Barnes and Yaffe 2011).

Interventions

Much of the research on nonpharmacological interventions for late-life cognitive impairment addresses, in part, the previously identified risk factors. The remainder of the chapter will now discuss two of the most widely studied nonpharmacological interventions for late-life cognitive impairment: cognitive training and physical exercise.

Cognitive Training. Cognitive training interventions can be grossly categorized as either remediation or compensation approaches. *Cognitive remediation interventions* seek to improve cognitive function through focused training and practice, whereas the *compensation interventions* promote independence and support daily functioning through modification of the environment via external aids (Rodakowski et al. 2015). Remediation interventions are more effective at improving selected cognitive abilities than compensation interventions. This is not surprising as the goal of compensation interventions is to teach individuals to adapt to changes in their cognitive function, rather than address specific cognitive abilities.

The Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) trial is the largest and most widely cited study of cognitive training in older adults. ACTIVE enrolled 2,802 nondemented, community-dwelling adults aged 65 years and older and randomly assigned them to one of four groups: memory training, reasoning training, speed-of-processing training, or no-contact control. Training was conducted in small groups in ten 60- to 75-min sessions over 5–6 weeks. Memory training focused on improving verbal episodic memory through by practicing learned memory strategies. Reasoning training focused on improving ability to solve problems that contain a serial pattern. Speed-of-processing training focused on visual scanning and information processing, where the speed and complexity

of stimuli grew increasingly more difficult. Each training intervention produced large and significant improvements in the trained cognitive ability that appeared to persist to at least 5 years for memory training and to 10 years for reasoning and speed-of-processing training.

Efforts to extend these cognitive benefits to those with mild to moderate cognitive impairment have generally been less successful than the ACTIVE trial or similar interventions with nondemented community-dwelling older adults. In a recent review of the literature of cognitive training interventions in MCI and early dementia, 12 of the 20 studies reported significant differences in cognition posttraining between control and treatment group (favoring the treatment group), but the between-group differences were generally modest (Rodakowski et al. 2015). Cognitive training focusing on memory included the teaching of compensatory and restorative strategies including errorless learning, spaced retrieval, visual imagery, associative learning, cueing, categorization, hierarchical organization, and method of loci. Across the 12 studies, intervention effects on cognitive function were generally detected in indices of working memory and delayed memory. Studies that combined cognitive training with some form of holistic or psychotherapeutic approach (i.e., social engagement, stress management) all demonstrated small improvements in cognitive function (compared to active and nonactive controls), suggesting that multimodal approaches should be further pursued in future research.

In addition to the in-person skills-based cognitive training programs discussed above, computerized cognitive training programs have emerged to combat MCI and dementia – but not without controversy. Computerized training has become a \$2 billion industry, and the concern has emerged that society's desire for an accessible and convenient intervention for dementia may supersede the scientific community's ability to adhere to the rigorous scientific process that clinical trials require. Given this ethical issue, computerized cognitive training has become an ongoing area of controversy, as many have questioned the quality (and often motives) of extant research.

There are numerous issues that face the computerized training field. First, critics have questioned whether computerized training improves cognition in a manner that extends beyond the task being trained. Put another way, critics ask do the training benefits generalize to daily functioning? Second, the utility of possible computerized training transfer effects is often questioned. Critics suggest that the reported benefits represent only statistically significant effects with little to no clinically significant benefits seen in cognitive or daily functioning.

Third, it is not clear from the computerized training literature as to what is considered the proper type of cognitive training, how often one must engage in training, and how long the benefits last (i.e., is this a time-limited intervention or a lifestyle change). Finally, it is not clear that the beneficial effects of computerized training are large enough to warrant engagement in this activity over activities that have more empirical support to improve overall health (e.g., exercise) or life satisfaction (e.g., socializing with friends, playing with grandchildren).

Citing these aforementioned issues, the Stanford Center for Longevity released a consensus paper on computerized cognitive training, stating: “To date, there is little evidence that playing brain games improves underlying broad cognitive abilities, or that it enables one to better navigate a complex realm of everyday life.” The authors do not argue that computerized cognitive training cannot, in theory, improve cognitive function, but rather that the empirical support at this time is inconclusive at best. They did, however, highlight several studies that showed promising results and were deemed to have sufficient scientific integrity. One such study found that older adults (60–85 years old) who engaged in a multitasking training videogame, NeuroRacer, reduced multitasking costs compared to both an active control group and a no-contact control group, and performed better than untrained 20-year-old participants, with gains still evident at a 6 month follow-up (Anguera et al. 2013). Further, these changes were corroborated by electroencephalography, with trained participants evidencing enhanced midline

frontal theta power and frontal–posterior theta coherence.

However, as there are two sides to every story, another group of scientists has released opposing position paper (cognitivetrainingdata.org) that highlights the broad and growing literature that suggests clinically significant beneficial effects can be achieved by computerized cognitive training. A recent meta-analysis of 52 RCTs compared the cognitive effects of computerized cognitive training in 4,850 healthy older adults and found that the effect of computerized intervention on overall cognitive outcome was statistically significant (effect size $g = 0.22$, $P < 0.01$) (Lampit et al. 2014). The beneficial effect of group-based computerized cognitive training was somewhat larger (32 trials, effect size $g = 0.29$, $P < 0.01$), which equated to an average improvement of approximately one point on the Mini-Mental State Examination (MMSE). Small to moderate effect sizes were also found for memory, speed, and visuospatial cognitive domains but not for executive functions. One of the most notable results was that “do-it-yourself” computerized training completed at home did not produce improvements. Rather, the modest improvements seen were in individuals supervised by a trainer in a center and undergoing sessions one to three times a week.

Overall, it appears that cognitive training can improve cognition, but the effect sizes are generally quite modest. With the largest meta-analyses on computerized cognitive training programs reporting an average improvement of only one point on the MMSE after training, the debate on the utility of computerized cognitive training interventions appears to be far from resolved. The literature on cognitive training is heterogeneous which complicates overall interpretations of the literature. Intervention studies differ with regard to modality (individual, group, computerized), goal (compensation versus remediation), population (healthy aging, MCI, dementia), treatment focus (single-domain versus global cognition), and the efficacy of the training program employed. Given this myriad of factors, it is difficult to draw unequivocal conclusions about the field as a whole.

Exercise. It is well established that engaging in exercise is associated with general health, including outcomes like improved muscle strength, arterial compliance, cardiovascular fitness, and overall functional capacity. It has also been observed that physically fit individuals have a reduced risk of developing MCI or dementia as compared to their sedentary counterparts in both cross-sectional and longitudinal studies. In longitudinal studies, older adults that participate in physical activity show less cognitive decline over 2- to 10-year follow-up periods (Bherer et al. 2013).

Despite this repeated observation in cross-sectional and longitudinal studies, RCTs on aerobic exercise have produced conflicting results. A recent Cochrane Review that included 12 trials and 754 participants reported that there was inconsistent evidence that aerobic exercise or increased fitness improved cognitive function in cognitively normal older participants (Young et al. 2015). This builds off of a previous review (Smith et al. 2010), which reported a modest effect of physical fitness on cognition, including improvements in attention, processing speed, executive function, and memory, in cognitively normal older adults. These findings were tempered with the concern that there is generally a high degree of variability of treatment effects across studies. The higher quality studies tended to show smaller effects and studies with the highest quality rating tended to show no effect of exercise on cognition at all. Intriguingly, larger gains in aerobic fitness were associated with lesser cognitive improvement. Thus, even in studies in which positive results are found, the relationship between physical fitness and cognitive function appears complex. This variability across studies raises the question of what variables may moderate the beneficial effects of physical exercise. For example, gender, age, APOE status, and baseline level of fitness have all been raised as possible subgroups that need to be considered when analyzing these results.

One possible moderator in the relationship between physical fitness and cognitive function is the degree of cognitive impairment. In a recent review of 22 RCTs examining the efficacy of

physical exercise on cognition in individuals with MCI or dementia, there was generally a positive effect found in participants with MCI. These effects were seen in global cognition, executive function, processing speed, and attention. However, the effect of exercise on cognition was not as clear in subjects with dementia and was confounded by poor quality studies and methodological issues. Thus, it may be that exercise is most beneficial for individuals with MCI (versus cognitively normal or demented).

While most studies have focused on aerobic exercise programs, there is emerging evidence that other types of exercise programs (e.g., resistance training, balance training, Tai-Chi) may also benefit cognition. Tai-Chi is a multimodal mind-body exercise that integrates physical, cognitive, social, and meditative components. A meta-analysis of 20 studies with a total of 2,553 participants on the impact of Tai-Chi on executive function revealed a large effect when Tai-Chi was compared to nonintervention controls and moderate effect when compared to exercise controls (Wayne et al. 2014). Thus, Tai-Chi represents a promising avenue for exercise research that extends beyond aerobic fitness.

The mechanisms through which exercise impacts on cognition and brain health remain elusive. Animal studies have shown that exercise increases cell proliferation and stimulates neurogenesis in the dentate gyrus of the hippocampus, an important brain area for learning and memory. Exercise regulates a number of growth factors, such as brain-derived neurotrophic factor (BDNF), which plays a crucial role in synaptic plasticity; insulin-like growth factor 1 (IGF-1), which promotes neuronal growth; and vascular endothelial growth factor (VEGF), which stimulates angiogenesis and vasculogenesis and promotes brain ischemic tolerance. Lastly, exercise reduces inflammation and oxidative stress, which are known to negatively impact the brain. As many of the proposed mechanisms are based on animal studies, there is a great need for replication in human subjects.

In summary, despite the repeated observations of a relationship between aerobic exercise and cognition in cross-sectional and longitudinal

studies, the empirical evidence of this relationship in intervention trials is inconclusive. Higher quality RCTs tend to show smaller effect sizes than lower quality RCTs. Further research on moderators of this relationship may help to clarify the mixed findings. There is emerging evidence of Tai-Chi as an effective intervention; however, this literature is still in its nascence compared to that of aerobic exercise. Given the benefit of physical exercise on overall health, providing exercise as a recommendation for patients still appears justified, although its impact on cognition is unclear.

A Multivariate Approach to Risk Reduction

As dementia is not caused by a singular pathway or mechanism, it is increasingly plausible that the prevention and treatment of dementia will also not be a simplistic and single-faceted intervention. Dementia risk factors are diverse and additive, thus an intervention that addresses multiple mechanisms may have a greater effect than interventions that only address one mechanism in isolation. Regardless of the type of single-factor interventions studied thus far (e.g., pharmacological vs. exercise vs. cognitive training), the beneficial effects are generally quite modest (if observed at all). It may be that addressing multiple risk factors simultaneously (e.g., exercise plus cognitive training plus pharmacological intervention) will have additive beneficial effects and thus may result in greater cognitive improvement. This multivariate approach is similar to the multifaceted intervention approach observed in numerous diseases (diabetes, cancer, heart disease) in which diet and lifestyle interventions are heavily emphasized in conjunction with medical intervention. A comprehensive approach in neurodegenerative disease is necessary and reflects the myriad of moderators and mediators in the clinical syndrome of dementia. Given that most of the identified modifiable risk factors are inter-related and connected to the general notion of a healthy lifestyle, focusing on one single lifestyle or health factor may be insufficient to reduce an

individual's risk of developing cognitive decline and/or dementia.

The most widely cited multivariate intervention to date is the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) study (Ngandu et al. 2015). The FINGER study is the first published randomized controlled trial on multivariate risk factors and cognitive decline. The main hypothesis was that simultaneous changes in several risk factors (even of smaller magnitude) would lead to a protective effect on cognition. The authors found significant intervention effects on the primary outcome (overall cognition), main cognitive secondary outcomes (executive functioning and processing speed), and other secondary outcomes (BMI, dietary habits, and physical activity). Improvement in the primary and main secondary cognitive outcomes was 25–150% better in the intervention group than in the control group. However, there was no main effect on memory. The FINGER trial provides a reliable reference frame by including at-risk elderly people from the general population in a large, long-term study (2 years).

Another multi-pronged intervention trial was The Study of Mental and Resistance Training (SMART) (Fiatarone Singh et al. 2014). The SMART study was a randomized, double-blind, double-sham controlled trial of adults with MCI. Participants were randomized to two supervised physical interventions – active or sham physical training – and two cognitive training interventions – active or sham cognitive training. The intervention phase occurred 2–3 days per week for 6 months with an 18-month follow-up. Primary outcomes were global cognitive function (Alzheimer's Disease Assessment Scale-cognitive subscale; ADAS-Cog) and functional independence (Bayer Activities of Daily Living). Secondary outcomes included executive function, memory, and speed/attention tests, and cognitive domain scores. One hundred adults with MCI were enrolled and analyzed. Physical activity (in this case, resistance training) significantly improved global cognition at 6 months and executive function across 18 months. Cognitive training only attenuated decline in the memory

at 6 months. It was concluded that the physical exercise intervention (resistance training) was effective at improving cognition over 18 months and was also more effective than cognitive training alone.

Future Directions

Thus far we have identified a number of risk factors that increase one's likelihood of developing MCI and dementia. However, there is still significant uncertainty with respect to the relationship between individual risk factors and dementia (for example, what mechanisms explain these relationships, and to what extent does a causal relationship exist). Many of the dementia risk factors discussed are also risk factors for other health outcomes (e.g., cardiovascular disease, cancer, all-cause mortality). There is a clear need for more research on risk reduction and brain health – both more longitudinal, population-based cohort studies and randomized controlled trials on the effectiveness of specific interventions that address modifiable risk factors.

The two primary foci of intervention in MCI and dementia are cognitive training programs and exercise (primarily aerobic) programs. Cognitive training programs have generally shown to be beneficial, though the cognitive improvements are generally quite modest with several moderating factors that impact treatment benefit. Future research needs to clarify what type of cognitive training is most beneficial (computerized versus in-person, domain-specific versus broad, etc.), optimal frequency and duration, what biological mechanisms are implicated, and who benefits most from this type of intervention.

Despite the legion of cross-sectional and observational studies noting a significant relationship between fitness level and risk for MCI and dementia, the intervention literature is mixed at best. The lack of clear causal relationship is somewhat surprising and requires further research. Specifically, future research should outline what types of exercise is most beneficial, in addition to the frequency, intensity, and duration recommended. Further, extant research suggests that certain

modifying variables may exist (e.g., gender, level of cognitive impairment), and other moderators should be identified and characterized. Lastly, the aerobic exercise literature often relies exclusively on peak VO_2 to definite cardiorespiratory fitness. Peak VO_2 has methodological considerations that may be contributing to the mixed literature. Specifically, peak VO_2 is affected by several demographic factors (e.g., age, gender) and physiological variables (e.g., muscle mass, cardiac symptoms). Given these issues, analyses focusing exclusively on peak VO_2 should address these possibly moderating variables. Additionally, studies on cardiorespiratory fitness should broaden their definition of fitness and pursue additional variables that might capture more or different aspects of fitness level.

Some of the most promising lines of research are multimodal in nature. This type of research is important because it addresses the complexity of pathways leading to the clinical syndrome of dementia. It seems plausible that no single pathway to dementia exists, and thus no single method of intervention will be effective in preventing or delaying this syndrome. Research studies that incorporate multiple aspects of lifestyle and health may have a better opportunity to result in clinically significant improvement in symptoms. There is sufficiently burgeoning evidence to conclude that life-long physical activity, maintaining a healthy diet, and prevention and management of cardiovascular risk factors (diabetes, obesity, smoking, and hypertension) is likely to reduce the risk of cognitive decline and dementia. Interestingly, with the exception of depression, many of the risk factors of dementia are more strongly associated when present at midlife rather than late-life (e.g., midlife hypertension is more strongly associated with dementia risk than late-life hypertension). Thus public health studies should focus their intervention on these risk factors in middle age to prevent or delay the development of cognitive impairment later in life.

Exceptional Longevity: The Iowa Centenarian Study

As life expectancy has increased, so has interest in understanding determinants of longevity and importantly, active life expectancy and maintenance of high quality of life in advanced age. The last census reported more than 53,000 centenarians in the USA, reflecting a 6% increase over the previous 10 years (Meyer 2012). The two largest centenarian studies in the USA have been conducted in the Northeast and the Southeast areas of the country in more densely populated areas (Perls and Terry 2003; Poon et al. 2007). The Iowa Centenarian Study is unique, in that it involves rural Midwestern centenarians. It is unclear to what extent longevity is related to geographic regions, and this study fills the gap of including participants from a generally rural area. Additionally, the Iowa Centenarian Study focuses on understanding the behavioral determinants and resources of exceptional longevity, especially in rural environments. With a focus on behavioral longevity components, the Iowa Centenarian Study addresses important issues in geropsychology, namely aspects of subjective

well-being and maintaining maximum potential in very late life.

A central premise in the Iowa Centenarian Study is the assumption that psychosocial resources in part determine physical and mental health in later life (Martin et al. 1996; Randall et al. 2010). Without adequate individual resources, such as a robust personality and socio-economic resources, it is much less likely for individuals to reach the century mark. Furthermore, psychosocial resources are important for continued well-being in very late life (Martin, 2002).

Study Design and Measures

The Iowa Centenarian Study emphasizes the importance of optimal functioning and adaptation as defined by three important areas: cognition, mental health, and activity. Less desirable outcomes include dementia, depression, and fatigue (Martin et al. 2000; Martin et al. 2006; Miller et al. 2010). The conceptual framework for the Iowa Centenarian Study centers on the ability of psychosocial resources to predict adaptation across these three essential functional domains (Martin et al. 2012b; Margrett et al. 2010).

The recruitment of 152 centenarians from Iowa established the baseline assessment for this study (Martin et al. 2012b). Participants were chosen from a list of centenarians maintained by the State of Iowa. Participants from care facilities are overrepresented in the study due to the fact that a survey of all care facilities in the state is conducted every year, whereas including residents in the community is dependent on information provided by centenarians themselves, their families, or community organizations. Participants had to be able to verbally answer questions and provide informed consent. No proxy reports were included. As in other centenarian studies, the vast majority of participants in the Iowa Centenarian Study is female (86.3%) and White (99.3%). The average age was 101.6 years (range = 100–112 years). Eighty-two percent of the centenarians lived in long-term care facilities. Twenty-three percent had some high school

education, 28.7% completed high school, and 48% reported educational experience beyond high school.

A smaller group of 28 centenarians participated in the longitudinal follow-up of the Iowa Centenarian Study. The follow-up assessments combined general baseline data with longitudinal data collected four times within a six-month period. There was only one significant difference between the baseline and the follow-up sample: participants who were included in both studies were more likely to live independently.

Baseline measures were selected using domain recommendations made by a National Institute on Aging panel for studies of exceptional survival in humans (National Institute on Aging 2009), including past history, demographic variables, cognitive status evaluation, and life events. Functional capacity was assessed with self-reports of activities of daily living (ADL). Physical health, nutrition, fatigue, personality and coping, social support, psychological well-being, and physical exercise were also part of baseline measures. Mental status, physical activity, fatigue, and subjective well-being were again assessed in the short-term longitudinal study (Margrett et al. 2012). Few other centenarian studies have directly assessed the “cognitive representation” of life at 100 years of age (Lehr et al. 2000). Thus, centenarians were asked to evaluate their situation as a person who has lived 100 years. Sample questions include, “What is it like to be 100 years?” or “Did you ever think you would live to be 100 years?”

Baseline Findings

Overall, Iowa centenarians had a positive view of themselves and thought it was positive to be a centenarian. In general, centenarians looked at being 100 years of age as meaningful, challenging, and exciting. Over half believed they had no influence on becoming a centenarian and very few thought they would ever reach that goal.

Over 70% of the centenarians in the Iowa study rated their health as excellent or good

with half reporting that they were able to get out and about. Over 80% reported no trouble eating on their own and did not report nutritional problems. Although the self-rated health of centenarians appeared to be quite good, functional capacity was more limited in the areas of mobility, cooking, housework, and managing money. For example, less than 10% of this oldest age group was able to go places independently. The next section highlights some of the findings in the three adaptation areas essential to quality of life in very old age: cognitive functioning, mental health, and activity.

Cognitive Status and Change Among Iowa Centenarians

Many older adults frequently worry about maintaining cognitive ability as they get older and consider it an important component of successful aging (Rowe and Kahn 1996). The risk of cognitive impairment or impaired mental status increases with age; however, the rate or the inevitability in very late life is still debated (Alzheimer’s Association and 2009; Crum et al. 1993). Relatively little has been determined about the cognitive status of the very old and we lack a clear understanding of the cognitive capabilities of centenarians.

Maintenance of cognitive functioning is important to quality of life, and cognitive deficits significantly impact later life functioning. Not only is the emotional and financial cost of caring for those with cognitive impairment significant, it also increases the probability that an individual will require long-term care in a skilled nursing facility (Gaugler et al. 2007). Short cognitive screening tools are typically used to assess mental and cognitive functioning across a variety of settings. However, studies reporting multiple assessments of mental status or cognitive functioning among centenarians over time are rare. Of the 152 Iowa centenarians assessed at baseline, a subset of 28 participated in four follow-up sessions occurring over a 6-month period. The goal of this aspect of the study was to determine the cognitive status of the centenarians at baseline and

to evaluate the degree of individual change in cognitive status at follow-up intervals.

Using the Short Portable Mental Status Questionnaire (Pfeiffer 1975), the Iowa Centenarian Study assessed mental status at baseline for all participants as well as change across baseline and four follow-up occasions for the longitudinal subsample. For the entire sample at baseline, diversity in mental status performance was observed: about 40% of participants scored in the “normal” range, 20% exhibited a score suggestive of mild cognitive impairment, and 40% evinced scores indicative of moderate to severe impairment. Next, the study investigated the degree of individual change in mental status using multiple approaches (i.e., categorical designation based on score, comparison to individual standard error of measurement). Findings indicated significant diversity in the degree and nature of intra-individual change. Decline was only one of the observed patterns of change; a significant number of centenarians maintained mental status across occasions while others exhibited improvement. Findings from this portion of the Iowa Centenarian Study illustrate the need to consider the range of cognitive functioning among very old individuals as well as the potential for change and the most useful assessments for gauging change. Future work is needed to examine correlates of change (e.g., depressive symptoms, fatigue) across a wider variety of cognitive indicators.

Mental Health Among Centenarians

A more complete understanding of centenarians from the geropsychology perspective requires a focus on mental health issues. Compared to information pertaining to physical and functional health among the very old, very little knowledge exists about the mental health and mental health changes in very late life. Are centenarians content and happy or are they discontented and unhappy as they move into their second century of life? Does subjective well-being in very late life depend on individual and socioeconomic resources? An important goal of the Iowa Centenarian Study was to shed light on the mental

health status of centenarians and to better understand it in order to gain important information about the quality of life for people surviving to one hundred and beyond.

There have been several previous studies demonstrating largely positive mental health among centenarians (Gondo and Hirose 2006). However, centenarians realize they only have a short time to live and although their well-being was relatively stable over their lifetime it may decline rapidly with impending death (Martin et al. 2000). Some may feel currently deprived of positive experiences and report feelings of uselessness and a diminishing sense of positive affect.

The Iowa Centenarian Study also investigated the level and change in mental health as measured by positive and negative affect (Martin et al. 2012a). These dimensions were repeatedly measured among a subset of Iowa centenarians over six months, and results suggested that there was a slight decrease in positive affect scores over time. In addition to assessing levels of positive and negative affect, individual trajectories also play an important role. Mean growth curves confirmed a relative decline in positive affect but no noticeable increase in negative affect. Centenarians who thought of their financial resources as being better when compared to others were able to draw on resources which allowed them to continue with activities that are meaningful and purposeful.

Even though mean levels of negative affect did not appear to change over time, there were individual differences. Relatively good perceived health and higher levels of physical activity were associated with an increase in negative affect over time. This result is somewhat puzzling but may reflect frustration by this group of centenarians. Specifically, centenarians who feel that they are more capable of participating in meaningful and purposeful activities may feel frustration due to limited opportunities to actually engage in such activities.

The findings of the Iowa Centenarian Study suggest that changes in affect levels occur even in very old age. Centenarians do not celebrate their longevity milestone of reaching 100 years of age and then wait for death; they continue to be interested in activities that promote better positive

affect and overall well-being. Therefore, it is important to provide positive experiences for old and very old adults. Those who continue to be relatively active will benefit from additional stimulating experiences. Future research should not only view centenarians with regard to physical health; it is also necessary to consider the important component of their emotional and mental well-being.

Activities of Daily Living and Physical Strength

Another important aspect of the Iowa Centenarian Study focuses on physical activity and strength. Handgrip strength has been recognized as a predictor of mortality among older adults (Franke et al. 2012; Gale et al. 2007). Hand grip strength and disability are associated with cognitive decline for nonagenarians and centenarians in a cross-sectional study (Jeune et al. 2006).

Of the baseline sample, 11 Iowa centenarians provided complete data for all follow-up assessments. Measures assessed at baseline (i.e., ADLs) and T1 (all other data) were assessed as predictors of functional limitations at T4. Findings indicated an association between ADLs, grip strength, perceived health, and markers of mental health and functional limitations. The results from this study suggested that measures of physical health, mental health, and perceived health were associated with physical functioning in centenarians. Greater levels of handgrip strength, positive affect, and self-rated health were associated with better function.

Objectively measured daily physical activity was assessed by a pattern recognition device (SenseWear Pro 4, BodyMedia, Pittsburgh, PA) that integrates information from two orthogonal accelerometers and thermal sensors assessing heat flux, body temperature, and galvanic skin response. Activity, quantified as average energy expenditure and expressed in metabolic equivalent tasks, was inversely associated with all four measures of physical function (i.e., global function, upper body function, basic lower body function, and advanced lower body function), whereas

handgrip strength was positively associated with all of them. At first sight, these findings are somewhat puzzling but they perhaps suggest that inactive centenarians are not troubled by their limitations; conversely, more active centenarians may be more aware of their limitations. Not surprisingly, better functioning was associated with higher levels of self-rated health. Clearly, more research with larger samples is needed to replicate these findings.

The Iowa Centenarian Study reported strong associations between affect and functional limitations. Centenarians with higher functioning scores demonstrated higher scores in positive affect, whereas those scoring lower in functioning reported greater negative affect. Causal inference is not possible; however, this suggests a positive relationship between affect and activities of daily living. Higher levels of ADL functioning may promote improved affect and vice versa. If exceptionally old people feel useless and weak, this may also contribute to less engagement in functional abilities (Martin et al. 1996).

When assessing functional limitations, the terms ADL and physical functioning are often thought of as being synonymous; however, physical functioning is a much broader term that includes both positive (e.g., physical abilities) and negative (e.g., functional limitations) components of the range of functioning (Cress and Meyer 2006; Selim et al. 2005). Because physical strength and physical activity can *increase* functional performance or “reserve” (Stewart 2003), it is important to include components that specifically measure late-life function and disability. It is noteworthy that handgrip strength was more strongly associated with late-life function and disability (e.g., visiting friends, going out with others) than with traditional ADL measure. The Iowa Centenarian Study also showed that the ADL measure was only weakly associated with the measures of physical activity, compared to the association observed with measures that include late-life function disability. Therefore, more sensitive measures of functioning and functional limitations need to be considered when assessing exceptionally old adults.

The Importance of Psychosocial Resources

In order to maintain and optimize functioning in activity, cognition, and mental health, centenarians rely on individual and socioeconomic resources (Martin 2002). Based on earlier work in the Georgia Centenarian Study (Martin et al. 1996), the primary resources in the Iowa study included personality as individual resources, social support as an indicator of interpersonal or social resources, and perceived economic status as financial resources.

Prior studies on centenarians have used personality traits in their assessment of individual resources (Martin 2002). In the Iowa Centenarian Study, centenarians had relatively low scores on neuroticism and extraversion, and higher scores on agreeableness with openness and conscientiousness at slightly elevated levels. There are different interpretations for these personality traits. For example, these personality traits could have developed recently as centenarians may find it more important to agree with others, particularly those who live with primary caregivers. Furthermore, centenarians may become more introverted as their contact with others declines and sensory and mobility impairment may make it more difficult to benefit from or engage in contact with others. At the beginning of one's second century there may also be fewer reasons to worry about everyday life. Alternatively, centenarians may have had very stable personality traits over many decades of life, and these "robust" personality traits may have allowed them to survive into very old age.

Another important resource includes social support. Because centenarians need to rely on social support, nearly all of the centenarians reported that they could depend on help when they needed it. Eight out of ten centenarians indicated that they had close relationships with other people and 75% felt a strong emotional bond with at least one other person. As indicated by this sample, perceived social support remains important and was very strong for this age group.

Economic resources are also important for optimal adjustment in very late life. Many

centenarians are concerned with outliving their accumulated resources but still tend to underestimate their financial difficulties (MacDonald et al., 2010). Research findings suggest that older adults with relatively low incomes are typically more satisfied financially when compared to younger adults (Goetting et al. 1996). This is known as the "satisfaction paradox" and is contributed to the psychological accommodation to poor financial circumstances and downward comparisons to younger counterparts (Garasky et al. 2012). The Iowa study examined perceived economic well-being among centenarians by investigating whether that perception is related to the ability to manage activities of daily living, cognitive functioning, and psychological well-being. In addition, the Iowa Centenarian Study addressed the question whether these relationships vary by residential status (i.e., community dwelling compared to long-term care residence).

The focus of the study was on six perceived economic status variables and their relationship to activities of daily living scale, cognitive functioning, and mental health. Most centenarians at baseline (87%) indicated that they had financial resources sufficient for emergencies and reported that paying their expenses was not a problem (82.3%). However, 66% of the participants responded that they were unable to manage their own finances. Of these participants, 81.5% resided in a long-term care facility.

One measure of financial activity includes aspects of bill paying. Of those centenarians who indicated paying their bills was not a problem, cognitive functioning was higher than those reporting that they were barely able to make ends meet. Those reporting they could not meet their expenses had the lowest cognitive functioning scores. Financial security also related to the activities of daily living. Those centenarians who indicated that their money met their needs very well had the lowest mean score on the activities of daily living scale, whereas those reporting their money poorly met their needs had the highest mean in activities of daily living. The results may suggest that economically disadvantaged centenarians simply cannot afford to buy services

that would help with their activities of daily living (cleaning, cooking, money management, etc.).

Having a better perception of their economic circumstances also related to reporting fewer depressive symptoms. Those centenarians indicating that their money barely met their current and future needs reported more depressive symptoms. In addition, those centenarians who indicated they needed assistance with their finances felt they were financially better off than others their own age. Receiving help, therefore, may allow centenarians to view their financial situation as more positive. On the other hand, centenarians who receive assistance may not realize the full extent of their financial difficulties.

Taken together, research on psychosocial resources indicates that very old adults show a robust personality profile (i.e., low in neuroticism, high in agreeableness), and they can rely on social support. The management of financial resources is often difficult for oldest old adults, and when resources are low, depressive symptoms are high. Future research should investigate to what extent increase or at least stability in resources may maintain levels of overall well-being.

Summary

There are many factors that contribute to longevity and adaptation in very late life. The Iowa Centenarian Study defines late-life adaptation as the maintenance and optimization of cognitive function, relatively high levels of activities of daily living, and robust mental health that are specifically relevant for this very old age group. If cognition, activity, and mental health decline, optimal adaptation is compromised and the benefits of longevity may be put into question. The Iowa Centenarian Study, in concert with other centenarian studies, provides evidence that many centenarians can continue to function cognitively on a very high level and remain autonomous and stay in good mental health. However, there are great individual differences within this group of survivors, and the Iowa study suggests that individual and social resources may distinguish those who do well from those who encounter problems.

It is therefore of paramount importance to strengthen psychosocial resources among the very old and their family members, and service providers need to be aware of the continued need of good cognitive and mental health for those who live a very long life.

Definition

The Irish Longitudinal Study on Ageing is a nationally representative longitudinal cohort study of people aged 50 and over in Ireland. It is a multidisciplinary study focusing on the health, economic and social circumstances of older adults in order to understand the determinants of ageing, early identifiers of the process, inform policy and track the effectiveness of policy change and interventions. The study has leveraged intelligence from previous technology research in clinical cohorts to create a unique dataset of physiological coupled with neuropsychological measures.

Description

The Irish Longitudinal Study on Ageing began in 2009 with the aim of increasing the knowledge and understanding of ageing and the needs of older Irish adults. 8,175 people aged 50 and over living in the community participated in the first wave, with follow-up interviews conducted biennially. The second wave was carried out between 2012 and 2013, and the third wave commenced in early 2014. The fourth wave is due to begin in 2016 and further waves are planned.

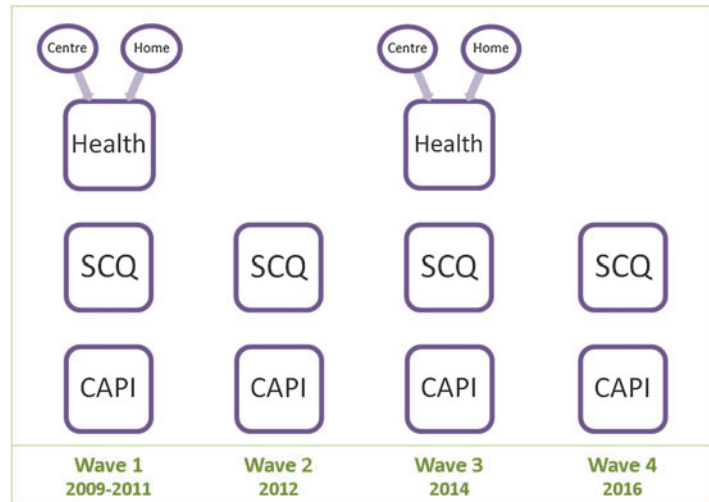

Design

To generate the TILDA sample, all postal addresses in Ireland were assigned to geographic clusters and a sample of these clusters was selected and stratified by socioeconomic status and location to ensure a nationally representative sample. Almost 30,000 households were screened to recruit participants and any individual aged 50 or over and their partners (irrespective of their age) were invited to participate. The response rate was 62% (Kearney et al. 2011).

At each wave of data collection, all respondents complete a structured computer-assisted personal (CAPI) interview which is carried out in their own home by a trained interviewer. The CAPI contains questions on family, health and wellbeing and financial circumstances. In addition, respondents are asked to fill in a self-completion questionnaire which contains more sensitive questions on mood, lifestyle, relationships and living environment. The CAPI and SCQ data are collected during each wave of TILDA. Every second wave all TILDA participants are also invited to undergo a health assessment, either a full assessment at a dedicated assessment centre or a modified assessment carried out in the participant's own home. The initial health assessment was carried out during wave 1 (2009–2011) with a response rate of 72% and is being repeated with additional measures at wave 3 (2014–2015). An outline of the TILDA data collection model is shown in Fig. 1. The health assessment comprises detailed measurements of health and physical functioning (Cronin et al. 2013). These include assessments of cognition, cardiovascular function, gait and mobility, vision, ocular health, and bone health. TILDA also has a unique focus on neurocardiovascular instability (Kenny et al. 2002). Accordingly, as part of the health assessment, sensitive measures of orthostatic blood pressure, heart rate variability, cerebral perfusion, and pulse wave velocity are carried out. This information will help unravel the complex relationship between vascular health, the autonomic nervous system and brain integrity, with a view to improving dementia and frailty risk detection.

Irish Longitudinal Study on Ageing (TILDA),

Fig. 1 A schematic showing the design of successive waves of the Irish Longitudinal Study on Ageing

Cognitive Function

A large part of the health assessment is devoted to assessing cognitive function using pen-and-paper and computer-based tasks. These tasks probe global cognition, visual and verbal memory, crystallized intelligence, attention, processing speed, multisensory perception and executive function. Several of the measures included are novel in the context of other longitudinal studies of ageing, such as the Sustained Attention to Response Task (SART) (Robertson et al. 1997) and the sound-induced flash illusion (Shams et al. 2000). In addition to the suite of detailed measures, shorter, primarily verbally administered cognitive tests are included in the CAPI interview. This ensures that every TILDA participant is cognitively assessed. The CAPI cognitive measures comprise tests of verbal and prospective memory and verbal fluency. These tasks are common to other population studies on ageing, namely the Health and Retirement Study in the U.S., English Longitudinal Study of Aging and the Northern Ireland Cohort Longitudinal Study of Ageing, thus facilitating international comparisons. TILDA CAPI also includes a common multi-domain measure of cognition (Mini Mental State Exam), which can be used as an indicator of general cognitive function.

Interviewers have the option to administer a quick seven-item cognitive screening test before commencing the interview if another person in the

household expresses concern about the respondent's capacity to proceed with the interview. Where it is established that an individual is mentally or physically incapable of giving the interview themselves a nominated proxy respondent is interviewed on their behalf. This is usually a spouse or close family member, or occasionally a friend or carer. Proxy respondents answer detailed questions about their relative or friend's cognitive status in order to find out whether or not cognitive impairment is an issue and to ascertain the severity of that impairment.

Mood

The presence of clinically significant anxiety and depression are ascertained during the CAPI interview using the CIDI-SF for anxiety disorders and depressive disorders. These instruments are in use from wave 2 onward. The Center for Epidemiological Studies Depression Scale (CES-D) is included in the CAPI at each wave and also forms part of physical and cognitive health assessment to assess concurrent depressive symptoms. The anxiety subscale of the Hospital Anxiety and Depression Scale (HADS-A) has also been included in all waves of data collection. At wave 3, a measure of state anxiety was added to the health assessment to investigate the impact of situational anxiety on objective measurements of cognitive and cardiovascular function. Other instruments measuring worry

and perceived stress are contained in the self-completion questionnaire.

Psychosocial Wellbeing

Psychosocial factors may have an important role to play in determining resilience or vulnerability to certain disease states. Fostering or maintaining an active, socially engaged lifestyle in later years is advocated to reduce the risk of physical and mental ill-health (Fratiglioni et al. 2004). There is a large psychosocial component to the TILDA SCQ at every wave. Participants are asked to indicate their frequency of participation in various social activities. Quality of relationships is assessed via questions about emotional closeness to a partner or spouse, other family and friends. Psychometric scales are included which measure loneliness, quality of life and perceptions of ageing. In the second wave of TILDA, a five-factor measure of personality (NEO FFI-3) was added to the SCQ to assess how various traits might be related to health outcomes and financial decision making. At wave 3, an inventory of coping styles and a measure of resilience to stressful events were included to provide further information on individual characteristics which may determine responses to and outcomes following the experience of adversity.

A social connectedness and caring section in the CAPI contains within it questions about the composition of the individual's social network, e.g., number of close children, other relatives and friends, participation in sports and social clubs, religious groups, charitable or community organisations. In addition, TILDA gathers information on care given and received; the type of care needed and the duration of time spent caring. Questions on volunteerism are also included.

Substudies

A number of substudies are underway using the TILDA cohort. Among these is an investigation of the relationship between hypotension, vascular reactivity and white matter hyperintensities. TILDA data is coupled with neuroimaging to study these phenomena in a subset of

600 TILDA participants over 65 years of age. The study commenced in 2014. Suitable participants are randomly enrolled into the substudy and have magnetic resonance imaging (MRI) scans carried out within 2 months of their TILDA health assessment. Scans include volumetric and functional MRI, diffusion tensor imaging and arterial spin labelling. These brain imaging measures will further be used to predict longitudinal changes in cognitive and daily life function over subsequent TILDA follow-ups. Understanding these relationships will inform future guidelines for blood pressure management in older adults and thus possibly contribute to the prevention of dementia.

TILDA also has a strong programme of biomarker research. Blood samples are taken at every second wave for the measurement of established and putative indicators of disease risk including lipids, vitamins, antioxidants, inflammatory, immune and genetic markers. Various substudies are in progress in this area. One such study of 1000 TILDA participants is investigating the relationship between cytokines, genetic variants of other immune signalling molecules and age-related macular degeneration. Age-related macular degeneration is a common cause of vision loss in older adults, and the ultimate aim of this study is to determine novel targets for intervention to halt the development and progression of this debilitating age-associated disease.

Findings

TILDA has made a number of significant findings to-date in the area of cognitive function, mental health and psychosocial well-being.

- Orthostatic hypotension (a large drop in blood pressure on standing) is more common in older adults and is associated with an increased risk of falls and faints. TILDA data shows that the prevalence of orthostatic hypotension rises steeply with age in the over 50 population (Finucane et al. 2014), and that these individuals are more likely to be depressed and have lower scores on tasks of global and executive function (Frewen et al. 2014). This research

suggests that this type of blood pressure variability adversely affects healthy brain ageing and may represent a modifiable risk factor for disease.

- Older adults who hold more negative perceptions of the ageing process are more likely to show a subsequent decline in executive function and memory independent of other psychological, health and demographic factors (Robertson et al. 2014). This finding highlights the importance of maintaining a positive attitude towards ageing for health and wellbeing in later years.
- Speed and variability of reaction time performance on the Sustained Attention to Response Task are associated with prevalent and incident frailty after controlling for other cognitive skills and related predictors (O'Halloran et al. 2014). Sustained attention may therefore be a novel marker of frailty.
- Macular pigment is located in the retina and is composed of three dietary nutrients which help to protect the eye. TILDA has found that having more pigment is associated with better cognitive function in older adults, irrespective of education and other socioeconomic factors (Feeney et al. 2013). As these nutrients are also present in the brain, this finding suggests that they may fulfil a neuroprotective role there also.
- TILDA research has shown that cognitive skills, particularly executive function, have a major role to play in the functional mobility of older adults and should be considered when assessing mobility difficulties in older individuals (Donoghue et al. 2012).
- There is a curvilinear relationship between age and quality of life in older Irish adults. Quality of life peaks at age 67 and declines thereafter. Mental health and social participation were the most important factors influencing quality of life in this cohort (Layte et al. 2013).
- Ireland has experienced several waves of emigration over the last century; however, a little is known about the psychosocial difficulties faced by return migrants when they come back to live in their country of birth. TILDA research shows that return migrants experience higher social isolation and alcohol problems compared to those who never lived outside their country of birth (Barrett and Mosca 2013). The degree of isolation varies by duration of time migrants spent away and how recently they returned.
- The importance of considering the entire lifecourse when investigating predictors of physical and mental health in late-life has been highlighted by a number of findings from TILDA. Early-life circumstances affect the experience of loneliness in later life. Poor childhood socioeconomic status and experiencing parental substance abuse growing up had independent effects on loneliness at older ages (Kamiya et al. 2014). TILDA data also shows a graded association between the experience of childhood adversity and increased risk of chronic diseases including cardiovascular disease, lung disease and psychiatric disorders (McCorry et al. 2014). Moreover, the experience of adversity was predictive of an earlier age of disease onset. Older adults who reported having experienced a greater number of adverse life events were also more likely to have impaired blood pressure regulation independent of current mood and health behaviours (Feeney et al. 2014). Taken together, these data add support to a growing literature showing that the experience of cumulative adversity can alter regulatory biological pathways resulting in an increased risk of disease in later life.
- Global population ageing has led to an increase in the "sandwich generation" – older adults with both living parents and dependent children who bear the burden of care for both generations. About one-third of women in TILDA aged between 50 and 70 were found to be in the "sandwich generation" (McGarrigle et al. 2014). Provision of non-financial support to children and financial support to parents were both independently associated with case-level depression among these women. However, women who provided financial support to children rated their self-rated health as being better than women who did not provide this support. These findings highlight the significant caring

responsibilities often faced by older adults and the need to try to reduce the psychological burden of care and financial transfers on this group.

Synonyms

Attitudes towards work; employee attitudes; job attitudes; work attitudes

Definition

An attitude is defined as “a psychological tendency that is expressed by evaluating a particular entity with some degree of favor or disfavor” (Eagly and Chaiken 1993). Attitudes include an evaluation of any entity such as people, objects, events, or organizations, and this evaluation may have affective, cognitive, and behavioral components. While affective components deal with the emotional side of individuals’ evaluations (i.e., how they feel towards an object, whether they like it or dislike it, or found it pleasant or unpleasant), cognitive components deal mostly with individuals’ beliefs and thoughts about those objects (i.e., what they think about an object or their judgments about a certain event). As a result of

these affective and cognitive evaluations, the behavioral component of attitudes refers to actual actions, namely, behaviors, guided by how individuals feel or think about specific objects.

Based on this general definition, attitudes towards a person’s job, namely, job attitudes, can be defined as “evaluations of one’s job that express one’s feelings toward, beliefs about, and attachment to one’s job” (Judge and Kammeyer-Mueller 2012). Moreover, as attitudes towards jobs are work specific, they contain evaluations not only of the tasks associated with the job but also of other job-related aspects such as coworkers, supervisors, and the organization itself (Ng and Feldman 2010).

The two most studied job attitudes are job satisfaction and organizational commitment. Job satisfaction refers to employees’ general positive feelings and beliefs about their jobs, assessing either an overall reaction or specific dimensions of the job including how satisfied they are with their pay, coworkers, supervisors, clients, as well as development and promotion opportunities (Judge and Kammeyer-Mueller 2012). Organizational commitment refers to an overall psychological bond between the employee and the organization either due to an emotional attachment or identification with the organization (i.e., affective commitment), perceived costs associated with leaving the organization (i.e., continuance commitment), or a perceived obligation to remain in the organization (i.e., normative commitment) (Allen and Meyer 1990).

Description

As individuals continuously make evaluations about their jobs, it is important to understand how they feel or what they think about their jobs in order to predict their job-related behaviors such as task performance, extra-role behaviors, counterproductive work behaviors, turnover, OCBs, and health and well-being.

An important implication of considering the intersection of job attitudes and age is that what individuals like about their jobs when they are younger may not seem appealing to them any longer as they grow older, or vice versa. Thus, while individuals' attitudes towards their job may change over time (within-person change), job attitudes may also show differences between younger and older worker groups (between-group differences). For example, one conclusion from a recent meta-analysis is that job attitudes generally improve with age (Ng and Feldman 2010).

These age-related differences on job attitudes have begun to receive more attention from scholars, especially due to the global trend of an increasing proportion of older workers in the workforce. According to the US labor force projections (Toossi 2012), the percentage of older workers (55 years and above) will climb up to nearly a quarter of the total workforce by 2020. Moreover, the decline in the percentage of the young (ages 16–24) and young and middle-aged workers (ages 25–54) is expected to continue in the coming years. The increase in the older worker population in the workforce also shows similar and often more pronounced trends in European countries: According to the most recent employment statistics, the employment rate of older workers aged between 55 and 64 increased to 50.1% in 2013 among EU member states, and it is projected that this increase will continue in the coming decades (European Commission 2014).

In short, considering the aging of the baby-boom generation (European Commission 2014; Toossi 2012), improved health in industrialized countries, changing retirement laws, and older workers' need for additional income, it is expected that older people will stay active in the workforce longer. As a result of this "graying"

trend, researchers have become interested in understanding the dynamics of aging in the employment context and its implications for human resource management. One line of research involves the exploration of the relationship between age and job attitudes and its impacts on job behaviors. These have included both cross-sectional and longitudinal studies (e.g., Ng and Feldman 2010; Wille et al. 2013).

Theories Behind the Age-Job Attitude Relationship

The following theories have received the most attention in explaining the relationship between age and job attitudes.

Socioemotional Selectivity Theory

Taking a lifespan development perspective, Socioemotional Selectivity Theory (SST; Carstensen 1995) suggests that individuals' resources, motivations, and goals change across the lifespan. SST posits that as we age, building and maintaining meaningful social interactions and goals becomes more important as a compensatory reaction against physical and cognitive losses (Kooij et al. 2011). When people are younger, they are more focused on attaining growth, which in the workplace may translate into building job knowledge and seeking career advancement. As people age, however, they tend to spend their energy more on strengthening social relationships at work since they have already accumulated work-related knowledge (e.g., Kanfer and Ackerman 2004; Truxillo et al. 2012). Moreover, as SST proposes, different perceptions of time in older and younger people affect their selection and pursuit of social goals. Because older people perceive their remaining time in life as shorter, they focus on meaningful emotional goals such as maintaining social relationships with colleagues. In contrast, younger people perceive their time as more open-ended; thus, they focus on gaining job knowledge and advancing their careers. Another proposition that SST adds to the age-job attitude research is that due to the perceptions of limited time remaining ahead of their life, older people

tend to maximize positive emotional experiences more than younger people. Older individuals tend to search for positive cues in their social relationships rather than focusing on negative events or outcomes.

Consequently, in explaining the age-job attitude relationship, SST suggests that individuals will develop more positive attitudes towards their jobs as they become older (i.e., higher satisfaction with the job, stronger commitment to organization) and have more positive attitudes than their younger counterparts. Ng and Feldman (2010) used SST to explain the findings of their comprehensive meta-analysis where there was a generally positive relationship between age and 35 job-related attitudes.

Selection-Optimization-Compensation Theory

Another lifespan developmental theory utilized in investigating the relationship between age and job attitudes is the SOC model (Baltes and Baltes 1990). According to this theory, individuals employ three basic strategies in the face of losses of their biological, mental, and social resources throughout their life. First, as people get older, they become more selective in investigating their limited energy and time while setting goals. Second, once people narrow down their goals and prioritize them, they try to match their resources with the goals they selected. In other words, they work to achieve an optimum level of performance with available resources. Last, they perform these strategies continuously to compensate any weaknesses related to the age-based losses.

Similar to SST, the SOC model suggests that older workers will have positive attitudes towards their jobs as they actively engage in the selection-optimization-compensation process. For example, an older employee may want to select a single task at a time rather than selecting multiple tasks to complete, taking advantage of his or her accumulated experience. As a result of actively engaging in these processes at work, a recent study also supported that older workers who used SOC-based strategies reported higher job satisfaction than their younger counterparts (Schmitt et al. 2012).

Personality Theories: Big Five Personality Traits

Recent studies on age and personality have begun to provide support for mean-level changes in some personality traits as people become older. The findings are consistent for some factors of the Big Five personality traits (aka five-factor model of personality; FFM; e.g., John and Srivastava 1999), the most widely used framework to assess personality traits in the work context. This personality framework consists of five broad dimensions of personality: extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience.

The results of a comprehensive meta-analysis investigating 92 longitudinal studies on personality traits (Roberts et al. 2006) found that some of the Big Five personality traits showed a consistent change in middle and old age. For example, there was a significant increase in agreeableness in old age (ages from 50 to 60). In addition, the results yielded a significant increase in the mean levels of conscientiousness from ages 20 to 30, 30 to 40, 40 to 50, and 60 to 70. The authors reported a significant decrease in the mean levels of neuroticism in people's 20s and 30s and again from ages 50 to 60. In addition, the mean-level changes in social dominance, one of the facets of extraversion, showed consistent increase with age, from adolescence through age 40. Finally, there was a consistent decrease in social vitality, another facet of extraversion, between the ages of 22 and 30 and then 60 and 70. In sum, the authors concluded that while people become more socially dominant, conscientious, agreeable, and emotionally stable in middle and old age, they also experience decreases in social vitality and openness to experience in old age.

Similarly, the empirical cross-sectional studies yielded support for higher mean levels in overall agreeableness and conscientiousness (Soto and John 2012; Specht et al. 2011) and lower mean levels in neuroticism for older people when compared to their younger counterparts (Soto et al. 2011). These consistent findings about the changes in some personality traits over time are believed to be helpful to explain the age-job attitude relationship and provide additional

insight to the lifespan developmental approaches discussed above. However, despite these evidence in changes in some personality traits over time, the possible mediating role of personality between age and job attitudes is received little empirical study.

Additional Mechanisms Relevant to Age and Job Attitudes

In addition to the lifespan developmental and personality theories discussed above, other broader assumptions that may explain why job attitudes change with age include the increased accumulation of financial resources, higher pay, working in a higher status jobs, or the ability to craft one's job to fit into one's skills and needs.

Age and Changes in Specific Job Attitudes

As the research on age and job attitudes is still in its development stage, there are relatively few publications that shed light on our understanding in this area, particularly the mediating and explanatory mechanisms involved.

In their meta-analysis, Ng and Feldman (2010) compiled 35 job attitudes under three distinct categories and analyzed how each attitude was related to age. The categories included task-based (e.g., overall job satisfaction, satisfaction with pay, satisfaction with promotions), people-based (e.g., coworker and supervisor support), and organization-based attitudes (e.g., organizational commitment, fairness perceptions, and organizational identification). Based on SST, the main study hypothesis was that older workers would have more positive attitudes towards work than younger workers would. The overall conclusion of the study supported that age and job attitudes were associated significantly and that the strengths of the relationships were reported as weak to moderate after controlling job tenure. Most importantly, the findings revealed that age was related to more favorable job attitudes, supporting that older workers generally had more positive attitudes than younger workers. The authors concluded that the overall study

findings were in line with the expectations based on SST. Namely, perceiving the time left ahead of their lives limited as opposed to open ended, older individuals are more likely to focus on positive and emotionally meaningful experiences rather than negative ones. It is worthwhile to note that only one job attitude, satisfaction with promotions, was found to have a negative relationship with age. One possible explanation aligned with SST would be that older employees may perceive available promotion opportunities in their remaining careers as very limited.

A longitudinal empirical study on age and job attitudes by Wille and colleagues (2013) focused on whether employees' attitudes regarding work will change over time as they grow older. Based on personality theories (i.e., Big Five personality model), the changes in the five personality factors and their influences on job satisfaction and work involvement were investigated over the first 15 years of workers' professional careers. The results supported that there were significant mean-level changes in personality factors between the two assessments conducted over 15 years. Specifically, workers' mean levels of agreeableness and conscientiousness increased, while neuroticism decreased over time. Although no significant mean-level changes were found in attitudes over time, the authors were able to show that the variability in attitude changes was related to the variability in the personality changes over 15 years, signaling the possibility that job attitudes mature over time along with personality.

Research Methodology

(a) *Linear versus curvilinear relationships*: In addition to the linear relationships, the studies on age and job attitudes have also examined curvilinear relationships to see whether the effects of age on job attitudes are uniform across various ages. In their meta-analysis, Ng and Feldman (2010) detected curvilinear relationships for only 2 out of 35 job attitudes, concluding that the job attitudes were fairly uniform across ages. Specifically, the only curvilinear relationships were found for

age-normative commitment and age-emotional exhaustion links where the strength of the relationships increased as individuals become older.

- (b) *Cross-sectional versus longitudinal study designs*: Although the field is still developing and there are only a few published studies, there are examples for both cross-sectional and longitudinal designs (see Van Der Velde et al. 1998; Wille et al. 2013). While cross-sectional studies help capture the individual differences in the relationship between age and job attitudes (i.e., between-level variations), longitudinal studies provide a more complete picture about how this relationship changes over time by investigating the fluctuations in the job attitudes in years (i.e., within-person variations).
- (c) *Moderators*: Ng and Feldman (2010) reported a significant moderating effect of organizational tenure for the link between age and satisfaction with work. Specifically, the relationship was stronger (0.24 vs. 0.16) when organizational tenure was higher. In addition, educational level moderated the links between age and job autonomy and affective commitment such that older workers without a college education reported stronger job autonomy (0.19 vs. 0.09) and affective commitment (0.27 vs. 0.16) compared to workers with college education. Finally, the publication year of the study moderated the relationships between age and some job attitudes (i.e., age-job involvement, age-normative commitment, age-distributive fairness). Overall, the results suggested a weaker relationship for studies that were published more recently, supporting the existence of possible age cohort differences in some job attitudes.

Implications for Practice

The understanding of how age relates to certain job attitudes has important implications for older workers in organizations. First, based on the preliminary findings, older workers are likely to have more favorable evaluations towards their jobs and

work-related aspects than their younger counterparts are. As attitudes are defined as influential components of actual behaviors, having positive attitudes towards one's jobs (i.e., higher satisfaction with work and colleagues, higher commitment to organization) may translate into increased job performance in work contexts. Thus, as stated by theory (i.e., SST, SOC) although older workers may experience physical or cognitive-related losses over time, they also accumulate valuable experiences and job-related knowledge. Also, older workers tend to actively develop strategies to use their resources more effectively to offset age-related losses. Thus, the field presents promising findings to help reduce the negative stereotypes against older workers in various organizational stages such as recruitment and selection, promotion, training, and work groups (Truxillo et al. 2014). For example, through a better understanding of motivations of older workers, organizations can assign emotionally meaningful roles to them, such as mentors. This strategy not only will foster social identities of older workers but also may help influencing the attitudes of younger workers positively.

In addition to helping in eliminating negative stereotypes towards older employees, organizations can develop strategies to motivate employees of different ages once the link between age and job attitudes is uncovered (Kanfer and Ackerman 2004). For example, while organizations may rely on extrinsic rewards such as performance-based pays or bonuses, older workers may need more intrinsic rewards such as praise and recognitions by colleagues or superiors.

Future Directions

Given that there are only a handful studies published on age-job attitudes, there is still little understanding of the mechanism by which age is related to certain job attitudes. Thus, more research investigating the effect of age on various types of work-related attitudes is needed. Although cross-sectional data may still provide

insights, longitudinal studies are needed to examine the types of within-individual changes that take place over time and explain age differences in attitudes.

Second, to test the possibility of whether job attitudes change uniformly across different ages, future research should analyze the curvilinear relationships between age and job attitudes rather than using strictly linear examinations. Finding curvilinear relationships would produce more research questions such as why and how job satisfaction or affective commitment start changing after a certain age.

Another suggestion for scholars is to conduct cross-cultural studies to see whether how individuals' job attitudes change over time is uniform across diverse cultures. For example, in cultures where individuals gain their self-esteem based on their group memberships and where cooperation is highly valued (i.e., collectivistic cultures), age may be more strongly related to favorable job attitudes compared to that in more individualistic cultures.

Finally, future research should investigate some additional moderators and mediators of the age-job attitude relationship. For example, researchers can examine whether organizational climates supporting diverse age workforce play a moderating role in strengthening the relationship between age and favorable job attitudes of older workers.

Conclusion

The relationship between age and job attitudes has started to receive more attention from researchers due to the increasing proportion of older workers in the global workforce. This "graying" shift in the workforce necessitates a better understanding of how age is related to individuals' evaluations of various aspects of their work. Taking lifespan developmental approaches into account, utilizing personality theories, conducting more longitudinal studies to track within-person changes, and searching for moderators and mediational mechanisms to explain how and why age is related to certain job-related attitudes are some ways to advance this newly emerging field further.

Job Crafting in Aging Employees

Darya Moghimi, Susanne Scheibe and
Nico W. Van Yperen
Department of Psychology, University of
Groningen, Groningen, The Netherlands

Definition

Job crafting is defined as self-initiated behaviors displayed by employees with the goal to increase

the fit between the individual and the job. Fit can be achieved by matching personal needs and abilities to work supplies and demands.

Definition and Predictors of Job Crafting

Person-Job Fit and Job Crafting

Job crafting is founded in the concept of person-environment fit (P-E fit; Lauver and Kristof-Brown 2001), and more specifically, in the concept of person-job fit (P-J fit). This concept describes the fit or match between the needs and abilities of the person on the one hand and the supplies and demands of the job, respectively, on the other hand. Employees' *needs* reflect indispensable requirements, such as a sense of autonomy and competence, that are necessary in order to function and thrive. *Abilities* reflect personal resources, such as knowledge about a certain topic, that help individuals to effectively perform their work tasks and to cope with stressful work demands. *Supplies* refer to external resources that individuals receive from their job and working environment, for instance, support from colleagues. *Job demands* relate to occupational expectations and obligations that employees are confronted with, for example, time pressure. When these four factors are in balance, employees are likely to feel a good P-J fit between themselves and what their job offers and requires from them. P-J fit, in turn, is positively associated with job satisfaction and performance (Lauver and Kristof-Brown 2001). However, employees do not always experience a good P-J fit between needs and supplies, or between abilities and demands. Job crafting is one type of proactive behavior that employees can engage in to modulate their job's supplies or demands (i.e., the J-side of P-J fit) in order to increase P-J fit (Tims and Bakker 2010).

The term job crafting was first introduced by Wrzesniewski and Dutton (2001). They defined job crafting as self-initiated behaviors displayed by employees with the goal to increase the meaningfulness of their jobs. Although these authors did not explicitly position the concept in the P-J fit framework, their definition fits well with the idea that job crafting is enacted to achieve a better fit

between the need for a meaningful job and the job's supply of meaning. An important notion of the concept of job crafting is that individuals actively change the job (i.e., the environment) rather than themselves. By actively crafting their job characteristics and changing physical, relational, and cognitive boundaries of their work tasks, employees can fit environmental supplies and demands to their individual needs and abilities and achieve a better P-J fit.

Based on qualitative data gathered through personal interviews, Wrzesniewski and Dutton (2001) concluded that job crafting can be observed in three different forms. From the *physical* perspective, job crafting involves changing the amount, scope, and type of the tasks the employee has to accomplish. The *relational* form of job crafting includes changing interactions with supervisors, colleagues, or clients by increasing or decreasing contact with certain people. Finally, employees can also make *cognitive* changes by, for instance, focusing attention on the positive outcomes of the job or reframing the job as more meaningful.

Grounded in the definition provided by Wrzesniewski and Dutton (2001), Tims and Bakker (2010) enriched the theoretical background by framing job crafting in terms of the Job Demands-Resources (JD-R) model (Bakker and Demerouti 2007) and P-J fit. Specifically, they defined job crafting as proactive behavior aimed at achieving a greater fit between employees and their work environment by increasing supplies (i.e., increasing structural and social job resources), decreasing hindering job demands, and increasing challenging job demands. This definition overlaps with the physical and relational forms of job crafting identified by Wrzesniewski and Dutton (2001). However, in contrast to Wrzesniewski and Dutton (2001), Tims and Bakker (2010) do not consider the cognitive changes in the perception of a job as a form of job crafting, given that job characteristics are not actually changed.

Motivation and Opportunities for Job Crafting

Job crafting behavior is initiated by the cognitive evaluation of a P-J misfit and the conclusion that

job crafting would be possible and beneficial in reducing the misfit (Tims and Bakker 2010). According to Wrzesniewski and Dutton (2001), employees evaluate whether their job satisfies three basic human needs, the need for job control, the need for a positive self-image, and the need for affiliation. If these needs are not sufficiently met, the *motivation to job craft* arises. From the P-J fit perspective, the motivation to job craft can not only arise from a misfit in needs and supplies, but also from a misfit in abilities and demands. If the demands do not match the abilities, and supplies do not fulfill needs, the motivation to job craft grows, and employees are motivated to change physical and/or relational boundaries of their work environment (Wrzesniewski and Dutton 2001), or adjust structural and social job resources, decrease hindering job demands, and/or increase challenging job demands (Tims and Bakker 2010).

Whether or not the motivation to job craft is translated into actual job crafting behavior depends on *perceived opportunities for crafting*. Perceived opportunities are presumed to moderate the relationship between the motivation to job craft and job crafting behaviors, such that with increasing opportunities employees engage more in job crafting (Wrzesniewski and Dutton 2001). Several job characteristics have been identified that promote or hinder opportunities for job crafting. One job characteristic that determines whether or not employees perceive job crafting opportunities is task interdependence, or the degree to which one employee's work task achievement depends on and feeds into other employees' work task achievement. Jobs with high task interdependence are considered as relatively less amenable to job crafting compared to jobs with low interdependence. Closely (and negatively) related to task interdependence is job autonomy, denoting the degree to which employees have discretion over the timing, location, and/or process to achieve their work tasks. When employees have low job autonomy, such that managers control time and location of work and strictly define tasks and responsibilities, job holders are less flexible in crafting their jobs to fit their

personal needs and abilities than when employees have high job autonomy.

Job Crafting and the Aging Employee

Age-Related Differences Impacting the Motivation for Job Crafting

Job crafting may be particularly relevant and beneficial as employees get older. With increasing age, certain within-person changes take place that result in changing needs and abilities (the P-side), which – if not accompanied by changes in the job (the J-side) – can result in greater P-J misfit. Therefore, it is assumed that there is a higher necessity for older employees to engage in job crafting behavior than is the case for young employees. However, not all age-related changes are negative, and some may even enhance P-J fit. An overview of age-related changes in different domains of functioning relevant to work functioning was provided by Kanfer and Ackerman (2004) and, more recently, by Ng and Feldman (2013) and (Truxillo et al. 2014). In the following, age-related changes that may enhance the motivation to job craft are categorized according to whether they primarily address changing needs or abilities.

Age-related changes in needs can be inferred from life-span variations in personality. *Personality changes* in relation to the Big Five traits include age-related increases in conscientiousness and agreeableness, coupled with age-related reductions in openness to experience, some facets of extraversion, and neuroticism (Roberts et al. 2006). These changes suggest that older employees may be less interested than young employees in learning new tasks in unfamiliar domains but more interested in executing familiar tasks and in having positive relations with coworkers. Age-related changes in needs can further be inferred from *changing goal orientations*, which are thought to emerge from the shifting balance of gains and losses as well as reductions in future time perspective across adulthood (Carstensen 2006). Typically, early adulthood provides abundant resources and opportunities to acquire skills and an extended

future time perspective. With advancing age, however, resource limitations become increasingly salient and future time perspective more limited. Accordingly, goal orientation tends to shift with age from growth and development to maintenance and loss prevention. Additionally, a positivity maintenance orientation emerges such that aging people tend to strive for positive and meaningful experiences and to avoid negative experiences.

Age-related changes in abilities comprise physical, cognitive, and emotional domains. *Physical changes* that are typically observed with increasing age include losses in vision and hearing, muscle flexibility and strength, aerobic capacity and immune response. These changes suggest that older employees are less capable of executing physically demanding tasks compared to their younger colleagues. Consequently, aging employees might be more urged to adjust office equipment, such as screens or chairs, to their changing physical health. Age-related changes in *cognitive capacity* include declines in information processing speed or fluid intelligence. These cognitive changes may make it more difficult for older workers to retrieve information, acquire new job-related knowledge, and work under time pressure. It should be noted that not all aspects of cognitive capacity normatively decline with age. Crystallized intelligence or experience-based judgment are stable or even improve with age, often allowing older employees to maintain their level of work functioning (Salthouse 2012). Age-related changes in *emotional ability* include improvements in emotional understanding and regulation and decline in emotional perception and resilience in face of chronic stress (Walter and Scheibe 2013). These changes help older adults to circumvent many negative situations, neutralize interpersonal conflicts, or defuse negative emotions quickly (Scheibe and Zacher 2013). At the same time, age-related vulnerabilities emerge in face of intense and sustained stressors, due to difficulties regulating physiological arousal, as well as in the accurate perception of others' emotions. These changes suggest, for instance, that aging employees might be more suited for jobs that require positive customer

interactions, but less suited for jobs that involve negative customer interactions on an ongoing basis.

Age-Related Differences Impacting the Opportunities for Job Crafting

In face of these within-person changes in needs and abilities, aging employees can use job crafting as a strategy to fit supplies (i.e., resources) and demands to needs and abilities and turn their work setting into a resourceful environment. However, aging may not only be accompanied by within-person changes that can affect the motivation to job craft, but also by environmental changes that affect the opportunities to job craft. In general, life course variations in opportunities interact with the motivation to job craft and determine whether an employee actually engages in job crafting behaviors or not. As stated above, within-person changes affect personal needs and abilities. In contrast, environmental changes in crafting opportunities refer to changes in supplies and demands. Within person changes in crafting motivation are rather generalizable to the aging workforce because they are highly related to physical aging processes in the human body. In contrast, environmental changes in crafting opportunities are predominantly dependent on the employee's specific work environment and can strongly vary between individuals, such that the same factors, for instance having more responsibilities at work, are perceived as supplies for one employee and as demands for another. In the following, the most prevalent environmental changes in crafting opportunities will be discussed in terms of supplies and demands.

Supplies are intrinsic or extrinsic vocational resources provided by the organization, the job, or the work group. Changes in supplies can comprise autonomy at work due to seniority, recognition due to higher organizational position, or increases in pay (Zacher et al. 2014). Older employees are often occupied in higher organizational positions which are usually also associated with greater *autonomy*. This enables the employees to act more freely and adjust their work conditions to their changing personal needs and abilities, for instance, in terms of working hours or location.

A higher organizational position can further be associated with greater *recognition* from colleagues and supervisors. As mentioned above, learning new processes and engaging in highly cognitively demanding tasks can become more effortful with increasing age (Salthouse 2012). Knowing that these efforts are recognized by supervisors and peers can serve as a buffering supply in highly cognitively demanding situations. Organizational recognition can be expressed verbally and through personal interactions or it can be expressed officially through increased *pay*. Higher pay does not exclusively refer to higher monthly salary but also to increased organizational benefits, such as more vacation days or higher pension that can help the employee to match his private needs to the organizational supplies.

The benefits of aging notwithstanding, many employees are also confronted with higher demands as they achieve a certain age and get closer to retirement. Work demands are extrinsic work factors that can be a threat to occupational well-being if not matched by personal abilities. The main changing work demands associated with aging can be categorized in changing responsibilities and age stereotyping (Truxillo et al. 2014). On the one hand *changing responsibilities* can be associated with the aforementioned higher organizational position that often comes with increasing age. On the other hand, many aging employees are confronted with a decrease in responsibilities either because they are assigned less demanding tasks or because they deliberately withdraw from work responsibilities as a preparation for retirement (Salthouse 2012). Dependent on whether these changes in responsibilities are voluntary and in line with the employee's needs and abilities, they can either be perceived as a supply or a demand. Yet another demand that can decrease the opportunity for job crafting in aging employees is *age stereotyping* (Truxillo et al. 2014). Older employees are often believed to be slow learners, low performers, and resistant to change. In the face of these beliefs, the work environment of aging employees might provide them with less opportunities for job crafting and indirectly coerce them to stay within their environmental boundaries.

Consequences of Job Crafting

Recent research has shown that job crafting leads to a number of benefits for employees and organizations. For instance, job crafting has been associated with greater supply availability in the sense that people who actively engage in initiatives to increase social job supplies, such as feedback, or structural job supplies, such as autonomy, also report higher availability of these supplies after several months (Tims et al. 2013). Furthermore, crafting challenging demands has been shown to increase work engagement (Bakker et al. 2012), which in turn contributes to organizational goals. This is due to the fact that engaged employees are more likely to focus on their in-role tasks and also show more organizational citizenship behaviors (Tims et al. 2013). Other studies suggest that work engagement is an antecedent of job crafting rather than an outcome. From this perspective, work engagement promotes physical and relational job crafting, and accordingly, increases the fit between the person and the job (Chen et al. 2014). Other aspects of occupational well-being have also been associated with job crafting in the past. More specifically, crafting more challenging demands has been shown to have negative effects on levels of burnout and therefore increasing effects on occupational well-being and health (Tims et al. 2013).

Job crafting has further been associated with greater job enjoyment at a day-to-day level. Job enjoyment, in turn, has been associated with better job performance. Hence, through job enjoyment, job crafting also promotes better occupational performance and is therefore also interesting from an organizational perspective (Tims et al. 2014).

A question that still needs to be addressed in the field of job crafting research is whether benefits of job crafting can be achieved through different job crafting behaviors at different ages. Based on the theoretical background discussed above, it can be assumed that there are indeed differences in the types of job crafting behaviors, and in their outcomes, between older and younger employees. Kooij et al. (2015) recently suggested that future research should take into account employee age,

focusing on age-specific job crafting activities and their effects on successful aging in the work context. Additionally, future research should focus on a broader set of job crafting outcomes such as job stress, work-life balance, and retirement intentions. Until today the main focus has been on employee attitude and affect which might not reveal the whole scope of the job crafting framework. These issues in the rather young field of job crafting also apply to job crafting measurement instruments which will be discussed in the following section.

Measurement of Job Crafting

The bulk of the existing research has defined job crafting as a rather static, trait-like concept, and the existing measurement approaches reflect this view. More recently, it has been suggested that job crafting also has more dynamic, state-like components and as such, is subject to daily fluctuations. Accordingly, new state-level measures of job crafting are beginning to emerge.

The basic assumption underlying early measurement approaches is that job crafting is a trait that some employees generally engage in more than others. When Wrzesniewski and Dutton (2001) first introduced the concept of job crafting, they exclusively founded their model on qualitative research conducted through behavioral observations and personal interviews with job holders in different sectors. As described above, these methods resulted in a taxonomy of three forms of job crafting behaviors namely, changing task boundaries, changing relational boundaries, and changing cognitive boundaries. In an attempt to expand the possibility for research on job crafting and supplementing the qualitative data, Tims et al. (2012) developed and validated a 21-item Job Crafting Scale (JCS), which operationalizes the four dimensions of job crafting emerging from the JD-R framework. The JCS comprises four subscales: increasing social job resources, increasing structural job resources, increasing challenging demands, and decreasing hindering demands. As part of the validation process the authors also compared self-rated job crafting

behavior with peer-rated job crafting, showing that there is indeed a positive correlation between self-rated and peer-rated job crafting activities. The finding that job crafting can reliably be observed by others supports the validity and relevance of the observational studies conducted by Wrzesniewski and Dutton (2001). The JCS is especially useful for researchers who are interested in individual differences in job crafting behaviors based on the most common supplies and demands mentioned in recent literature (feedback, social support, autonomy, etc.).

There are two alternative measures to assess job crafting, both grounded in the JCS and the definition of job crafting provided by Tims and Bakker (2010). The first one, developed by Nielsen and Abildgaard (2012), also considers job crafting as static and trait-like but not universal across different professions. Emphasizing that blue-collar jobs are characterized by a special constellation of high demands and low supplies, these authors developed and validated a five-dimensional job crafting questionnaire representing more dimensions of demands and less resources relative to the JCS (Tims and Bakker 2010). These five dimensions, each measured with two to four items, are: increasing challenging demands, decreasing social demands, increasing social job resources, increasing quantitative demands, and decreasing hindering demands.

The second alternative measure of job crafting grounded in the JCS is developed by Petrou and colleagues (2012) and reflects the dynamic character of job crafting. Rather than looking at individual differences in the tendency to use certain job crafting behaviors, this measure rests on the assumption that job crafting behaviors are dynamic and that their expression varies on a daily basis and therefore cannot be measured at only one point in time. This state-level job crafting scale, which was validated in a 5-day diary study, contains three subscales: seeking resources, seeking challenges, and reducing demands. It should be noted that although Petrou and colleagues (2012) based their questionnaire on the JCS, their conceptual definition of job crafting is slightly different. That is, Tims and colleagues

(2012) categorize supplies (i.e., resources) as social and structural, and demands as either being challenging or hindering. Fit can therefore also be achieved through challenging demands because they satisfy certain needs but do not exceed the employees' abilities. In contrast, Petrou and colleagues (2012) define demands as generally negative environmental characteristics that should be reduced in order to achieve greater P-J fit.

While there have been some first attempts to create a job crafting instrument that consider different work groups and different definitions of job crafting, age group differentiations are still missing. Future research should aim at adjusting the current measure to aging employees and further specifying whether job crafting should best be measured as a trait, a state, or both.

Future Directions

Developing Age-Differentiated Taxonomies of Job Crafting

In the previous sections, job crafting has been defined as proactive employee behavior that is aimed at increasing the meaningfulness and the feasibility of the jobs through a greater fit between the employees' needs and abilities and the job supplies and demands, respectively. This definition is rather general and applicable to different age groups and different jobs. However, Kooij et al. (2015) suggest that job crafting behaviors may differ between young and older workers. They introduce three major forms of job crafting which slightly differ from the definitions given above. The authors base their assumptions on the life-span model of selection, optimization, compensation (SOC; Freund and Baltes 2002) and on age-related intra-individual changes in needs and abilities as reviewed above. *Accommodative crafting* refers to crafting activities that are targeted at regulating age-related demands and changing supplies. This includes the delegation of responsibilities or looking for alternative ways to achieve goals and satisfy needs. *Developmental crafting* is targeted at increasing activities that promote personal growth and the acquisition of

new abilities. *Utilization crafting* comprises the application of existing abilities and knowledge. This can be achieved by seeking tasks that require unused supplies and are attainable with current personal resources (Kooij et al. 2015).

In further developing age-differentiated job crafting taxonomies based on the SOC model and other lifespan theories, it will be important to ensure that identified behaviors aim indeed at changing the job – and not the individual – in order to increase P-J fit. Developmental crafting, for instance, only fits the definition of job crafting to the extent that the focus is on work tasks and characteristics, such as asking for challenging work assignments, rather than personal resources, such as enhancing personal skills and knowledge. In the latter case, employees would craft themselves rather than their jobs. Future research may pay closer attention to job crafting in aging employees and specify whether crafting among older workers entails the same dimensions, motivations, and opportunities as crafting among younger workers.

Distinguishing Job Crafting from Related Concepts

Tims and Bakker (2010) suggest that there are several concepts similar but not identical to job crafting. Job crafting entails unsupervised, spontaneous, self-initiated, voluntary, and sometimes short-term changes in the work environment (Tims and Bakker 2010), whereas related concepts typically depend on employer approval, are supervised, and result in objective, long-term changes which are in line with the organizational mission (Demerouti 2014). For example, *idiosyncratic deals* (i-deals) are defined as agreements negotiated between the job holder and the employer in order to improve work and/or payment conditions (Demerouti 2014). *Role innovation* denotes actions where employees proactively and in discussion with the supervisor redefine their role in order to reduce a mismatch between the role definition and the actual working situations. *Personal initiative* is associated with occupational behavior through which an employee aligns goals and actions with long-term organizational goals. Initiatives that are rather directed at

organizational goals might not satisfy individual needs as much as job crafting because job crafting is exclusively focused on the individual. Additionally, supervised adjustments to the job might decrease the sense of autonomy that especially aging employees require to increase their P-J fit and experience greater occupational well-being. Future research should investigate whether job crafting does indeed differ from related concepts such as I-deal, role innovation, and personal initiative in terms of antecedents and job related outcomes.

In conclusion, job crafting appears to be a fruitful strategy for aging workers to actively change their job when experiencing age-related changes in needs and abilities, in order to maintain P-J fit at later stages of their career. At the same time, more research is needed to define whether job crafting behaviors differ between different age groups, and whether job crafting behaviors lead to different work outcomes for different age groups. At this point, there are specific definitions and validated measures of job crafting available which allow extended research on job crafting in aging employees.

Job Loss, Job Search, and Reemployment in Later Adulthood

Ruth Kanfer and Gina Bufton
School of Psychology, Georgia Institute of
Technology, Atlanta, GA, USA

Synonyms

(Mass) layoff; Displacement; Job loss; Job search; Reemployment; Self-regulation; Unemployment

Definition

This entry focuses on job search and reemployment among older adults (individuals aged 55 or older) who have experienced involuntary job loss due to economic conditions or organizational change.

Job loss refers to an adverse life event in which an employee has been involuntarily terminated from his/her job through no fault of his/her own (Gowan 2014). Following job displacement, many individuals seek new employment. Although the term “unemployment” generally refers to the state of being without work, the US Department of Labor (USDOL) defines adults as unemployed only when they (a) have had no

employment during the reference week, (b) are available to work except for temporary illness, and (c) have made specific efforts to find employment at some point during the last 4-week period ending with the reference week (USDOL 2014). For these individuals, reemployment speed is synonymous with the length of the unemployment spell.

During unemployment, job seekers typically engage in a variety of job search cognitions and behaviors, including developing a job search strategy, preparing resumes, conducting online job searches, and interviewing. A variety of methods have been used to measure job search activities. The most commonly used measure is job search intensity, designed to assess the frequency and time an individual spends on job search activities over a specific period of time (e.g., past week). Because job loss and job search often entail strong affect, many studies also assess the frequency of emotion-focused coping activities (Kinicki and Latack 1990).

Kanfer et al. (2001) describe job search as a motivated, self-regulatory process by which individuals manage cognitions, behavior, and affect for the purpose of obtaining new employment. In this and related models (Liu et al. 2014b; Wanberg et al. 2010; Lopez-Kidwell et al. 2013), self-efficacy is defined in terms of the referent. Self-efficacy for reemployment refers to confidence in one's ability to sufficiently mobilize personal resources to obtain reemployment. Self-efficacy for job search refers to the individual's judgment about his/her ability to successfully perform job search activities.

A central problem in the study of job search and reemployment among older adults pertains to defining reemployment. Wanberg et al. (2015) propose a four-factor criterion matrix by which to evaluate reemployment outcomes: (1) reemployment status and speed (i.e., whether or not a job is found, how quickly the job is obtained); (2) reemployment basis (i.e., whether employment is temporary, contract, or part-, or full-time work); (3) job rewards, including both extrinsic (i.e., wages, noncash benefits) and intrinsic (i.e., psychological need fulfillment, such as

need for competence) rewards; and (4) the perceived person-job demand fit (i.e., the perceived degree of match between a person's knowledge, skills, and abilities and the new job's requirements). To date, however, most research investigating the relationship between job search variables and reemployment has focused on reemployment status and speed.

Introduction

Over the past two decades, scientific and public interest in older adult job loss, job search, and reemployment has burgeoned. At least three reasons for this growing interest may be identified. First, unprecedented population aging in developed countries around the world has highlighted the high demands that older, nonworking populations may place on societal resources. Second, financial insecurity, healthier aging, positive attitudes toward work, and relaxed retirement policies in many countries have led many older individuals to work longer in life. In the USA, for example, workers aged 55 and older represent the largest growing segment of the national labor force (Bureau of Labor Statistics et al. 2015). Third, and perhaps most importantly, poor economic conditions in the USA and other developed countries at the turn of the twenty-first century resulted in millions of involuntary layoffs of late-career workers, many of whom have experienced difficulty in finding new employment (Johnson and Mommaerts 2011).

The purpose of this entry is to review and integrate theory and empirical advances related to job loss, job search, and employment outcomes in later adulthood. The entry is broadly organized into three sections. The first section reviews foundational concepts, such as older worker, job loss, self-regulated job search, and evidence on age and job search – reemployment relationships. The second section integrates findings on adult development with evidence on job search and reemployment to describe the unique challenges that older workers face in establishing reemployment goals, engaging in job search, and obtaining reemployment.

The third and final section provides a summary list of promising areas for future research.

Foundational Concepts and Issues

Defining Later Adulthood and the Older Worker. There is no universal definition and indeed considerable controversy about what defines an older worker (Schwall 2012). Some researchers have found important differences in work-related behaviors as a function of the individual's subjective age identity (Huang et al. 2015; Kunze et al. 2015) or the individual's future time perspective (Zacher and Frese 2009). To date, however, most researchers employ a definition based on chronological age. In the USA, employment statistics often organize individuals into three age-based categories: young (16–24 years of age), midlife (24–54 years of age), and older (aged 55 and older). In the organizational psychology research literature, the age range that distinguishes midlife and older individuals often varies between 45 and 60, depending on the research question and sample. In the cognitive aging and lifespan research literatures, studies often include individuals in their 80s and 90s, so that the category of older individual may even be further subdivided into young-old and old-old. The precise chronological age at which an individual is considered older also varies as a function of legal, political, and sociocultural norms across countries. In the USA, an individual 40 years or older is defined as an older worker for purposes of age discrimination litigation.

The value of chronological age in defining an older worker stems largely from advances in adult development that focus on the normative, intraindividual changes in abilities and nonability traits that occur across the lifespan (see Kanfer and Ackerman 2004). Studies in cognitive aging and lifespan psychology document a variety of normative, age-related changes in cognitive, physical, and psychological attributes that occur gradually across adulthood and have important implications for job search and reemployment outcomes. Although meta-analytic reviews of the relationship between chronological age and job

performance consistently show negligible relations (see Ng and Feldman 2008; McEvoy and Cascio 1989), older workers in jobs that make particularly strong demands on age-sensitive abilities (e.g., air traffic controller, firefighter) may develop new career goals following job loss. Research in the area of cognitive aging also shows normative, age-related decline in learning abilities that demand fluid intellectual abilities (Salthouse 1996). These findings are consistent with studies of job skill training that show that older individuals are more likely to experience greater difficulty compared to younger adults (Beier et al. 2012). Psychological and economic research that focuses specifically on job loss and reemployment typically uses between- rather than within-subject research designs that compare the employment experiences and outcomes among individuals organized into three chronological age groups: young adults (e.g., ages 16–24), midlife adults (e.g., ages 25–54), and older adults (e.g., ages 55+). Based on theorizing and research in developmental and lifespan psychology, current age-graded retirement age norms, and workforce participation trends, older workers in this entry are defined as those aged 55–75.

Job Loss. Job loss is an adverse life event that has long been associated with a host of negative economic, psychological, and physiological outcomes (McKee-Ryan et al. 2005). The loss of income following job loss frequently produces financial strain that can serve to motivate the search for reemployment (cf. Kinicki et al. 2000).

Early work on unemployment and well-being assumed a U-shaped effect between age and well-being (Jackson and Warr 1984), such that job loss had its largest negative effect on adults in midlife. However, recent evidence suggests the largest negative impact of job loss may be among older adults. Research by Gallo and his colleagues (Gallo et al. 2000; Gallo et al. 2006) used data from the US Health and Retirement Survey and found relationships between late-life involuntary job loss and reduced mental and physical health. Job loss among older workers is also associated with increased rates of depressive symptomology (Riumallo-Herl et al. 2014) that can diminish search motivation and job search intensity.

Gallo et al. (2006) found that the depressive effects of job loss were limited to older adults with fewer financial resources. Taken together, these studies suggest that job loss among less wealthy older adults creates a more negative environment for job search and a more pressing need for reemployment than job loss among more financially secure older adults.

How individuals appraise their job loss affects the ways in which they cope with unemployment, which in turn also contributes to the context in which reemployment goal setting and self-regulated job search take place. Most studies of reactions to job loss assess appraisals of unemployment rather than the event itself, although Leana and Feldman (1992) found that individuals with less negative reactions to their job loss engaged in more problem-focused coping activities. Several studies also suggest that job loss and unemployment appraisals vary as a function of sociodemographic and contextual factors (Gowan et al. 1999). Among 45–61-year-olds, Ludāne and Bite (2013) found that sense of loss was greater among lower-wage earners. However, beliefs about the reversibility of the loss (i.e., reemployment) and the view of job loss as a challenge were not determined by wage level but by the individual's beliefs about a just world and age (with age negatively related to beliefs about reversibility).

Self-Regulated Job Search. For most individuals who experience involuntary job loss, job search begins with the commitment to pursue a reemployment goal. Consistent with goal theories of motivation and action (see Kanfer 2012), features of the reemployment goal can be expected to shape the individual's job search strategies for goal attainment. Reemployment goals can vary in terms of clarity and other goal attributes. Studies of job search clarity (Wanberg et al. 2002; Bao and Luo 2015) show that individuals who have a clear idea of their job objectives engage in more job search activity than individuals who have not formed a clear idea of the type of job they want to attain. Other attributes of the reemployment goal have received less attention, but may also be important for facilitating job search and reemployment, particularly among older workers.

For example, reemployment goals may differ in the priority placed on pay (e.g., obtaining a job with a wage similar to the previous job wage), work conditions (e.g., finding a job with a flexible work schedule), basis (e.g., full time vs. part time), or the nature of the work (e.g., finding a job similar to the previous job).

In the self-regulation model of job search, the individual's reemployment goal activates the development of search strategies and self-managed activities designed to bring about the goal. Older workers with high level of financial need may, for example, limit job search activities to obtaining full-time work that pays as well as the previous job. During job search, individuals engage in a variety of activities, such as talking to others about job possibilities, conducting online job searches, making job applications, and interviewing. Because job search occurs over time, individuals must also engage in activities that sustain search motivation over time and adjust search activities based on new information. For many individuals, sustaining search motivation requires the activation of emotion regulation strategies to prevent the individual from becoming discouraged or becoming distracted from the search task (Wanberg et al. 2012).

The self-regulatory model emphasizes the self-organizing and self-managed nature of job search. Job assistance programs provide help (most often in the form of social support, skill building, and providing search strategy advice). But individuals must sustain search motivation over weeks and often months in the face of setbacks (e.g., poor interviews, rejection letters, increasing financial strain), distractions, and discouragement. During job search, individuals must also monitor their goal progress and adjust employment goals and/or adjust search strategies. The self-regulatory search process is terminated when individuals either accomplish or abandon their goal.

Self-efficacy is a key motivational variable in self-regulated job search and may be distinguished in terms of self-efficacy for job search (process goal) and self-efficacy for reemployment success (outcome goal). Both forms of self-efficacy appear important for effective self-regulated job search but may work to affect search

motivation in different ways (Liu et al. 2014b). High levels of search self-efficacy or confidence in accomplishing the activity motivate the initiation of job search activities. Older workers who have not been in the job market for years may have low self-efficacy for effectively using online search resources and so avoid use of this search method. Results of a recent meta-analysis on the impact of job search intervention programs by Liu et al. (2014a) found that reemployment success was significantly higher for job seekers who participated in programs that developed job search skills and enhanced search motivation using techniques such as setting of goal, boosting self-efficacy, and enlisting social support. Liu et al. (2014b) also found a significant moderating effect of age, with younger and older job seekers benefiting more from participating in a job search program, compared to middle-aged (mean age 35–50 years of age) individuals.

High levels of reemployment self-efficacy refer to expectations about the likelihood of reemployment success (Liu et al. 2014b; Westaby and Braithwaite 2013). Westaby and Braithwaite (2013) found five variables that significantly contributed to reemployment self-efficacy: having potential jobs lined up, job availability, low perceived discrimination, possessing necessary work skills, and knowledge of job listings. However, high reemployment expectations may reduce sustained job search effort, even if the individual has high search self-efficacy. For example, Liu et al. (2014b) found that high reemployment self-efficacy was negatively related to job search intensity.

Age and the Job Search – Reemployment Relationship. Results of a meta-analytic review on the relationship between job search and reemployment by Kanfer et al. (2001) showed a significant positive relationship between job search intensity and reemployment success and number of job offers and a significant negative relationship between job search intensity and duration of unemployment. However, moderator analysis by sample type showed a weaker positive relationship between job search intensity and reemployment success among older job losers compared to younger new job entrants or younger

employed job seekers. They also found that self-esteem and self-efficacy were more strongly related to job search among older job losers than other sample types.

Findings from a recent meta-analytic investigation of the relationships between age, job search, and reemployment outcomes by Wanberg et al. (2015) suggest a more complex picture. In this study, older individuals reported weaker intentions to engage in job search ($r = -0.06$), lower job search self-efficacy ($r = -0.08$), and lower levels of job search intensity ($r = -0.08$) than younger individuals. Although the effects of age on reemployment success and reemployment speed were partially mediated by job search intensity and job search self-efficacy, age also had a direct impact on reemployment outcomes. These findings are consistent with findings by Liu et al. (2014b) suggesting age-related deficits in self-regulated job search, but they also suggest that other external factors contribute to the finding that older workers take longer and are less likely to obtain reemployment.

Adult Development and Older Worker Challenges in Job Search and Reemployment

Older workers typically have longer job tenures compared to younger workers. As a consequence, they have historically been less affected by economic downturns and less subject to involuntary job loss compared to younger workers. However, when older adults do lose their jobs, they typically experience more difficulty obtaining reemployment. As a consequence, the likelihood of long-term unemployment and exit from the search process increases with age (Klehe et al. 2012; Wanberg et al. 2015).

This section addresses how changes in person attributes, such as abilities, skills, and social relationships, may affect self-regulated job search and employment outcomes.

Adult Development and Reemployment Goals. Some lifespan theories of human development (e.g., Heckhausen and Schulz 1995) suggest that as individuals enter later adulthood, employment

becomes less important for providing attainment of important financial, psychological, and social life goals. By age 55, many adults have already spent two to three decades in a career or work role, during which time they have likely satisfied many of the life tasks that characterize early adulthood and midlife, including a sense of mastery over their work role, job promotions, pay raises, and financial resources to support exit from the workforce.

During later adulthood new challenges arise related to maintaining good health, developing avocational skills, and satisfying family-based generativity motives. For example, as individuals age there is normative, gradual decline in nearly all physical abilities. Physically, older adults exhibit declines in strength (Warr 1994), psychomotor abilities, visual acuity, and hearing abilities (Fortexa and Prieto 1994). Given that approximately 45% of workers over age 45 perform work roles that require repetitive physical tasks or work in uncomfortable conditions (Johnson et al. 2011), health decline is a salient issue for many older individuals. These age-related shifts also often lead to a corresponding decline in the perceived value of continued career employment for accomplishing important new life goals and tasks. As a consequence, commitment to obtaining reemployment and job search intentions following job loss may be lower for older adults nearing retirement age than for younger adults more interested in maximizing achievement opportunities (Kanfer et al. 2013; Wang and Shultz 2010).

At present, relatively little is known about the determinants of reemployment goals among older workers following job loss or the factors that may affect goal revision during job search. As noted previously, older individuals may differ in the clarity of their reemployment goal or the features of a new job that are most important. Low-wage earners and older adults with little financial wealth are likely to generate reemployment goals that emphasize income replacement, but such goals may be ill formed with respect to generating helpful job search strategies. Studies that have focused on aging and reemployment are consistent with these notions and indicate that factors such as

financial security, poor health, and attitudes toward retirement play a significant role in older adult reemployment outcomes (Lotters et al. 2013; Patrickson and Ranzijn 2003). Further, older adults who are less committed to reemployment goals are more likely to terminate job search following early search failure.

Adult Development and Job Search. Gradual age-related declines in fluid intellectual abilities that contribute to decline in short-term memory and reasoning are well documented (Salthouse 1996). In contrast, crystallized intellectual abilities and occupational knowledge tend to increase through late adulthood (Ackerman 2008). According to the theory of selection, optimization, and compensation (SOC; Baltes and Baltes 1990), older workers adapt to these changes by selecting environments and tasks that capitalize on existing knowledge and skills and by using social and technological supports to complete tasks.

Although older workers may successfully compensate for age-related declines in cognitive abilities on the job (Ng and Feldman 2008; Yeung and Fung 2009), different adaptive strategies may be required in the employment marketplace. Older adults are more likely to use outdated search methods than younger adults, such as job listings in newspapers, even though most job listings and applications today are exclusively online (Gibson et al. 1993; Government Accountability Office 2012; Heidkamp et al. 2010), and older workers who have not been on the job market recently are less likely to have updated basic job search skills, such as preparing an effective resume (Patrickson and Ranzijn 2003) or practicing for an interview (Gibson et al. 1993). Age-related changes in cognitive abilities place a greater burden on the older individual during new skill learning, but older job seekers must often learn new job search skills, such as using online job listing sites. Low self-efficacy for learning new search methods may reduce the use of these methods and ultimately weaken job search intensity. Although SOC theory has yet to be applied directly to job search and reemployment, the theory suggests that job search skill learning and motivation may be enhanced by developing skill training programs that provide

the older adult with access to technological and social support aids when learning new job search methods.

Another area in which age-related changes may affect job search pertains to social relations. Although networking has become an increasingly important tool in modern job search, age-related declines in social network size (Wzrus et al. 2013) may reduce the effectiveness of this search method for older adults. For example, Van Hove et al. (2009) found that older job seekers' social connections were smaller and consisted more of weaker ties to lower-status individuals than did the social networks of younger job seekers. Older job seekers are also less likely to use networking as much as younger job seekers (Zikic and Klehe 2006). These findings suggest that older adults' networking abilities during job search are limited in both quality and scope compared to younger adults. Additional research is needed to evaluate the effectiveness of interventions that help the older worker develop more effective social networks for job search.

Environmental Challenges to Older Adult Job Search and Reemployment

Changes in the nature of job skills most desired by employers and employer negative age stereotypes represent two formidable barriers to older adult reemployment.

Skill Obsolescence. Compared to younger employees, older employees (with longer job tenures) are at higher risk for having outdated skills. Following job loss, older job seekers with obsolete skills are less likely to obtain reemployment. Skill obsolescence may occur when employees fail to update skills needed to accomplish new job tasks or when employment declines in an industry or occupational sector reduce the market value of an employee's skills (van Loo et al. 2015). Findings from several research streams suggest that the origins of job-specific skill obsolescence among older job seekers compared to younger employees lie in two areas: (1) the lower rate at which older employees participate (prior to job loss) in employee

development activities that afford opportunity for skill updating (Warr and Birdi 1998) and (2) organizational unwillingness to invest in older employee development (Hamil-Luker and Uhlenberg 2002). Other factors contribute to marketplace skill obsolescence. For example, because declining industries, such as textile manufacturing, are more likely to conduct mass employee layoffs that include older workers, the demand for job skills in those industries is lower (Hirsch et al. 2000), further reducing the number of potential jobs that call for the older worker's skills. Maestas and Li (2006) also suggest that older workers with longer job tenures tend to accrue "firm-specific" skills that may be valued by the organization, but not the larger external job market of that organization (Maestas and Li 2006). Finally, Hamil-Luker and Uhlenberg (2002) suggest that because older individuals tend to have lower levels of education and less job skills training than younger individuals, prospective employers often perceive older workers as less employable.

Following job loss, there is often little an individual can do other than to participate in skill updating or new skill training in order to reduce the negative effects of skill obsolescence on reemployment outcomes. However, for some older job seekers, the immediate financial, social, and psychological costs of training may well surpass the long-term benefits of training to improve the likelihood of reemployment for what may be perceived to be a relatively short period of time (until retirement).

Negative Age Stereotypes and Age Discrimination. Age stereotypes are beliefs and expectations about individuals based on their age (cf. Posthuma and Campion 2009). Employer age biases, developed from age-based stereotypic beliefs, operate as subtle and pervasive impediments to older worker reemployment success (Bal et al. 2011; Roscigno et al. 2007). Although the 1967 Age Discrimination in Employment Act makes employer decision-making based on age illegal, the legislation does not preclude attitudinal or affective biases that employers may hold about older individuals or their unintentional effects on hiring decisions.

There is extensive research on the prevalence of negative, age-based stereotypes, but less direct evidence on the impact that such negative stereotypes exert in real-world hiring decisions (Hedge et al. 2006). Ahmed et al. (2012) provide evidence for negative age stereotype bias in their study of hiring decisions across a range of restaurant and sales jobs. They found that younger applicants who submitted resumes for restaurant and sales jobs received significantly more responses from employers than older applicants (who submitted the same résumés).

Qualitative and meta-analytic reviews on the validity of negative age stereotypes by Posthuma and Campion (2009) and Ng and Feldman (2012) indicate that common negative stereotypes about older workers are not valid. For example, results of a recent meta-analytic review by Ng and Feldman (2012) on six negative age stereotypes (e.g., that older workers are less motivated or less healthy) found support for only one stereotype, namely, that older workers are less willing to participate in training and career development activities.

During job search, older adults often attempt to overcome negative age stereotypes by concealing their age on résumés, making changes to physical appearance, and using updated language in interviews (Berger 2009; Lyons et al. 2014). The use of negative aging stereotypes by employers during the hiring process can also be discouraging to older job seekers and may spur these individuals to exit the labor force after several unsuccessful reemployment attempts (Maestas and Li 2006). Although little support exists for most negative age stereotypes, their influence on employer decisions can reduce job search motivation as well as the likelihood of reemployment.

Summary and Future Research Agenda

Job loss and job search during later adulthood is becoming increasingly common as older individuals seek to remain in the workforce longer, whether by choice or financial necessity. Research findings support the use of a self-regulation model of the job search process as a viable framework for

understanding the job search process and how it relates to reemployment outcomes. Evidence to date suggests that following job loss, older job seekers, particularly those over age 50 (Wanberg et al. 2015), experience greater difficulties in job search, longer job search, and lower likelihood of obtaining reemployment than younger job seekers. Theories of adult development have proved fruitful for identifying some of the unique challenges that older job seekers confront during the search process, but do not fully account for age-related differences in reemployment outcomes. Findings from research focused on environmental determinants suggest that skill obsolescence and negative age bias in employer hiring decisions also play a significant role in older job seeker reemployment. Although certainly not an exhaustive list, three broad and promising avenues for future research on job loss, job search, and reemployment in later adulthood may be identified:

1. *The development and dynamics of reemployment goals*

Findings to date suggest that job search clarity plays a positive role in self-regulated job search and reemployment outcomes (Zikic and Klehe 2006). Additional foundational research is needed to understand the latent structure of reemployment goals for older adults nearing normative retirement age and to provide for valid assessment of these goals. Advances in these areas can be expected to aid in the development of at least three promising research streams: (1) research aimed at identifying key patterns of reemployment goal revision among older adults across the job search process, (2) studies that examine the relationship between reemployment goals, employability, and well-being, and (3) studies to examine the prevalence of “job choosiness” among older job seekers and its impacts on job search and reemployment outcomes (Trivellato and Giraldo 2006).

2. *Job search and reemployment outcomes*

Most studies of job search and reemployment following job loss employ relatively high-level measures of reemployment

outcomes, such as whether the individual obtained reemployment and the duration of unemployed job seeking before employment was secured. Over the past 15 years, organizational researchers have repeatedly called for more research attention to reemployment quality (Saks 2006; Koen et al. 2010; Wanberg et al. 2015). This issue is particularly important for older adults, for whom poor-quality reemployment may hasten exit from the workforce.

3. Adult learning, job loss, and employability

Although macro-level economic conditions and organizational restructuring may account for a substantial portion of older adult job loss, a few recent findings suggest that older adults who continue to develop work skills of value to the organization are less likely to lose their jobs than individuals who do not participate in development opportunities (Allen and de Grip 2012; de Grip and van Loo 2002). Similarly, individuals who engage in continuous learning may be more desirable in the employment marketplace. Although many studies have focused on the impact of age-related declines in cognitive function in traditional training settings, less attention has been given to the participation and learning outcomes of older adults in alternative training methods, such as on-the-job training and informal training (Van der Klink et al. 2014). Future research into the determinants and patterns of later adulthood learning (Beier and Ackerman 2005) and its relationship to employability and reemployment outcomes holds strong theoretical and practical promise.

Synonyms

Continuity management; Intergenerational knowledge transfer; Intergenerational learning; Knowledge management; Reverse knowledge transfer

Definition

In the context of aging workforces, knowledge retention refers to management practices and processes designed to preserve older workers' valuable organizational knowledge before they enter retirement.

Introduction

Workforces in most developed countries are aging because of the simultaneously operating trends of increased life expectancies and decreased birth rates (United Nations 2013). Due to the large numbers of very experienced older and retiring

workers from the so-called baby boomer generation, organizations are facing an unprecedented and unintentional loss of valuable organizational knowledge (Beazley et al. 2002; Daghfous et al. 2013). When valuable employees retire, valuable knowledge retires with them if there are no effective knowledge management or human resource (HR) management processes in place to prevent it. Calo (2008, p. 404) argued that this combination of interrelated and undesirable demographic conditions creates a “perfect demographic storm.” Several researchers have focused attention on the risks associated with losing older and retiring workers' knowledge. These risks range from reduced quality, efficiency, and performance (Ashworth 2006; Beazley et al. 2002; Strack et al. 2008) to diminished creativity (Calo 2008) and limited capacity of organizations to learn from past experience (Dunham and Burt 2011). To prevent *corporate amnesia* (Harvey 2012), organizations need to develop knowledge retention strategies to safeguard valuable organizational knowledge of older and retiring workers.

The objective of this entry is threefold. First, the main terms related to knowledge retention are clarified, the nature of the knowledge retention process is discussed, and its antecedents are identified. Second, knowledge retention is related to life span development theories, such as socioemotional selectivity theory (SST; e.g., Carstensen 2006), and motivations of workers to engage in knowledge retention, and these theories

are reviewed. Third, implications for practitioners and directions for future research are discussed.

Knowledge Retention Through Knowledge Transfer

In the context of aging workforces, knowledge retention refers to practices and processes that preserve valuable organizational knowledge of older workers before they enter retirement. For this entry, we take older workers to be employees who are older than 50 years and due for retirement within the next 15 years (Joe et al. 2013). Currently, these workers are members of the so-called baby boomer generation, which is large in numbers and consists of workers born between 1946 and 1964 (Kuyken 2012). This kind of generational concept has been challenged because of its lack of theoretical and empirical foundation (Costanza et al. 2012; Costanza and Finkelstein 2015) and will only be used descriptively in this entry to distinguish between the different actors involved in the knowledge retention process.

Knowledge of Older Workers

Older workers' knowledge has been defined as the sum of their explicit and tacit knowledge (Lahaie 2005). Knowledge can be defined as "information [interpretation of data (i.e., facts)] interpreted by an individual and applied to a purpose for which it is needed" (Bender and Fish 2000, p. 126). Tacit knowledge is different to explicit knowledge and describes knowledge that is complex, difficult to codify, and difficult to teach (Zander and Kogut 1995). Researchers have argued that the knowledge of older workers is mainly tacit (Beazley et al. 2002; Kuyken 2012; Martins and Meyer 2012). For example, older workers possess knowledge about the functioning of their organization with regard to its norms, politics, and culture, and they have extended intra- and interorganizational networks (Ebrahimi et al. 2008; Joe et al. 2013; Kuyken 2012). In addition, the knowledge of older workers has been related to the concept of *organizational memory* (Dunham and Burt 2011; Lahaie 2005), which is defined as "stored information from an

organization's history that can be brought to bear on present decisions" (Walsh and Ungson 1991, p. 610). Importantly, this knowledge held by older workers is useful for learning from past experiences (Dunham and Burt 2011). In addition, older workers' knowledge about who knows what, and their potential ability to connect different knowledge sources, has been explained using *transactive memory* theory (Ashworth 2006; Ebrahimi et al. 2008). Transactive memory theory (Wegner 1987) explains how group members tend to rely on each others' expertise to perform demanding tasks, such that each member specializes in specific areas, thus ensuring that all relevant information is available through combining all their specialized knowledge.

Resulting from the diverse attributes that have been associated with the knowledge of older workers, they have been described as *deep smarts* (Kuyken et al. 2009). The use of this term highlights that older workers' knowledge goes beyond traditional definitions of knowledge that focus on asocial, objective, rational truths (e.g., Bender and Fish 2000). Researchers have used the terms *expertise* (Ebrahimi et al. 2008; Joe et al. 2013) and *wisdom* (Beazley et al. 2002) to more accurately depict the depth of the knowledge and capabilities of older workers. Expertise is acquired over longer periods of time and refers to "specialised, deep knowledge and understanding in a certain field, which is far above average" (Bender and Fish 2000, p. 126). Wisdom is based on reason while explicitly allowing for the nonrational (McKenna et al. 2006, 2007; Rooney et al. 2010a). However, one should be careful not to assume that wisdom necessarily comes with age, experience, and expertise. Many older people, experienced people, and experts are not wise. Wisdom is linked to how one learns, deeply, from experience, regardless of age, and how one transcends technical expertise with insight, imagination, values, and empathy.

Knowledge Transfer

Knowledge is profoundly social and works within communities of practice (Nonaka and Takeuchi 1995; Rooney 2005; Tsoukas 2005). Knowledge exists in the relationship between people as much

as it does within individual minds. More particularly, the value of knowledge is created as it passes or transfers or is communicated between people in social exchanges (Owen-Smith and Powell 2004).

Researchers argue that older and retiring workers who possess valuable organizational knowledge need to be involved in knowledge transfer initiatives to prevent knowledge loss (Beazley et al. 2002; DeLong 2004). Knowledge transfer involves sharing or communicating knowledge (Szulanski 1996; Wang and Noe 2010). For knowledge retention to occur, older and retiring workers and those workers that are potential knowledge recipients need to interact and communicate in knowledge transfer processes, that is, social interaction and communication. Importantly, these interactions require some level of intimacy for tacit knowledge to be transferred (Rooney et al. 2013). In the context of this entry, these potential knowledge recipients will be younger than the retiring workers, and they often belong to different generations (e.g., generation X, generation Y; Baily 2009). Therefore, researchers refer to knowledge retention through knowledge transfer as *cross-generational knowledge flows* (Liebowitz et al. 2007), *intergenerational learning* (Baily 2009), and *intergenerational knowledge transfer* (Burmeister and Deller low risk R&R; Harvey 2012).

Competing Models: Source-Recipient Model and Mutual Exchange Model

Extant research discusses whether knowledge retention through knowledge transfer is more accurately represented by one-directional or bidirectional exchange processes. Drawing on the source-recipient model, older workers are depicted as knowledge sources, and younger workers as knowledge recipients. Transfer occurs through the one-directional transmission, older workers' knowledge to younger workers. In contrast, the mutual exchange model proposes that knowledge is codeveloped by older and younger workers and that both groups of actors engage in sharing and reception of knowledge (Harvey 2012). For example, younger workers can contribute current scientific and technical knowledge and function as catalysts that unlock the knowledge

base of older workers (Ebrahimi et al. 2008; Tempest 2003). As a result, knowledge retention through knowledge transfer is understood as a bidirectional, dynamic, and interactive process. We argue that both models can be accurate representations, depending on situational characteristics and the type of knowledge to be transferred. For example, if highly tacit knowledge must be transferred, older and younger workers need to engage in more intense or intimate interactions to make sense of the knowledge. The mutual exchange model more accurately depicts this type of transfer. Conversely, the retention of explicit knowledge that can be documented in written form is more easily transferred without meaningful social interactions. This type of transfer describes the source-recipient model. It is important to understand that most knowledge, and high-value knowledge in particular, is rarely in the form of purely explicit knowledge (Rooney et al. 2003). There is usually a high degree of tacitness in knowledge, and so the mutual exchange model is usually the most relevant model.

Antecedents of Knowledge Transfer Success

Knowledge transfer research argues that four groups of antecedents influence knowledge transfer success: (1) knowledge characteristics (e.g., Zander and Kogut 1995), (2) individual characteristics (e.g., Argote et al. 2003), (3) relationship characteristics (e.g., Hansen 1999), and (4) contextual characteristics (e.g., Kostova 1999). Researchers have started to examine the applicability of these antecedents to knowledge retention processes. First, knowledge characteristics and particularly knowledge tacitness are argued to influence the degree of social interaction between senders and recipients that is necessary to facilitate knowledge transfer (McNichols 2010). In addition, knowledge characteristics are considered in terms of the relevance and importance to an organization of older workers' knowledge because not all knowledge is relevant to organizational performance. Therefore, organizations need to assess the relevance of the knowledge from older workers before they invest in knowledge retention (Beazley et al. 2002).

Second, the discussion about individual characteristics revolves around the ability and motivation of older and younger workers to interact and share knowledge (Dunham and Burt 2011; Kuhn and Hetze 2007). Thus, the more able and motivated individuals are to engage in knowledge transfer behavior, the higher the probability of successful knowledge retention. Third, relationship characteristics refer to variables that affect the quality of the relationship between knowledge senders and recipients. In the context of intergenerational knowledge transfer (IGKT), the age differences between older and younger workers have been discussed as barriers to transfer success because dissimilarities might result from a lack of shared cognitive frames of reference and mental models (Harvey 2012; McNichols 2010). In addition, lack of mutual trust and respect are emphasized as other barriers to IGKT (Harvey 2012; McNichols 2010). Mutual trust reduces the risk involved in engaging in knowledge transfer behavior. Fourth, contextual characteristics are highlighted as an important factor for IGKT. Accordingly, HR managers can support IGKT processes by creating opportunities for exchange, enabling and motivating workers to engage in IGKT through, for example, training and reward programs, and aligning HR practices and processes to facilitate knowledge retention (Beazley et al. 2002). Furthermore, organizational cultures need to support a learning environment and encourage openness, teamwork, and knowledge sharing, to facilitate IGKT (Beazley et al. 2002; McNichols 2010). IGKT should, therefore, be seen as part of the work of managing organizational diversity and creating organizational cultures that are open and inclusive (Pauleen et al. 2010).

Knowledge Retention and Life Span Development Theories

Theories of psychological aging focus on how individuals experience their own aging and how they anticipate time-induced changes (Hertel and Zacher *in press*). Life span development theories propose that behavioral development should be seen as a lifelong process in which growth and

decline occur jointly (Baltes 1987). To understand IGKT behavior of older and younger workers, life span development theories that focus on age-induced changes in goal orientations are particularly useful. For example, socioemotional selectivity theory (SST) introduced by Carstensen (2006) claims that individuals select and pursue goals as a function of subjective perceptions of remaining time. As a result, if time is perceived as unlimited, individuals prioritize knowledge-related goals, whereas individuals who perceive time as limited tend to focus on emotional goals and social values (Carstensen et al. 1999). This prediction is in line with Erikson's (1963) theory of psychosocial development that introduced generativity as a fundamental motive in the seventh of eight stages of human development and as gaining in importance through adulthood (Hertel et al. 2013). Generativity can be defined as "the concern in establishing and guiding the next generation" (Erikson 1963, p. 267). In accordance with these theoretical assumptions, empirical research has indeed shown that age is positively related to generativity values (e.g., helping, legacy) and negatively related to extrinsic growth values (e.g., gaining influence, advancing one's career; Hertel et al. 2013).

Using SST and psychosocial development theory, IGKT can be seen as a mechanism that addresses the different needs and motivations of older and younger workers. On the one hand, the growth values of younger employees are addressed by providing them with access to important and useful organizational knowledge of older workers. Younger workers can use this organizational knowledge to increase their performance and advance their careers. On the other hand, older workers receive the satisfying opportunity to share their knowledge with others and give something back. As a result, IGKT can ensure that the knowledge of older workers is safeguarded and will continue to be used in the future, even if they leave the organization.

Future Directions

The theoretical foundation of knowledge retention research needs to be strengthened. Studies

either lack theoretical foundation or provide limited reasoning for how and why older and younger workers engage in knowledge retention and IGKT. One exception is provided by Ropes (2013), who used Erikson's (1963) generativity concept to argue that IGKT contributes to the self-fulfillment of older workers. Future studies can draw on life span development theories to explain age-related differences with regard to knowledge transfer behavior. In addition, other theories that are relevant to knowledge transfer behavior, such as social exchange theory (Blau 1964), social identity theory (Tajfel 1974), place identity theory (Rooney et al. 2010b), organizational learning theory (March 1991), social learning theory (Wenger 2000), communities of practice theory (Wenger 1998), intergenerational communication theory (Williams and Nussbaum 2013), and wisdom theory (Oktaviani et al. online first), should be considered.

An important concept in education research is authentic learning (Lombardi 2007). Authentic learning is primarily about giving students the opportunity to encounter complex questions, problems, or situations that they are likely to face in the future and to develop mastery through that engagement (Cronin 1993). Rule (2006) says the core dynamics of authentic learning are (1) encountering (close approximations of) real-world problems, (2) using higher order thinking skills, (3) communicating between members of a community of learners, and (4) empowering students to choose their own learning pathways. Based on the discussion set out above, and particularly our discussion following the mutual exchange model, there is clearly much scope for applying an authentic learning approach in IGKT. To date, there appears to be no empirical research on authentic learning in IGKT situations, and there is much to be gained in the future from such research. Of course, in the IGKT context, we are talking about adult learning in the workplace, rather than school students in the classroom, but Rules' four core dynamics are readily transferable to the workplace and organizational learning.

Future research should also aim to overcome the methodological shortcomings of research on

knowledge transfer in general and with respect to IGKT in particular. Wang and Noe (2010) showed that current studies on knowledge transfer have the following limitations: overreliance on self-reports, single-source and cross-sectional data, and unclear definitions of outcome variables (e.g., frequency/quality/extent of knowledge transfer). In addition, studies on IGKT are often based on qualitative analyses or case studies (e.g., Harvey 2012), and samples are often small or not designed for generalizability. Having said this, qualitative research using discourse analysis and sociolinguistics, phenomenological, and grounded theory approaches will add significant new findings in relation to complex and hard to quantify aspect of the intersection of knowledge, values, and organizational culture with IGKT. In sum, future studies should aim to provide stronger theoretical contributions and use more advanced research epistemologies, designs, data collection approaches, and measurement instruments.

Practical Implications

To address the risk of losing valuable older and retiring workers' organizational knowledge, HR practitioners and knowledge managers need to develop an integrated knowledge retention strategy that includes the following three elements. First, key knowledge holders need to be identified, and the valuable knowledge that they possess needs to be documented. Second, mechanisms need to be set up that enable the transfer of this critical knowledge to other organizational members, in particular younger workers. Third, HR policies and practices and the organizational culture need to be aligned with the objective of knowledge retention.

Facts; Information; Skills

Definition

Knowledge represents a body of factual information, skills, and tools for understanding the world.

Types of Knowledge

Over the course of the last several decades, psychologists have settled on parsing knowledge into three different types. Ryle (1949/2000) first suggested two different types of knowledge, namely, knowing *that* (which has been termed “declarative knowledge”) and knowing *how* (termed “procedural knowledge”). Declarative knowledge is essentially factual knowledge, such as knowledge of geography (capitols of the world), history (names and events), humanities (artists, composers, and their works), and so on. Generally speaking, the common encyclopedia contains a comprehensive compendium of the declarative knowledge of a culture. Procedural knowledge mainly concerns skills that allow an individual to accomplish a task, whether it be driving a car or riding a bicycle, calculating a tip at a restaurant, or tasks such as diagnosing a car engine malfunction or a radiologist making a diagnosis from a chest X-ray. In the normal course of events, the acquisition of procedural skills typically involves declarative knowledge at the early stages of skill acquisition. For example, in learning to drive a car, a novice driver might attempt to memorize a set of condition-action pairings. For example, the driver might say to him/herself: “If I want to turn left, I need to turn on my signal, slow down, check for oncoming traffic, and then turn the wheel to the left.” With extensive practice, these condition-action pairings become automatized, such that the skilled individual “knows” how to accomplish the task without the explicit engagement of considering the sequence of condition-action pairings. At this point, psychologists consider the knowledge “proceduralized.” However, although it is common for skilled individuals to accomplish tasks without much explicit cognitive mediation (e.g., thinking about which keyboard keys to select to type an e-mail or which piano keys correspond to particular notes on the music score), proceduralized knowledge need not entirely be automatic. When an individual is performing a procedural knowledge skill, he or she may choose to explicitly consciously monitor his/her performance, especially when attempting to improve on

past performance, such as when attempting to improve one’s tennis or golf game.

The third type of knowledge, identified by Polanyi (1966/1983), called “tacit knowledge” represents a domain that is less well defined, when compared to declarative and procedural types of knowledge. Tacit knowledge represents the kinds of knowledge that people rely on to solve novel problems or to conduct means-ends analyses when confronted with tasks that cannot be solved directly by drawing on declarative knowledge or previously learned procedural knowledge/skills alone. Broudy (1977), for example, suggested that tacit knowledge is not easily accessible, so that it is often difficult or impossible for the individual to articulate the knowledge used for such problem solving. Nonetheless, Broudy suggested that tacit knowledge represents the foundation for what an individual “thinks, perceives, and judges with everything he has studied in school, even though he cannot recall these learnings on demand” (Broudy 1977, p. 12).

Knowledge Acquisition

Over the last century, psychologists and others have explored numerous ways in which acquisition of knowledge can be effective and efficient. Novel attempts at making procedures such as implicit learning or sleep learning effective have been tried and generally found largely useless. Variants of more traditional approaches that typically involve direct memorization or associative learning (e.g., when learning a new language, pairing known words in the home language with words having the same or similar meaning in the new language) represent the most effective means of acquiring new declarative knowledge. Periodically, researchers rediscover that drill and practice, and periodic tests for knowledge learned, may increase the overall effectiveness of declarative knowledge acquisition over learning without frequent testing (see Bransford et al. 2000).

Acquisition of procedural knowledge is somewhat more complex, and as a result, the most effective methods for acquiring procedural knowledge are less well understood, in

comparison to the acquisition of declarative knowledge. Because, as discussed earlier, acquisition of procedural knowledge often starts with an individual acquiring a declarative knowledge representation of the material (such as learning to pilot an airplane or become a radiologist), it is necessary for the learner to spend a considerable amount of time and effort acquiring a declarative representation of the task requirements before even starting to practice the procedural task. Individuals seeking to become a pilot or a medical doctor may spend hundreds of hours in classroom instruction to learn basic principles or system functions, before a novice pilot climbs into the pilot's seat or a novice medical student attempts a diagnosis of a human patient. Because acquisition of such procedural skills involves a combination of declarative knowledge learning and hands-on task practice, researchers have investigated various combinations of such skills, mixing different amounts and sequences of rote and associative learning and task practice, in order to find an optimal process for building new procedural skills. Some attempts have been aimed at breaking the tasks into components and providing part-task training prior to complete task practice or "scaffolding" learning in a sequence that allows the learner to build up procedural knowledge in phases (for a review, see Druckman and Bjork 1991).

With respect to tacit knowledge, there is virtually no direct research on how to build new tacit knowledge, mainly because it is not currently possible to determine exactly how individuals develop tacit knowledge. Even attempts at determining the nature and scope of tacit knowledge have been largely very narrow (restricted to particular tasks or occupations) and not entirely successful in eliciting such knowledge in a reliable fashion.

Aging and Knowledge Acquisition

Laboratory research comparing younger and older adults in the acquisition of knowledge started in the early part of the twentieth century. The findings from this older literature indicated that children and young adults acquire new knowledge faster than middle-aged or older adults and have

higher degree of knowledge at asymptotic levels of practice (e.g., see Hollingworth 1927; Ruch 1934; Thorndike et al. 1928; for a review, see Ruch 1933). More recent research efforts have typically compared the knowledge acquisition performance of college students and adults over the age of 60. These comparisons yield largely similar results to those found in the 1920s and 1930s. That is, young adults learn faster and retain knowledge after explicit learning exposure at a higher level than older adults (see, e.g., reviews by Light 1991; Johnson 2003; and by Verhaeghen et al. 1993).

Transfer and Knowledge Acquisition

The one area where middle-aged and older adults can be expected to perform as well as young adults in the acquisition of new knowledge, or at least show less of a deficit, in comparison to young adults, is when new knowledge is built on a foundation of old knowledge. That is, middle-aged and older adults are found to be at a disadvantage in acquiring "novel" declarative knowledge (i.e., knowledge where there is no external context – such as the task of memorizing random words or numbers), compared to young adults. However, most real-world declarative knowledge is highly contextualized, that is, the knowledge to be acquired is part of a larger network of interconnected foundational knowledge. Those individuals who have higher levels of relevant domain knowledge will be faster in learning new factual information than those from whom the new knowledge is novel. For example, when reading a newspaper (or online news item), the typical adult scans the article for information that is "new" and can either refresh old knowledge or give it only a cursory examination. For an adult, information about politics, entertainment, current events, and even science and technology is acquired incrementally, so that the load on the individual's memory capabilities is much lower than for someone who is not familiar with the general foundational content of the new information. Middle-aged adults who have higher levels of what is called "crystallized intelligence" (basically, their depth and breadth of domain knowledge) are much more effective in acquiring

new declarative knowledge, compared to either younger adults or other middle-aged adults who have lower levels of crystallized intelligence (e.g., see Beier and Ackerman 2005).

Knowledge Retention

Clearly, older adults are at a general disadvantage, compared to young adults, in acquiring new declarative and procedural knowledge. Studies of short-term knowledge retention, both in and outside of the laboratory, consistently show that middle-aged and older adults are at such a disadvantage compared to young adults (e.g., see Light 1991; Kubeck et al. 1996). Nonetheless, once knowledge is acquired, whether by younger or older adults, there are critical and open questions about the effects of aging and long-term knowledge retention. The problem is difficult, given numerous methodological obstacles in studying long-term knowledge retention, mainly because time delays between assessments involve aging effects, but also often intervening opportunities for use of the knowledge, new learning, and reminiscence effects. Thus, the studies described below provide somewhat indirect evidence on the resilience of knowledge over long periods, but together they present an optimistic view about aging and knowledge retention.

Declarative Knowledge

The first long-term study of knowledge retention was performed by Owens (1953). He examined a group of men who had completed the Army Alpha test battery (an early adult test of intellectual abilities) in 1919, when they were about 19 years of age. He readministered the test to the same men 31 years after the original test and found significant gains in performance on two subtests, a test of information (general knowledge) and a verbal ability test (synonym/antonym). It is impossible to determine how much exposure to these materials or use of the knowledge was experienced during the intervening years, but these results indirectly suggested that declarative knowledge retention can be very good over a long period of time. In a more precisely controlled study of individuals

over several decades, starting in 1956, Schaie (1996, 2005), in the context of the Seattle Longitudinal Study, found similarly impressive performance of individuals on tests of verbal knowledge (e.g., vocabulary).

In a different line of inquiry, Bahrck and his colleagues (e.g., Bahrck et al. 1974) examined adults, 35 years after graduating from high school. They found that these individuals correctly recognized 90% of their classmates, based on photographs. In another study, Bahrck (1984) examined Spanish language retention, over various time periods, up to 50 years after initial instruction. What he found was that although much of the acquired knowledge was lost in the 6 years following instruction, substantial knowledge was retained up to about 25 years after instruction. Most importantly, Bahrck determined that individuals retained more knowledge when it was originally acquired over a long period of initial instruction and that individuals with superior performance at initial knowledge acquisition (e.g., students who had received higher grades) retained substantially more knowledge than those who did not have such high level of initial performance.

From a different perspective, Beier and Ackerman (2001) examined “current-event” declarative knowledge in a sample of individuals from age 20 to 69, where the events had occurred during the decades from the 1930s to 1990s. They found that adults tended to have the highest levels of current-events knowledge from the respective periods of late adolescence or early adulthood. Although this was a cross-sectional study (i.e., individuals were not followed over time, but rather separate age groups were examined at a single time), these results are consistent with the notion that there may be critical periods for acquisition of declarative knowledge around late adolescence – an idea that is also supported in studies of autobiographical memory (e.g., Rubin 1995).

Procedural Knowledge

Measurement of procedural knowledge retention can be performed with two related methods. The first method is relatively straightforward – individuals are confronted with a task previously

learned and asked to reproduce the performance. However, this is a one-shot examination. That is, if the individual is given an opportunity to try the task more than once, or even if the task is extensive in time, the problem then becomes one of an unknown amalgamation of assessing retention and assessing relearning of the procedural skill.

Consider the task of riding a bicycle. One could conceivably train a group of young adults or even children on how to ride a bicycle. At some later point, these individuals return to the lab and are asked to ride the bicycle again (presumably excluding those who had intervening experience with bike riding). In the first minute or so of performance, those individuals are both attempting to show their retained knowledge and also increasingly are becoming re-familiarized with the skill (one frequently hears such individuals say something on the order of: “it is all coming back to me now”). From this perspective, the typical method for assessing retained procedural knowledge is to examine a relearning curve. That is, one compares how much time (or how many discrete task trials) is required for the individual to again reach a criterion level of task performance, against the original learning curve for those individuals and/or initial learning curves for a separate group of individuals of the same age, who had no prior experience with the task.

The most interesting investigation of this type was reported by Hill (Hill et al. 1913; Hill 1934, 1957). In the original investigation, Hill learned how to touch-type on a typewriter in daily practice sessions over a 5-month period. Hill returned to the typewriter only twice – once 25 years after the initial procedural knowledge acquisition and then 50 years after the initial practice (when he was 80 years old). At 25 years without practice, Hill performed at the same level of performance that had been achieved after 27 days of initial practice. At the 50-year retention evaluation, it only took Hill 8 days of relearning to reach the level of performance that he had achieved 25 years earlier!

Because study of long-term retention of procedural knowledge requires that individuals, like Hill, do not practice the task over long periods of time, there are no other similarly designed

investigations in the literature. However, the evidence from relatively short-term studies (on the order of weeks or months, rather than years) is that “forgetting increases as a positive function of the retention interval, overlearning is beneficial for retention, relearning after a retention interval is more rapid than the original learning, [and] discrete procedural responses are forgotten more readily than continuous motor skills” (Adams 1987, p. 65; see also Farr 1987).

When it comes to generalizing these findings to the area of adult aging, one important caveat is needed. That is, procedural knowledge skills almost always involve a major component of physical operations, whether they be gross motor movements (as in riding a bicycle) or fine motor coordination (such as in performing cardiac surgery). Thus, the effects of aging on the expression of procedural knowledge may be adversely affected by normal effects associated with the reduction of motor capabilities with advancing age (not to mention additional issues associated with visual and auditory sensory changes also associated with aging). With that caveat in mind, the existing research suggests two important things about the retention of procedural knowledge: (1) High levels of retention are substantially associated with periodic exposure and practice with the skill; and (2) Once learned to a high degree of competence, many procedural skills may be very much like the old adage about riding a bicycle (i.e., once learned, never [entirely] forgotten).

Knowing With. As discussed earlier, the nature of tacit knowledge makes direct study of retention exceptionally challenging. Thus, there are really no studies that establish the retention of tacit knowledge in the course of adult aging. Several investigators have attempted to reframe aspects of tacit knowledge, for example, in the study of “wisdom” and aging (e.g., see Baltes and Staudinger 2000). However, such studies fall short of the goal of examining tacit knowledge, as they depend on performing novel tasks, rather than explicitly calling on an individual’s repertoire of previously acquired strategies for problem solving. Currently, it is not clear what the pattern of retention and forgetting is for this type of knowledge.

Summary and Conclusions

Psychologists have categorized knowledge into three types: knowing that (declarative knowledge), knowing how (procedural knowledge), and knowing with (tacit knowledge). After nearly 100 years of investigations into the relationships between aging and knowledge, researchers have come to a general consensus on at least some of the critical issues. First, acquisition of new knowledge is faster and more effective for adolescents and young adults, compared to middle-aged and older adults. In laboratory studies of novel fact learning or acquisition of novel procedural skills, older adults tend to perform less well initially and typically do not reach the asymptotic levels of performance obtained by young adults. However, it is important to keep in mind that these are average differences – there is substantial overlap in the distributions of learning rates and overall performance between younger and older individuals. Second, because real-world knowledge acquisition is influenced by an individual's domain knowledge, differences between young and old adults in acquiring contextually dependent knowledge in many domains are smaller than those found for acquiring context-free or novel knowledge.

Studies of knowledge retention suggest that both young and older adults benefit greatly from continued access and use of domain knowledge. When declarative knowledge is not accessed over long periods of time (such as when learning a foreign language in school, but not using or practicing again for many years), the degree of retention is dependent on how well the knowledge was acquired to begin with. But in general, lack of use leads to substantial losses in declarative knowledge. For many types of procedural knowledge and skills, the extant research suggests that after long periods of time without practice or use of such skills, performance is reduced, yet is much more quickly reacquired with new practice than the rate the material was acquired during initial learning and skill acquisition.

Aging effects on the acquisition and retention of tacit knowledge remains much less well understood, compared to declarative and procedural

forms of knowledge. Related investigations suggest that when this type of knowledge is well integrated into an individual's day-to-day activities (such as having a job that makes substantial cognitive demands (see Schooler et al. 1999), such knowledge might be retained well into older adult years.

In the final analysis, acquiring new knowledge and skills is easiest for adolescents and young adults. But, knowledge acquired during this period can be well maintained in middle age and beyond, when the knowledge is accessed and used and when the procedural skills are practiced. An individual's knowledge in adulthood is the result of early investments and continued efforts toward maintenance. There may ultimately be a good scientific basis for the common belief of the benefits of efforts with tasks such as doing crossword puzzles and similar activities.

Korean Centenarian Study, Comprehensive Approach for Human Longevity

Sang Chul Park
Department of New Biology, DGIST, Daegu,
South Korea

Definition

The nationwide Korean Centenarian Study is special in that a multidisciplinary team approach has been successfully applied through the collaboration of medical, genetic, psychological, nutritional, ecological, economic, family, social, and anthropologic experts. Thereby, it could be possible to explain the features of the centenarians through a holistic approach for the differential and interactive influences of genes, gender, eco-habitats, diets, and socio-cultural variables on longevity. Genetic traits of the Korean centenarians are unique, illustrating the gene and environmental interactions. Gender ratio of centenarians is rather biased to female, and not uniformly but regionally localized. Male centenarians, though fewer in number, are better off functionally and need less medical care than female centenarians. Centenarians living in the mountainous regions are better off than those living near the seashore. Centenarians with outdoor activities showed the significantly higher levels of serum albumin, but a lower serum triglyceride level as compared to the sedentary centenarians. The proportion of centenarians who scored high in dietary diversity was significantly higher in mountainous areas than in the coastal areas. These data implicate the heavy interactions among many variables for longevity. Based on the integration of these variables, a new model for human longevity is proposed, “Park’s Temple Model for Human Longevity.” In this model, the longevity-associated variables are classified into layers of bottom, pillars, and rooftop. The bottom component of the temple consists of the variables, such as genes, genders, personality, ecology, and social cultures, which are basically

not readily changeable. The pillar components are related with personal life styles, such as exercise, nutrition, relationship, and participation, which are more or less readily modifiable. The rooftop components are rather socially or politically determining variables, such as social care, safety, and medical support system. Therefore, this compensating, balancing, and comprehensive model for human longevity, based on the Korean Centenarian Study's multidisciplinary and integrative team approach, may provide a new tool to explain the mechanism of human longevity and also may contribute to analyze the dynamic changes of population longevity.

Genetic Variables for Longevity

Multiple candidate genes for longevity have been reported in previous centenarian studies. Genes, involved in inflammation and the immune responses (e.g., *IL6*; *LMP2*; *TNFA*; *TGFBI*; and *PPARγ*), genome maintenance and repair (e.g., *P53*), lipid metabolism (e.g., *APOE*; *CETP*; *MTTP* and *PONI*), glucose metabolism (e.g., *IGF1* and *HFE*), oxidative stress (e.g., *SOD1*; *PARP*; and *GSTT1*), mitochondrial mutation, premature aging syndromes such as Werner syndrome (i.e., *WRN*), and telomere length, have been suggested with respect to both age-related diseases and longevity (Murabito et al. 2012). However, genetic variation exists across ethnic groups. Significant association of genes for human leukocyte antigen (*HLA*), *ACE*, *APOE*, *MTTP*, and *CETP* with human longevity in Caucasian populations has not been replicated in studies using Korean centenarians (Choi et al. 2003; Park et al. 2009). Rather, a reverse relationship between the incidence of cancer and degree of longevity has been observed, indicating that prevention of cancers may be an important strategy to enhance lifespan in Korea (Kwon and Park 2005). This notion could be applied to other age-related illnesses such as diabetes mellitus and cardiovascular diseases as well (Park et al. 2009). Individual survival differences may reflect the effect of deleterious genotypes of age-related diseases. Some longevity genes (e.g., *klotho*) buffer the

deleterious effect of age-related disease genes (e.g., lipoprotein, Lp(a)), which may explain an observed paradoxical increase of deleterious genotypes in centenarians. Among many of the genes, the Korean centenarian Study revealed two interesting features of longevity-associated genes. First, a relationship between apoE4 and longevity, well proven in Western countries for its linkage with longevity, could not be reproduced, though its association with dementia status could be confirmed (Choi et al. 2003). Second, an association of MLH1, a feature of the DNA repair system, with longevity was observed in the Korean centenarian Study (Kim et al. 2006). Also, V-yes-1 Yamaguchi sarcoma viral-related oncogene homolog (*LYN*) was found to be associated with longevity (Kwon and Park 2005). These data reflect the unique feature of Korean longevity distinct from those of Western countries. Mortality in Western countries is mainly related to cardiovascular diseases, while mortality in oriental countries such as Korea and Japan is linked to cancer. The major differences in mortality factors could be traced to regional traditional dietary patterns. The dietary habits of Western countries are dominated by animal products, while those of Asian countries are mainly vegetable oriented, leading to morbidity and mortality differences. These data would be good examples for gene and environmental interactions for longevity, implying that the evolutionary genetic selection for the fittest in the respective regions has been operated towards longevity in a tradition-dependent life style course.

Gender and Ecological Variables for Longevity

The distribution of centenarians in Korea is not random but relatively localized, and those areas with high density of centenarians could be defined as the long live zones. For designation of long live zones, both of the centenarian index (number of centenarians/1,00,000 population) and longevity index (number of oldest old people over 85 years of age/number of old people over 65 years of age) were used for comparison. The southwestern area

of Korean peninsula, specifically localized with four counties (Gurye gun, Goksong gun, Sunchang gun, and Damyang gun, in short named GuGokSunDam area), was designated as the representative long live zone in Korea (Park 2002). But when regional longevity was compared by gender difference, male longevity was highest in cold mountainous northeastern areas, whereas the highest female longevity stemmed from southwestern hilly and warm areas. The regional gender-specific differences of longevity might be affected by the area-dependent environmental factors such as ecological habitats, and social and cultural traditions in addition to habitat-dependent lifestyles. In terms of habitat, the climate would be an important factor in the observed regional differences in longevity in addition to the amount of physical activity and medical service. Warm climate is assumed to be beneficial for longevity because of its protective effect against many respiratory diseases. However, in Korea, mountain centenarians living in cold areas showed a tendency to perform more outdoor activities as compared to seaside centenarians living in warm areas, suggesting that the climate effect on longevity can be overcome by increased physical activity, though limited to male centenarians (Park 2002). Self-rated health status is much better in mountain-living and male gender centenarians, implicating the importance of taking part in active regular exercise and outdoor activities in their daily lives. Some notable differences in health statuses were observed according to region and gender. Only 4% of mountain centenarians had serum albumin levels lower than 3.3 g/dl, while 26% of seaside centenarians had such levels with a higher anemic index, suggesting that the mountain centenarians are in better health as compared to the seaside centenarians (Park 2008).

Life Style Variables for Longevity

The Korean Centenarian Study reported significant differences in the occurrence of centenarians by gender, location, lifestyle, and diet (Lee et al. 2005). Korean centenarians on average

had normal levels of total cholesterol, LDL-cholesterol, and triglycerides, though these levels were a little bit lower than those of the oldest old people (Korean Nutrition Society 2000). However, an abnormally low serum HDL-cholesterol was observed in four-fifths of seaside centenarians, and this level was lower than that of the octogenarians (Korean Nutrition Society 2000). The cholesterol intake in their diets was lower in female centenarians than in males (Park 2008). Reduced exercise and low protein consumption may have resulted in reduced HDL-cholesterol levels in female centenarians, while greater exercise and high protein consumption may have caused the observed high HDL-cholesterol in male centenarians. Antioxidant nutrients such as β -carotene, vitamin C, and vitamin E and minerals such as calcium and selenium might be potent protectors against age-associated diseases such as cancer and heart disease. The centenarians living in mountainous areas consumed adequate amount of vitamin A, vitamin C, vitamin B₆, and phosphorus (more than 90% of RDA), while the seaside centenarians showed a tendency of lower intake of antioxidant vitamins, such as carotene, vitamin C, and vitamin E (Park 2008). The high intake of antioxidant nutrients by mountainside centenarians may come as a result of their high consumption of the blanched vegetable food, "Na-Mool." Na-Mool is a traditional Korean recipe for cooking vegetables containing leaves and shoots from a variety of vegetables by mild blanching. The high average INQ (Index of Nutrient Quality) of male centenarians suggests that their diet supply provides very good amounts of nutrients for energy, though some nutrients including Ca, Zn, and vitamin B₂ require supplementation. Korean male centenarians demonstrated better nutritional and health statuses than females. This can be explained by socio-cultural factors and the unique traditional male-priority culture of life. Male centenarians, who represent only a small surviving fraction of the male population, benefit more from socio-ecological factors than females. Korean males receive generally higher education and better care from their families than their female counterparts. Compared to female centenarians, male centenarians had

probably worked harder and had engaged in a variety of physical activity, resulting in better bone functions (Park 2008; Jang et al. 2008). In sum, the Korean Centenarian Study suggests that geographic differences may influence the health and nutritional status of centenarians perhaps through area-dependent differences in physical activity and nutritional intake in daily life as well as cultural tradition. The data thus far indicate that habitat exerts differential influences upon gender differences in longevity perhaps through a modulation of nutritional intake, physical activity, and a socio-cultural pattern of life style.

Discovery of Nutritional Complementation by Traditional Food: Vitamin B₁₂

The physiological role of vitamin B₁₂ was well reported not only for hematopoietic function but also for a broad spectrum of neurological functions. Therefore, maintenance of the normal blood level of vitamin B₁₂ was emphasized in the aged people (Hausman et al. 2011). It is well established that the major source of vitamin B₁₂ is of animal origin, while vegetable foods do not contain the vitamin. However, despite a traditional preference to vegetable food, the Korean Centenarian Study revealed that 95.8% of mountain centenarians and 73.7% of the seaside centenarians demonstrated normal levels of serum vitamin B₁₂ and folate. Previous reports also suggested the relative high level of vitamin B₁₂ status in older Korean people (Park 2002). Therefore, it has been presumed that traditional Korean cuisine might contain a certain source of vitamin B₁₂, which led to discover that Korean traditional fermented products, such as *DoenJang* (Japanese *Miso* equivalent), *Cheonggukjang* (Japanese *Natto* equivalent), *Gochujang* (hot pepper paste), contain considerable amounts of vitamin B₁₂ (Park 2002). Moreover, it has been observed that Korean *Kimchi* (mixed vegetable fermented products) and seaweeds such as *Gim* (laver) and *Parae* (sea lettuce) are enriched with vitamin B₁₂ (Kwak et al. 2010). These dietary sources of vitamin B₁₂ might have contributed considerably for the

relative lack of B-12-deficient subjects in Korean population. Therefore, these traditional fermented foods might have played a role in complementation of nutritional balance for the vegetable-oriented dietary pattern, which thus may have contributed to a considerable degree for enhancing longevity in Korea.

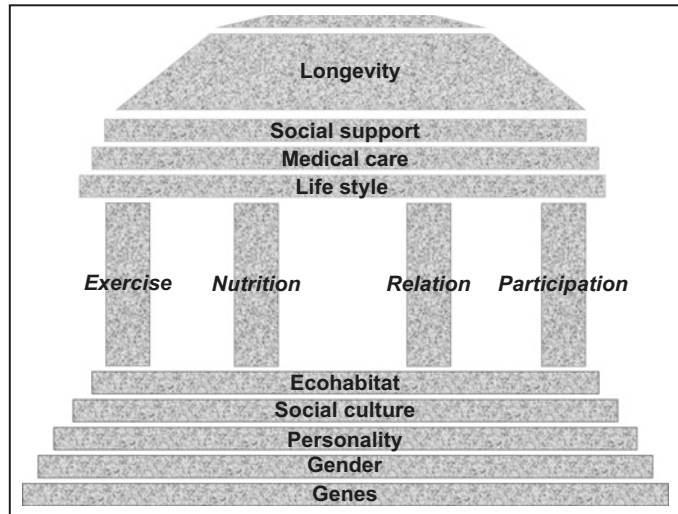

Social Care and Medical Support Variables for Longevity

The average life span of Koreans increased almost 30 years within the last 50 years of period (Korea National Statistical Office 2005). The number of centenarians in Korea also grew rapidly in the last single decade, suggesting a rapid increase in longevity. These demographic changes in average life span and longevity of Korean individuals are directly paralleled with the development in economy and the medical insurance system. The medical insurance system in Korea has been expanded to the national level since 1990. The effects of this expansion could be readily recognized by the rapid parallel increase of the population longevity in Korea. These data implicate the significant role of socio-political variables in the extension of human longevity, suggesting the requirement of comprehensive integration of these factors with biological variables for the longevity phenomenon.

Integrative and Comprehensive Approach for Human Longevity

Korean Centenarian Study data implicate the tight interactions among many variables for longevity. The variables for longevity are as follows: genes, gender, habitat, nutrition, physical activity, social care, and life style, etc. For the integration of these variables, a new model for human longevity is proposed, which might be named, "Park's Temple Model for Human Longevity" (Fig. 1) (Park 2012). In this model, human longevity can be explained in terms of different levels through a comprehensive approach. The longevity-associated variables are classified into three

Korean Centenarian Study, Comprehensive Approach for Human Longevity, Fig. 1 Park's Temple Model of Longevity (Park 2012)

different layers, each layer containing several variables. The premise of this model is based upon the concept that longevity could be compared to the building of a temple, which consists of three essential components: the bottom, pillars, and rooftop. In building a temple, each component should be strengthened and balanced for safety and stability. The bottom components of the temple are basically fixative or not readily changeable. Variables such as genes, genders, personality, ecology, and social cultures fit into this category. The pillar components of the temple are related to personal lifestyles, which are changeable or readily modifiable variables, such as exercise, nutrition, relationship, and participation. The rooftop components of the temple are socially or politically determined variables, such as social care, social safety, and a medical support system. These different layers of the components are interacting with and compensating for one another in order to accomplish building up the temple of longevity (Park 2012). Since compensation mechanisms among the longevity components could be operating, the balancing mechanism among the variables would contribute to overcome some shortages of the specific components. As such, it is suggested that longevity could be achieved by the interaction of many different variables, which are actively interacting and compensating. These compensating and

balancing mechanisms of longevity may be useful to explain the recent dynamic trend in the rocketing increase in population longevity.

Korean Longitudinal Study of Ageing (KLoSA): Overview of Research Design and Contents

Soong-Nang Jang
Red Cross College of Nursing, Chung-Ang
University, Seoul, South Korea

Introduction

In order to outline the factors of healthy aging, a longitudinal study contributes explanatory power to separate the usual aging process from causal factors associated with poor health and disability in later life.

The Health and Retirement Survey (HRS) launched in 1992 in the USA was one of the first panel studies for older people. HRS has made longitudinal data available to capture time trends and major factors related to health and functional

status, family relationships, occupational status, income and consumption, life after retirement, and the effects of social policies for the elderly (see the Health and Retirement Study: A Longitudinal Data Resource for Psychologists). HRS has influenced British and European longitudinal studies of aging which benchmark HRS. In Britain, ELSA (English Longitudinal Study of Ageing) was started from 2002; SHARE (Study of Health, Ageing and Retirement in Europe) involving 13 nations was launched in 2004.

While these studies have produced systematic evidence regarding life course pathways, health and developmental pathways, and evidence for policy, the findings do not necessarily apply to those in different social and cultural contexts, particularly older people in Asian countries and developing countries. In the face of these research gaps, it is necessary to draw on evidence from the longitudinal studies of aging in particular countries. The development of national panel data on aging will provide comparative international evidence for gerontology, geriatrics, and policy. Such comparisons will show both common and unique factors related to health and well-being in later life across both developed and developing countries.

In Korea, the proportion of those aged 65 or higher stood at 13.1% as of 2015, still lower than the 16.2% average of OECD nations. But Korean society is very rapidly aging owing to a recent dramatic rise in average life span and sharp drop in birthrate. The time it will take for Korea to go from an aging society to an aged one, then to a super-aged one, is expected to be much shorter than for any other countries. It took France 115 years to move from aging to aged, the USA 71, Great Britain 47, Germany 40, and Japan 24. For Korea, it will be 19 years. Going from an aged society to super-aged (20% of the population aged 65 or older), it took Great Britain 45 years, France 41, Germany 40, the USA 15, and Japan 12. Korea is likely to travel that path in only 7 years (Korean Statistics Office 2012, 2015). The issue of aging is not only about change in the demographic structure – it entails enormous social and economic repercussions. The “compressed” aging

process demands that Korea pay greater attention to designing responses and solutions than other countries that had to deal with the phenomenon in a more gradual fashion (Jang and Kim 2010).

Korea needed to build up a solid set of statistical data that may be tapped for the purposes of policy-making and evaluation. With the funding of the Ministry of Labor, the Korea Labor Institute established the Korean Longitudinal Study of Ageing (KLoSA), launching its baseline survey in 2006. The purpose of this entry is to introduce the KLoSA and to overview its research design and first findings. The purpose of the KLoSA can be described as twofold. First is to compile information on the various aspects of aging to use as basic statistical data for research on aging. Since aging affects all parts of society, the KLoSA project is designed as an interdisciplinary one, in order to reflect on the social, economic, physical, and psychological aspect of aged persons. The second purpose of the KLoSA is to gather data to be used for international comparative researches. Aging is a common phenomenon occurring in developed economies. The USA, the UK, and 11 EU nations have been conducting panel surveys of those aged over 50 since 1992, 2002, and 2004, respectively. KLoSA was initially designed to benchmark HRS, ELSA, and SHARE.

Methods

Target Population and the Sampling Procedure

The survey target for KLoSA is Korean people aged 45 or older who live in ordinary households whereas the benchmarking data included those over the age of 50. The reason for the age criteria expanding to 45 years was that following the Asian financial crisis in the late 1990s, the number of people in their mid-40s retiring increased. The drastic change in the working age limit for the middle aged became a huge social issue. KLoSA, by including both the middle-aged and the elderly, will be able to shed light on not only the issue of aging itself but also the retirement

process experienced by the middle-aged and their old-age planning.

Sample Selection Procedure

The expected effective sample size was 10,000 residents aged 45 or older living in ordinary households; thus, the necessary number of households surveyed was 6000 households. Region was stratified into urban area and rural area according to 15 metropolitan cities and provinces of Korea. The stratified region was then classified into apartment area and ordinary housing area. Common enumerated districts refer to ordinary house, townhouses, and multifamily houses. One thousand sample districts were first allocated into 15 districts by municipal city and province, and the rest were allocated in proportion to the number in the population. The reason for this was to evenly allocate the districts to obtain credible statistics in low-populated areas. A total of 803 districts and 197 districts were each allocated in the urban area and rural area.

Selection of Households

With the list of households in the main sampling units and relevant tools, interviewers visited the households and identified the compatibility of each. With fixed samples, 15 households and 12 households were selected for each urban and rural district on a random basis, and interviewers were given the list together with the order of visit. Interviewers conduct the interviews if there is at least one eligible family member (aged 45+) in the household (Korean Longitudinal Study of Ageing Website, <http://survey.keis.or.kr>).

Research Design

Since the baseline survey of the KLoSA was set up in 2006, its follow-up survey will be conducted in every even year. Supplementary surveys may be conducted with special topics in odd years. As a panel survey is conducted on the same topics repeatedly across a long period of time, the data provides the advantage of identifying dynamic social phenomena over time and analyzing the causation. Likewise, it is likely to be more useful than cross-sectional data in observing the social consequences of aging.

Korean Longitudinal Study of Ageing (KLoSA): Overview of Research Design and Contents, Table 1 Response rate of Korean Longitudinal Study of Ageing and other longitudinal studies of aging

	Household sample	Individual sample
HRS	80.2%	81.6%
ELSA	69.9%	96.5%
SHARE	55.4%	86.3%
KLoSA	70.7%	75.4%

Questionnaires

The KLoSA instrument comprises the following sections: demographics, families, health, employment, income, asset, and subjective expectations (Table 1). Basic demographic information included is gender, birth date, marital status, academic background, religion, social network, and social activities.

Family

The family section aims to examine the senior citizen's familial relationship and asks about the respondent's children, grandchildren, siblings, and parents. The section also includes inquiries on the level of income of each family member and their relationship with the respondent. Questions regarding the respondent's children require basic personal information and proximity of their residence, frequency of contact, and level of financial support and care exchange. As for grandchildren, the respondent is asked to provide the same set of personal information. Additional questions are included to assess the level of exchange of financial support and the time spent on taking care of the grandchildren.

The same set of basic information is requested again for the respondent's siblings. Questions on parents are divided into two scenarios, depending on whether the respondent's parents are still alive. If alive, their age, educational level, employment status, cohabiting family members, proximity of residence, frequency of contact, financial status, housing ownership, level of exchange in financial support, ADLs, and the level of the respondent's caregiving are asked. If not alive, the timing and age of their death are asked.

Health Status and Health Behaviors

The health section comprises four subtopics: health status, functional limitations and helpers, health insurances and services, and cognition. Grip strength is directly measured at the end of this section.

In the health status section, the respondent is asked about self-reported health, chronic illnesses, fall, fracture, vision, hearing, pain, urinary incontinence, and depression. To allow international comparison, the health section mostly keeps in line with the HRS structure. The gastrointestinal diseases have been added to eight chronic illnesses included in HRS (hypertension, diabetes, cancer, lung diseases, heart problems, strokes, psychiatric problems, and arthritis). Additional questionnaires included the timing of diagnosis, current status of medication/treatment, and difficulties resulting from the illness. In health behaviors, health screening attendance, exercising, smoking and drinking habits, and body mass (height and weight) are also included.

Functional Limitations and Helpers A functional status section begins with the Korean version of ADLs and IADLs: K-ADL (including 7 items) and K-IADL (including 10 items) developed by the Korean Geriatrics Society. The number of helpers, relationship with the respondent, and relevant costs are also asked. The series of questions on the helper are included in each of the K-ADL and K-IADL sections. Cognitive function was measured by the Korean Mini-Mental State Examination (K-MMSE). K-MMSE is a brief screening test that quantitatively assesses the cognitive status of elderly people with 11 items, divided into two sections; the first requires verbal responses to orientation, memory, and attention questions. The second section requires reading and writing and covers ability to name, follow verbal and written commands, write a sentence, and copy a polygon.

Health Insurances and Services The health insurance section is divided into three parts: national health insurance (NHI), medical aid program (MAP), and private health insurance. Those receiving NHI benefits are asked about the

amount of monthly insurance payment and missing payments, if any, based on the beneficiary's coverage type (workplace/community). Questions are also included about the level of overall satisfaction in NHI. The MAP part is inquiring about whether the respondent has received or is receiving aid. Questions on private health insurance first attempt to determine whether the respondent has private insurance coverage and then asked about the insured, amount of insurance payment, and types of benefits.

In the medical service utilization section, topics are divided into hospital stay, outpatient surgery, visit to the doctor, dentist clinics or hospitals, oriental clinics or hospitals, health centers, in-home health care, prescription medication, and over-the-counter drugs to understand the usage frequency and period, payment method, and payment responsibility in each category.

Employment

It is important for KLoSA to measure the degree of senior citizens' labor market participation as one of the most serious consequences expected from population aging is the aging and shortage of workforce. In Korea, inadequate provision of old-age income security (compared to western countries) tends to push the elderly into the labor market to sustain their livelihood. Understanding the process of retirement, therefore, gains greater significance.

The employment section includes topics on employment, unemployment, and retirement. In the employment subsection, overall circumstances of the respondent's employment are assessed, starting from participation in the labor market. The type of employment is identified: wage earner, self-employed, or unpaid family worker. Additional questions follow on the general characteristics of the work the respondent is engaged in: industry and size of the workplace, type of work, position, starting period, working hours, overtime work, level of wage/income, and retirement age. Level of satisfaction and the degree of physical strength required from the current work are also evaluated. The general characteristics of a second job (if any) are also requested.

Unemployed respondents are asked about the reason of their unemployment, job-seeking status, and method and types of desired employment. They are also asked some general questions on their last job, similar to the set of questions on the current job, including the starting and ending period, industry and size of the workplace, type of work and position, working hours, and income. Characteristics of the respondent's primary employment are also explored if the last job was not the main job in his/her lifetime. Questions are mostly similar to the ones for the last job, including ending period, industry and size of the workplace, type of work and position, working hours, and income.

If the respondent is retired, the general circumstances of the retirement are assessed: reason for retirement, the respondent's attitude, and current activities. As for the unemployed, they are asked about their last job as well as their primary job if the last job was not the main employment. The set of questions here are identical to the ones posed to the unemployed.

Income and Assets

The individual income section is divided into earnings, pension (annuities), social security, cash transfer, and others. The amount of income generated from each category in the last calendar year is investigated. Wage is further broken down into wage and income from assets. Income generated from real estate and financial activities is explored in the asset section. Income-dispensing pension includes public, corporate, and private pensions.

As for the social security subsection, it probes all types of payment provided by social security schemes in Korea except the national pension. They include insurance (employment insurance, workplace, and injury compensation insurance), government assistance (elderly pension is provided only to the 65-or-older population with low income), and national basic livelihood protection program. In addition, transportation cost subsidy to the elderly (covering everyone aged 65 or older) and veteran benefits (Ministry of Patriots and Veterans Affairs' payment to the winner of the medal of honor and their families,

pension to military or police officers injured on duty, nursing fees, etc.).

Financial support provided from family and/or relatives is also measured, but in the family section, not in this income section. As much of welfare-providing responsibility still lies with the family in Korea, income received from private channels such as family takes up a significant proportion of the elderly's overall income. In consideration of the difference, whereas HRS questions are limited to financial support and alimony, KLoSA explores the entirety of financial support from members of the immediate or extended family.

This section deals with assets and debts, namely, real estate, business/farm, financial assets, nonfinancial assets, assets of family members, debts, asset variation, tax return, charity contribution, inheritance, and will.

Under assets, ownership of real estate, or business/farm, the cash value and income generated from real estate (e.g., land revenue, rent) in the past calendar year are investigated. Financial assets include the following: demand deposits such as savings, household checking accounts, CDs, CMA, and MMF; savings deposits with liquidity constraints such as time deposits, installment deposits, and mutual funds; and stocks, bonds, savings-type insurance (including annuities), private loans to others for the purpose of investment (including private money lending), and mutual savings clubs (Gye in Korean). There are also questions on nonfinancial assets such as mode of transportation (e.g., cars) and paintings/antiques/memberships that, together with financial asset questions, are intended to determine the types and amount of all assets held by the respondent.

Expectations

Expectations of the elderly are measured in areas of both the public and private domains: economic activities of the Korean society at large, the labor market, South–North Korea reunification and social security as well as individual financial support, inheritance, use of nursery facilities, survival rate, and savings plan. This section is designed to collect information on senior citizens' psychology.

Response Rate

After 5 months of fieldwork, the KLoSA includes 10,254 persons as panel respondents; 999 survey units have at least one respondent. Each survey unit has on average 6.2 households, and a total of 6171 households were surveyed. Household response rate is 70.7% and individual response rate within households is 75.4%.

Reliability and Validity

The validity and reliability of the KLoSA data were assessed by comparing the prevalence of major chronic diseases to the findings of the Korean National Health and Nutrition and Examination Survey (KNHANES) which contains national health data produced by the Ministry of Health and Welfare. Self-reported physician-diagnosed hypertension, diabetes, stroke and disability, and smoking rates were calculated according to age groups by gender. In addition, we evaluated the reliability of structured questionnaires such as the Mini-Mental Status Examination (K-MMSE), Activities of Daily Living (K-ADL), Instrumental Activities of Daily Living (K-IADL), and Center for Epidemiological Studies of Depression 10 (CES-D 10) by calculating Cronbach's alpha. Self-rated health, one depression questionnaire and indicating any disability, was used as the gold standards for related health outcomes: the CES-D 10 score, total K-ADL, K-IADL deficiency, and total K-MMSE score. A linear regression of grip strength with age was used to calculate a coefficient for evaluating the validity of the measurement of muscle strength.

The prevalence of self-reported hypertension was somewhat lower than that from the KNHANES data.

The difference averaged 2.0 (minimum 1.0, maximum 10.0). In contrast, the prevalence of diabetes, stroke and disability, and smoking were slightly higher than from KNHANES. These differences resulted from the sample size, sampling methods, and survey process used to obtain each data set. Because health behavioral data were extracted from a subsample of the total KNHANES sample, the sample size was too small to obtain health indicators for older adults, especially with respect to the oldest groups.

Korean Longitudinal Study of Ageing (KLoSA): Overview of Research Design and Contents, Table 2 Contents of Korean Longitudinal Study of Ageing Questionnaires

Section	Description
Cover screen	
Information on household members (gender, age, marital status, relationship [with the respondent, etc.])	
A. Population	
Date of birth, gender, background, religion, marital status	
Not living together/the spouse aged below 45: date of birth. Academic background, employment status	
Religion, social activities, and relationship	
B. Family children and grandchildren	
Children: gender, age, academic background, employment status, house ownership, marital status, number of children	
Not living together with children: access, frequency of contact, financial aid given to/from children	
Number of grandchildren, care of grandchildren, time/period of care	
Parents and sibling	
Sibling: relationship with the respondent, age, marital status	
Parents: age, academic background, presence (if dead, at what age?), employment status, house ownership	
Not living together with parents: access, frequency of contact, financial aid given to/from parents	
Other family members: financial aid given to/from them	
Presence of a family member with difficulty in ADL/IADL, time and period of caregiving	
C. Health	
Health status	
Subjective health judgment, chronic disease, treatment, experience of traffic accident/injury from a fall/fracture of a bone	
Signs of aging (vision, hearing, pain), BMI, health-related habits (smoking, drinking), depression measurement	
ADL/IADL and caregiver	
ADL and IADL	
Caregiver for ADL (first/second/third): relationship with the respondent, day and hours of caregiving, payment	
Health insurance and facility usage	
Health insurance subscription: health insurance, reimbursement, private health-care insurance, payer of premium, premium in arrears, delayed period	
Health-care facility usage: hospitalization, dental clinic, public health center, oriental medical center, outpatient, home call, prescription drugs, purchase and price of health-care equipment	
Recognition capability	
MMSE-K application of a measurement set tailored to Korea	
Physical performance assessment	
Measurement of grasping power	
D. Employment	
Employed	
Details of employment (workplace information, type of employment, position, industry, labor contracts, working hour, days of leave, salary determination, etc.)	
Perception of and satisfaction with work	
Job position desired, side job, part-time job, etc.	
Self-employed	
Reason of running a business, workplace information, working hour, working day, perception of working hour, days of leave, perception of and satisfactions with work, job desired, side job, part-time job, etc.	
Unpaid family business	
Reason of doing the work, workplace information, status of other workers, revenue, working hour, working day, days of leave, perception of and satisfaction with work, job position desired, side job, part-time job, etc.	
Job seeker	
Job-seeking activities in the last one week/month, willingness to find a job, employability, reason of losing a job, reason of seeking a job, job-seeking activities, difficulty in job seeking, retirement plan, work experience, the latest job, etc.	

(continued)

Korean Longitudinal Study of Ageing (KLoSA): Overview of Research Design and Contents, Table 2
(continued)

Section	Description
Retiree	Time and reason of retirement, spouse's economic activity at the time, pastime items, perception of retirement and economic activity, the latest employment, etc.
E. Income	
	Earned income (salary, one's own business, agricultural and fishery, side job)
	Annuity (national/workplace/private)
	Social benefits (status of grants, type)
	Other income, total household income in the last 12 months
F. Asset	
	Residence (type of ownership)
	Real estate assets excluding residence (real estate ownership, lease, factory/farm)
	Financial asset (including money from the mutual financing association)
	Other nonfinancial asset
	Inheritance/donation, debts, household asset
G. Expectations	
	Subjective judgment about future economic conditions (inheritance/donation, estimated working hour, economic activity), life expectancy, living standards, expectations on the government
	Satisfaction with life

The trends in prevalence by age did not differ significantly between KLoSA and KNHANES, indicating that both of the data sets show similar associations between age and chronic conditions.

Our findings suggest that CES-D 10, K-ADL, K-IADL, and K-MMSE are reliable; the overall raw alpha exceeded 0.7 in all cases, which indicates a good cutoff value. The alpha coefficients for the CES-D 10, K-ADL, and K-MMSE were 0.796, 0.949, and 0.880, respectively, compared to respective values of 0.80, 0.937, and around 0.8 from previous reliability studies. The association between self-rated health and one depression questionnaire was significant for the CES-D 10, which means that the criterion validity of the CES-D 10 is acceptable. The K-ADL and K-IADL were also significantly associated with the self-rated health and K-MMSE scores, indicating that the K-ADL and K-IADL are valid for measuring functional status.

The estimated coefficient of grip strength according to age gave results similar to previous studies, demonstrating its reliability as a measure of muscle power. In general, the validity and reliability of the KLoSA measures are reasonable, and the data provide reliable observations of health indicators for representative Korean adults 45 years old and above.

Conclusion

As population aging is expected to affect changes in different sectors of our society, KLoSA makes it its primary objective to collect information in a wide range of areas. The topics include basic demographics, participation in the labor market, retirement, income and assets, savings, health, cognition, ADLs, activities and costs to maintain health, family structure, and so on.

The KLoSA tries to provide data that is conducive to international comparison in the areas of aging and policy impact. Industrialized nations today already strive to build panel data that allows cross-border comparisons. The European SHARE, which recently finished its first year of survey, is a joint project of 11 nations that is designed to be comparable with the British ELSA and the US HRS, two panel surveys on the issue of aging that have preceded SHARE. Similarly for KLoSA, it aims to generate data that facilitates comparison with the ones produced in the USA and Europe.

Working toward the stated objectives, the KLoSA is expected to obtain microdata on the phenomenon of aging and the accompanying socioeconomic changes by collecting data from different fields and accumulating such data over time. Availability of the panel data will also

Definition

The comprehension of language in the domains of both written and spoken communication requires the decoding of print or acoustic features of speech to create mental representations of meaning, events, and situations. In spite of the apparent ease with which it is accomplished, language comprehension is a complex process requiring the synchronization of a variety of cognitive components (e.g., recognizing letters and words, accessing and integrating word meanings to represent ideas, and using existing knowledge to develop a representation of implied situations). As such, language comprehension is interwoven with core cognitive mechanisms, which show multidirectional patterns of change as a function of both primary aging processes and experience.

Introduction

Successful execution of language processing components depends to some extent on both mental mechanics, which are vulnerable with aging, and knowledge, which has potential for experience-based growth. Given this, it is not surprising that language comprehension can show dynamic change over the life span. On the other hand, there is also growing evidence for the benefits of language proficiency in building cognitive reserve. In this article, this bidirectional relationship between aging and language is reviewed by considering first the way in which age-related changes in cognition can influence language comprehension, and then briefly how literacy practices and engagement with language can influence cognition and health in late life.

Effects of Aging on Language Comprehension

Age differences in language comprehension are reflected in the multidirectional effects of age on cognition. Declines in mechanics have been conceptualized in terms of working memory, speed, and interference control. Recent work has considered the role of interactions between mechanics and sensory processing. On the other hand, growth in knowledge and literacy skills as a function of engagement with reading can be a

significant strength in adulthood. A foundation of domain knowledge allows depth of comprehension in specialized domains that is almost impossible to achieve in any other way. Importantly, experience-related growth in knowledge and literacy skill opens pathways to compensation in terms of both processing mechanisms and in the way language input is regulated.

Implications of Age-Related Declines in Mental Mechanics

Many aspects of language comprehension are unaffected by variation in mental mechanics and are well preserved with healthy aging (Thornton and Light 2006; Wingfield and Stine-Morrow 2000). In fact, older adults with developed literacy skills generally are at least as efficient as the young in word recognition and in accessing meanings of individual words. Nor does aging appear to impair the appreciation of basic sentence structure (i.e., using syntactic form to determine how the meanings of individual words are connected to form ideas). For example, older adults are as able as the young to quickly infer the particularized meanings of words in context (e.g., that the “insect” in *The insect stung the professor* is likely to be a bee or wasp and not a termite). Aging also does not impair the ability to distinguish between grammatical and ungrammatical sentences or to use syntactic structure to infer semantic focus. This was demonstrated in a series of studies by Price and Sanford (2012) who manipulated the syntactic form of a sentence with clefting so as to put different elements in the foreground of attention to examine whether there were age differences in using these cues for focus (e.g., The core idea *John lost his daughter* can be expressed with the subject clefted as, *It was John who lost his daughter*, which puts the focus on John, or with the object clefted as, *It was his daughter that John lost*, which puts the focus on the daughter). Reading times were faster for a continuation in which the grammatical subject was matched to the focused element (e.g., *He had wandered off*, in the former case; and *She. . .*, in the latter). Older adults showed strong effects of focus, at least as robust as those of the younger adults, demonstrating that they were able to use linguistic structure to

modulate activation of concepts in language comprehension. Also, in spoken language, older adults make good use of prosodic contour (i.e., the temporal patterning and changes in frequency that are characteristic of natural speech) to recognize syntactic structure, as well as the differential emphasis of concepts.

On the other hand, a hallmark of language is that it is generative, in the sense that we produce sentences that have never been produced before and comprehend sentences that we have never encountered before. Even though aging does not compromise the ability to use the rules that afford generativity, these rules allow the construction of sentences that are very complex so as to tax mental mechanics. Thus, age-related declines in mechanics may result in comprehension deficits as the demands of language processing increase. When older adults meet these demands so as to show good performance, they do so through the allocation of extra effort. This has been demonstrated with a number of methods, including exaggerated neural recruitment in imaging, increases in reading time, and interestingly, with pupillometry.

It is well established that the pupils dilate with increased cognitive demands. This phenomenon has been used to explore age differences in the effort required to understand syntactically complex sentences (Piquado et al. 2010). The contrast between subject-relative (e.g., *The doctor who was advised by the plumber went on vacation*) and the more complex object-relative (e.g., *The doctor who advised the plumber went on vacation*) constructions has been well studied. Object-relative constructions are more difficult to understand for a number of reasons, including the violation of canonical subject-verb-object ordering, and the fact that the agent of the matrix clause (in this example, the doctor went on vacation) is also the object of the embedded clause (i.e., the plumber advised the doctor). Comprehension is typically more error prone for object-relative sentences, especially for older adults. Piquado et al. (2010) presented younger and older adults with spoken sentences of these forms in order to answer comprehension questions afterwards. They found that for both age

groups, pupil size increased as they listened to the sentences, especially so when they were trying to comprehend the object-relative constructions. Consistent with the idea that syntactic complexity is more demanding of attention for older adults, they showed an exaggerated increase in pupil size when listening to object-relative sentences.

Caplan and colleagues (2011) investigated speed and accuracy of sentence comprehension under varying levels of syntactic complexity. Sentences also varied in plausibility (e.g., *It was the movie that terrified the child because it showed a monster* versus *It was the child that nourished the food in the pantry*). Participants self-paced the presentation word by word, and reading times were recorded as an online measure of comprehension as the sentence unfolded. After each sentence, subjects indicated whether the sentence was plausible or implausible as a measure of comprehension accuracy. Both younger and older adults were less able to distinguish plausible and implausible sentences when they were more syntactically complex, with an exaggeration of this effect for older adults. To some extent, older adults also took differentially more time to process the syntactically complex forms.

There are competing theories regarding the nature of declines in mental mechanics and how these mechanisms affect language processing with aging. Working memory is the capacity for mental computation and simultaneous storage of the products of these computations and is particularly important for comprehension and learning. Processing speed, on the other hand, is the efficiency with which these computations are computed. Finally, inhibition is the ability to ignore contextually irrelevant information. Aging has been shown to be associated with decreased working memory capacity, reduced processing speed, and failure to inhibit, all of which have consequences for language processing.

In the Caplan et al. study, reading time measures were negatively correlated with both working memory and processing speed. Borella et al. (2011) examined the differential impact of processing speed, inhibition, and working memory on text comprehension using structural equation modeling. In this study, processing speed was

measured using the letter and pattern comparison tasks. Working memory measures included assessments of simultaneous storage and manipulations of verbal and visuospatial information. Inhibition processes were operationalized using a number of tasks requiring resistance to interference (e.g., intrusions in working memory). Younger and older adults read a series of narratives followed by comprehension questions for each text. These questions were answered under one of two conditions, text-present or text-absent, such that the texts were either available when participants answered the comprehension probes or not. In addition, half of the comprehension questions probed specific details from the text (i.e., facts explicitly stated in the text), and the other half were inferential in nature (i.e., relying on inferences necessary for text coherence). The best-fitting model was one in which the effects of processing speed and inhibition on text comprehension were mediated by working memory, with working memory as the proximal cause of age differences in text comprehension. A further model comparison examining the statistical fit of this model separately for text-present and text-absent conditions suggested that age and mechanics accounted for more variance in the text-absent condition than the text-present condition. Interestingly, age differences in text comprehension were moderated by condition such that older adults performed equally as well as the younger adults when the text was present during the comprehension probe. Together these results suggest, first, that working memory is a core cognitive mechanism responsible for age differences in text comprehension, but that working memory itself has dissociable components that contribute to comprehension. Second, this study suggests that demands on working memory from comprehension are less related to online processing than they are to the maintenance of information in memory. Finally, evidence from this study suggests that age-related differences in text comprehension may be minimal in typical conditions in everyday life, in which text is available as it is used for particular tasks.

There are both negative and potentially positive implications of inhibition failure for text

comprehension. In a study by Thomas and Hasher (2012), older and younger adults read stories containing irrelevant information, cued with a change in font, and were explicitly told to ignore this information. Later, subjects were given a memory task for a short list of words, half of which were the distracting words from the stories. Older adults were more disrupted in reading by the presence of distraction and were also more likely to recall the distracting words than new words in the memory task. When participants were explicitly told that some of the words in the recall task were from the stories they had just read, younger adults then recalled more of the distracting words and even outperformed older adults in this recall task. Thus, these results are consistent with the view that younger adults not only have more efficient inhibition mechanisms but also have more cognitive control over when to engage these mechanisms than older adults and that this plays a role in language comprehension.

Even though older listeners can take good advantage of cues from prosody to distinguish important and unimportant concepts in speech, mechanics can place limits on this ability as well. For instance, pitch accents (i.e., a change in tone to cue the emphasis of a word or phrase relative to other words in the text) have been shown to boost memory in both younger and older adults (Fraundorf et al. 2012); this is known as an *accent boost*. In Fraundorf et al. (2012), older and younger adults listened to brief stories that included the mention of two contrast sets, for example, about some British and French scientists searching for endangered monkeys in Malaysia and Indonesia. In the target sentence that resolved the story, one element of each contrast set (i.e., British vs. French; Malaysia vs. Indonesia) was selected (e.g., *The French spotted a monkey in Indonesia*). Pitch accent was systematically manipulated so as to stress one (e.g., *The FRENCH spotted a monkey in Indonesia, or The French spotted a monkey in INDONESIA*), both (e.g., *The FRENCH spotted a monkey in INDONESIA*), or neither element. Memory was tested with a fill in the blank task (e.g., *The _____ spotted a monkey in _____*). Both younger and older adults showed an

accent boost. However, when both words were emphasized with a pitch accent, older (but not younger) adults showed a reduction in the accent boost, which Fraundorf et al. called the *other-accent penalty*. They attributed this other-accent penalty to the lower working memory capacity of older adults. The other-accent penalty was also found for younger adults with relatively low working memory scores, supporting the idea that the age differences were due to working memory declines that limit the ability to focus on multiple concepts in discourse.

Collectively, this literature suggests that many aspects of language comprehension are preserved with aging (e.g., word recognition and basic syntactic and semantic operations). However, age-related changes in mental mechanics can impact language comprehension across text type (sentence, discourse) and modality (print, speech) in more difficult conditions.

Implications of Age-Related Decline in Sensory Processing

Whether it involves listening to speech or reading print, language comprehension depends on the perception of accurate sensory input. While word recognition processes are generally automatic among those with well-developed literacy skills, when the sensory information is unclear, decoding the surface form can require attentional resources to the extent that comprehension may be compromised. In other words, decoding and semantic processing draw on the same pool of attentional resources. When the surface form is clear (e.g., print that is legible and appropriately sized, speech with well-articulated phonology and good prosody), decoding is accomplished easily so that working memory resources can be devoted to constructing a representation of the meaning. Challenges to signal fidelity – because of noise in the environment, deficits in sensory processing, or a combination of both – can compromise language comprehension.

A number of recent studies support these claims in both the auditory and print domains. When individuals read text in visual noise (i.e., text degradation imposed by embedding the text in a visually complex environment), patterning of

reading times can be used to show that relatively more attention is devoted to decoding and relatively less attention is devoted to semantic processing, which results in poorer memory performance (Gao et al. 2012). Older adults are more impaired than younger adults at lower levels of visual noise suggesting that limits on mechanics exacerbate sensory effects on comprehension.

Similar phenomena have been demonstrated with speech comprehension. Van Engen and Peelle (2014) described three sources of acoustic challenge: within the listener (e.g., hearing loss), from the environment (e.g., background noise), or from the speaker (e.g., increase speech rate, prosodic disruptions, unfamiliar dialect). Such acoustic challenge decreases the attentional resources available for higher-level language processes (i.e., comprehension of meaning) because they are allocated to lower-level decoding processes. Additionally, this shift of attentional resources seems to be moderated by age and working memory capacity such that those with lower working memory capacity (e.g., older adults, and younger adults with lower WM) are more likely to show performance deficits when sensory fidelity is compromised than those with higher working memory capacities.

Implications of Age-Related Knowledge Growth

Age affords time for experience, and among adults with good literacy skills and practices, preservation or growth of crystallized ability and print exposure is the norm. This “expertise” can boost performance in text comprehension through several different pathways. In fact, among older adults who have achieved strong literacy skills, the effects of declines in mental mechanics on comprehension and memory for text can be negligible. For example, Payne et al. (2012) showed the effects of working memory on sentence recall were only found among older adults with relatively low print exposure (an index of reading experience). Based on word-by-word reading times, they also showed that print exposure conferred an advantage in the efficiency of word recognition processes and was also related to greater effort allocated to semantic

integration processes. Older adults with higher verbal abilities also have advantages in more efficient resolution of lexical ambiguities (Stites et al. 2013) and in using statistical properties of language to guide parsing (Payne et al. 2014). Thus, lifelong habits of literacy experience can help to preserve language processing and comprehension so as to trump declines in working memory.

Domain-specific knowledge can also support language comprehension processes. Chin and colleagues (2015) examined the differential effects of health-specific domain knowledge and domain-general verbal ability (measured as vocabulary) on reading comprehension among older adults. Participants read sentences that were either related to health topics or about other topics (but matched in readability), using a self-paced word-by-word reading paradigm. Based on reading time patterns, results showed that verbal ability was related to increased conceptual integration regardless of domain, but that health knowledge (controlling for verbal ability) was specifically related to increased conceptual integration in health-related sentences. Thus, domain-specific knowledge had effects on processing above and beyond that of verbal ability to support comprehension and memory for text.

Self-Regulation and Attention

One implication of the effects of mechanics and crystallized abilities on comprehension is that there can be wide variation in the way in which the mental representation of meaning is constructed as language unfolds. In the early history of psycholinguistics, the emphasis was on language *competence*, how the rules of language are used in an idealized way to construct the language representation. Questions about variation in comprehension as a function of abilities are ones about *performance*, how language is actually understood and interpreted in situ. It would be a mistake to think about abilities simply as fuel for the operation of language processing machinery that operates in an obligatory and uniform way (e.g., performance does not simply reflect incomplete computations defined by competence). Rather, as we have described

above, the nature of the language representation is that it is multifaceted, and these different facets can be constructed to varying levels of fidelity.

One view of age differences in self-regulation of language is that older adults show more shallow or “good enough” processing in comprehending language. For example, Christianson and colleagues (2006) showed that when encountering sentences with temporary ambiguities, such as *While Anna dressed the baby played in the crib*, both younger and older adults are likely to incorrectly answer “yes” to the question, *Did Anna dress the baby?* with older adults even more vulnerable to this error. According to the “good enough” account, as the sentence unfolds, the initial interpretation that Anna dressed the baby is maintained in memory even after the interpretation that the baby played in the crib is encoded (in fact, participants are also likely to say that the baby played in the crib). Christianson et al. argued that rather deriving meaning strictly based on the rules of language, we use heuristics to create meaning representations that are consistent with world knowledge. Thus, even though the coexistence of these two meanings is not allowed by the sentence structure, we maintain them because it is easy to create a mental model of the situation. Because older adults tend to rely on knowledge-based heuristics, they are more likely to use such “good enough” processing.

In fact, language comprehension is often shallow. As any middle schooler who has snagged someone with the problem of the plane crash on the border between the USA and Canada can tell you, when you pose the question of where one should bury the survivors, most people will puzzle over the border issue without realizing they are being asked about burying living people. Daneman et al. (2006) measured eye movements as younger and older adults read and attempted to solve problems containing such anomalies (embedded among problems that did not). There were no age differences in the probability of noticing the anomalies (i.e., young and old were equally likely to say that the survivors should not be buried). Based on the eye movement record, Daneman et al. concluded that older adults

were actually quicker in detecting the anomalies, but required more effort (as measured by rereading) to resolve them.

Collectively, this literature suggests that it is not that language comprehension is generally more superficial with age. Rather, that there is a shift in how resources are allocated among the different levels of analysis (Stine-Morrow et al. 2008).

Behavioral research tends to show that older adults are differentially facilitated in word recognition processes by context in both the auditory and print modalities. This is particularly interesting in light of findings from electrophysiological studies suggesting that meaning is slower to come online for older adults. Event-related brain potentials (ERPs) are a time-sensitive measure of brain activation in response to a particular stimulus (e.g., word) widely used to examine online comprehension. In particular, the N400 is a negative ERP component occurring about 400 ms after stimulus onset. Because its amplitude is very sensitive to the predictability from context, the N400 is taken as an index of very early effects of context on lexical processing. Younger adults show reduced N400s for words predictable from the prior sentence context as well as words that do not fit the context but are from the same semantic category (e.g., *To make the hotel look more like a tropical resort, they planted rows of palms/pines*). This is taken as evidence that younger adults actively predict in language comprehension so that items related to the target are activated. However, older adults show only an N400 reduction for expected endings (e.g., *palms*). This suggests that older adults are not using predictive processing. A recent study examined age differences in predictive processing by manipulating constraint and expectancy of sentence final words. Wlotko and colleagues (2012) measured the N400 effect for target words preceded by strong (e.g., *At night the old woman locked the door*) and weak (e.g., *Mr. Smith enjoyed showing people his newly installed stereo*) sentence context. Although both younger and older adults showed reduced N400s for expected endings when contextual constraint was strong, only younger adults showed reduced N400s

for weakly constrained endings. These results suggest that although older adults are equally proficient at conceptual integration (as shown by age-equivalent performance in the strongly constraining condition), younger adults are more likely to use contextual information for predictive purposes. Collectively, age-comparative studies using ERPs suggest that older adults (in general) do not engage in predictive processing in the same way as younger adults. However, older adults with high verbal ability show predictive processing comparable to the young.

The nature of comprehension is that the ideas given by the text are integrated and interpreted in light of existing knowledge, but this balance changes with age to give priority to knowledge-based interpretation (over direct computation of meaning). At the same time, the ability to compute the meaning from the text as an integrated set of ideas is preserved with aging, though the way in which effort is regulated to achieve this may change. Older readers have to allocate more effort to integrate ideas and may engage integration processes more frequently as they read in order to offset the demands of integrating larger segments of text (Stine-Morrow and Payne 2015). To some extent, segmentation itself is a procedural skill that is intact into very late life, though integration processes may become less effective with late-life cognitive declines (Payne and Stine-Morrow 2016).

Self-regulation, then, plays a large role in the preservation of language comprehension with aging. This is seen in both greater reliance on knowledge-based processing and in text-based processing that accommodate working memory limits.

Effects of Language on Aging

An emerging body of literature suggests that over time a mentally stimulating lifestyle can create cognitive and neural reserve that may delay age-related cognitive decline, with some evidence supporting the idea that language experience may impact cognitive health.

Education, Literacy, and Longevity

There is increasing interest in educational attainment and literacy as predictors of longevity and cognitive health (Sisco et al. 2015; Spittle et al. 2015). This body of research has grown in recent years and has shown that controlling for demographic factors known to contribute to life expectancy (e.g., sex, ethnic group, income), educational attainment is a reliable predictor of life expectancy, more so than perhaps more obvious predictors of longevity such as cholesterol level or frequency of health checkups. According to Spittle et al., if all Americans attained a high school diploma, annual mortality would be reduced by about 240,000 persons. However, measures of educational attainment (e.g., years of formal education) are of many varieties and do not take into account the quality of educational experience. One hypothesis for why education has such powerful effects on lifelong cognition is that it is a proxy for literacy, with evidence that, in fact, print exposure is a better predictor of cognitive health than education level and can delay the onset of dementia.

Language is, of course, important for many aspects of life in predominantly literate societies such as in the USA. But perhaps surprisingly, studies comparing low-literacy adults to those with well-developed literacy skills have revealed significant behavioral and anatomical consequences of literacy for cognition and neural substrates, which have the potential to impact late-life health. Often, with comparisons of high- and low-literacy samples in the USA, it is difficult to disentangle the effects of literacy from the social and economic factors associated with literacy illiteracy. However, a number of studies in recent years have focused on populations in which illiteracy is not necessarily a consequence of poverty or socioeconomic stressors that have their own significant effects on cognition and health (e.g., children in Columbia who were conscripted into service during civil war at the expense of early schooling and literacy acquisition; older daughters in the Algarve region of Portugal, who by tradition were given childcare responsibilities while younger siblings went to school to receive literacy instruction). Such natural experiments have shown that illiterates have impoverished

phonological processing, visual attention, abstract reasoning, semantic fluency, and memory compared to their literate counterparts. Literacy acquisition also enhances cortical responses to two-dimensional objects and words and supports the development of verbal working memory capacity. Furthermore, results from neuroscience research (e.g., functional and structural imaging) suggest that literacy reorganizes cortical networks to change the brain's response to both spoken and written language, with greater selectivity of activation (Huettig and Mishra 2014). However, as Huettig and Mishra (2014), in most cultures, literacy acquisition is tightly woven with schooling, so that it is a challenge to disentangle effects of literacy from educational experience more broadly.

Bilingualism

Further evidence for language impacting cognition is a considerable body of work suggesting that bilingualism (or even better, multilingualism) confers advantages for adult cognition. Early bilinguals (i.e., those who learned a second language early in life and continue to use both languages) show reduced declines on measures of executive control as they age and show a delay in the onset of symptoms for dementia (Bialystok et al. 2012). The roots of these effects are still being explored, but likely derive from multiple mechanisms. First, proficiency in a second language is enhanced among those with strong skill in the first language, so it is possible that the bilingual advantage is grounded in part in early literacy acquisition. More importantly, in managing multiple linguistic codes, only one of which is typically appropriate at a given time, bilinguals are routinely engaging suppression mechanisms in ordinary communication. Thus, bilingualism entails routine practice in attentional control that may contribute to cognitive health in late life.

Conclusions and Future Directions

Language comprehension is a highly active form of mental engagement. Older adults with

well-developed literacy skills have a number of advantages that support comprehension. Word recognition and use of syntactic cues to guide semantic processing are largely intact. On the other hand, there are a number of ways in which language complexity can tax attentional demands so as to compromise comprehension.

With the rise of neuroscience, there are provocative puzzles that arise in reconciling findings between imaging and behavioral data. For example, older adults typically show exaggerated contextual facilitation in behavioral data, suggesting that the build up of message-level semantics can support decoding processing. Electrophysiological data, however, often show the reverse (e.g., Federmeier et al. 2010), in particular less predictive processing from sentence context with age. Thus, it will be important for future work to develop a theoretical account of age differences in how different sorts of processes come on line in language processing, so as to accommodate both behavioral and neuroscience data.

Literacy is a form of expertise that is often taken for granted in cognitive aging research, and adults who have not developed these skills are typically underrepresented in research samples. However, a nontrivial proportion of adults in the USA have literacy skills inadequate to the demands of everyday life, and they are especially vulnerable to declines in cognitive health in later life (National Research Council 2012). More needs to be known both about the effects of literacy skill as a moderator of cognitive aging and as potential pathway to resilience.

Synonyms

Autobiographical speech; Complex language; Discourse; Language production; Narrative; Off-topic speech

Definition

Language production is complex task. A person must create an idea or message, activate the meaning elements, called semantic features, for that message, map those semantic features onto words, and then construct a sentence structure that will encode the relationships between those words specified in the initial message. Only then can the phonological encoding of the words for a sentence begin. Moreover, if the goal is to produce a narrative with several interrelated sentences, the person must decide which information will be included in each sentence, and these sentences have to be ordered logically. Considering the complexity of the process, it is, perhaps, not unexpected that language use has been found to activate nearly the entire brain, including regions that are also associated with complex cognitive tasks like working memory and executive function; moreover, these regions and networks remain relatively unchanged in aging (Shafto and Tyler 2014). Considering the intensive use of cortical resources during language production and age-related differences in cognitive performance, it may be somewhat surprising that the impact of age on language production is not more profound.

Despite the complexity of sentence and discourse production processes, older adults are very good story tellers. Several studies have documented that both older and younger adults

rate the autobiographical narratives of older adults as being of higher quality on several dimensions (James and Burke 1998; Kemper et al. 1989; Pratt and Robins 1991). These findings are often interpreted as reflecting older adults' copious experience with language use (Kemper et al. 1989; Trunk and Abrams 2009). Paradoxically, they also have been found to produce more off-topic, less coherent speech than young adults, as well as to be somewhat less fluent and less grammatical in a range of naturalistic discourse tasks, as well as more controlled picture-guided narrative production, and experimental tasks. This article reviews the literature on sentence and discourse level language production in older adults with a focus on identifying both age-related strengths and vulnerabilities. An overarching goal is to try to identify differences in language production between young and older adults that might contribute to the improvements in story quality reported in old age.

Story Quality and Off-Topic Speech

A good story is easy to follow, dramatic, vivid, humorous, interesting, and makes a point (Pratt and Robins 1991). Increased age correlates with better story quality ratings in several studies. Pratt and Robins (1991) report that both older age and higher vocabulary size correlate with ratings of narrative quality. Moreover, they find that older adults employ the use of classic story structure, consisting of a precipitating event, efforts to address the problem, and the resolution of the problem, much more often than younger people. In this study, young adults produce only 60% of their narratives in this classic style, while middle-aged adults incorporate the classic story structure in 75% of their narratives, and 95% of the narratives of the older adults employ this structure. This suggests that, in contrast to current conceptualizations of language development in which people are experts in all aspects of language by age 21 or so (e.g., Owens 2015), some aspects of language use, like story-telling, continue to develop across the lifespan (Köber et al. 2015; Trunk and Abrams 2009).

However, not all studies have found age differences in story quality. Beaudreau et al. (2005) report little difference in the story quality of young and older adult speakers who describe pictures and tell stories with differing emotional valence (positive, negative, and neutral). Perhaps a contributing factor to the differences in findings between studies is the fact that the language samples in the Beaudreau et al. study are much shorter compared to those in other studies (e.g., James and Burke 1998), despite the fact that participants were told they had up to 10 min to speak. This suggests that extraneous differences in testing methods may have encouraged shorter narratives and differences in story quality in Beaudreau et al.

Reports of high quality narratives produced by older adults are intuitively inconsistent with reports of off-topic speech, also called off-target verbosity (James and Burke 1998; Pushkar et al. 2000). Off-target speech occurs when a speaker apparently changes topic in the middle of an ongoing conversation, thus, disrupting the coherence of the narrative. Off-topic speech also tends to increase the length of narratives. Research suggests that only a small proportion of older adults, about 20%, tend to habitually produce extremely high amounts of off-topic speech (Gold et al. 1988). The work of Gold et al. (1988) has identified several predictors of off-topic speech that include personality factors (extroversion), declining cognitive ability, and declining ability to inhibit cognitive interference. Other studies have shown that, in general, older adults tend to produce more off-topic speech than young adults, even when off-topic speech is relatively rare (e.g., James and Burke 1998; Juncos-Rabadán et al. 2005; Trunk and Abrams 2009). This raises the question of why older adults' narratives are rated more highly than those of young adults, when they contain more off-topic speech. A possible explanation for this is that off-topic speech may enhance the quality of the narratives in some way, perhaps by adding depth and context to the story.

To address this issue, James et al. (1998) investigate whether the increased amounts of off-topic speech produced by older adults relative to young adults might relate to either differences in

communicative intent or to inhibitory deficits. More specifically, James et al. point out that young and older adults may have different goals for the narratives they produce or may feel the need to provide more background information for young adult researchers when producing stories. In addition, James et al. raises the possibility that early studies on off-topic speech (e.g., Gold et al. 1988; Pushkar et al. 2000) typically collect speech samples using autobiographical questions, raising the possibility that differences between older and young adults may be found only in this type of narrative. For example, older adults may realize that young adults are likely unaware of the details of everyday life 50–60 years in the past and so they elaborate on these topics more. To address these possibilities, James et al. ask young and older adults to produce narratives that describe pictures (objective, expository narratives) or answer autobiographical questions. In fact, in this study both young and older adults produce longer stories during autobiographical narratives. Even so, this study reports that older adults talk more and include more off-topic speech than young adults but only for autobiographical topics. Further, they find that older adults' narratives continue to be longer even when instances of off-topic speech are removed. Subsequently, all the stories were rated by groups of young and old raters. Both young and old groups rated the older adults as being more talkative but also rated the stories of the older adults as more interesting, more informative, and of higher quality. These findings strongly suggest that the off-topic speech of older adults is specific to autobiographical speech. Further, the increased length and off-topic speech in the stories of this group of older adult speakers does not interfere with the quality of their stories.

More recently, Trunk and Abrams (2009) have expanded on the study by James et al. (1998) by investigating more explicitly the possibility that young and older adults' goals for narratives differ. They first ask older and young adults to rate how important they consider certain communicative goals are when producing two types of discourse, procedural and autobiographical narratives. The authors present the goals to be rated in pairs – one

implicitly associated with conciseness and one with increased length, so that participants must decide which of two goals is more important for each of the two types of narrative, (e.g., clarity, interesting; fascinating, focused; comprehensible, elaborative; entertaining, simple; logical, stimulating; and educational, objective). Results reveal that young adults have very different goals for the two types of narratives: Young adults prefer procedural narratives to be clear, focused, comprehensible, simple, logical, and objective; whereas, they prefer autobiographical narratives to be interesting, fascinating, elaborative, entertaining, and educational. In contrast, older adults' ratings show no strong preferences between most pairs of goals presented, suggesting older adults apparently value both goals in each pair relatively equally. Further, the older adults seem to have similar expectations for both types of narrative; for example, they seem to equally value both being clear and being interesting for both types of topics. As Trunk and Abrams point out, it may actually be this equal weighting of priorities – both clear and interesting, both focused and fascinating – that makes the narratives more preferred by both young and old raters. Subsequently, a subset of the original participants produces two procedural and two autobiographical narratives, and the narratives are rated on the same dimensions included in the earlier questionnaire. As in James et al. (1998), the narratives of older adults are longer and contain more off-topic speech than those of young adults, and autobiographical narratives are longer than procedural narratives. Ratings of the narratives of young adults correlate with their own previous judgments of the importance of different characteristics of speech, but the ratings of the older adults' narratives do not correlate with their previous judgments of the importance of these goals. As the authors point out, however, the latter finding may be due to insufficient variance in rating ranges, since older adults show no specific preference for goals. Interestingly, Trunk and Abrams also report that, while objective measures of off-topic speech show older adults produce more off-topic speech in both autobiographical and procedural narratives, raters only notice that older

adults are more talkative, less focused, and less clear in the procedural narratives. These findings suggest that listeners may not expect or appreciate the extension of some of these goals to procedural discourse. However, in general, the findings are compatible with a developmental view of narrative expertise (Köber et al. 2015), in which adults learn over the course of their lives that good narratives must embody a number of somewhat competing goals particularly in autobiographical speech, whether they are able to tailor their narratives to fit these expectations or not.

By definition, off-topic speech should be highly related to measures of global coherence. Global coherence refers to the extent to which the sentences in a narrative relate to the overall topic or theme of the narrative. Wright et al. (2014) compare global coherence between young and older adults in five discourse tasks: single and sequential picture descriptions, stories based on a wordless picture book, recounts of autobiographical events, and procedural narratives. The only type of narrative showing age differences in this study is the recount of autobiographical events, which is the most common type of narrative analyzed in the literature. Moreover, they find that better global coherence in the autobiographical recounts is associated with better episodic memory and executive function, in particular inhibitory and switching ability. These findings are consistent with those of James et al. (1998) who only found age differences in off-topic speech in autobiographical narratives but Wright et al. take the additional step of relating coherence/off-topic speech to age-related changes in cognition.

These studies indicate that, although older adults may start to show increasing off-topic speech, the quality of narratives remains high (Beaudreau et al. 2005), indeed usually higher than young adults (James and Burke 1998; Kemper et al. 1989; Pratt and Robins 1991; Trunk and Abrams 2009). The improving quality of narratives may represent a learning process over the lifespan (Kemper et al. 1989; Köber et al. 2015) during which speakers learn to integrate diverse goals, such as the complex balance between elaboration and focus in a narratives

(Trunk and Abrams 2009) to increase the quality of their narratives. These improvements in narrative quality occur in tandem with decrements in other aspects of language production.

Lexical Diversity and Information Content

Two aspects of narrative structure that may contribute to narrative quality are lexical diversity and information content. Lexical diversity refers to the variety of words used relative to the number of words used. Thus, if the words are repeated over and over, the lexical diversity ratio is low; conversely, more unique words in a narrative increase the lexical diversity. Information content refers to just that: how much information is conveyed. In constrained tasks, such as telling particular stories or describing pictures, the amount of information is often measured as the proportion of predetermined main concepts that are included in the narrative. In unconstrained speech, such as conversations or responses to open-ended questions, propositions are counted (e.g., Kemper et al. 2003; Kemper and Sumner 2001). Many studies examine information content not only by analyzing the absolute amount of information conveyed but also by analyzing the density of the information, which is essentially a measure of how many words are needed to produce a proposition or main concept and can be calculated in a number of different ways.

A well-established measure of lexical diversity is type-token ratio (TTR), which is the ratio of the number of different words to the number of total words. Higher TTRs are associated with more diverse word choice, while lower TTRs signal repeated use of the same words. Kemper and Sumner (2001) report older adults actually produce a higher TTR than young adults in autobiographical narratives. More recent findings support and refine this finding across narrative types. Fergadiotis et al. (2011) compare lexical diversity in young and older adults across several types of language samples. They find that older and young adults produce similar levels of lexical diversity when asked to tell a story based on a picture or on

a wordless picture book. In contrast, older adults employ a more varied assortment of words when describing how to do something or recounting autobiographical events. Similarly, in a large-scale corpus-based analysis of telephone conversations, Horton et al. (2010) also report that TTR correlates with age: older speakers use a larger variety of words. Thus, in at least three types of language samples, procedural narratives, autobiographical speech, and conversations, older adults have been shown to use a greater variety of words than young adults.

In general, these findings have been attributed to differences in vocabulary between groups, which is well attested (e.g., Kemper and Sumner 2001). While this is a logical conclusion, in fact, there is little support in the literature for assuming that TTR is related to vocabulary. Kemper and Sumner (2001) report that, in autobiographical narratives, TTR loads on a working memory factor rather than a vocabulary factor in both young and older adults. Considering that, it is somewhat surprising that they also find TTR is significantly higher in the older adults than in the young adults, while working memory scores are lower. This finding likely arises because the models of verbal abilities are calculated separately for young and older adults. Thus, within the young adult group and the older adult group, those with higher working memory also produce a greater assortment of words in their narratives.

In summary, research has found that the narratives of older adults have greater lexical diversity than those of young adults when producing relatively unconstrained speech. However, when narratives are constrained, such as in picture description or telling stories based on a picture book, lexical diversity shows no age-related changes.

Information content is another vulnerable aspect of language production in aging. Several studies examine age-related change in the inclusion of main events in stories, proposition counts in narratives, and proposition density. Further, many of these studies examine the relationship between information content and cognitive abilities, specifically working memory and executive function. Wright et al. (2011) investigate how

young and older adults create stories based on different picture stimuli and the extent to which each group reproduces predetermined main concepts inherent in the stimuli. As predicted, older adults produce fewer main events than young adults. Juncos-Rabadán et al. (2005) report a similar study in native Spanish speaking young and older adults. In the latter study, older adults' narratives contain a lower density of information content (i.e., more words are needed to produce the same amount of information) than the narratives of young adults, although the actual amount of information produced by the two groups is similar. Further, these researchers also determine that density of information content correlates significantly with vocabulary scores of their participants.

Similarly, Kemper and Sumner (2001) report lower proposition density in older adults' narratives compared to those of young adults. Furthermore, they relate low proposition density to poor processing ability, assessed by a number of fluency tasks. Specifically, when processing resources and, in young adults, working memory are limited participants may add additional words, particularly lexical fillers (i.e., words like "you know," and "like" that do not add to the semantic content or syntactic complexity of the sentence) to maintain their fluency while accessing words and formulating sentences. Thus, poorer processing, signaled by poor verbal fluency, is associated with increases in verbosity. These studies are consistent with the findings in Kemper et al. (2001) who report that, in a longitudinal study, propositional density declines with increased age. Moreover, similar to the findings in Juncos-Rabadán et al. (2005), Kemper, Thompson, and Marquis report that participants with higher vocabulary scores at initial testing have higher proposition counts initially; however, the ameliorating effect of vocabulary on proposition density declines with increasing age.

Taking a different approach, Wright and colleagues (2011) elicit stories from young and older adults using wordless picture books. Contrary to their expectations, they find no differences in the number of main concepts produced by the two groups. Extending their analysis, these

researchers find that older adults produce significantly longer stories than young adults for the same picture books. Consequently, older adults produce more words per main concept or lower information density. This is consistent with findings reported above suggesting that older adults are more verbose than young adults. Additionally, using canonical correlations, this study identifies a significant association between the proportion of main concepts produced and cognitive abilities, including working memory, long-term memory, and executive function in the older adults. However, the same analysis was not significant in young adults.

These studies demonstrate that age-related differences in the density of information in narratives exist, even when the absolute amount of information produced does not differ (Juncos-Rabadán et al. 2005; Wright et al. 2011). Interestingly, the density of information seems to rely on both vocabulary size and cognitive abilities. Considering this, older adults with more robust lexical-semantic networks and better cognitive abilities appear to have more linguistic and cognitive resources to support information density in speech, making their narratives more concise and precise. However, the evidence suggests that the initial advantage provided by a robust vocabulary early in the aging process wanes over time (Kemper et al. 2001), perhaps due to declines in other critical cognitive abilities, such as executive function, working memory, and long-term memory.

Declining Syntactic Complexity

One of the undisputed findings in geropsychology is that many cognitive functions decline in aging (Lindenberger and Baltes 1997). Consequently, much of the research examining language production in older adults has focused not only on documenting age differences in different quantifiable features of language but also on whether these effects are related to between age group differences in cognitive function, such as working memory, executive function, and speed of processing. Analyses have addressed language

produced in response to several elicitation techniques, including open-ended questions, stories composed to fit a wordless picture book, and single sentence responses in constrained sentence production tasks. One of the most commonly analyzed features of narratives has been syntactic complexity. Research has documented age-related declines in syntactic complexity and occasionally, in the accuracy of syntactic processing.

Taking a lifespan perspective, Marini et al. (2005) examine the picture descriptions of adults from age 20 to 84. They report a systematic decline in syntactic complexity (i.e., the number of embedded clauses per sentence) starting at age 40. Several studies by Kemper and colleagues also compare syntactic complexity differences in the productions of young and older adults. In an early study, Kemper et al. (1989) examine language production in young and older adults using three elicitation methods, a structured conversation, and two open-ended, autobiographical questions, one answered orally and one in writing. Analyses reveal lower syntactic complexity in the language samples of older adults than in those of young adults. Moreover, this study also finds that adults with better vocabulary and/or better working memory ability produce more complex sentences. Two subsequent studies by Kemper and colleagues further elucidate the effects of aging and cognitive abilities on language complexity and semantic content.

Kemper and Sumner (2001) analyze the structure of verbal abilities in 100 young and 100 older adults in separate structural models. Using language samples elicited by autobiographical questions, these researchers analyze sentence complexity, sentence length, propositional density, and type-token ratio (discussed above) in relation to a range of vocabulary, reading, working memory, and executive function tasks. Importantly, they find that the language samples of older adults are significantly less syntactically complex and shorter than those of young adults. In both groups, the structural model identifies three underlying constructs, referred to as vocabulary, working memory, and processing, although the language measures align slightly differently for

young and older adults. For both young and older adults, sentence complexity is associated with working memory, supporting the hypothesis that working memory capacity limits sentence complexity in both young and older adults. They find that, for older adults, lower processing ability is associated with longer sentences, while for young adults longer sentences are associated with both lower processing ability and lower working memory.

Converging evidence for these findings come from Kemper et al. (2001) who report a longitudinal analysis of autobiographical narratives collected from 30 older adults. Study participants are tested annually over periods of between 7 and 15 years. Strong within-person declines in sentence complexity are evident over time, with a steep drop between age 74 and 78. Further, the growth curve model of change over time indicates significant effects of both initial working memory scores and the interaction between age and working memory. Interestingly, robust differences in sentence complexity at the onset of the study are minimized over time as age increases and working memory declines. This suggests that limitations in cognitive abilities like working memory and executive function may constrain the syntactic complexity of narratives, leading to an overall simpler style of speech.

Evidence that older adults adopt a speech style with significantly limited syntactic complexity and information content in language production to accommodate changes in cognitive abilities can be found in the fact that, except for speech rate, their speech is relatively impervious to dual task effects. In a series of studies examining narrative production while walking (Kemper et al. 2003) or doing a rotary pursuit task (Kemper et al. 2009), Kemper and colleagues have found that only young adults simplify their syntax and reduce their proposition density in dual task conditions. In fact, during a complex dual task the syntactic complexity and sentence length of young adults typically drop to near that of older adults in the single task. Further, the extent of dual task effects on sentence complexity in young adults is related to working memory; young adults with lower working memory, who had limited syntactic

complexity in their narratives with no dual task, experience more limited dual task declines. In contrast, the syntactic complexity and proposition density of older adults remain relatively constant (Kemper et al. 2003, 2009). Similarly, speed of cognitive processing predicts changes in words per minute in both young and older adults; people with faster speed of processing show the greatest slowing under dual task conditions (Kemper et al. 2009). Kemper suggests that the speech of older adults is already optimized for communication under conditions of reduced working memory and processing speed and is, in effect, at a functional floor – their speech cannot get more simple or contain less information without breaking down completely (Kemper et al. 2003).

The juxtaposition of high quality narratives in combination with decreased syntactic complexity in the narratives of older adults suggests the interesting possibility that decreased syntactic complexity may actually play a role in the quality of narratives. Indeed, this particular possibility was explored in an early study by Kemper et al. (1990). Fewer clauses per utterance and fewer embedded clauses modifying the sentence subject significantly predicted both the quality (i.e., “interestingness”) and clarity of language samples from young and older adults. Thus, the simpler syntax used by older adults, while clearly reflecting declines in working memory and other cognitive abilities, may actually reduce the processing burden on listeners, making narratives clearer and the information in it more accessible.

Conclusion

Throughout this entry, we have compared young and older adults’ language production with the overarching goal of identifying characteristics of older adults’ language production that might account for the rather consistent judgments that older adults’ narratives are of higher quality, more interesting, and clearer than those of young adults (James and Burke 1998; Kemper et al. 1990; Trunk and Abrams 2009). Several themes have emerged. First, most of the differences in young and older adults’ narratives have been found in

autobiographical narratives. Older adults’ autobiographical narratives, produced in response to questions about events or people in their lives, are longer and contain more off-topic speech; however, these do not seem to interfere with narrative quality (Trunk and Abrams 2009). Moreover, older adults’ narratives have greater lexical diversity, and often take more words to convey the same amount of information. But, it is unknown whether these latter characteristics contribute to story quality. Second, older adults may be more expert at producing autobiographical narratives, and this expertise may continue to improve even into their 80s (Kemper et al. 1989), although syntactic complexity and information density may decline concurrently (Kemper et al. 1990; Marini et al. 2005). One piece of evidence for this is that older adults appeared to realize that a good narrative must be both clear and interesting, both comprehensible and elaborative (Trunk and Abrams 2009), and apply these criteria to both autobiographical and procedural narratives. In contrast, young adults seemed to have strict and contrasting schema for procedural versus autobiographical narratives, and actually use these schema for producing these genres of narratives, though they led to poorer story quality ratings. Another piece of evidence for the greater expertise of older adults in producing narratives is that their narratives are typically structured using classic story grammar elements, whereas only about half of the young adults typically include classic story grammar episodes in their narratives (Pratt and Robins 1991). Further evidence for greater age-related expertise in narrative production is the greater lexical diversity in older adults’ narratives, relative to those of young adults (Fergadiotis et al. 2011; Kemper and Sumner 2001). In contrast, several aspects of language production seem to be impaired in older adults relative to young adults. There is robust evidence that the narratives of older adults, compared to those of young adults, are syntactically less complex (Horton et al. 2010; Kemper and Sumner 2001), are not as globally coherent (Wright et al. 2014), and have lower information density (Kemper and Sumner 2001; Wright et al. 2011). Intuitively, these seem to be characteristics that

would detract, or at least distract, from the quality of the narratives. However, Kemper et al. (1990) found negative correlations between sentence complexity and ratings on interestingness and clarity. This suggests that the simplified syntax used by older adults may contribute to story quality, likely by making the story easier to understand. This reasoning, in turn, suggests that lower syntactic complexity need not be considered a deficit in aging, as it may actually benefit the listener. On the other hand, no one has yet directly examined whether age-related differences in global coherence or propositional density detract from or add to story quality, or whether increased lexical diversity and use of classic story grammar structure benefit story quality. Understanding which aspects of narratives contribute to judgments of narrative quality in older and young adults will help us better understand language changes in aging and determine which changes facilitate and which interfere with communication. Understanding these effects may help us determine which changes truly represent age-related deficits and which merely represent differences.

Synonyms

Word production; Word retrieval

Definition

The verbal production of a single, specific word to represent a concept

Main Text

The cognitive process of producing a known word is called *word retrieval*. Most of the time, speakers engage in word retrieval while producing phrases, sentences, or even larger units of language as part of their verbal communication with others (see Altmann's entry on "[► Language, Discourse Production and Communication](#)"). However, some

word retrieval requires the production of a single, predetermined, specific word to represent a concept, in which case it is called *naming*.

In this review, typical effects of adult aging on naming are presented, along with suggested accounts of the age differences. Early work in the field of cognitive aging suggested that language processes were generally unchanged in healthy adulthood. This conclusion is now known to be inaccurate and probably had at least two causes. First, much of the initial "language" research in aging involved comprehension of vocabulary words, which is at least as good for older as young adults (see entry about "[► Language, Comprehension](#)" and/or Rabbitt's entry about "[► Crystallized Intelligence](#)"). Second, age-related changes in language processes can be easily overlooked because they are much less salient than age-related changes in the ability to form new memories (see entry about "[► Memory, Episodic](#)"). However, older adults are aware of and are often concerned about their word retrieval problems, and research has established some reliable differences between young and older adults' naming abilities.

Many factors about a word itself can make it more difficult to retrieve and produce in a naming task, for speakers of all ages. For example, words that are used infrequently are harder to name than words used on a regular basis, and proper names (e.g., President *George Washington*; celebrity tennis player *Serena Williams*) are harder to name than common words (e.g., the noun *photosynthesis*; the adjective *prosperous*). However, aging is an independent factor that contributes to the difficulty of word retrieval and naming. The cognitive changes that occur with healthy aging do not impact all aspects of naming to the same degree. Developing a comprehensive understanding of these multidimensional changes in naming with age is critical for understanding the normative changes that occur in older adulthood.

Research on naming has adopted a variety of measures to index how readily word retrieval and production occurs. One such measure is accuracy, or how frequently people produce the correct word or name. People are generally accurate when naming objects or concepts, but the types

of errors that speakers make are somewhat predictable and have been influential in understanding the processes underlying successful naming. Because correct production is the most common outcome for each stimulus during a naming study, response times are a second index often used to provide a sensitive measure of subtle changes in the naming process. Response time measures can encompass both the time to initiate articulation (also called *onset times* or *naming latencies*) and the time to complete articulation of the word, with slowed naming taken as an indication of difficulty. Another measure of naming ability is the occurrence of tip-of-the-tongue (TOT) states, in which a word cannot be articulated and feels like it is currently just beyond the speaker's reach. A TOT reflects a partial failure to retrieve a known word or name, and its occurrence thus indicates naming problems.

First, research that uses a variety of these measures to assess age-related changes in producing common (i.e., non-proper name) words is reviewed, and then the effects of various word characteristics on the naming abilities of young and older adults are described. Next, older adults' disproportionate difficulties with retrieval of proper names are summarized. Finally, some of the theoretical mechanisms suggested to cause age-related naming deficits are briefly described.

Age Differences in the Retrieval of Common Words

Retrieval failures for common words (i.e., words that are not proper names) become more frequent with age and are often cited as a source of frustration for older adults. Decades of research have elucidated the ways that these naming difficulties manifest, and this work has been particularly useful in illustrating the stages at which the process of naming is most affected by aging. For example, older adults are less accurate than young adults when naming a picture or recalling a word from a definition and are more likely than young adults to use circumlocution (i.e., to produce a synonym or description of the desired term) when attempting to produce a specific word (Maylor 1995).

Although this could reflect age-related increases in vocabulary (older adults generally know more names than young adults to describe a pictured object or a definition), this idea is challenged by the fact that older adults are also generally slower to retrieve words. Early research on naming comparing people between their mid-20s and mid-70s showed age-related increases in time to accurately name pictures depicting everyday objects. People named items more quickly as the trials progressed, presumably because the early trials served as "practice" that facilitated naming on later trials. However, while there was a trend toward reducing age differences, notable age-related declines in naming speed still remained across the experimental session, suggesting that practicing the naming task does not eliminate age differences in word retrieval (Thomas et al. 1977). Naming latency and accuracy have been shown to decline with age in both cross-sectional and longitudinal comparisons. For example, when adults between the ages of 30 and 70 named pictures of line drawings depicting actions (e.g., *running*, *diving*) three times over a 7 year period, accuracy decreased and response times increased across the decades (i.e., cross-sectional declines were established), and adults over age 50 experienced decreased accuracy over time (i.e., adults in this age range evidenced longitudinal declines). The diversity of errors also increased with age: The types of errors older participants made were more varied, including more substitutions of nouns for verbs (*surgeon* for *operating*), more incorrect responses that had served as answers on a previous trial (saying *running* for *winning* after producing *running* in response to a prior picture), and more fragments of incorrect words (often resulting in self-correction; e.g., "*swi – diving*") (Ramsay et al. 1999).

In addition to reduced accuracy and longer reaction times, some research has shown that aging leads to more frequent production of other types of errors during naming. Specifically, dysfluencies such as pauses, hesitations, and fillers (e.g., "umm") can increase with age, perhaps as attempts to "buy time" to find the word in the face of retrieval difficulties (Burke and Shafto 2008). For example, when researchers presented

multiple pictures (e.g., pictures of a *snake*, *lamp*, *brush*, and *cart*) for young and older participants to name, onset times for the groups did not differ. However, older adults took significantly longer to fully articulate each word and paused more between picture names, leading to a slower speech rate for older than young adults (Belke and Meyer 2007).

A specific word retrieval problem that can occur during naming is the aforementioned TOT state. Despite being able to retrieve and produce conceptual information about a specific term (e.g., “It’s a reptile that has the ability to change colors to match its environment. People who fit in well in all type of situations can also be called this.”), a speaker may be unable to produce the desired word (*chameleon*) at the moment they need to name it. A speaker experiencing a TOT feels that production of the word could occur at any time. This fleeting and imminent nature of TOTs distinguishes them from cases where a person does not know the word at all or from cases where he or she “feels” like they might or should know the word. At some point, the speaker will remember the word (or will be prompted with the word) and will then be able to retrieve and produce it. This is called *resolution* of the TOT state.

Older adults experience more TOT states than young adults and also differ from young adults on the duration of their TOTs and the type of information they have available during their TOT experiences. For instance, older adults have access to less information about an intended word during a TOT state. Young adults can often retrieve the first letter or number of syllables of the word and sometimes produce other alternate terms (i.e., words that are similar in sound or meaning to the correct word, but the participant knows to be incorrect) instead of the intended word. However, older adults are more likely to experience “drawing a blank” during a TOT, meaning they cannot recall any part of the word. They are also less likely than young adults to have alternate words that are similar in sound or meaning come to mind. Additionally, although older adults are just as likely to resolve their TOTs as young adults, they take longer to do so (Burke et al. 1991).

Factors that Influence Naming

The claim that naming worsens with age is quite broad. Research has examined specific conditions under which age differences in word retrieval are more or less likely to emerge. Properties of a word itself can influence how easy it is to produce, and the influence of these factors on age-related changes in naming is described below.

Frequency. Words with high frequency (e.g., *decide*) are used quite regularly in everyday speech and are more readily retrieved and produced by speakers of all ages than low-frequency words (e.g., *decry*) that are rarely used. Both young adults and older adults have more TOTs for low- than high-frequency words, suggesting that words that are not used often are more difficult to retrieve. Further, one result indicated a trend toward an interaction of age group and word frequency, such that older adults experienced disproportionately more TOTs when naming low- than high-frequency words (Burke et al. 1991).

Research has also examined the influence of word frequency via picture naming. A study of aging and naming in monolingual and bilingual speakers showed that young adults named pictures more quickly and accurately than older adults. Both age groups exhibited longer naming latencies and poorer accuracy for low- than high-frequency words, with a trend toward larger frequency effects in older adults. In other words, older adults had larger differences in accuracy and reaction time between low- and high-frequency words than did young adults. Although bilingual status effects on word retrieval are beyond the scope of this entry, the findings related to age suggest exacerbated naming difficulty for low-frequency words in older adulthood (Gollan et al. 2008), similar to the finding with TOTs (Burke et al. 1991).

First-syllable frequency refers to how often a word’s initial syllable is used within a language. The word *decanter* has a high-frequency first syllable because the initial syllable /dɪ/ is found in many words. The word *omnibus* has a low-frequency first syllable because /ɒm/ does not begin many words. A word’s first-syllable

frequency influences young and older adults' TOT incidence, and TOTs increase more with age when the word contains a low-frequency first syllable (Farrell and Abrams 2011).

Neighborhood Characteristics. Another factor affecting naming is the word's *neighborhood density*, or whether it shares sounds with many other words. For example, *decanter* has high neighborhood density because it shares sounds with many words (e.g., *decide*, *decry*, *banter*, *otter*) but *omnibus* has low neighborhood density because it shares sounds with relatively few words (e.g., *omnivore*, *rhombus*). People are more likely to have TOTs for words with low than high neighborhood density, and neighborhood density interacts with word frequency. Specifically, low-frequency words that *also* have low neighborhood density are particularly likely to result in TOTs for young and older adults (Vitevitch and Sommers 2003). However, high neighborhood density has also been shown to have a cost for older adults, in that their picture-naming accuracy declines with increased neighborhood density (Gordon and Kurczek 2014). The high-frequency phonological neighbors have been suggested to compete with the target for production.

Like neighborhood density, *neighborhood frequency* describes a feature of the words that are phonologically related to a target word. However, instead of describing how *many* phonological neighbors a target word has, neighborhood frequency is the average word frequency of those neighbors. Thus, words that have low neighborhood frequency have neighbors that are low in word frequency (are used infrequently), whereas words that have high neighborhood frequency have neighbors that are high in word frequency. Young adults' naming is not impacted by neighborhood frequency, but older adults experience more TOTs for words with low than high neighborhood frequency, so long as the words also have low neighborhood density or low word frequency (Vitevitch and Sommers 2003). That is, low neighborhood frequency compounds word retrieval difficulties traditionally associated with low neighborhood density and low word frequency, but only for older adults.

More work is needed to better understand the relationships among word frequency, syllable frequency, neighborhood density, and neighborhood frequency. Specifically, very little is currently known about how the interplay of these factors might change across adulthood, particularly using reaction times or accuracy measures in addition to TOT rates. However, current research indicates that the effects of neighborhood characteristics emerge more prominently and in a more complex fashion as people progress into older adulthood.

Effects of Alternate Words on Naming

Researchers have relied on typical naming paradigms, such as picture naming or recalling a word from a definition, to isolate the processes involved in retrieving and producing only a single intended word. These procedures typically allow participants to focus on the task of retrieving the desired word. However, everyday naming often does not occur under such controlled conditions, free from distractions or interference. Often, people must retrieve words when other stimuli are competing for attention, as when trying to recall a specific word while on a crowded bus with other people who are talking. Additionally, people sometimes have incorrect alternate words spontaneously come to mind during attempts to produce a word or name (e.g., *thermometer* comes to mind when trying to retrieve the word *barometer*). Research has explored how these alternate terms can affect naming, with the goal of elucidating how they influence young and older adults' word retrieval.

Picture-word interference paradigms and TOT priming studies both measure the success and efficiency of word retrieval, but they do not always produce parallel results, and the precise influence of alternates on word retrieval should be considered in light of the specific procedure used. In the picture-word interference paradigm, a to-be-ignored distractor word (e.g., *cat*) is presented with a to-be-named picture (e.g., *dog*). Distractors can either be shown visually somewhere on or near the target image or can be presented auditorily. Participants are to produce the name of the pictured item and ignore the

distractor word, and slowing of response times to name the picture indicates the degree to which the distractor word influenced target word naming. The TOT priming paradigm involves traditional TOT-eliciting techniques, in which participants must retrieve a word from a definition or a picture. In one version of the priming paradigm, an alternate word (or set of words) is presented *before* the definition or picture is shown, allowing researchers to assess how the word(s) influence the likelihood of experiencing a TOT for the target word. In another version of the priming paradigm, alternate words are presented *after* the participant initially attempts to retrieve the word and experiences a TOT. This method allows researchers to examine the effect of alternates on TOT resolution, or how likely the word will be retrieved once a TOT has occurred.

Phonologically Related Alternates. In some cases, alternate words that share phonology (i.e., sounds) with the target word have been shown to facilitate word retrieval. For example, in picture-word interference studies, presenting a distractor word that is phonologically related to the target word (e.g., seeing the word *doll* and a drawing of a *dog*) speeds picture naming when compared to an unrelated word (e.g., *book*), so long as the picture and distractor word are presented simultaneously. This *phonological facilitation effect* occurs in both young and older adults, to a similar degree (Taylor and Burke 2002). The distractor word prepares the target word's phonology to be articulated more quickly, an effect that does not vary across adulthood. Further evidence that phonologically related alternate words facilitate naming comes from studies using the TOT paradigm: Compared to unrelated words, phonologically related words (sharing at least the first syllable) that are presented prior to a TOT-inducing question reduce both young and older participants' TOT rates. Similarly, when phonologically related words are presented while a participant is in a TOT state, both young and older adults are more likely to resolve their TOTs (James and Burke 2000). Providing at least part of the TOT word's phonology is critical for both avoiding TOTs and resolving them when they do occur. However, these facilitative effects are not necessarily

uniform across the lifespan: As individuals progress into advanced adulthood (late 70s/early 80s), phonologically related words may no longer help resolve TOTs compared to unrelated words (White and Abrams 2002).

Additional research using the TOT paradigm illustrates that phonologically related alternates have the potential to interfere with word retrieval, particularly in advanced old age. TOT resolution is only facilitated when phonologically related primes do not share grammatical class with the target (e.g., prime word *robust*, an adjective, for the TOT word *rosary*, a noun). Presenting phonologically related alternate words that share grammatical class with the target (e.g., prime word *robot*, a noun) does not help young or older adults resolve their TOTs compared to unrelated words. In fact, for the oldest adults (aged 75–89), phonological alternates that share grammatical class actually make the resolution of TOT states less likely (Abrams et al. 2007). These alternates seem to compete with the target for retrieval, whereas alternates that do not share grammatical class do not, and older adults might experience more competition than young adults.

Semantically Related Alternates. Contrary to phonologically related alternates, picture-word interference studies have shown that it takes longer to name a target picture (e.g., *dog*) when the distractor word shares meaning (e.g., *cat*) compared to an unrelated distractor word, specifically when it is presented shortly before or at the same time as the target picture. This is called the *semantic interference effect*, and although it occurs for young adults, research has shown that older adults experience differentially greater interference than young adults (Taylor and Burke 2002).

Whereas semantically related words can delay word retrieval in picture-word interference studies, they do not increase the likelihood of TOTs for either young or older adults. For example, in one study, young, young-old, and old-old participants read TOT-inducing questions, and if they had a TOT (e.g., for the word *chameleon*), they were either shown the first letter of the target word with dashes representing the rest of the word (*c-----*) or were shown a semantically related alternate word (*salamander*). Participants from all

age groups were still able to resolve their TOTs after semantically related alternates were presented, although less often than when the first letter of the word was presented (Heine et al. 1999). In other words, semantically related alternates were not helpful to TOT resolution in the way phonological cues were, but they did not completely prevent resolution of TOT states (see also proper names section, below).

Retrieval of Proper Names

As noted before, individuals of all ages have more difficulty retrieving proper names than other types of words, and this difficulty is exacerbated in older adulthood. Older adults experience more TOTs than young adults for all types of words, but they have disproportionately more TOTs for proper names, as demonstrated in picture-naming tasks as well as definition-based tasks (Burke et al. 1991; James 2006). Part of the reason that proper names have become a focus of research relates to the special status proper names have in social settings and conversation; regardless of whether a proper name is used in a confrontational manner (e.g., used as a means to greet or summon someone) or referentially (e.g., used to refer to others not present in the conversation), successful retrieval of a proper name has direct social consequences. For instance, most proper name retrieval failures cannot be compensated with a description or synonym, and are very noticeable when they do occur because they can lead to social embarrassment or misunderstandings.

Most research regarding proper name retrieval has focused on differences in accuracy as opposed to reaction time because response times for proper names are generally much longer and a lot more variable than for common names (e.g., object names). Diary studies were among the earliest techniques used to document older adults' specific deficits for naming people or producing other proper nouns. Questionnaires assessing the frequency and details associated with young, middle-aged, and older adults' naming failures in everyday situations indicate that adults of all ages experience more naming failures for proper

names than object names or abstract words, with a particularly dramatic age-related increase in failures for proper names (Cohen and Faulkner 1986). Results from one diary study in which participants recorded information about TOTs they experienced over a 4-week period indicated that middle-aged and older adults experienced a differentially greater proportion of proper name TOTs than young adults (Burke et al. 1991). These studies also found that the majority of older adults' naming failures occurred for the names of friends or acquaintances. Perhaps this is because these names are retrieved more frequently than other proper names (e.g., place names or celebrity names), thereby offering more opportunities for retrieval failures to occur.

Although there is utility in understanding naming problems that occur in everyday life, there are limits to the conclusions that can be drawn from diary studies. Naturally occurring naming failures may be influenced by a number of factors such as how frequently a name is encountered or recalled and the time and effort an individual expends on retrieving names. To control for such factors, laboratory research has been conducted to more clearly determine whether proper name retrieval is disproportionately impaired in older age. In a laboratory-based, controlled study on aging and word retrieval, young and older adults saw a series of definitions designed to elicit TOTs for either common words (objects, adjectives, and verbs) or proper names (places or people). Older but not young adults experienced more TOTs for person names than any other word type, and older adults experienced more TOTs for person names than young adults (Burke et al. 1991).

Production of proper names in response to celebrity pictures does not appear to be susceptible to interference from alternate names, contrary to the frequently articulated belief that other names produce interference that disrupts or "blocks" name retrieval. For example, when young and older participants answered a question about a famous fictional character (e.g., *Eliza Doolittle*) and then immediately saw a picture of a celebrity depicting that character (*Audrey Hepburn* as the character *Eliza Doolittle*), TOTs did not increase compared to an unrelated condition

(Cross and Burke 2004). Additionally, presenting the name of a celebrity that is famous for similar reasons as the target celebrity, and who shares a first name with the target celebrity, facilitates naming. In fact, older adults benefit at least as much as young adults from the prior encounter with the alternate name (Oberle and James 2013).

Within the category of proper names, person names appear more vulnerable to naming failures than other classes of proper names, such as place names (Cohen and Faulkner 1986). One possibility is that unlike person names, place names have particular features that facilitate their retrieval and make them more resistant to naming problems in old age. For example, the place name *Paris* brings a lot of vibrant characteristics to mind. In fact, it is so descriptive that it can even be used as an adjective, *Parisian*. Regardless of why place name retrieval is less affected in older age than person name retrieval, the significance of this observation is that proper name retrieval is differentially susceptible to decline in older age and that not all aspects of naming decline uniformly.

Explanations for Naming Difficulties in Older Age

Why does aging lead to increased naming difficulty? A number of possibilities have been proposed. The idea that older adults have reduced cognitive resources compared to young adults has maintained popularity over the years, and one specific example of this type of explanation is that older adults have reduced *working memory* capacity (see entry on “► [Working Memory in Older Age](#)”). Working memory acts as the gateway for the entrance of information into the mind, and it plays a critical role in the active mental processing of information. Thus, age-related deficits in working memory might be expected to cause reduced naming abilities in older adulthood.

Older adults’ naming deficits could also be caused by their slowed cognitive processing. The ability to process information becomes less efficient in older age so that cognitive processes are generally slower and more error-prone (see Madden’s entry on “► [History of Cognitive Slowing](#)

[Theory and Research](#)”). When naming processes are slowed, it may take longer to find the intended word (leading to dysfluencies or pauses, in addition to longer response times), or the word may fail to be retrieved, resulting in a TOT state resulting in a TOT state.

Age-related difficulties in word retrieval might arise because older adults have more difficulty suppressing or inhibiting unintended words that come to mind during word retrieval, as indicated by the *inhibition deficit hypothesis* (see Hasher’s entry on “► [Aging and Inhibition](#)”). Inasmuch as the production of any particular word requires suppression of potentially competing words, older adults’ decreased inhibitory function would make fast and fluent naming more difficult. Older adults also have a lifetime of accumulating vocabulary, which means they know more words that could come to mind and compete for retrieval compared to young adults.

Some research on naming in aging has seemed to support the inhibition deficit explanation. Older adults can experience greater semantic interference effects than young adults in a picture-word interference task (Taylor and Burke 2002), and the oldest adults are less likely to resolve TOTs if they are presented with a phonologically related alternate word that is the same grammatical class as the TOT word (Abrams et al. 2007). The inhibition deficit hypothesis suggests that older adults are less capable of ignoring or suppressing competitors than are young adults, resulting in more naming difficulties. However, this account of age-related changes in naming is challenged by other research findings. For instance, older adults’ TOTs are less frequently accompanied by alternate words than young adults’ TOTs, and neither older nor young adults report increased TOTs when alternate words are presented prior to TOT-inducing questions (Cross and Burke 2004; Oberle and James 2013). In fact, TOTs are often less likely to occur for people in both age groups when the presented alternates share phonology with the target word (James and Burke 2000). These findings are inconsistent with an inhibition deficit explanation, as all alternate words that are similar to the target in sound or in meaning would be expected to increase naming difficulties,

especially for older adults. Thus, inhibition deficits may play a role in age-related changes in word retrieval, but they do not seem able to account for all of the findings regarding naming in aging.

The observation that aging leads to increased naming failures, with generally less information about a word available during them, has led to an explanation referred to as the *insufficient activation* or *transmission deficit hypothesis* (MacKay and Burke 1990). This approach is couched in theories of speech production that claim word retrieval begins with creation of a nonverbal message, during which a word's meaning is accessed. This is followed by lexical access, where a word that is consistent with the chosen meaning and is also grammatically appropriate is selected to convey the message. The final process involves retrieving the phonology of the word so it can be articulated. For example, producing the word *chameleon* requires retrieving appropriate semantic information (e.g., *lizard, changes color*), followed by the lexical representation of the individual word (*singular common noun*) and finally, the word's phonology (*/kə'mi/li/ən/*). The transmission deficit hypothesis proposes that TOTs occur when the meaning of the word has been accessed and the word has been appropriately selected, but the complete phonology of the word cannot be retrieved. This explains why individuals often have a strong feeling of imminent resolution during a TOT state and can often provide detailed descriptive information about the word they cannot produce.

Why would the cognitive processes involved with accessing the phonology of a word fail? Simply, the connections between the word and its associated phonology become weak. Weakened connections can result when a word's sounds are not produced regularly (e.g., a low-frequency word like *omnibus*) or recently (e.g., last name of one's third grade teacher), similar to a use-it-or-lose-it explanation. The transmission deficit hypothesis also proposes that the natural process of aging independently weakens connections between the word and all other information (semantics *and* phonology), which accounts for the fact that older adults are slower and less accurate when producing words during naming tasks

compared to young adults. The utility of the transmission deficit hypothesis is that it provides an explanation for older adults' increase in TOTs, reduced access to phonological information, and increased interference from alternates in specific tasks (e.g., picture-word interference tasks), all on the basis that older adults have weakened connections among semantic, lexical, and phonological information.

Conclusion

This entry has detailed the ways in which the normal aging process influences naming, a task in which people engage every day. As individuals age, word retrieval generally becomes more difficult. That is, older adults typically take longer to retrieve known words, are less accurate and produce more dysfluencies (filler words, stutters, etc.), and have more naming failures (i.e., more TOT states) than young adults. Specific factors about the word, such as its frequency or its lexical "environment" (e.g., its neighborhood density and frequency), affect the likelihood of naming difficulties, particularly for older adults. Specific environmental or situational conditions can also affect the likelihood of word retrieval difficulties, such as when an alternate word modifies the ability to access a target word.

It is important to note that these factors do not affect aging adults in a single way. As this entry illustrates, some indices of naming may be particularly affected in older age while others are not. For example, older adults' reaction times are much longer than young adults when producing a target word while a semantically related alternate word is presented, but the likelihood of experiencing a TOT for a target word is unaffected by the presence of a semantically related word. It is crucial to understand the varied way in which aging interacts with these influences to impact naming.

Several explanations for age-related declines in word retrieval were also reviewed, including age-related declines in working memory ability, general slowing of cognitive processes in older age, age-related inhibition deficits, and

transmission deficits brought on by the normal aging process. There is still much debate as to which approach most comprehensively explains the specific word retrieval deficits experienced by older adults, and future research will continue to delineate the exact causes of decreased naming efficiency with age.

This entry covers the effects of age-related changes on the processes involved with word retrieval in healthy older adulthood. Individuals suffering from neurodegenerative diseases, like dementia or Alzheimer's disease, experience more diverse and extensive naming difficulties than those discussed here (see entry on "[► Behavioral and Psychological Symptoms of Dementia](#)"). However, understanding the changes in word retrieval that are associated with healthy aging is important for establishing a normative "baseline" to distinguish between normal and non-normal age-related changes in naming.

for psychosocial functioning. Specifically, psychosocial correlates of retirement, widowhood, and disability are discussed, with a focus both on relevant theoretical perspectives and selected empirical studies related to each transition. This is followed by an analysis of the means by which older adults adapt to altered life circumstances resulting from transitions in the context of perspectives on self-regulation of development.

Late Life Transitions

Synonyms

Adaptation; Adjustment; Change

Definition

Transitions broadly represent life events or circumstances that entail relatively enduring changes in an individual's behavior and/or outlook (Parkes 1971). Transitions can involve abrupt changes, such as the unexpected death of a loved one, or can be cumulative, taking place over a period of time, as in the increasing severity of symptoms arising from a chronic illness. Transitions can have positive or negative implications for well-being, and the same type of transition can produce contrasting outcomes for different individuals. A range of potential transitions are experienced by older adults. These can take place across multiple developmental domains and social contexts (e.g., death of network members), affecting physical health (e.g., onset of chronic illness, or recovery from illness), cognitive capacity (e.g., onset of dementia), mobility (e.g., driving cessation), generativity (e.g., becoming a grandparent), and productive activity (e.g., becoming a volunteer), to name a few. This entry focuses on a subset of transitions that are commonly experienced by older adults and often have significant implications

Transition to Retirement

For many adults, establishing and maintaining a career throughout younger and middle adulthood represents both a financial necessity and an important context for goal-directed activity; imbuing life with a sense of purpose. Consequently, it is not surprising that retirement from the workforce is recognized as a significant late life transition and has been the subject of extensive research. Early conceptual perspectives suggested that the retirement transition involved a series of sequential stages, beginning with a honeymoon period, before subsequent stages of challenge and eventual adjustment (Atchley 1976). More recent theoretical perspectives have taken a life-course approach, emphasizing individual differences and dynamic developmental processes occurring within environmental and social contexts, in shaping retirement outcomes (Hesketh et al. 2011; Kim and Moen 2001, 2002). For example, Kim and Moen's (2001, 2002) life course ecological approach emphasizes the role of social interrelations, life and role contexts, and human agency in influencing the ways in which retirement is experienced differently by different individuals. For example, whether or not an individual is married, the quality of the marital relationship, and spouse's employment status represent important contextual factors influencing the retirement transition.

Heterogeneity in retirement experiences is also thought to arise from the transition out of the identity-relevant social role of "employee." This significant role change has the potential for positive and/or negative impacts on subjective well-being. For retirees who identify strongly with their career-based identity, retirement can represent a

role-loss that produces feelings of vulnerability and distress. Alternatively, individuals who experience significant strain associated with their employment role may experience relief and enhanced well-being as a result of transitioning out of employment. Recently, Wang et al. (2011) outlined a resource-based dynamic perspective on retirement in an endeavor to better account for the complex interrelationships among the various factors believed to influence the retirement process. This integrative perspective acknowledges the role of the social, contextual, and individual-level influences on retirement emphasized by life-course contextual perspectives, but also focuses on how the effect of these factors on retirement adjustment over time is mediated by physical, cognitive, motivational, financial, social, and emotional resources.

Through highlighting the broad array of different social-contextual circumstances, and resource profiles that contribute to retirement adjustment, recent theoretical perspectives provide frameworks to account for the mixed nature of findings concerned with retirement and well-being that has characterized the literature to date (for reviews see Kim and Moen 2002; Wang et al. 2011). Recently, empirical studies have addressed the complex, heterogeneous nature of retirement adjustment by applying profile-oriented statistical methods to the analysis of longitudinal data. Wang (2007) used growth mixture models to examine different patterns of adjustment to retirement (indexed by psychological well-being) across four measurement occasions over a 6 year interval. Three subgroups were identified according to differences in trajectories of change. The largest subgroup showed a *maintaining* pattern, characterized by consistently high levels of psychological well-being across the postretirement years. The next largest subgroup displayed a *U-shaped* pattern with an initial small decline in psychological well-being at the beginning of the retirement transition followed by an improvement post transition. A third small group showed a *recovering* pattern, characterized by a linear increase in psychological well-being in the years following retirement. Correlates of subgroup membership with contextual variables provided support for

the role of context and resources in influencing retirement adjustment. For example, retirees who reported demanding, stressful jobs with low levels of satisfaction were more likely to be classified into the *recovering* subgroup.

Pinquart and Schindler (2007) used a similar approach to examine longitudinal trajectories of life satisfaction from pre- to postretirement among Germans who retired between 1985 and 2003. Three subgroups were identified. The largest showed a small temporary increase in life satisfaction after retirement. Two smaller subgroups were characterized by (i) a larger temporary increase and (ii) a larger temporary decrease in life satisfaction across the retirement transition. Once again, patterns of transition were related to resource availability. For example, those who showed the smallest changes in life satisfaction with retirement also reported higher SES and were more likely to be married and in good health, whereas those who showed a decline in life satisfaction were more likely to be in poorer health.

In sum, retirement from work represents a significant transition that can have different implications for psychological health, depending on social-contextual factors and individual resources that influence psychosocial adjustment over time. Longitudinal studies that span the retirement transition, and include detailed measures of relevant contextual and resource-related influences are likely to be critical to enhancing our understanding of the retirement transition process and the characteristics of individuals and their life contexts that are most important in shaping adjustment.

Transition to Widowhood

For those who are partnered, the spousal dyad represents a unique and central social context for development. This is likely to be particularly the case in later life when spouses have accumulated a long history of shared experiences, and frequently take on compensatory coping roles in response to declining health, function, or cognitive capacities experienced by one or both partners (Berg and Upchurch 2007; Hoppmann and Gerstorf 2009).

Not surprisingly, the commonly experienced late life transition to widowhood can result in significant psychological distress, as well as new challenges for adapting to everyday activities that were previously performed by, or in collaboration with a spouse.

Whereas experiences of distress and disorganization are regarded as common responses in the months following the death of a spouse, research also indicates that older bereaved individuals typically adapt to their loss over time. For example, Ott et al. (2007) identified distinct clusters of older bereaved adults based on longitudinal changes in grief and depressive symptoms. Five out of six bereaved spouses either maintained low levels of grief and depressive symptoms or showed a pattern of adjustment over time after initially elevated levels of psychological symptoms. The remaining one out of six participants showed a more chronic pattern of higher levels of grief maintained over time. Parkes and Prigerson (2010) suggest that grief reactions are often less intense among older relative to the younger widowed and speculate that this may be due to the death of older spouses being more timely, and less unanticipated, providing greater opportunities for anticipation of and preparation for the loss. However, as is the case for younger adults, losing a spouse in late life increases vulnerability to psychological distress. For example, it is estimated that at some point during the 12 months following bereavement, between 10% and 17% of older widows experience clinically significant levels of depressive symptoms (Parkes and Prigerson 2010).

Carr and Utz (2001) outlined a conceptual framework for understanding individual differences in the experience of widowhood by identifying how broader macrosocial factors, the nature of the spousal partnership, and individual characteristics can each influence processes of adjustment. The increases in life expectancy that occurred in the twentieth century mean that the transition to widowhood is now more commonly experienced as a long process associated with the chronic illness of a spouse, which takes place over months or years. The drawn-out nature of a spouse's illness can ease the transition to

widowhood by providing time needed to resolve outstanding family and financial issues and plan for the future. However, a prolonged death can also create significant stress for the bereaved resulting from emotional strain, caregiving burden, and medical expenses. The psychological consequences of widowhood also depend on the quality of the marriage, with widows who feel a strong emotional closeness with their spouse more likely to experience a longer and more difficult period of adjustment. Individual characteristics such as cognitive ability and personality are also likely to play a role in influencing processes of adjustment. Carr and Utz (2001) emphasized the relevance of gender as an individual difference factor. For example, women tend to be embedded in stronger social networks, which could result in the greater availability of social support, providing an important coping resource that may be less accessible to bereaved men. However, recent research using data from the Health and Retirement Study found no gender differences in trajectories of depressive symptoms following widowhood. Rather, results suggested that previous findings showing gender differences are influenced by selection effects, whereby women are more likely to be selected into widowhood at younger ages and men are more likely to experience widowhood for a shorter (and as a result more emotionally intense) duration as a result of gender differences in remarriage and mortality (Sasson and Umberson 2014).

The multifaceted nature of the transition to widowhood is reflected in the results of a number of empirical studies that have examined factors that moderate patterns of psychosocial adjustment after loss of a spouse. For example, Utz et al. (2012) examined whether physical health modified trajectories of change in grief and depressive symptoms over 1.5 years following bereavement in a sample of adults aged over 50. Their results indicated that participants with poorer health following widowhood also reported higher levels of grief and depressive symptoms, but that rates of recovery over time did not vary as a function of health. Findings from the Changing Lives of Older Couples (CLOC) study have shown that sudden death of a spouse is associated

with higher levels of intrusive thoughts following the bereavement, whereas more prolonged death is associated with higher subsequent levels of anxiety. Research based on CLOC has also showed that spouses from lower-quality marriages yearn less for their spouse after bereavement and that widowhood resulted in increased informal (but not formal) social engagement (Carr and Utz 2001).

Widowhood represents one of the most significant normatively experienced late life transitions, which commonly results in substantial distress and upheaval. Although depressive symptoms among bereaved older adults tend to become reduced over time, a proportion will struggle to adjust to their loss over the long term, and those who become widowed early and remain unmarried represent a particular at-risk group (Sasson and Umberson 2014). Ultimately, research that continues to enhance our understanding of the risk and resilience factors that modify trajectories of adjustment to widowhood will play an important role in informing the development of effective pre- and postbereavement interventions.

Transition to Disability

The risk of physical health limitations becomes greater with advancing age. Among the oldest-old (e.g., ages 85 and above), frailty, morbidity, and limitations in the ability to perform instrumental activities of daily living are commonly experienced (Baltes and Smith 2003). Functional ability is important for maintaining quality of life, and those with functional impairments are at increased risk of institutionalization and death (Mor et al. 1994). Thus, it is perhaps not surprising that disability has been linked to poorer psychological health, with possible mechanisms including the direct negative impact of disability as a source of stress on emotional well-being, and possible indirect paths whereby disability reduces one's capacity to perform valued activities such as being socially engaged, that in turn reduces quality of life (see Yang and George 2005).

Research concerned with correlates of disability in later life points to numerous links between

functional limitations and poorer mental health and subjective well-being. For example, Yang and George (2005) showed that being classified as having greater stable levels of disability (based on measures of strength, mobility, and ADL/IADL difficulties) and transition in status to a higher level of disability were associated with increases in depressive symptoms over a 6-year study interval. Boerner (2004) reported associations of functional disability and visual impairment with greater depressive symptoms, social dysfunction, and mental health problems, and mobility limitations have been found to correlate negatively with life satisfaction among older adults in residential care (Mollaoğlu et al. 2010).

The empirical links between physical and mental health in older adulthood have led researchers to focus on underlying mechanisms, in an effort to identify potentially modifiable factors that could help protect against the effects of aging-related physical losses on psychological functioning. For example, Yang (2006) examined the extent to which the longitudinal association of functional disability with depressive symptoms was mediated by social support, control beliefs, and self-esteem. The results supported the role of the psychosocial variables operating as mediators, with psychological resources (in particular self-esteem) emerging as critical in accounting for the association between disability and depressive symptoms.

Other researchers have focused on the extent to which specific methods of coping could buffer against the deleterious effects of disability on mental health. Boerner (2004) examined whether persistence in pursuit of goals or the flexibility to adjust goals in response to situational constraints were protective against the negative association of disability with mental health. Results supported the role of flexible goal adjustment as a moderator, with those reporting stronger tendencies toward flexible goal adjustment showing weaker associations of disability with mental health. Dunne et al. (2011) also focused on the role of goal orientation in buffering the association of disability with depressive symptoms, using 6-year longitudinal data. The ability to disengage from blocked goals emerged as a moderator, with participants scoring higher on disability showing less increase in

depressive symptoms over time if they also reported stronger tendencies toward disengaging from blocked goals.

Like widowhood, the transition to disability is a relatively normative late-life experience that represents a risk factor for psychological health. However, appropriate methods of coping that allow for adjustment of goals and expectations in response to aging-related health transitions could represent an important protective resource. This issue is explored in more detail in the subsequent section.

Negotiating Late Life Transitions Through Self-Regulation

Not all transitions associated with aging will have negative implications for well-being. However, as discussed, several normative transitions (such as widowhood and the onset of chronic illness and disability) do commonly pose a risk to psychological health and quality of life. Despite this, older adults typically adjust successfully to transitions over time, and research shows that, at least prior to the more serious declines across multiple domains of functioning that can emerge in the few years preceding death (e.g., Gerstorf et al. 2013), older adults report high levels of subjective well-being relative to younger adults (e.g., Windsor et al. 2013).

One means by which older adults are able to cope with the challenges posed by significant transitions is through the use of effective self-regulation – that is, processes concerned with the management of goals in response to changing life circumstances (Hooker et al. 2010). Baltes and colleagues' theory of Selective Optimization with Compensation (SOC; e.g., Baltes 1997) provides a framework that explains how individuals regulate their development across the lifespan by selecting and pursuing developmental goals that provide an appropriate fit to their life context. Fundamental to SOC is the notion that individuals select achievable goals, maximize the resources available to them that facilitate goal attainment, and find ways to compensate and counteract losses when goals are blocked. Experiencing late life transitions often results in the need to flexibly

select new goals in response to losses and/or to develop effective methods of compensation when the means of goal attainment are no longer available. For example, an older widowed adult might respond to the loss of their closest social partner by selecting new goals aimed at enhancing their social networks through participating in volunteering. Being a successful volunteer and benefitting from the experience might involve optimizing resources needed to perform the volunteer role, such as undertaking relevant training and maintaining fitness. Obstacles to being a volunteer might be overcome through the use of compensatory strategies. For example, barriers to participation resulting from increasing frailty might be overcome through adopting a less physically demanding volunteer role and using public transport to attend meetings if driving independently is no longer an option.

A complementary perspective on self-regulation is provided by Brandtstädter (2009; Brandtstädter et al. 2010), who outlined a dual-process model of assimilative and accommodative processes to describe how older adults manage aging-related losses. *Assimilation* refers to active efforts to engage with the environment in the pursuit of desired goals in line with social and self-evaluative standards, whereas *Accommodation* refers to the flexible adjustment of goals in response to changed circumstances and resource availability. Processes of accommodation are thought to be particularly important for maintaining well-being in the face of aging-related losses, including significant late life transitions. For example, an older adult experiencing the transition to disability may need to exercise accommodation in the form of disengaging from goals that are dependent on mobility (e.g., participation in sports) and instead invest their assimilative efforts around alternative goals that are less dependent on physical attributes (e.g., participating in generative activities with grandchildren). Thus, assimilation and accommodation coexist as complementary processes within a system of adaptation that operates throughout the lifespan, but may hold particular relevance to late life when accommodative processes become a central means of dealing with losses and transitions (for

a related perspective on self-regulation of development also see (Heckhausen et al. 2010)).

Conclusion

Individuals typically experience various transitions from childhood through to old age. Normative aging-related changes in resources (e.g., declining health) and social roles (e.g., transition to retirement or becoming a grandparent) mean that a number of transitions that commonly occur in older adulthood can have significant implications for psychosocial functioning and quality of life. Research also indicates that a high proportion of individuals who experience potentially stressful transitions return to pretransition levels of well-being after periods of adaptation and adjustment. Flexible processes around the pursuit of developmentally relevant goals and disengagement from blocked goals are believed to play an important role in contributing to the effective negotiation of transitions.

Definition

This entry concerns the relationship between leadership and aging. More specifically, the entry focuses on how aging of leaders and followers affects leadership behaviors or styles as well as leadership effectiveness. In general, the entry tries to give some answers to the following questions: (1) How do younger and older leaders differ in the leadership behavior they utilize and are younger or older leaders more effective? (2) How do leaders need to react to an aging workforce? (3) How do age differences between leaders and followers affect leadership effectiveness? To date, research on leadership and aging is scarce; however, in recent years, both theoretical and empirical developments have shed some light on this topic.

Introduction

Leadership is a central concept in both organizational psychology and management science and has been studied for more than 200 years. Accordingly, a myriad of concepts and ideas exist of what leadership is. Nevertheless, most leadership researchers seem to agree that leadership concerns a social influence process between people that is geared towards achieving shared goals (Yukl 2010). In addition, several generations of theories exist that describe what *successful* or *effective* leadership looks like. While early leadership theories focused on stable traits of leaders, newer theories generally concern assumptions on how different leader behaviors are related to performance and other follower outcomes. One of the most influential leadership theories of the last decades is the transformational leadership concept. This theory argues that certain (transformational) leadership behaviors, such as providing a vision and acting as a role model, can motivate followers to go beyond what is expected of them in terms of the employment contract and can result in higher performance and introduce changes within organization. Other theories focus on leadership behaviors that are task related, for example, assigning tasks and setting goals,

Leadership and Aging, Fig. 1 Overview

while some theories are focused on the relationship between leaders and followers.

While the interest in lifelong perspectives and aging in general is growing, research on leadership and aging is still scarce (Walter and Scheibe 2013; Zacher et al. 2011a). Given the centrality of leadership in both organizational psychology and management science, this is quite surprising. However, there is an emerging field that tries to delineate the relationship between leadership and aging both theoretically and empirically. This entry will summarize the extant theory and the empirical work that has been done so far.

When considering the relationship between aging and leadership, the age of two groups becomes important: leaders and followers. The structure of the entry will build on this distinction (see Fig. 1). The focus of the first part of the entry will be on the age and aging effects of leaders. The second part will summarize work on how leaders need to react to an aging workforce. The final part will then discuss age differences between leaders and followers and the role of age relations between leaders and followers.

Aging Leaders

Leadership is hardly a homogeneous or straightforward matter but includes a wide array of different tasks and responsibilities, for example, coordinating and structuring tasks, representing the work group to persons outside the group, acquiring resources, or supervising and developing team members (Yukl 2010). Given this multitude of activities that require quite a few different competencies, it is unlikely to expect that either

older or younger leaders in general are more effective. Some leadership tasks, such as making complex decisions, require rapid information processing which has been found to decline with increasing age (Salthouse 2012). On the other hand, other activities, such as advising and mentoring, rely to a greater extent on experience and accumulated knowledge as well as social competencies that are constant over time or even increase with age (Salthouse 2012). Thus, there is no easy answer to the question of how leadership and leadership effectiveness develop with increasing age. Recently, two review articles have made an attempt to summarize the effects of aging on leadership and leadership effectiveness (Walter and Scheibe 2013; Zacher et al. 2015). The conclusions of those reviews will be briefly discussed in the following. First, leadership behavior that mainly focuses on task accomplishment and goal achievement, such as initiating structure or transactional leadership, is largely unrelated to leaders' age. Thus, older and younger leaders utilize these task-related behaviors to a similar extent. Second, older leaders seem to engage more in leadership behaviors that concern their relationship with followers, such as consulting team members or including team members in decision making, although the results are not unequivocal. To date, most research on age and leadership behavior has examined transformational leadership and similar leadership styles that are oriented towards change. In general, research seems to indicate – with some exceptions – that leaders become less charismatic, change-oriented, and willing to take risks with increasing age. Finally, older leaders tend to engage in more inactive or passive types of leadership behavior than younger leaders.

In line with the assumption that it is unlikely to expect a clear positive or clear negative relationship between age and leadership effectiveness, Walter and Scheibe (2013) describe research that found both negative and positive relationships but conclude that the overall picture rather reveals a negative influence of leaders' age on task effectiveness. When it comes to relational effectiveness of leaders, such as follower satisfaction, however, older leaders seem to be in general as effective as younger leaders.

Over and above the general change over time in leadership behavior or effectiveness, research has tried to disentangle boundary conditions of this change. In other words, research has attempted to answer the questions of under which conditions age is related to leadership behavior and under which conditions younger and older leaders are effective. This approach is in line with the overall assumption that older leaders do not generally become better or worse with increasing age, but conditions and motivation for leading may change over time. Accordingly, these conditions and motivation need to be considered to get a clearer picture of the relationship between aging and leadership. In the following, some examples of this research will be discussed to identify the factors that might explain the rather inconclusive results concerning the link between age on the one hand and leadership as well as leadership effectiveness on the other hand.

One prominent theory in lifespan development is generativity theory. Generativity is defined as the concern for guiding and supporting future generations and is related, for example, to helping and mentoring younger individuals (McAdams and de St. Aubin 1992). As generativity can be understood as a developmental challenge for older individuals, whether or not older leaders are motivated by generative concerns might decide whether these leaders are motivated to keep up effective leadership behaviors over time. The idea behind this assumption is that older leaders who are not motivated by generative concerns lack the necessary motivation to lead as other forms of motivation, such as advancing one's own career, decline with increasing age. Zacher and his colleagues were able to demonstrate this effect in two studies: One study revealed that only older leaders with high generativity were able to maintain high levels of leadership effectiveness, compared to younger leaders, whereas older leaders with low generativity displayed lower effectiveness (Zacher et al. 2011b). In a similar vein, a second study showed that older leaders who were concerned with leaving a legacy (which is a dimension of generativity) displayed higher levels of transformational and transactional leadership than older leaders who did not believe in being

able to leave a legacy (Zacher et al. 2011a). Taken together, this research reveals that a crucial issue that decides over leadership in older age is whether leaders are able to maintain an age-appropriate motivation to lead. If other forms of motivation deteriorate over time and older leaders are not able to generate new forms of motivation, it is highly unlikely that they will be effective leaders.

Another important factor in this regard is whether leaders are perceived to be effective by followers and other persons. Implicit leadership theory argues that leaders who match implicit assumptions of followers of what a leader should be like are perceived as being more effective than leaders who violate these assumptions. Experimental research by Spisak and colleagues (Spisak 2012; Spisak et al. 2014) indicates that followers are biased towards perceiving older leaders as being more effective than younger leaders in situations of intergroup conflict and in situations when stability is more important than change. Thus, not only leaders' actual behavior changes over time but the same behavior might be assessed differently depending on the age of leaders.

Taken together, the relationship between leaders' age and leadership as well as leadership effectiveness is complex. Whereas some leadership behaviors seem to become less utilized with increasing age (e.g., change-oriented leadership), other leadership behaviors are employed by younger and older leaders alike (e.g., relationship-oriented leadership). A general tendency of an increase or a decrease of leadership effectiveness is difficult to detect. Instead, first studies could demonstrate that boundary conditions play an important role, such as follower perceptions and an age-appropriate motivation to lead.

Leading an Aging Workforce

In addition to the leader's age, the age of followers is central in the relationship between aging and leadership. The next paragraphs thus concern the challenge of leading an aging workforce. As a result of an increased participation rate of more

elder employees in the workforce and young academics beginning their working life earlier in the aftermath of changes in the educational system, the working lifespan is becoming longer and the number of employees at both extreme ends of the age continuum is growing. Hence, the age diversity of work teams and organizations alike is increasing. In this context, leaders face two central challenges: First, leaders need to deal with an increased proportion of older workers among their followers. Second, leaders need to integrate younger and older followers in order to successfully manage all generations at work.

Previous studies revealed that leaders, especially their attitudes and behaviors, have an important influence on followers' performance and well-being across their working lifespan (Ilmarinen and Tempel 2002; Ries et al. 2013). In that vein, a Finnish longitudinal study revealed that leadership behaviors directed towards the needs of older followers were the only significant factors that maintained and enhanced the work ability among older followers (50 years and older) across 11 years. These leadership behaviors encompass an open, non-stereotyped attitude towards age and aging, openness to participation and cooperation, ability to communicate, and age-differentiated work organization (Ilmarinen and Tempel 2002). Thus, leadership that is sensitive towards the specific needs of older followers seems to be critical for maintaining high work motivation and performance with increasing age of followers.

Especially leaders' attitudes towards age and aging are crucial for an age-related leadership. Age stereotypes, as assumptions and expectation about people based on their age, influence the way one thinks about and behaves towards older followers. Despite of several positive stereotypes about older followers such as experience, honesty, and loyalty, the majority of age stereotypes ascribed towards older followers are negative attributes such as being absent more often, being less productive than younger followers, and having less potential in as well as a lower motivation for personal development (Posthuma and Campion 2009). Leaders tend to have high levels of age stereotypes towards older followers.

As stereotypes are an important antecedent of related behavior, such as discrimination, leader stereotypes towards older followers increase the likelihood of age-biased or discriminatory decisions and behaviors, for example, concerning assessment or participation in training and development (Posthuma and Campion 2009; Kunze et al. 2011).

For an effective age-related style of leadership, it is important that leaders learn about and reflect upon the different work-related abilities and characteristics of younger and older followers (Kunze et al. 2011; Wegge et al. 2012). With that in mind, an individualized leadership focusing on the individual characteristics of younger and older followers seems most promising for healthy and well-performing followers. In line with this idea of an individualized leadership, a generational approach to leadership (Kunze et al. 2011) emphasizes adjusting leadership behavior to individual follower's needs and values. For example, leaders need to create a work environment that enables all generations to perform and engage at work depending on each generation's specific strengths and demands towards leaders. Based on historic events during their childhood or youth, each generation of employees is characterized by certain strengths and features. Leaders can address these and consider them in their leadership approach. For instance, the generation of baby boomers (born 1956–1965) prefers leadership behaviors directed towards cooperation among colleagues and offering opportunities for further development, that is, relationship-oriented leadership, whereas the "Internet" generation (born from 1981) demands their leaders to set clear goals and visions and provide them with learning opportunities; thus, they prefer task-oriented or change-oriented leadership. Despite these leadership behaviors being of a high practical value, there is only scarce research evaluating the effectiveness of this generational approach. However, the described studies show the need and the positive impact of leaders changing their mindset and adapting their behavior towards an age-sensitive leadership approach.

Besides an aging workforce, an increasing age diversity in work teams is another challenge

for leaders. Previous research revealed both positive and negative effects of increased age diversity on team performance. Theoretical approaches are used to explain the contradictory results. Studies on group composition reveal that the composition of a group is an important factor influencing group performance (van Knippenberg and Schippers 2007). Based on theories of social categorization processes and models of information processing, age diversity in teams may result in advantages (e.g., utilization of differences in experience for problem solving) as well as disadvantages for teamwork (e.g., intensification of emotional conflicts in groups, activation of stereotypes, reduced team climate due to communication problems). With regard to age as a group composition characteristic, the negative effects of age diversity in teams seem to outweigh the positive effects (Joshi and Roh 2009). Across contexts, age is a very salient characteristic and thus likely to activate stereotypes that in turn can negatively influence the health of the team members and performance of the team as well as increase ageism within the team (Ries et al. 2013). In this vein, Ries and colleagues (Ries et al. 2013) demonstrated that not age differences per se but rather age becoming salient within a team is associated with increased conflicts and reduced performance. The positive effects of age diversity in teams only emerge in teams with a positive team climate, complex tasks, and when team members value working together in age-diverse teams (i.e., have positive diversity beliefs; Ries et al. 2013). All of these aspects can be facilitated by leaders (depending on either a task- or relationship-oriented leadership style).

Furthermore, transformational leadership can buffer the negative effects of age diversity on team performance. Kearney and Gebert (2009) could show that when transformational leadership was high, age diversity increased the elaboration of task-relevant information and, in turn, performance. In contrast, low levels of transformational leadership were associated with a negative relationship between age diversity, elaboration of task-relevant information, and subsequently performance. Thus, leaders seem to create an environment that fosters information

elaboration – instead of social categorization – and group identification within a team.

In line with the characteristics for age-related leadership proposed by Ilmarinen and Tempel (2002), Wegge and colleagues (2012) broadened the concept to address not only the needs of older followers but to explicitly consider age-diverse teams. In their model for age-differentiated leadership, they postulate behaviors directed towards the age-related changes in needs and motives of younger and older followers as well as address behaviors that are relevant for an effective leadership of age-diverse teams. First studies (Wegge et al. 2012) show the positive impact of age-differentiated leadership on followers' health, turnover intentions, and performance in various work fields, such as nursing, call centers, and production.

Taken together, these studies reveal the need and also the opportunities for leaders to know about and act upon the respective needs and demands of younger and older followers in an aging workforce. Thus, in order to successfully manage the aging workforce, leaders are required to change their mindsets regarding aging and learn new leadership skills to face specific challenges and conflicts at work that are related to aging followers and age diversity in teams.

The Interplay of Older and Younger Leaders and Followers

The relational demography literature suggests that not only the specific age of leaders and of followers is important, but age differences between leaders and followers may also have an impact on leadership effectiveness (Vecchio 1993). To be accepted by followers or to be perceived as being an effective leader, leaders need a justification to be in the leading position. As argued before, this justification might be a consequence of matching the followers' implicit assumptions of what a leader should be like. Traditionally, leaders have been older than their followers. Comparable to a teacher-student relationship, leaders are expected to be more experienced, knowledgeable, and powerful which legitimizes them to be in

the position to teach and direct their followers. In line with the earlier mentioned implicit leadership theories, people expect leaders to be older than their followers and hence older leaders in comparison to younger leaders are more likely to be accepted as leaders or to be perceived as adequate leaders. At the same time, due to demographic changes in recent years, it has become more common that older individuals report to younger leaders. Several theoretical frameworks can be utilized to explain why older leaders might be more easily associated with a leader role and what the consequences might be for younger leaders leading older followers. Theories of status congruence suggest that agreement between different aspects of status, such as age, experience, and hierarchical position, is important for social functioning (Vecchio 1993). When a leader is younger and less experienced than his or her followers, this represents an example of status incongruence, as the leader is higher on some dimensions (hierarchical position), but not on other dimensions (age, experience). Both leaders and followers might react negatively to status incongruence, for example, by being less supportive or less loyal. Consequently, status incongruence will be related to lower leadership effectiveness perceptions. Related to status incongruence assumptions, theory on age grading and implicit career timetables similarly suggests that younger leaders violate social norms, yet provide a slightly different explanation for this effect (Lawrence 1984). Implicit career timetables describe the age distribution of organizational members in relation to their organizational positions. Such career timetables thus prescribe age norms in terms of the position one is supposed to have acquired at a certain age in one's career. Reporting to a younger leader is a quite clear signal to an older follower that he or she is out of sync with the organization's implicit career timetables. Such a perception of "being behind schedule" will evoke negative reactions by older followers and lower effectiveness perceptions of their respective younger leaders (Lawrence 1984).

In contrast, some scholars have argued that the direction of age differences between leaders and followers, that is, whether the leader

or the follower is older, is not important but only the magnitude of age differences has an effect on leadership effectiveness (Vecchio 1993). A first approach arguing for such nondirectional effects of age differences draws from the similarity-attraction paradigm that argues that similarity – for example, in age but also in other attributes – increases attraction between individuals. Hence, positive work attitudes as well as positive experiences are supposed to occur more frequently within leader-follower dyads when leaders and followers are of similar age than when one of them is much older or younger. In contrast, a second nondirectional approach that argues for the exact opposite effect (i.e., that age similarity has negative effects on leadership effectiveness) builds on social comparison processes. The idea behind this approach is that individuals of a similar age are in a social competition situation. A social comparison of a follower with his or her leader who is of the same age but obviously not in the same hierarchical position will be less favorable and more likely to lead to lower effectiveness perceptions than the social comparison of a follower with a leader who is dissimilar in both age and hierarchical position.

To date, unfortunately, only little empirical work on age differences between leaders and followers exists that helps to disentangle the competing predictions of the summarized theoretical approaches. The few exceptions that do exist paint an inconsistent picture of the empirical situation: While some studies showed negative effects of young-leads-old configurations, other studies found (unexpected) positive effects of these configurations. The empirical evidence for the similarity-attraction hypothesis is rather weak, although some studies found negative effects of age dissimilarity. Across studies, the effects of leader-follower age differences were rather small. In line with the contradictory theoretical assumptions, it can be expected that the overall effect of age differences on leadership effectiveness is complex and it is likely that several different effects operate at the same time. Clearly, much more empirical work is needed to be able to draw reliable conclusions on the consequences of age differences between leaders and followers in

general and of younger leaders leading older followers specifically.

Conclusion and Future Directions

Leadership is a central concept in organizational research as well as in organizational practice. Unfortunately, to date research on the impact of the demographic change on leadership and leadership effectiveness is still scarce. Nevertheless, one important conclusion might be drawn in these early stages of research on leadership and aging: the question of how aging of both leaders and followers is related to leadership and leadership effectiveness will unlikely find easy and simple answers. Human development over the lifespan is complex and related to positive and negative changes in affective, motivational, and cognitive processes. On the other hand, leadership is far from being a simple or one-dimensional process, including many different competencies and behaviors. Taken together, a complex interaction of many different variables emerges that affects how leaders of varying ages lead followers of varying ages. Thus, future research needs to address this complexity by designing studies that are sensitive to pick up subtle influences of possibly contradictory effects. For example, future studies might address how qualitative changes in the motivation to lead influence the utilization of leadership behaviors. Thus, a young leader who is driven by the motivation to advance his or her own career might engage more in task-oriented leadership behaviors than an older leader who is motivated by generativity concerns and thus utilizes relationship-oriented leadership behaviors. Nevertheless, both leaders can be equally effective. Only focusing on the relationship between age and task-oriented or relationship-oriented leadership will overlook such important functions of motivation.

Moreover, as easy and straightforward direct effects of aging are unlikely, future research needs to focus on boundary conditions of aging effects. As discussed before, research might explore under which conditions – for example, followers' motivational or affective states – specific leadership styles of older leaders are more likely to be related

to leadership effectiveness. Specifically, based on implicit leadership theories, research might focus on which leadership styles or behaviors are perceived by followers as being age appropriate. In terms of leading an aging workforce, implicit leadership theories might play a role as older and younger followers might have different assumptions about how leadership should look like. In the sense of an age-differentiated leadership approach, leaders might not only need to be sensitive towards the specific needs of older and young followers but also towards the followers' differential expectations of themselves, especially when younger leaders violate age norms.

Despite the scarce empirical literature on the relationship leadership and aging, the first steps towards a clearer picture of this relationship are promising. Fortunately, researchers in this area are able to build on rich theoretical foundations in both leadership and aging literatures. Thus, future research that utilizes these theoretical foundations will most likely be able to disentangle the complex interrelations of leadership and aging.

Learning in Older Adults

Philippe Rast

Synonyms

Behavioral modification; Skill Acquisition; Conditioning; Instrumental Learning

Definition

Learning is used in different contexts and a uniquely accepted definition does not exist. Here, learning is broadly defined as a process in response to repeated exposure to environmental demands that results in the accumulation of skills, knowledge, or responses and attains enduring and long-lasting behavioral or cognitive changes.

Learning

Learning represents a fundamental aspect, not only in humans but in all organisms, that lasts a lifetime. Across the life span, changes occur to the ability and rate of learning, but, as in other areas of human development, these changes are not happening uniformly across all forms of learning. Generally speaking, learning rates are smaller in older adults compared to younger, but the extent of these differences is not uniform across all forms of learning, but different domains are affected at different times and changes occur at different rates (Kausler 1994). In the context of aging, learning needs to be related to development. In contrast to development, learning concerns the “microgenesis,” while development relates to “ontogenesis,” and as such both processes describe distinct phenomena (Voelcker-Rehage 2008). However, learning and development are interdependent in the sense that developmental status also guides the learning process and, in

turn, learning outcomes are incorporated into developmental changes. Most importantly, learning remains a resource throughout all stages of life.

Given the definition of learning, it is evident that learning comprises relatively basic forms, such as conditioning, as well as more demanding forms such as verbal or spatial abilities. More complex forms of learning are very strongly tied to other cognitive and possibly age-sensitive resources such as memory functioning and working memory. As such, a clear distinction of age effects among these different systems is difficult to obtain. However, with increasing age, individual differences in the ability to learn and in changes in learning are probably the most prominent feature which offers the possibility to untangle to some degree effects of aging and maturation from other individual effects such as socioeconomic status, education, verbal or motor skill levels, or other individual cognitive resources.

In the remainder of this entry, learning will be subdivided in five areas that are sorted according to increasing demands in terms of complexity as well as cognitive and computational effort: conditioning, instrumental learning, skill learning, and verbal learning.

Conditioning

Classical or Pavlovian conditioning is considered to be a simple kind of learning, not because it lacks complexity but because it contains clearly delineated single response elements in the form of stimulus and response (Kausler 1994). Two kinds of conditioning are typically distinguished: classical and operant conditioning.

Classical conditioning. Classical conditioning involves an unconditioned stimulus (UCS) that elicits a reflex as the unconditioned response (UCR). For example, the UCS might be a puff of air to the eye with the eyeblink reflex serving as the UCR. A third element is introduced to serve as the objective of conditioning, the conditioned stimulus (CS). The CS is initially unrelated to the UCR. Given sufficient trials where the CS precedes or overlaps the UCS, a new conditioned response (CR) will be acquired that resembles the original UCR. That is, the puff of air (UCS) to the

eye may be preceded by a tone (CS). After a number of trials, the eyeblink will occur before the onset of the puff of air, thus turning the UCR into a CR. Due to its simplicity, eyeblink conditioning is frequently used in research on aging and Alzheimer's disease in humans and rodents.

Although the bulk of work in classical conditioning has been conducted throughout the 1940s to the 1970s, it is still relevant in today's research on learning in older adults, and its implications are considerable in everyday settings. For example, the learning mechanism of classical conditioning is habitually used in clinical contexts such as in the treatment of anxiety disorders or substance abuse. In these contexts, the therapeutic approach is to pair or un-pair stimuli and responses following the logic of classical conditioning (e.g., aversive therapy and (de)sensitization). By and large, research on conditioning in older adults shows that older adults need more exposure to the CS–CR pair to be conditioned than younger adults, but the conditioning mechanism remains intact throughout the life span into old age and even remains present in people with severe amnesia (Woodruff-Pak 1993).

The acquisition of the CR usually follows a negatively accelerated learning curve with the strongest behavioral changes early on and diminishing adaptation in later trials. In a number of classical conditioning settings using eyeblink conditioning, older adults showed weaker responses and usually needed more trials to successfully link the CS to the UCR. The slower rate of classical conditioning has also been found in other responses ranging from involuntary changes in galvanic skin response to voluntary reflexive retraction of the hand due to electric shocks (Botwinick 1970). Parts of these age differences are also due to other factors than conditioning. A factor that influences the rate of conditioning is the latency of the interstimulus interval (ISI) among the CS and UCS. Generally, small ISIs increase age differences, while larger ISIs decrease age differences in acquisition rates, although the difference among young and old remains pronounced overall.

Most studies based on conditioned eyeblink responses found the age of about 50 years to be

critical with respect to decreasing acquisition rate (Kausler 1994). Note, however, that these findings were mostly based on cross-sectional data which tend to bias critical change points toward early decline because birth cohort differences cannot be fully separated from aging effects.

Operant conditioning. Operant conditioning differs from classical conditioning in several ways. The response is not a reflex but is more deliberate and procedural in nature, and the CS is not presented before but after the response. Also, the response itself may be modified, typically through the use of positive or negative reinforcement. A certain positive behavior might be reinforced by rewarding the subject. Research on operant conditioning has a long history in psychology and is rooted in Thorndike's *law of effect* (Thorndike 1898) that posits that behaviors that are followed by positive experiences tend to be repeated, while behaviors that are followed by negative experiences tend to be avoided (Skinner 1938). Research on operant conditioning on older adults largely focused on populations with mental or health conditions. Generally, most studies find that the use of reinforcement does alter the behavior in patients with dementia or psychoses. While most of these studies used positive reinforcement techniques, more recent results show that the valence of reinforcement also depends on the level of dopamine in the basal ganglia. An intact dopaminergic system supports positive feedback, while lower levels of dopamine seem to favor learning experiences that avoid negative outcomes. In fact, the reward system is tightly related to operant conditioning as it mediates the effects of reinforcement.

In the context of normal aging, positive reinforcement has been mainly used in studies to enhance responses in speeded tasks. Positive reinforcement may be in the form of offering money for faster responses, while punishment may be operationalized as taking away of money. Older adults tend to be very responsive to this form of reinforcement in laboratory settings. Especially for cognitive tasks, such as paired-associate learning, positive and negative reinforcements effectively increase older adults' performance, while younger adults' performance is generally

influenced less from this type of incentives and punishments.

Instrumental Learning

Instrumental learning, or instrumental conditioning, entails behavior that was instrumental in the past for producing certain consequences and reaching a goal. Instrumental learning plays a central role in Thorndike's *law of effect* (e.g., Thorndike 1898), but its distinction to operant conditioning remains somewhat arbitrary. Generally, most work that involved instrumental learning tasks in aging made use of animal subjects, and work with humans typically focused on young college-aged populations. Findings from rodent populations suggest that older animals tend to be slower maze learners. The effect of age on the learning performance is largely guided by the complexity of the maze, where older animals display more pronounced difficulties if complexity is high. While most work on maze learning was done on rodents, it has been shown that middle-aged adults erred more often than their younger counterparts on paper and pencil maze tests (Brooks and Baddeley 1976).

Similar age-related effects are found in spatial learning which is in some ways similar to learning a complex maze but additionally entails the acquisition of spatial features and their relation to each other in novel environments. Across different learning conditions, such as the ability to successfully navigate in a nursing home and knowledge of buildings, shopping malls, or neighborhoods after exploratory trips or virtually touring these environments, older adults' accuracy is typically impaired compared to young adult populations. Moreover, while information on landmarks seems to be less age sensitive, it is the acquisition of routes that results in large performance differences among young and old adults. Generally, however, the acquisition and maintenance of spatial information seem to be a highly age-sensitive process.

While current research clearly shows that instrumental learning is age sensitive, the vast majority of studies in this area exclusively relied on cross-sectional samples that compared older and younger adults, thus confounding age and

cohort effects. For example, parts of age differences reported in instrumental learning may be also due to cohort differences resulting from different degrees of familiarity with the environment, such as the ability to navigate in a modern shopping mall.

Skill Learning

Skill learning can be broadly distinguished depending on the task examined, for example, motor, perceptual, or cognitive tasks. Generally, skill learning involves a shift from a rule-based, computationally more or less demanding response to a memory-based, effortless automatic response. Hence, skills are thought to consist largely of collections of automatic processes and procedures (Logan 1988). Findings with respect to age-related performance decrements are mixed: Motor skill learning, when measured with a pursuit rotor task, and perceptual skill learning, when assessed with a serial reaction-time learning task, have been reported to be either spared or impaired in older adults compared to younger ones. Regarding motor and perceptual tasks, there are a number of studies that have compared skill learning in young and old adults.

Motor skills. Recently, Voelcker-Rehage (2008) reviewed a number of motor skill learning studies showing that motor performance is highly age sensitive and tends to decline into old age. At the same time, older adults clearly benefit from learning exposures and are able to substantially increase their performance throughout most of the conditions. As with other forms of learning, age-related differences in motor skill learning are sensitive to the complexity of the task. That is, with increasing complexity age differences are exacerbated, whereas low complexity tasks result in very similar performance among young and old adults. Studies that compared fine motor skills in young and old adults mostly report faster rates of skill acquisition in younger. With respect to accuracy, results seem to be mixed with some studies reporting no differences among young and old adults and others reporting reduced accuracy in older adults. Findings from studies investigating gross motor skills largely corroborate findings from fine motor skills with lower performance

levels in older adults and faster skill acquisition in younger adults. Nonetheless, older adults are able to considerably improve their performance. Overall, the nature of the task in terms of familiarity, complexity, difficulty, and structure largely influences the size of age differences. Another common finding, with few exceptions, is that younger adults benefit more from learning in terms of final performance. That is, young adults not only increase their performance more rapidly, but their responses are generally more accurate, and they achieve higher levels of motor skills compared to older adults who learn at slower rates and remain at lower levels overall. In terms of onset of decline in fine motor skill learning, cross-sectional studies suggest that decline is apparent in young adults in their late 20s. For coarse motor skills, some cross-sectional studies report a shift in peak performance gains following practice from young adults to 30–39-year-olds.

As with studies on conditioning, almost all findings are from cross-sectional studies, and results from long-term longitudinal studies on motor skill learning are not available yet. As such, it must be acknowledged that cohort effects are confounded with age differences in the sense that effect sizes may be inflated to some degree, exacerbating the effect of age on skill learning performance. Also, the extent of individual differences in the motor performance is increasingly pronounced in old age which makes statements of average decline less representative for older populations.

Cognitive skills. Regarding age differences in cognitive skill learning, it seems that older adults are able to maintain their performance when given enough time to work on the tasks. For example, Charness and Campbell (1988) reported spared cognitive skill performance in older adults using a task where participants were required to square two-digit numbers mentally via an instructed algorithm. Older adults learned at the same rate as younger, but their calculation speed was about half that of the younger adults. In addition to response times, Touron et al. (2004) asked young and old participants to report the strategies used for obtaining solutions in a novel arithmetic problem. Older participants reported shifting from

computing the solution to memory-based retrieval later in the learning process than younger. As a result, older adults tended to solve cognitive skill learning tasks slower than younger adults, but they also tended to show an age-related delay in strategy shift.

Some authors distinguished cognitive skill learning situations from those in which the transition from effortful, slow, and generally poor task performance to relatively effortless, fast, and accurate performance fails to occur. Results from that branch of learning research show that two general types of processes appear to underlie a wide range of tasks in the experimental literature, namely, *controlled* and *automatic* types of information processing.

Controlled processes are used when the task requirements are novel or when no consistent rule to solve a task is present. Controlled processing is characterized as slow and effortful, and it limits the availability of the cognitive system which allows mostly serial processing. Given this definition, a number of studies on skill learning using a range of different experimental manipulations found that general intelligence and working memory (WM) are the crucial processes required for controlled, effortful performance (Ackerman 1992). As such, the relation between general cognitive abilities such as WM with skill learning decreases as a function of practice as one transitions from controlled, effortful computation of the response to automatic processing (cf. Logan 1988). Hence, working memory is seen to be an important resource of controlled and effortful cognitive processing that plays a crucial role in the early phase of skill acquisition because relevant information needs to be maintained in order to correctly compute the response before automation is achieved (Rogers et al. 2000).

Automatic processes, by contrast, are characterized as fast, effortless, and unitized, such that they may not be easily altered by a subject's conscious control. The use of automatic processing is implied in the operations of various types of skilled behavior, such as encoding words during reading. These processes may only be developed through extensive practice under consistent conditions. Research has highlighted the

importance of consistency in skill learning, which refers to invariant rules for information processing, invariant components of processing, or invariant sequences of information processing components that may be used to attain successful task performance. As an empirical criterion, memory-based responding can be taken as definition of fluency or mastery of a cognitive skill. Accordingly, it has been shown that prior to mastering a cognitive skill, processing takes longer, and, hence, response times are slower. After successful learning, response times are shorter, implying that retrieved solutions are faster than computed solutions (Logan 1988).

Response-time measures have been used in studies examining the effect of age on skill acquisition and have shown substantial learning deficits in older adults. To illustrate, Jenkins and Hoyer (2000) compared young and old adults' performance using a dot-counting task. At the completion of 10 learning sessions, 7 out of 17 older participants failed to reach the automaticity criterion which was defined by zero slopes in the response times. In the young group, only 1 out of 17 missed the criterion. A similar finding was reported by Rogers and Gilbert (1997) in a noun–noun table lookup task. Participants were asked to judge whether a pair of nouns present at the bottom of a computer screen matched a pair from a table, presented at the top of the screen. After 60 blocks of training, only 3 out of 16 older adults retrieved the solution from memory, compared to 11 out of 14 younger. Hence, given enough time to work on the tasks, older adults' performance is comparable to that of younger adults (Charness and Campbell 1988), but given the same time or practice trials as young, older adults show substantial learning deficits.

Verbal Learning

Verbal learning has traditionally been assessed with paired-associate tasks structured in stimulus–response elements and serial learning tasks. A common approach is to present lists of single words, paired associates, or short stories in several learning trials or in self-paced learning until a certain level of mastery is achieved. Subsequent recall tests then reveal the amount of

successfully memorized verbal material. These tests are typically examined in terms of correctly recalled items, omissions, repetitions, or intrusions. The paired-associate task was the most commonly applied test procedure in the earlier investigations on verbal learning and was strongly tied to the stimulus–response framework which went out of fashion in the early 1970s and was replaced by the concepts and vocabulary of information processing. With this replacement, also the term “learning” lost much of the popularity it had in conjunction with verbal memory phenomena, while, at the same time, “memory” became the more often used notion. Paired associates and similar types of tasks have been frequently used in memory research, and many findings reported in the learning literature are equally representative of memory research in general. As such, the line among results from memory or learning research remains somewhat blurred. Both learning and memory necessarily entail acquisition, storage, and retrieval of (verbal) material, and a clear distinction among these areas of research remains difficult and arbitrary to some degree. One pragmatic way to distinguish memory research from learning research is in the form of the presentation of the material and the design of the study. Typically, memory tasks entail only once-presented material and one single recall trial, whereas examining verbal learning usually requires multiple presentations of material and several or multitrial recall cycles (Zimprich et al. 2008). Taking up such a working distinction between verbal learning and memory, one has to acknowledge that most of the research on verbal memory phenomena is conducted using single recall trials, that is, it represents memory research (Kausler 1994). This is especially true for the investigation and comparison of learning and memory performance in different age groups.

The first comparison of older and younger adults, almost 100 years ago (Ruch 1934), in a paired-associate task yielded a result that has been confirmed ever since: Learning performance in paired-associate tasks produces pronounced age differences in average correct responses and younger adults accumulating and recollecting more items than older adults. However, as with

nonverbal material, verbal learning in older adults remains functional into old age, and older adults are in general able to benefit from learning. At the same time, verbal learning is highly age sensitive with younger adults outperforming older adults in most aspects. A number of studies highlighted the impact of increasing difficulty of the verbal learning tasks in terms of higher rates of interference and lower learning rates in older adults.

Work on serial learning, introduced as early as 1885 by Hermann Ebbinghaus (1885), entails the memorization of a series of verbal items. These items are typically either nonsense words or real words from the own or a foreign language with different properties to guide item difficulty such as word frequency and number of syllables. In the first application, a word list was memorized and reproduced in the correct order to produce a learning curve characterized by a steep increase in word accumulation early on and diminishing returns from additional learning trials later in the study. In recent applications, serial learning has been described using nonlinear statistical models that are able to capture the curvature and the asymptotic nature of this task resulting in three psychologically relevant parameters. The initial performance after the first learning and recall trial, the learning rate that describes the speed of accumulation, and the maximal or asymptotic performance which is a point when additional learning trials no longer increase learning performance.

Work on serial learning uncovered the effect of the serial position of an item in the list. Beginning items and those at the end of the list are recalled with few errors, while error rates peak in the midfield of a serial learning task. This serial-position effect has been reported for both young and old participants with older adults generally producing more errors overall. An important modifying aspect in the comparison of recall performance among young and old adults is the speed at which words in the list are presented. Not surprisingly, the correct recall performance of older adults dramatically decreases as items are exposed with shorter rates. In turn, older adults strongly benefit from longer exposure times. Anecdotically, in a classic study on serial learning that

used a vocabulary test, older adults produced on average 40 errors when items were presented at 10 s each, but when presentation time was reduced to 4 s, the average error rate increased to 80 (Eisdorfer and Service 1967). Next to exposure times, verbal knowledge seems to have an important mediating effect on error rates, learning rate, and initial test performance. Older adults with higher verbal ability tend to be less affected by exposure time and have faster learning rates and better initial performance (Eisdorfer and Service 1967; Rast 2011).

Individual differences in verbal learning. Classically, the interest was on comparing average learning performance among young and old. In recent years, however, the interest has shifted to investigating and explaining individual differences in verbal learning. As with other forms of learning, verbal learning is maintained into old age but is also largely intertwined with other higher-order and age-sensitive cognitive functions. As a result, performance differences among individuals in acquisition rates and in recall performance are substantial, and the amount of individual differences typically increases with advancing age. That is, as people age, the average verbal learning performance becomes less descriptive because the amount of individual differences increases strongly into adulthood.

Recent work has shown that reliable individual differences can be found in the initial performance, the learning rate, and the maximal performance (e.g., Zimprich et al. 2008; Rast 2011). Advances in statistical modeling also led to more advanced models of learning, and recent studies on verbal learning have utilized nonlinear models to capture different aspects of learning, such as the initial performance, the maximal performance, and the learning rate. A common finding is that the maximal performance and the learning rate are negatively correlated, showing that those with a higher maximal performance tend to have slower rates of learning; that is, they need more trials to achieve their maximum performance. Further, verbal learning seems to be a restricted process. Higher learning rates come at the expense of the maximal performance in the sense that those who learn faster, reach their maximum earlier

compared to those who started slower but end at a higher maximum performance. These findings have been reported for verbal and nonverbal material.

In order to explain individual differences in learning, a number of explanatory variables have been discussed and investigated in the context of verbal and nonverbal learning. The most common are chronological age, processing speed, educational level, verbal knowledge, and working memory. Probably the most prominent variable in explaining individual differences in learning is age. Age-related effects are most pronounced in the initial performance of learning. Young and old participants start at different levels, with older adults having smaller initial performance. As learning unfolds and individual differences play into the learning gains, chronological age loses predictive validity and typically explains smaller amounts of variance in maximal learning performance. This implies that other person-specific variables gain importance in explaining learning performance differences among individuals. Accordingly, a number of studies using linear and nonlinear models of verbal learning showed that learning rate is only weakly related to age in midlife and old age. Instead, processing speed, educational level, verbal knowledge, and working memory have been consistently related to performance differences in verbal learning. Higher levels of working memory and education as well as faster processing speed positively affect the initial and asymptotic learning performance, while verbal knowledge has been linked to faster acquisition rates. The finding that better educated people perform better in learning is well known in the literature on cognition and memory and expands into nonverbal material. In positional learning, for example, education has been shown to influence learning capacity parameters positively such as initial and asymptotic performance, but not the more dynamic learning rate parameter. It is now generally acknowledged that learning is differentially affected by a number of variables and that the age of the respondent mainly influences the initial performance but less the learning rate and the maximal learning performance.

These newer findings also underscore the view on the existence, or absence, of a general learning factor, comparable to a general intelligence factor. During the early twentieth century, human cognitive abilities and learning were commonly assumed to be closely related. In fact, some authors even considered learning to lie at the core of intelligence in the sense that, for example, “intelligence means the capacity for learning” (Ellis 1929, p. 62). Contrary to this assumption, studies in the 1930s and 1940s indicated only small correlations between individual differences in intelligence and “gain” scores on diverse learning tasks. In addition, learning scores from different tasks also appeared to be only weakly related to each other. These findings, which have been replicated ever since, called the notion of a single, general learning ability underlying intelligence into question. Rather, comparable to the positive manifold among intellectual abilities, such findings point to the existence of specific learning abilities. More recent findings corroborate the view that a general learning factor does not exist. Rather, learning seems to be very domain and material specific. Similarly, changes across domains are only weakly related indicating that learning abilities are differentially affected by the passage of time and the aging process in individuals.

Leisure Activities in Later Life

Douglas A. Kleiber
University of Georgia College of Education,
Athens, GA, USA

Synonyms

Enjoyable engagement; Valued activities; Voluntary activities

Definition

Leisure: a context of discretionary time with the opportunity for preferred activity. Leisure activities: those that occur in the context of leisure.

Introduction

Leisure activity in later life has been addressed most thoroughly in the relatively new field of leisure studies (e.g., McGuire et al. 2013), but there is a long history of interest in the subject in sociology and gerontology. A number of theories about aging were shaped to some extent around leisure in the 1950s and 1960s, notably arguing that (1) one should stay active and busy after years of work and family production (*activity theory*), (2) the abandoning of activities is natural with age and perhaps in the mutual best interest of self and society (*disengagement theory*), and (3) older people are most inclined to continue preferred and valued activities, albeit at a reduced level (*continuity theory*), as a way of maintaining personal identity and perpetuating nonwork role identities. The first two were seen as oppositional until the disengagement theory was largely discredited as being both a justification of neglect of older people and inconsistent with what older people were actually doing with respect to activity and aging. Robert Atchley (1989) offered continuity theory somewhat later to characterize what people actually *did* in later life and not prescribe

what they *should* do to age well as the other two theories had done.

Much of the difficulty with the research on leisure activity in later life is that leisure is an ambiguous construct. Thus, gerontologists have preferred to use “valued activities” or “voluntary activities” in their research and writing to characterize “leisure.” From its earliest Western traditions, some still hold to leisure as being rooted in the Aristotelian/Platonic ideal of “*scholē*” (the root word for school as well) as a context wherein freedom from obligation was dedicated to the refinement of character and the development of civility (cf. de Grazia 1964). Some would even question the pairing of leisure and activity; for them it is redundant to add activity since their understanding of leisure equals activities such as play, games, sports, recreation, entertainment, hobbies, crafts, etc., i.e., those activities culturally recognized as leisure. For others, however, leisure is equated with free time and indeed may be used – and used well – for bringing peace, relaxation, and contemplation without *doing* much at all. Historian, philosopher, and theologian Josef Pieper (1963) regarded leisure as

...an attitude of non-activity, of inward calm, of silence; it means not being ‘busy’ but letting things happen. . . . Leisure is not the attitude of those who intervene, but of those who are open to everything . . . of those who leave the reins loose and who are free and easy themselves.

The best reflection of its contemporary use, however, is to see leisure as free time with the expectation of preferred experience, whether that be through engagement or disengagement, excitement or relaxation, stimulation or contemplation, or even work-like involvement such as volunteering or gardening (as a way to enjoy the weather while getting exercise and producing flowers or vegetables after all), as long as the action taken is freely chosen and intrinsically enjoyable (Kleiber 1999).

Leisure Activity Patterns in Later Life

Research in the interdisciplinary field of leisure studies generally reaches the same conclusion as

the gerontology literature: continuity of involvement best describes older people's inclinations toward an activity, even though there is often a decline in number of activities and intensity of activity involvement overall (for a review see Nimrod and Janke 2011). One of the most comprehensive earlier studies of leisure and aging was J.R Kelly's (1987) investigation of a large sample of older people in Middle America. Among the important findings of *Peoria Winter*, beside the preference for continuity and the inevitability of decline in especially physical activities, was the distinction between activities that were part of one's daily routine – such as conversation over meals and watching television together – thus serving as “core” activities for couples and families and other more individualized “balance” activities that expanded one's repertoire and offered a greater prospect for self-actualization.

The strongest cross-sectional evidence for changing activity patterns in aging and later life suggests a progressive decline in both number and intensity over the course of later adulthood (e.g., Robinson and Godbey 1997; Strain et al. 2002). This is especially true of physical activities and those undertaken outside the home, such as travel and attending movies and musical events. Other activities, such as hobbies and crafts and volunteerism, are more consistent with a pattern of continuity (e.g., Iso-Ahola et al. 1994; Strain et al. 2002; see also Nimrod and Janke 2011), while still others increase in frequency (e.g., cooking for men, television watching, and visiting with friends). Initiating new activities is relatively less common but still occurs (e.g., Nimrod 2008). A tendency to embrace new possibilities is particularly evident after losing a spouse, as one's options change dramatically, though some studies (e.g., Jaumot-Pascual et al. 2016; Lopata 1993) show this to be true of widows, but not widowers. This gender difference is also apparent among non-widows; women appear to be more likely to embrace changes in later-life leisure activities than do men in general (Iso-Ahola et al. 1994; Jaumot-Pascual et al. 2016). This is evident, for example, in the growth of the international “Red Hat Society,” where widows and other older

women conspire to be “outrageous” (Cooper 2004).

The tendency to introduce new activities has been studied more often using retrospective than prospective designs. Searle et al. (1993) found that among a sizeable sample of people over the age of 65, 16% were “adders” (who introduced new activities while not dropping any the previous year), 20% were “replacers” (adding at least one while quitting another activity in the previous year), 25% were “quitters” (who eliminated at least one activity from their repertoires while not adding any), and 40% were “continuers” (who neither added nor quit any activities in the last year). In a slightly more refined analysis, Nimrod et al. (2009) used the *Americans' Changing Lives* data set and a comparable one from Israel and found that a reduction in both the number and frequency of activities was the most commonly observed pattern in both populations, at 51% and 41%, respectively. This was followed by “expanders” who increased both the number and frequency of activities at 21% and 35%, respectively, and then by “concentrators” who reduced the number of activities but increased the frequency and intensity of some, at 16 and 11%, respectively. A final group, comprising 12 and 11% of the samples, respectively, showed a “diffuser” pattern, increasing the number of activities but with reduced frequency. While the two populations had a similar profile overall, Israeli retirees were somewhat more likely to start new activities and engage in them more often relative to the American sample who showed a slighter greater tendency to reduce both time and frequency of activities. The activities most likely to be increased were religious activities, walking, gardening, and talking and visiting with friends.

Longitudinal research on leisure and aging published in gerontology journals has also addressed central questions about how specific leisure activity patterns change in later life as a function of the theories highlighted earlier. Supporting continuity theory, Strain et al. (2002) found that in a group of 380 Canadians aged over 65, few changed their top leisure activities – television watching (99%) and reading (98%) – over an 8-year period. In contrast, their

walking, traveling, attendance at movies and plays, playing cards, and working in the yard decreased by as much as a third, providing some support for a pattern of disengagement. In their review of the literature, Strain et al. noted that engagement with television and radio was the most commonly reported leisure activity in later life, while engagement in sports and exercise, despite being strongly encouraged, was among the least likely to be found in older people.

Much of the research on leisure activity in later life focuses on the factors that undermine or prevent it. Declines in physical capacity and health, loss of companionship, and reduced financial resources are the most commonly reported reasons for changes in activity (e.g., McGuire et al. 2013). Among the constraints that limit participation in leisure activities in later life, ageist stigma may be the most impactful (Dionigi and Horton 2011). Resulting isolation and exclusion contributes to marginalization and a type of oppression of expression. There is also an impact of self-stereotyping and self-handicapping that occurs among older people in youth-oriented societies. Fortunately, though, there is also evidence that many people are *less* influenced by social norms and expectations as they age, helping to challenge these social conventions. Along these lines, as with Red Hat Society members referred to earlier, leisure may serve as a context of resistance, as when older people defy stereotypes and engage in high intensity and physically competitive activities and sports (Dionigi and Horton 2012).

The Impact of Leisure Activities on Well-being in Later Life

Despite being more descriptive than prescriptive, the idea of continuity is consistent with the “use it or lose it” prescription for the well-being in later life, advocated in activity theory. More recently, prominent perspectives on adaptation in later life have recognized choice of, and persistence with, *valued* activities to support both development and adjustment to aging. The selective optimization with compensation (SOC) theory (Baltes and

Baltes 1990) and the socioemotional selectivity theory (SST; Carstensen et al. 2003) recognize that voluntary activities are a valued source of meaning in later life and are only optimized in their action if they are carefully selected, vigorously engaged in, and supported in various ways through adjustments that compensate for losses in capacity. SOC processes are now commonly invoked (Burnett-Wolle and Godbey 2007; Kleiber et al. 2008) to explain the process of adapting to leisure constraints through the substitution of more manageable activities, finding ways to continue (with some modifications), or actually dropping activities that are no longer satisfying or meaningful.

Whether they are done alone or with other people, such activities usually reflect a prioritizing of positive emotion over future gain and a willingness to prune activities and relationships that are no longer satisfying, which is somewhat reminiscent of the earlier disengagement theory. Indeed, disengagement theory has been reconsidered specifically in terms of the voluntary and selective abandonment of activities (Achenbaum and Bengtson 1994) rather than seeing it as simply a response to loss or being socially dispossessed. Nor is it a new idea to recognize that the “busyness” created by the demand to look and stay busy after retirement can and does reach maladaptive and even neurotic proportions (cf. Eckerd 1986).

The *selection* component of the SOC model is not only about loss-based disengagement due to abandonment of activities but also includes “elective selection” of *new* activities, making the case that self-expansion and growth more generally are still possible in later life. Indeed, “old dogs *can* be taught new tricks” (or they can teach themselves). The commonality with which older people do so has given rise to an innovation theory of aging (Nimrod 2008; Nimrod and Kleiber 2007). This may be more common among the young old (60–75) than the older old, but there is still ample evidence for interest in, and appreciation of, novelty in later-life engagements. Superficially, this seems more consistent with activity theory than continuity theory, but as Atchley (1989) pointed out, continuity is inclusive of

internal and external processes such that one's sense of identification with the activity can be preserved even if co-participants, venues, and forms of the activity may change. Nimrod and Kleiber (2007) reflected this distinction in identifying patterns in their participants of both *self-preservation innovation*, where activities have some earlier variation, and *self-reinvention innovation*, where they are entirely new.

Other models of successful aging also invoke the quality of engagement in activity as a critical component. The otherwise well-regarded MacArthur study of successful aging by Rowe and Kahn (1998) is commonly criticized for defining "success" as being free from illness and functional impairments, despite evidence of people aging well in the face of disability as evidenced in their engagement in enjoyable activities. Rowe and Kahn do refer to engagement as one of the critical components of successful aging, but they characterize such engagement as necessarily *productive*, as in the case of volunteer work. Indeed, such models of productive aging would generally see little value in leisure activities, with the exception of volunteer work and perhaps gardening, wood working, or other activities where products might be marketed.

Nevertheless, there is ample evidence from the leisure studies and the gerontological literature more generally that activities that are psychologically engaging and meaningful, simply by virtue of being shared with others, contribute substantially to life satisfaction and psychological well-being in later life (see Adams et al. 2011, for a review). The link between physically active leisure and subjective well-being (SWB) is especially strong. For example, McAuley et al. (2000) found evidence of subjective well-being benefits for both physical and social activities, while others show that any activity that is particularly "meaningful" enhances SWB (Cuenca et al. 2014). Mannell and Dupuis (1994) even suggested from their review of the literature that leisure activity levels are better predictors of life satisfaction in later life than health and income.

Dupuis and Smale (1995) found an inverse relationship between leisure activity and

depression in later life, but such findings raise questions about causality and the degree to which this is affected by illness. In their modeling of potential influences of activity and depression in widows over time, Janke et al. (2008a) found a better fit for increases in depression leading to decreases in leisure activity rather than the reverse. However, the fact that Dupuis and Smale (1995) found that breadth rather than depth of involvement was associated with lower depression does suggest that having a repertoire of possibilities may be a hedge against the impacts of loss in later life, including the loss of activities, as per other studies of coping. In fact, there is relatively little longitudinal research that relates leisure activity to improvements in well-being, but Menec (2003) found such indications. Moreover, in a longitudinal life span study of Harvard graduates, Vaillant (2002) found that joyful activities, especially creative activities and involvement with games and sport, were instrumental in aging well for those who were followed over time.

Variations in Leisure Activity and Experience in Later Life

Three of the more common activities of older people warrant a closer analysis when it comes to changes in leisure activity with age and historical change as well as to their impacts on well-being in later life.

Media Use

Television watching is clearly the most ubiquitous leisure activity of older adults (e.g., Lucas et al. 2011; Robinson and Godbey 1997), if not the most beneficial (e.g., van der Goot et al. 2012). While it is hardly unique to later life, it is proportionally more common than other activities relative to other developmental periods, even childhood. Television watching may be adaptive, though, to the extent it compensates for a lack of social contact (older people sometimes think of television characters as the "family" that they no longer have around them) or engages individuals cognitively in some respects. Yet research on television generally shows that it engages people in

minimal ways, often being used as background “company,” while other activities of daily living are undertaken or simply as a sleep aid for naps and retiring in the evening.

Among the more significant changes in the media activity of older people is the extent to which they use internet technology. While there still remains a “digital divide” of sorts between the young and the old, the use of the internet has become commonplace in the lives of many in later life (e.g., Smith 2014). As with other age groups, it is used for instrumental purposes to get or exchange information, but it is also used more leisurely as a news source and as a forum for social participation (Nimrod 2011). Seniors’ online communities in particular are available both for support and problem solving on issues such as coping with the loss of a spouse, but also for a variety of leisure activities including communicating with family (often grandchildren) and friends as well as with other “virtual” companions with whom they may not be personally acquainted but who share common leisure interests (see Nimrod 2010, 2011, 2016). Internet use is just one among many forms of communication (e.g., telephone, radio, television, newspapers) and has not replaced these more traditional sources for seniors (Nimrod 2016). Rather it has expanded the time, especially “screen time,” devoted to communication and entertainment. As far as the quality and impact of the experience, it is important to note that internet use is considerably more active and interactive than television use and also seems to be associated with higher levels of subjective well-being and social integration (e.g., Erickson and Johnson 2011). At the same time, if it is in addition to and not replacing television use, it may be preempting activities, such as exercise, that provide other benefits. While a concern, such speculation requires further research.

Travel

Leisure travel for working people often accompanies job-related travel, extending the time in attractive locales before the work or after it is done. Considerably more freedom for travel comes about after retirement, especially when

other needs (financial, health, family related, or otherwise) have been adequately addressed in hours normally devoted to work. Due to the increase in numbers of people retiring in many countries, the tourism industry is well attuned to this potential market (e.g., Patterson and Pegg 2011). Adventure travel, for example, has increased due to its popularity among newer cohorts of retirees. Although it is an under-researched area, the benefits of travel to quality of life may relate to a need for stimulation, change (innovation), and exposure (Patterson and Pegg 2011). For many, travel is as much about education as entertainment and luxury. Elderhostel (known now as *Road Scholar*) programs grew from 220 participants in 1975 to over 4 million by 2008 (Patterson and Pegg 2011). For others, work is combined with travel in doing volunteer work in other places. While it isn’t restricted to retirees, “voluntourism” has become a popular option for those who retire with the resources to travel and the commitment to help (Wearing 2001). The benefits of this kind of travel are perhaps better reflected in the research on volunteerism.

Volunteerism

Volunteerism clearly fits the definition of engagement to promote successful aging (e.g., Rowe and Kahn 1998), primarily because it is productive. It is not always characterized as leisure in the minds of those doing volunteer work, but it is generally freely chosen during discretionary time and offers intrinsic satisfaction, as well as being instrumental, and is commonly recognized in studies of discretionary time use (e.g., Robinson and Godbey 1997). Indeed, volunteer workers rarely continue if they are not enjoying the work in some ways, which captures both the intrinsic satisfaction in the experience as well as the good they are doing. As to its frequency, it is more common among the young old than the older old, in spite of a greater call of duty with the current older cohort. Furthermore, its popularity has increased because of the general understanding that it contributes to positive emotion and life satisfaction, which is well supported by research (e.g., Morrow-Howell et al. 2003).

Leisure Activities in Coping with Loss and Disability

It may be considered somewhat ironic that while the reduction of work and family responsibilities defines retirement to a great extent, illness and disability can reduce the time that people can engage in leisure. Nevertheless, leisure activity of older people with illness, disability, and loss does appear to alleviate pain and suffering (cf. Nimrod and Janke 2011), particularly with respect to the loss of a spouse (Janke et al. 2008b). For some, the role loss is even liberating where new activities are initiated as part of one's personal transformation or "blossoming" (as Lopata (1993) characterized it). Importantly too, when long-term care is required, most facilities offer leisure activity programs as part of standard care and use such activities to enhance the quality of life of residents (Dupuis et al. 2011).

Future Research

While some of the research on leisure activities in later life shows sensitivity to gender and disability, there is very limited research on race and ethnicity and other sources of national and cultural variation. It is worth noting that this review probably speaks mostly to leisure activity and aging in North American and other English-speaking countries. Patterns of activities and their relationship to well-being likely vary considerably across countries and regions. But this is also the case for minority, ethnic, and racial groups and even lower SES groups, where differences may be established with further research. And even among those studied, it is the relatively well resourced who have drawn the most attention because they are privileged to have leisure in the first place, even in later life.

Lewy Body Disease

Sarah E. Cook
Duke University, Durham, NC, USA

Synonyms

Parkinsonism; Parkinson's disease dementia; Mild cognitive impairment due to Parkinson's disease

Definition

Dementia with Lewy bodies (DLB, also referred to as Lewy Body Dementia) is a progressive neurodegenerative disease with fluctuations in attention and arousal, changes in cognition and sleep, psychotic features, and development of problems with voluntary movement. It has commonalities with Parkinson's disease dementia making diagnostic differentiation challenging. It has only been recognized as a separate condition since the 1960s (Troster 2008). DLB is now considered the second most common form of progressive dementia, following Alzheimer's disease (AD) (Latoo and Jan 2008), accounting for about 15–35% of all dementia cases depending on the study (Troster 2008). DLB often manifests earlier in life than some of the other dementias, often with onset between age 50–70 (Schoenberg and Duff 2011). It affects up to 5% of older adults (Troster 2008). Average course of disease is generally 5–7 years from diagnosis to death (Schoenberg and Duff 2011). An examination of risk factors for DLB by Boot and colleagues (2013) found that a clinical diagnosis of DLB (as opposed to pathological) was associated with history of depression or anxiety, family history of Parkinson's disease, history of stroke, and being an APOE 4 homozygote. Protective factors were noted to be history of cancer and caffeine use, although the exact mechanism by which they protect against DLB is not known.

This entry will provide a broad overview of DLB, starting with the relevant neuropathology. This will provide a framework for understanding the common clinical presentation of DLB, including the neurologic, psychiatric and cognitive signs and symptoms, diagnostic criteria, and treatment considerations.

Neuropathology of Dementia with Lewy Bodies

On neuropathological examination, DLB is characterized by abnormal aggregates of alpha synuclein protein which were called Lewy bodies, named after Friederich Lewy who discovered

them in the early 1900s in patients with Parkinson's disease (Latoo and Jan 2008). Lewy bodies are almost universally found in the brainstem of individuals with DLB (most often in substantia nigra and locus ceruleus) and may account for the parkinsonian and sleep symptoms often seen in DLB which will be reviewed later. It is believed that this area is the site of initial neuropathological change in DLB and that aggregation of alpha synuclein then ascends sequentially rostrally to the limbic area (including the amygdala, anterior cingulate, entorhinal cortex) and neocortex (frontal, temporal, and parietal lobes) (Donaghy and McKeith 2014). It is believed that the neuropathological changes in these areas may account for the changes in behavior and cognition that are often part of DLB which will be described later. All of these areas of the central nervous system are investigated for Lewy bodies during postmortem analysis to assist with making a definitive diagnosis. In addition, Lewy bodies can also be found in the autonomic branch of the peripheral nervous system, which may be related to the orthostatic dysfunction that can be seen in DLB. The pattern of Lewy body involvement within the central nervous system is important in diagnosis (McKeith et al. 2005), but research has found that the amount of Lewy bodies present is not strongly correlated with disease severity or duration of disease since onset (McKeith et al. 2004).

It is important to note that the presence of Lewy bodies in the central nervous system is not specific only to DLB. In fact, depending on the study, between 24% and 55% of cognitively normal (nondemented) older adults have significant Lewy body burden on autopsy. There is also a high degree of comorbidity of LBD and other neurodegenerative conditions, especially AD but also with vascular disease (Zupancic et al. 2011). McKeith and colleagues (2005) state that the likelihood of DLB is directly related to the amount of Lewy body pathology and inversely related to the amount of AD pathology. But others have recognized the high degree of comorbidity of DLB with other neurodegenerative conditions by dividing pathological cases into two groups: "common" LBD in which both Lewy body and AD pathology (amyloid plaques and neurofibrillary tangles) are

present and both meet neuropathological criteria and the second group is called a “pure” DLB in which only Lewy bodies are of sufficient severity to meet neuropathological criteria but other pathology might be identified (Simard et al. 2000).

In distinguishing DLB from Parkinson’s disease dementia (PDD), there are some differences in the pathological changes in the two conditions. According to Donaghy and McKeith who provide a thorough discussion of the pathological changes in DLB (Donaghy and McKeith 2014), while both LBD and PDD can have diffuse presence of Lewy bodies in certain subcortical and cortical areas, there is often more amyloid deposition in the striatum, alpha synuclein deposition in the hippocampal area, and greater serotonin receptor density in the frontal lobes in DLB compared to PDD. Individuals with DLB have less necrosis in the substantia nigra and less striatal dopamine receptor upregulation than those with PDD.

In addition to the presence of Lewy bodies, DLB has been associated with other neuropathological changes, most notably decreased acetylcholine available in the basal forebrain and decreased dopamine in the basal ganglia (Morra and Donovick 2014). Neuroimaging studies suggest that there could be atrophy of cortical and subcortical areas in DLB, including temporal, frontal, and parietal lobes as well as in the amygdala and hippocampus. However, the atrophy is not as pronounced as in AD making detection by structural imaging more challenging (Morra and Donovick 2014). According to Donaghy and McKeith (2014), there are no radioligands available yet to detect alpha synuclein deposition on neuroimaging, as is the case for imaging amyloid deposition in vivo in AD.

Neurologic Presentation of Dementia with Lewy Bodies

Diagnostic Criteria for Dementia with Lewy Bodies

DLB is a neurodegenerative process that by definition includes a progressive cognitive decline

that interferes with daily functioning (i.e., must have dementia), with motor features starting after, concurrently, or within 1 year of these cognitive symptoms (Donaghy and McKeith 2014). If motor features are present for longer than 1 year before cognitive symptoms first present, then Parkinson’s disease dementia is typically diagnosed rather than DLB (Rongve et al. 2015). Clinical diagnosis is accomplished with history of signs and symptoms as well as physical and neurological examinations, usually by a neurologist. As with some several other dementias, definitive confirmation of diagnosis is not possible until pathological examination postmortem.

According to the most widely accepted criteria for DLB by McKeith and the DLB Consortium (McKeith et al. 2005), there are core features of DLB and then features that help support the diagnosis, often called suggestive features. In order to meet criteria for probable DLB, in addition to the progressive cognitive decline/dementia, an individual needs to have either two or more core features or one core feature and one suggestive feature.

Core Features of DLB

1. Fluctuations in attention or arousal leading to disorientation and mental status changes over hours or days (least common core feature; Donaghy and McKeith 2014)
2. Visual hallucinations, most often well-formed but not threatening to the patient and often images of people or animals (70–85% of DLB cases; Morra and Donovick 2014)
3. Parkinsonism, most often bradykinesia, rigidity, or postural changes as opposed to the tremor commonly seen in PD (60–92% of DLB cases; Zupanic et al. 2011)

Suggestive Features of DLB

1. REM sleep behavior disorder, which is an enacting of dreams during rapid eye movement sleep, can start decades before other clinical manifestations, up to 93% of individuals with this disorder go on to develop a form of synucleinopathy, including DLB, if followed long enough (Donaghy and McKeith 2014)

2. Sensitivity to neuroleptic (antipsychotic) medications marked by the development of extrapyramidal signs in mild cases but sedation and fever possible with more severe reaction
3. Low uptake of dopamine transporter in basal ganglia on SPECT or PET imaging (research has shown >75% sensitivity and 90% specificity for detecting DLB from other cause dementia; Zupancic et al. 2011)

In addition to the core and suggestive features already mentioned above, there are other signs that are frequently seen in DLB, including: autonomic dysfunction which can lead to falls and/or syncopal episodes, delusional beliefs and/or hallucinations in modalities other than visual, incontinence, mood disturbance, and slow wave activity on EEG with temporal sharps (Donaghy and McKeith 2014).

If psychotic symptoms are present, the possibility of antiparkinsonian medications causing hallucinations needs to be ruled out, as several of these medications can induce hallucinations among myriad other potential side effects. The timeline of onset of symptoms should help clarify if this is the case, but if the hallucinations persist after discontinuation and clearance of the possibly offending medication, then DLB should remain on the differential (Zupancic et al. 2011).

Differentiation from Other Neurodegenerative Conditions

DLB is often mistaken for AD or other neurodegenerative conditions due to commonalities in clinical presentation. Given the high rate of dementia in Parkinson's disease (see Parkinson's disease entry in this volume by Cook for review on Parkinson's disease dementia; Cook 2016) and overlapping clinical features, it is important to differentiate DLB from Parkinson's disease dementia (PDD). If the onset of cognitive problems occurs more than a year, and most often several years, after the onset of motor symptoms, it is considered to be PDD and not DLB. If the cognitive symptoms present first, then it is

more likely DLB (Rongve et al. 2015). In addition to examining onset of symptoms, individuals with PDD often respond to levodopa therapy better than individuals with DLB (Zupancic et al. 2011). There is increasing speculation that PDD and DLB may be syndromes along one continuum for a few reasons. First, some authors have suggested that the 1 year rule between cognitive and motor symptoms is arbitrary. Second, there are not well-accepted definitive diagnostic criteria for diagnosing PDD in vivo to assist with separating them. Third, they have striking neuropathological similarities postmortem. Fourth, cognitive domains impacted are relatively similar. And lastly, therapeutically, there appears to be little difference in medication efficacy between them (Rongve et al. 2015).

Distinguishing DLB from an Alzheimer's dementia (AD) is best done by examining the clinical history of symptoms and if available, neuropsychological testing data. Specifically, AD most often does not present with parkinsonism, nor are visual hallucinations common early in the disease course of AD. Individuals with DLB are more likely to have autonomic signs, such as orthostatic hypotension and constipation (Morra and Donovick 2014). On neuropsychological testing, AD affects the medial temporal lobes and typically begins with progressive short-term memory loss, with memories not being triggered by cueing. In DLB, if there are changes in memory, it is often much later in the disease course and qualitatively different, such that a patient with DLB will often benefit from repetition and cueing. Generally speaking, cognitive symptoms in DLB would be considered more subcortical in nature (i.e., attention, processing speed, and/or executive deficits), as opposed to the cortical features in AD. However, many studies have noted that individuals with DLB have more problems with constructional skills than individuals with AD. A matched study of decline in individuals with DLB and AD by Stavitsky and colleagues (2006) also confirmed this finding, but also found that those with DLB had more problems with carrying out everyday skills earlier than individuals with AD.

Is There a Prodrome to Dementia with Lewy Bodies?

In Alzheimer's disease, the most common form of dementia, there is a large literature about a prodrome, which has been called mild cognitive impairment (MCI). While initially conceived to be the prodrome for AD, research has found that there is heterogeneity in clinical symptoms and neuropsychological test performance in MCI, leading to more descriptive labels (e.g., amnesic MCI, nonamnesic MCI) and acknowledgement that not all MCI will lead to AD, but that some will progress to other dementias including DLB (Molano et al. 2010). There has been very little research about a possible prodromal phase in DLB, although some preliminary information has been provided from studies looking at conversion of MCI to dementia. As outlined in Troster (2008), one study found that in a group of 34 individuals with amnesic MCI that later converted to dementia and came to autopsy, three had a pathological diagnosis of DLB and one had a final clinical diagnosis of DLB. Another study of 440 cognitively normal individuals and 141 individuals with MCI were followed for 30 months and found possible DLB in 10 participants, 4 who had normal test findings at baseline, 4 who had nonamnesic MCI at baseline, and two with amnesic MCI at baseline.

In another related study, researchers at the Mayo Clinic (Molano et al. 2010) examined their databases to find cases of MCI that later progressed to DLB to find clinical correlates of a pathological diagnosis of DLB at autopsy. Only eight cases were identified, including six males. Seven of the cases had REM sleep behavior disorder with onset preceding cognitive symptoms in six patients by a median of 10 years. Six patients had visual hallucinations, six patients had problems with executive functioning, and six patients had problems with visuospatial functioning on formal testing. Seven patients had parkinsonism, with a median onset of 3 years after cognitive symptoms. They provide clinical history including progression and course of symptoms for some of these cases to show the heterogeneity in DLB. According to Donaghy and McKeith (2014), a

study is now underway to learn more about not only the prodromal phase but also clinical markers of those who eventually develop DLB using an at-risk group, those with REM sleep behavior disorder.

Treatment in Dementia with Lewy Bodies

Since DLB is a progressive neurodegenerative condition, the prognosis is poor. As noted earlier, survival following diagnosis is often relatively short compared to AD, with estimates of about 5–7 years from diagnosis (Morra and Donovick 2014). The cognitive deficits in DLB are thought to arise at least partially from the cholinergic decline, and therefore research has examined if acetylcholinesterase inhibitors, mostly used in Alzheimer's disease, would be beneficial for individuals with DLB and PDD. In a recent Cochrane review on this topic by Rolinski and others (2012), a total of six clinical trials were considered. However, there was only one study with exclusively DLB patients (McKeith et al. 2000). The Cochrane review suggested that in PDD, the use of acetylcholinesterase inhibitors significantly improved global assessment, cognition, behavior, and activities of daily living. In the single trial with only DLB cases randomized to treatment with rivastigmine or placebo by McKeith and colleagues (2000), those on rivastigmine had symptomatic benefit, primarily with respect to decreasing apathy, anxiety, and hallucinations. Once the drug was withdrawn, these benefits washed out.

In a more recent meta-analysis by Stinton and colleagues (2015) on pharmacological treatment of DLB, they too found that acetylcholinesterase inhibitors (donepezil and rivastigmine) were helpful for cognitive symptoms, delusions, and activities of daily living. They concluded that memantine, a different class of medication used in AD, had limited effectiveness in treating symptoms of DLB but was tolerated well. In terms of antipsychotics for psychiatric symptoms, they found that most agents had a high degree of adverse events or were generally ineffective. Instead of using antipsychotics for the neuropsychiatric symptoms often seen in DLB, which can

include depression, anxiety, as well as psychotic symptoms, treatment with selective serotonin reuptake inhibitors (SSRIs) and/or serotonin-norepinephrine reuptake inhibitors (SNRIs) is often considered. Psychiatric medications that reduce acetylcholine should be avoided so as to not increase cognitive problems (Morra and Donovick 2014).

While dopamine agonists, such as levodopa, that increase the amount of dopamine in the brain are the first line treatment for Parkinson's disease (PD), some of these medications can cause or worsen hallucinations. In general, individuals with DLB tend to respond less to such treatment than patients with PD, which can help in the differential diagnosis. If such a treatment is considered in DLB, dosing is often started low with titration being slow with regular monitoring of symptoms (Zupancic et al. 2011).

Neuropsychological Presentation of Dementia with Lewy Bodies

There are several neuropsychological deficits seen in individuals with DLB, with deficits primarily in attention, working memory, and other executive functions as well as visual perception and construction. Memory is much less impacted early in the course of disease, and semantic knowledge is often intact (Schoenberg and Duff 2011). Each of these cognitive domains will be discussed in more detail.

In a review by Troster (2008), the specific impairments that have been found in literature are discussed, particularly as it relates to AD and PDD. For attention, individuals with DLB often have significant problems with attention skills, including tasks of basic attention, complex or divided attention, sustained attention, and cancellation/visual search. Such skills have been found to often be worse for DLB than for AD. Other higher level executive skills such as abstraction, thinking flexibly, and judgment follow a similar pattern in that they are more impacted in DLB compared to AD. It is posited that the dysfunction of basal forebrain

cholinergic system is responsible for these deficits in DLB (Troster 2008).

Individuals with DLB often have deficits on tests of visual perception and construction. For example, they often have problems copying a picture accurately, matching figures, or conducting a visual search. Given the possibility of motor problems in individuals with DLB, one might think that such deficits could simply be related to the motor demands of testing. However, on deeper examination of the deficits across a wide array of tests, it is more likely that the deficits may be secondary to problems with praxis and perceptual processing. Individuals with DLB with visual hallucinations may have particularly poor visual processing even compared to others with DLB but without visual hallucinations. It is believed that the deficits in visual processing are related to dysfunction in the two visual streams, the dorsal parietal-occipital and ventral temporal-occipital pathway (Troster 2008).

With regards to memory, at least early in the course of illness, individuals with DLB may not be amnesic and may do well on recognition measures. They are more likely to have reduced learning and difficulty with retrieval secondary to executive deficits. They also may do better with verbal as opposed to visual memory tasks due to changes in perceptual processing. Language skills are also generally less affected, with intact semantic knowledge. Object naming may be impacted secondary to visual processing problems and fluency may be reduced due to slowed speed of processing (Troster 2008).

Due to the cognitive changes outlined above, individuals with DLB are likely to have an impact in their ability to carry out tasks of everyday living. Specifically, there can be problems with driving associated with judging distances. Walking on stairs may be challenging due to depth perception changes. Objects may be misidentified, which could lead to medication errors. Attention and arousal may wax and wane making the individual with DLB appear lethargic or apathetic.

In addition to considering treatment of symptoms with medication, families should be educated about the importance of nonpharmacological

treatment options, including occupational therapy and psychotherapy aimed at learning ways to compensate for cognitive losses in concrete ways. In addition, education about the importance of future planning, need for respite assistance, and resources for local support groups should be provided. The Lewy Body Dementia Association website (www.lbda.org) can be a good resource for individuals with DLB and their families.

Definition

This entry describes a longitudinal study of advanced age, set in New Zealand. The cohort study has equal size groups of Māori indigenous to New Zealand, and non-Māori, to allow identification of inequalities in health outcomes related to ethnicity and accurately describe health status until advanced age. The study aims to identify predictors of successful aging.

Background

Advanced aging is the focus of this study. Within the next 40 years, the proportion of the New Zealand population aged over 65 years will increase from 13% to 25% along with international trends. More importantly, those aged 85 years and over (advanced age) will be the fastest-growing group, growing from 1% to 6% of the total population by 2050 (Statistics New Zealand 2012). Expenditure on health and disability support for people aged 85+ in NZ is the highest for any age (Ministry of Health 2002). Balancing this projection are the valued contributions to society of all older people. The projected increase in number and proportion of the oldest population group could lead to a net positive national benefit as there is likely to be some

capacity for these older people to increase their civic contributions. However, not enough is known about the exact health and social status of those in advanced age or how the aspects of New Zealand lifestyle impact success in advanced age.

In examining advanced aging of the New Zealand population, important cultural and environmental aspects come to the fore. The trajectory of demographic aging is steeper for the Māori population with a five times increase in Māori aged 85+ compared with a doubling for non-Māori (Statistics New Zealand 2010). This study of advanced aging includes a large number of Māori participants which enables analyses of disparities in health and health outcomes between the Māori and non-Māori.

The New Zealand Context

The Māori hold a very important place in the cultural fabric of New Zealand society. The LiLACS NZ study embraces Maori kaumātua (elders) and their whanau (extended family) living in the Bay of Plenty/Te Moana a Toi (the sea of Toi). Spanning the east coast of the North Island from Tauranga Moana to Te Kaha, LiLACS NZ research sites include participation and representation from a number of iwi including Ngāti Ranginui, Ngāi te Rangi, Te Arawa, Ngāti Awa, Te Whakatōhea, Ngāi Tai, Tūwharetoa Ki Kawerau, Tūhoe, and Te Whānau ā Apanui. In Maori society kaumātua have vital leadership roles in their whānau and are often expected to perform duties within the wider whānau and tribal community. They are respected for their age and accumulation of knowledge. Kaumātua are often featured in traditional Māori stories as nurturers of the young and keepers of knowledge that is passed on from one generation to the next. The famous ancestor Māui was rescued and raised by his grandfather Tamanui-ki-te-rangi. He gained knowledge from his kuia (female elder), including the secret knowledge associated with fire. Whaitiri, the grandmother of Tāwhaki and his brother Karihi, is another revered ancestor who taught her grandsons the best way to climb up to the heavens to attain knowledge.

Currently, Māori people make up approximately 14.6% of the total New Zealand population of 4.4 million (Statistics New Zealand 2013), and the Māori population is aging faster than the non-Māori population (Ministry of Health 2011). Life expectancy at birth now lags by about 7 years for Māori, and there is an excess of morbidity related disability for older Māori. About half of the differences observed in the aging of Māori peoples are due to socioeconomic disadvantage (Ministry of Health and University of Otago 2006). Linked New Zealand census and mortality data show that older Māori and Pacific men and women have a higher relative risk of dying than those of European descent. Controlling for socioeconomic factors accounted for only 40% of this difference in mortality (Jatrana and Blakely 2008). Other sources of disadvantage in health may relate to access to health services (Ministry of Health and University of Otago 2006). For this reason investigation of the health and longevity of the very old in New Zealand must include a focus on Māori health.

LiLACS NZ examines the health, social, cultural, and environmental status of Māori and non-Māori in advanced age and identifies health, social, cultural, and environmental predictors of successful advanced aging denoted by quality of life, health-related quality of life, functional independence, maintenance of health, and longevity.

The Cohort Study

The LiLACS NZ is based on a 1 year birth cohort following the design of the Leiden 85-plus (Poortvliet et al. 2013) and the Newcastle 85+ (Collerton et al. 2009) studies. The age at which 90% are expected to live at least one more year in the New Zealand population is 85 years; however, the need to engage equal numbers of Māori and non-Māori to enable meaningful findings for Māori meant a broadening of the age band to a 10-year age group (80–90 years) for Māori.

The LiLACS NZ study is informed by Kaupapa Māori methods and ideology. Research that is based on a Māori worldview acknowledging the idea that “knowledge is rooted in cultural

contexts.” The ideology offers a counter-hegemonic approach to Western forms of research. It has roots in critical theory and in a similar vein combines transformative practice and structural analysis. Importantly, the research has been guided by Te Rōpū Kaitiaki o Ngā Tikanga Māori [Protectors of Principles of Conduct in Māori research]. This group of Māori elders was responsible for the translation of questions and ensured that practices of engagement and interview processes with Māori participants were appropriate (Dyall et al. 2011; Kēpa et al. 2014).

The cohort study began in 2010 with the identification of all eligible participants (tribal group) and recruitment of those who were interested in participation. Geographical boundaries were identified to be the Bay of Plenty District Health Board regional funding body (DHB) and the Lakes (DHB) (regional funding body excluding the Taupo area) as these were areas with stable populations and strength in Māori cultural activities. Eligibility criteria included living within the geographic boundary and Māori aged 80–90 years, born in 1920–1930, or non-Māori aged 85 years, born in 1925. Overlapping strategies formed the sampling frame. Potential participants were identified from: electoral rolls (general and Māori), primary care and tribal databases, word of mouth, advertising, and whakawhanaungatanga (to establish good relations with people within Māori networks).

Extensive consultation with Māori tribal local groups in the region of the study (Dyall et al. 2011; Dyall and Kerse 2013) led to local organizations being engaged to invite participants and complete assessments. Awareness of the study was raised with newspaper, radio, and television events. Interviewers and nurses were locally based, and the university-based research team provided training, developed the interview and assessment schedule, and supported the interviewers with regular visits and online and telephone contact.

Recruitment and Retention

Participants were invited by a person known to them, and a personal explanation in the presence

of family (if desired) led to written informed consent for those who participated. Local organizations continued engagement through the cohort study with regular communications, cup of tea events, and the University of Auckland provided yearly feedback and discussions in all regions.

At baseline (Wave 1) 927 completed some form of data collection. At the end of Wave 2 (12 months follow-up), 660 contributed data with 25% attrition. By Wave 3, 137 had died (15% mortality), and 534 completed data collection (84% of survivors). Subsequent attrition was low with 428 completing Wave 4 (36 months follow-up). This represented a further 10% mortality and 91% of survivors from Wave 3 completing data collection.

Wave 1 in the Maori cohort had a response rate of 56%, yielding 421 participants, 176 (42%) were men and 245 (58%) women. At Wave 2, 267 Māori (63%) were interviewed. In the non-Maori cohort, a response rate of 59% yielded 516 participants; 237 (46%) were men and 279 (54%) women. At Wave 2, 393 non-Māori (75%) completed data collection (Dyall et al. 2013).

Measures

Consent was sought separately for an interview, a health assessment, a blood test, and an access to general practice and hospital records. Trained lay interviewers completed either a brief interview of core questions of a comprehensive interview using standardized techniques. Comprehensive measures were identified, and assessment procedures developed during a feasibility study including questions about participation in cultural activities from focus groups with older Māori (Dyall et al. 2011). Full details are published (Hayman et al. 2012) of the sociodemographic; general health and health-related quality of life; psychological and mental health; functional status and physical function; health behavior and nutrition risk; health services used; culture and cultural practice; social network and social support; activity and pastime; transport; housing and environment; economic, housing,

environmental, and cultural; and politics and respect questions. Trained nurses used standardized techniques to complete a health assessment consisting of anthropometric measures, blood pressure lying and standing, spirometry, and an electrocardiogram.

Assessments were planned yearly to 5 years follow-up to repeat health, health-related quality of life, and functional measures. Administrative data on hospitalizations and mortality were accessed for those that gave consent to this component yearly, based on the National Health Index of participants, an individual identification number. A blood sample was taken for biochemical analysis.

At Wave 2, in addition to the comprehensive interview and health assessment, a detailed 24 h multiple pass recall nutritional assessment (Adamson et al. 2009) was completed on two different days. The remainder of the yearly assessments for participants focused on function and health. During Wave 3 a series of questions about expectations and wishes at the end of life were added, and a main caregiver was nominated by the participant and, if agreeable, was interviewed about amount, type, and attitude to caregiving. Bereavement interviews were offered to the family of those who passed away.

Health Status

Despite difference in socioeconomic status and education between the ethnic groups, self-rated health did not differ. Self-rated health was rated as excellent or very good by 24% of Māori and 23% of non-Māori in advanced age. Falls had occurred for 34% of Māori and 40% of non-Māori (not significant when adjusted for age). A median of five chronic conditions were observed for Māori and non-Māori. Cardiovascular disease was present in 67%.

Disparities in the prevalence of chronic conditions were present with non-Māori being less likely to have congestive heart failure (odds ratio (OR) 0.58, 95% confidence interval (CI) 0.41–0.82), and atrial fibrillation on ECG [OR (95% CI) 0.56 (0.32–0.96)] and diabetes [30% of

Māori, 16% of non-Māori, OR (95% CI) 0.53 (0.36–0.78)]. Non-Māori were also less likely to have dementia [OR (95% CI) 0.59 (0.37–0.95)]. Around one-quarter of the LiLACS NZ sample had depression with the lowest prevalence observed in Māori men (22%) and highest in Māori women (30%) and 23% and 26% in non-Māori men and women, respectively. Eye disease, established by self-report, was very prevalent with non-Māori being more likely to have eye disease (66%) than Māori (48%) [OR (95% CI) 1.62 (1.17–2.25)].

A median of five (range 0–18) medications was taken by Māori and non-Māori. Gait speed was observed to be on average 0.8 m/s for non-Māori and 0.7 m/s for Māori. A gait speed of less than 0.8 m/s is considered to highlight significant risk from poor health outcomes (Abellan Van Kan et al. 2009a, b). Hospitalization had occurred in the 12 months prior to the first interview in 40% of Māori and 35% of non-Māori.

Overall self-rated health was good considering that comorbidities were common, and Māori were resilient to greater socioeconomic disparity as self-rated health was equivalent between the ethnic groups.

Ongoing Analysis

Analyses of factors associated with change in function over time, description of management of common conditions, and prediction of cardiovascular outcomes related to that management are ongoing. Predictors of high functional status, community living (in comparison to admission to residential aged care), and mortality are ongoing. Nutritional intake will be described in terms of macro- and micronutrients and the food groups contributing to intake. Change in physical performance will be related to protein intake and cardiovascular outcomes related to salt and fat intake.

Analysis of end of life wishes and carers' contribution to the lives of those in advanced age will follow.

Future Directions

The cohort study inception to Wave 3 was funded by the New Zealand Health Research Council, and funding for 2014–2016 was from the New Zealand Ministry of Health. This will complete 5 years of follow-up. The contribution of nutritional intake and health status to ongoing function and quality of life will be a major focus of ongoing analyses. Identification of ethnic disparities and factors showing resilience to these disparities will contribute to the Māori focus.

Widespread dissemination and consultation with the communities engaged in the research will inform development of local solutions to issues identified as well as interventions to improve quality of life in advanced age for Māori and non-Māori.

Life Events and Older People

Yvonne Wells

La Trobe University, Melbourne, VIC, Australia

Synonyms

Developmental trigger; Incident; Milestone; Occurrence; Stressor; Transition

Definition

A life event is commonly understood as a very important occasion or experience in someone's life, such as marriage, the birth of a child, or the death of a family member. George (2001) defined life events as “identifiable, discrete changes in life patterns that create stress and can lead to illness onset or the exacerbation of pre-existing illness” and pointed out that the life events perspective is compatible with the view that aging is defined largely by the losses that older people experience. More recently, life events have been incorporated into the life course perspective and understood as developmental triggers with positive, as well as negative, effects. However, any changes to one's circumstances, positive or negative, require a process of adjustment.

Studies have shown that life events at any stage in life may have an impact on wellbeing in later life. However, the focus here is on life events experienced in late adulthood.

Related Concepts

The concept of life events is related to that of transitions, which are discontinuities in a person's life space and often preceded by a life event; for example, changing one's marital status from married to single may be preceded by divorce or widowhood. Transitions are often seen as occurring at specified times in the life course, whereas life events can potentially occur at any time. Another related concept is that of milestones:

events identified with the completion of one life stage and moving on to the next.

The impacts of life events and transitions on stress levels and illness have been studied extensively. Two broad approaches to conceptualizing life stress have been identified; the first approach sees life stressors as major, taxing life events that create change and require substantial adaptation. On the other hand, relatively minor events have been identified as equally important for understanding how much stress people experience. Hassles are “the irritating, frustrating, distressing demands and troubled relationships that plague us day in and day out” (Lazarus and DeLongis 1983), while uplifts are minor positive experiences: the pleasures and rewards of everyday life.

Taxonomy

Life events may be unexpected or anticipated. A serious car accident, for example, is an unexpected life event, whereas retirement is usually anticipated and often well planned. Both anticipated and unexpected life events may be experienced positively or negatively, and this experience depends on both the circumstances of the event and how the individual interprets and copes with the event.

Similarly, life events and transitions may be normative or not. Some transitions are normative because they are linked with one’s age: graduation from secondary school and retirement, for example. Some are linked with one’s position in history and so are normative for the cohort with similar experiences: for example, life events associated with conscription to the armed forces, sweeping economic or technological changes, major epidemics, or natural disasters. On the other hand, life events may be non-normative; winning the lottery and being the victim of a random burglary are both non-normative life events. (However, neither may be entirely unexpected, depending on the circumstances.)

What Life Events Do Older People Experience?

Later life is characterized by some relatively common life events. Retirement is sometimes seen as

the defining transition to later life. Health events are common, and aging is frequently depicted as synonymous with the onset of poor health and disability. However, individuals may age successfully with few health problems or disabilities, and many people deal effectively with particular events or difficulties while others with similar difficulties become functionally impaired.

Seematter-Bagnoud and colleagues interviewed a large number of young-old men and women (aged 65–70 years) using a geriatric adverse life events scale (Seematter-Bagnoud et al. 2010). They found that three-quarters (72%) of participants had experienced at least one adverse life event during the preceding year. Common events included the death of a friend or nonprimary relative (18% of men and 20% of women) and new major physical illness (17% of men and 19% of women).

Studies have documented consistent differences in life events listed by younger and older adults. In comparison with younger adults, older adults report fewer stressors (and especially fewer traumatic events such as physical and sexual assaults), less heterogeneous sources of stress, and lower impacts of stress on daily life. Younger adults are more likely to experience “tragic” deaths, while older adults are more likely to report deaths resulting from physical illness. As well as recent life events, people in later life may be influenced by the long-term impacts of events that occurred earlier in life, both in childhood and in earlier adulthood.

Consequences of Life Events

Many life events involve changed life circumstances and demand a process of adjustment that may impact on various aspects of a person’s functioning. Studies have focused on a range of outcomes, including physical health, health behaviors, social networks, and memory functioning, as well as depression, anxiety, and feeling stressed.

Some life events are intrinsically more difficult to cope with than others; health and interpersonal events are rated as more severe than financial or

work events. The way in which events are viewed, or appraised, is also critical to how much stress they cause. Lazarus and colleagues defined primary appraisal as the personal significance of the encounter – “How much is at stake?” – whereas secondary appraisal refers to the individual’s assessment of what resources they bring to their situation (Lazarus and DeLongis 1983).

Hatch and Dohrenwend (2007) argued that at least six dimensions determine the nature and extent of the impact of life events: their source (i.e., whether arising from external events in the environment or from the individual’s own actions and behaviors), their valence (positive or negative), their magnitude (the amount of change in usual activities), their centrality (from threat to life at one extreme to threat to social goals at the other), and whether they induce physical exhaustion.

Stressful life events have consistently been shown to be associated with adverse mental and physical health outcomes in adults of all ages. Depression has received the most research attention; the occurrence of any negative life event during the previous 2 years is associated with developing symptoms of depression. Among older adults, the most salient life events for risk of depression in late life are personal illness, bereavement, and theft.

Other mental health problems have been linked with life events. Negative life events are a risk factor for developing late life psychosis, for example. Cognition may also be affected: memory problems in older adults are associated with daily stressors, particularly among individuals who are anxious.

An interesting phenomenon is that stress can “spill over” from one domain to others. This suggests that experiencing one stressful event can cause higher emotional reactivity to other events occurring shortly afterwards. Stress may also accumulate. Symptoms of depression are associated with exposure to many negative life events during adulthood and late adulthood; at particularly high risk are those who have also experienced negative life events during childhood. However, dealing with adversity may also strengthen an individual’s

resilience, as is shown by studies of Holocaust survivors in later life.

Life Events and Aging

Both increases and decreases in emotional reactivity to life events with increasing age have been reported in the literature. Low reactivity to life events and daily hassles may reflect self-regulation and the capacity to deal with challenges of day-to-day life; older adults seem to benefit from lifelong learning in coping with daily stressors. On the other hand, older adults are more likely than younger ones to experience physiological limitations in their capacity to deal with stress (such as high blood pressure).

Several studies have shown that older adults may be better at dealing with stressful life events than younger ones. In comparison with younger adults, older adults report fewer stressors and hassles overall and lower impacts of stress on daily routines. The incidence of a serious health event causes larger changes in life satisfaction in middle-aged adults than it does in older adults, perhaps because health events are more normative for older than younger adults. More generally, emotional stability in response to life events tends to increase along the life span. In addition to the benefits of maturity, having a positive view of aging (i.e., seeing older age as a time of ongoing development) has a beneficial effect on health and life satisfaction, even in the presence of a serious health event.

The following sections address one-at-a-time life events experienced by older people.

Retirement

Role theory predicts that the loss of a valued social role – bread-winner, worker, or employee – will have negative impacts on people’s health and wellbeing and increase the risk of mortality. Some studies have found that early retirement increases the risk of poor health and mortality. However, an issue with many of these studies is that poor health may have prompted the decision to retire in the first place.

It is now recognized that the transition to retirement is positive for many people. Retirement affords an opportunity for people to reassess their health behaviors, and individuals often increase their physical activity over the retirement transition. The European SHARE study found that retirement leads to improvements in both self-rated health and objective health indicators, as well as psychological wellbeing. Similarly, the prestigious Whitehall study found improved mental health among those who retire, especially in higher status groups, but worsening mental health among those who continue to work (Mein et al. 2003).

The impacts of retirement on emotional wellbeing depend on a range of objective circumstances and reasons for retirement. People who retire for “push” reasons, such as poor health or inability to respond to changing workplace demands, experience poorer emotional wellbeing over the retirement transition than those who retire for positive (“pull”) reasons, such as because their spouse has retired or to take up opportunities to travel.

Being compulsorily retired is usually experienced negatively, whether anticipated or not, whereas having control over the timing and nature of retirement usually leads to positive consequences for the individual and is more important than whether retirement is sudden or gradual (de Vaus et al. 2007). Retirement planning may assist people to deal with this transition prospectively.

Relocation

Relocation may occur several times during later life. People may move to retirement housing, downsize to smaller quarters to reduce the burden of property upkeep, move to a different community to live closer to family members, or relocate to residential care because of physical frailty or dementia. Primary reasons for moving to retirement housing include avoiding home upkeep and anticipating future needs for support. One of the most often cited theoretical perspectives on relocation is the retirement–migration model (Wiseman 1980), a two-stage model of migration decision-making that proposes that the decision to

move and the decision where to move are influenced by different considerations.

Some studies have reported significant increases in engagement in social activities and higher quality of life in groups of older people who have relocated to retirement housing or to long-term care. Moving to age-specific housing may also increase people’s feelings of control. Many people who move are glad they made the decision to move and satisfaction with this decision may increase over time. Advantages of moving include an easier lifestyle and more time for social activities, whereas disadvantages include constraints imposed by living in a congregate housing setting.

Prominent risk factors in relocation to a nursing facility include poor health, functional or cognitive impairment, low socioeconomic status, living alone, having no children living nearby, and feeling lonely. Potential negative impacts of relocation to a care facility may be eased by minimizing stress associated with the move and by assisting the older person to retain a sense of control.

Especially for older people who have memory loss, a move away from familiar surroundings may intensify confusion and dependence on others and lead to frustration. The decision to relocate to residential care and the subsequent adjustment period is a difficult time for people with dementia (and their family caregivers). Admission has been linked to increased behavioral symptoms in people with dementia: in particular, depression and agitation, decreasing cognition, frailty, and falls.

However, many older people are able to adjust positively to relocation and to develop new relationships. A qualitative study of older women who had relocated to an apartment complex found that they developed four types of relationships with different functions: for feelings of security, for casual interactions, for opportunities to be supportive, and for friendship (Dupuis-Blanchard et al. 2009).

The extent to which people benefit from relocation may depend on their own and others’ efforts to integrate into the destination locality. In contrast, older people are at risk for poor

relocation outcomes if, prior to moving, they have low self-esteem, symptoms of depression, or low quality of life.

Widowhood

Bereavement is one of the most common life events for an older person and affects many aspects of life. The well-known 43-item Holmes and Rahe scale of life events (Holmes and Rahe 1967) places the death of a spouse at the top of the list, with 100 for the degree of adjustment required, compared with 45 for retirement and 20 for a change in residence.

Widowhood has pervasive impacts on all aspects of an individual's life. Older people may experience a decline in their own health after the death of a close family member or friend, and being newly widowed is a risk for symptoms of depression. Widowhood may also entail reduced economic security, especially for women and those from ethnic minority groups.

The death of a spouse increases the risk of mortality, but differently for men and women. In the 2 years after death of a wife, the mortality rate in men tends to increase, especially if the wife's death was unexpected; for women, the impacts of widowhood are less clear and generally less severe.

Widowhood has a negative impact on the size of people's social networks and older widow(er)s may experience decreases in social interaction and companionship. Loneliness is higher in older widowed than partnered people; some studies have shown that loneliness explains the excess risk of depression in widowed people. However, social networks established before widowhood do not necessarily buffer the negative impacts of widowhood.

Studies on impacts of widowhood among migrant groups and ethnic minority groups suggest that detrimental impacts of widowhood on wellbeing may be greater among those who are aging outside their country of origin and who have retained the linguistic, cultural, and religious practices and traditions of their home country.

While most studies have focused on negative impacts of widowhood, some have shown few

differences between married women and their widowed counterparts. For example, widowhood is not associated with changes in physical activity and does not predict whether or not older people are classified as aging healthily.

Qualitative studies have documented positive outcomes associated with widowhood, such as opening up opportunities for a new life phase. Adaptation to the death of a spouse is facilitated by engagement in familiar, meaningful occupations and experiencing positive emotions associated with everyday activities and contact with other people.

Health Events

Physical ill health is a strong predictor of emotional ill health in all age groups. In older people, frailty is a dynamic process, characterized by frequent transitions between frailty states over time. Having a stroke and diseases such as diabetes, cancer, and respiratory system disease comprehensively impact on all dimensions of successful aging. However, studies have shown that individuals' perceptions of health – subjective health – have a stronger influence on emotional wellbeing than objective health indicators such as number of health conditions.

Hospitalization has been described as a “sentinel event” whose impacts may be particularly poor. Bed rest is known to cause loss of muscle strength in healthy older adults and patients spend most time in hospital lying in bed, even those who are able to walk independently. Identified predictors of functional decline in an acute hospital setting include age, low functional status on admission, cognitive impairment, and depression, as well as length of hospital stay.

As with other life events, psychological processes may buffer negative impacts of health events on wellbeing. The best self-protective strategy to use depends on whether the health condition is acute or chronic; persistent engagement with goals works well for people whose condition is acute, whereas two alternative strategies – disengagement through downgrading expectations and self-protection through positive reappraisal – are likely to work better for people with chronic health conditions.

Spouse Caregiving

While people may be required to take on family caregiving in middle age and even earlier, most family caregivers are older people; this is particularly true for spousal caregiving, which often precedes widowhood.

Becoming a family caregiver is a relatively common transition in later life. In a longitudinal study of people aged 65 years and over, Burton and colleagues (2003) found that only half of noncaregivers at baseline remained noncaregivers at 5-year follow-up. The remainder experienced one or more transitions, including moving into the caregiving role, their own or their spouse's death, or placement of their spouse in a long-term care facility.

The trajectory of health and wellbeing outcomes associated with caregiving is generally downward. Those who transition to heavy caregiving have poorer self-reported health and health behaviors than those who do not. Results of many studies have confirmed that the transition to caregiving for primary kin (i.e., a child, spouse, or biological parent) is associated with an increase in symptoms of depression. The impacts of caregiving for someone with dementia are particularly deleterious, and the probability that caregiving will be relinquished and the care-recipient placed in residential care within a few years is high.

However, caregiving may also be associated with beneficial effects, such as greater purpose in life. Uplifts, rewards, and satisfactions of caregiving have all been documented. Such satisfactions include feelings of pride, improved self-worth, greater closeness in relationships, and enhanced sense of meaning and pleasure in life.

Finding positive meaning in caregiving can buffer its negative impacts. Qualitative studies have also identified a range of feelings about caregiving and shown how these may impact on outcomes. Some caregivers express no positives in caregiving, focus largely on their own unmet needs, and report high burden. In contrast, others describe both their past and present relationship with the care-recipient in loving terms, express satisfaction with their caregiving, and report low burden.

People transition out of the caregiving role when the person they care for dies or is admitted to residential care. Some studies have shown continuing negative impacts after placing a spouse in a nursing home, including high blood pressure and anxiety and depression. In contrast, bereavement may be accompanied by positive changes for people who have been caregiving. Documented positive changes among people who have relinquished caregiving or are widowed caregivers (especially those who previously cared for people with dementia) include personal growth, improved psychological wellbeing, and greater participation in social activities.

Buffers to caregiving stress have been identified. For example, getting social support is important; for spouse caregiving, the quality rather than the quantity of support is critical. Motivations for providing care are also important. Some studies have contrasted caregiving from love and loyalty with caregiving from a sense of duty. Other researchers have described motivations to care as either autonomous (volitional) or externally controlled (introjected). People experience autonomy when they perceive their behavior to be voluntary rather than driven by external controls. Being able to articulate benefits in providing care to a spouse is associated with having autonomous motives to care. On the other hand, high depression in caregivers is associated with caring from a sense of duty and having little choice.

Moderators

As noted above, the impacts of life events and transitions vary a great deal between individuals. Studies on life events and transitions have identified specific moderators of the impacts of stressful life events on outcomes. Moderators that assist people to adapt positively are called buffers.

Gender and Demographic Variables

The influence of age on reactivity to life stressors has already been discussed above. In general, older people react in less extreme ways to life events than do younger ones.

The influence of gender on both the life events experienced and the severity of outcomes depends on the event. Some literature shows both more significant life events for older women than older men and greater impacts of similar events on women than men. Women report events as more upsetting than men do and take longer to get over their effects. For example, studies have consistently documented that women in caregiving roles report more symptoms of stress and depression than men. In contrast, in response to some life events, women report higher levels of positive emotion than men: this is true of both retirement and widowhood.

Cultural differences also influence how life events are appraised and experienced in later life. The role of cultural beliefs in how illness and family caregiving are understood and experienced is well-established. For example, the notion of filial piety is much stronger in some cultures than others. Understanding dementia and cognitive impairment presents particular difficulties for people from cultures where dementia is not differentiated from mental illness and carries stigma.

Psychological Factors: Personality, Appraisal, Coping Strategies, and Social Support

The individual's personality can influence how much impact life events have. For example, it has been demonstrated that life events and hassles have stronger impacts on memory function in people with high emotionality. On the other hand, focusing on positive emotions appears to have a protective effect against stress. In widows high in trait resilience, feeling positive emotions contributes to effective emotional recovery.

Having high quality social supports promotes resilience in the face of both major life events and daily stressors. Individuals with low levels of social connectivity are more likely to have difficulty regulating the emotional intensity of negative emotions, once triggered.

Many studies have focused on coping strategies used in response to life events and daily stressors. These strategies are commonly divided into emotion-focused strategies, such as ignoring, escapism, and wishful thinking, and problem-focused

strategies, such as cognitive restructuring, seeking information, and negotiation. Similar terms used in the literature are avoidance versus approach coping strategies. Middle-aged and older adults who rely on approach coping strategies rather than avoidance coping strategies are more likely to report some benefit from encountering life events, while avoidance coping is associated with developing depression and drinking problems. An integrative literature review (Cotter and Gonzalez 2009) on older adults' self-concept in the face of normative age-related bodily and functional declines and numerous social changes, as well as life events, identified a range of successful coping strategies, including religiosity, positive attitudes to aging, and preserving continuity of both self-image and social networks.

How Can Older People Who Experience Adverse Life Events Be Helped?

Several strategies have proven useful to promote emotional wellbeing in older people, whether living in the community or in residential care. Many can be adapted to assist people with dementia or mild cognitive impairment.

Exercise: Several good quality studies and reviews have demonstrated the benefits of exercise on depression and emotional wellbeing more generally in older people. Short-term benefits are well documented but the evidence on longer term outcomes is less clear. Exercise has also been shown to reduce the risk of developing anxiety and depression and to reduce agitation in people with dementia living in residential care.

Music: Music therapy and singing have been shown to improve psychosocial wellbeing in a variety of settings and with a variety of people, including those with dementia. Interventions that involve the use of music are also helpful in alleviating symptoms of anxiety and depression and improving quality of life. More informally, music is used by older people as a source of entertainment as well as a forum for sharing and interacting with others. Music is easily personalized to the individual and devices to play recorded music are now portable and inexpensive.

Behavioral activation: Behavioral activation, or behavior therapy, focuses on increasing a person's level of activity and pleasure in life, rather than changing the person's beliefs and activities. Behavioral activation can be carried out with individuals or groups. An informal form of behavioral activation is to include a range of enjoyable events in a person's daily routine, such as bus trips and outings, social events, religious activities, board games, and special meals. Behavioral activation can be an effective therapy for depression and low mood. It has also been used to reduce depression, stress, and cardiovascular risk in older caregivers of family members with dementia.

Life review: Reminiscence is a general term covering a range of interventions that involve thinking or telling someone about past experiences that are personally significant. Three kinds of reminiscence can be distinguished: simple reminiscence, life review, and life review therapy. Simple reminiscence involves simply describing past events, whereas life review focuses on the re-evaluation of life events to form a coherent life story. Life review can improve emotional wellbeing and reduce symptoms of depression in people living in the community or residential care, and there is emerging evidence that it may be used successfully with people living with dementia, relying on prompts such as photograph albums, scented objects, and music.

Life review therapy: One of the best-supported therapies used by health professionals is life review therapy. Therapies based on reminiscence have been shown to be effective as a way of adapting to critical life events and chronic medical conditions in older adults with mild to moderate symptoms of depression. Cappeliez and O'Rourke (2006) developed a taxonomy of reminiscence functions: positive functions such as supporting identity, problem-solving, and preparation for death; negative functions such as reliving feelings of bitterness, reducing boredom by romanticizing the past, and maintaining intimacy with previous relationships, often with people who are deceased; and prosocial functions, such as teaching and informing others and using memories to promote conversations in order to connect or reconnect with others. It has been

suggested therapists focus on techniques that reduce bitterness revival in people with depressive symptoms and problem-solving reminiscence for people with symptoms of anxiety.

Other therapies: Cognitive behavior therapy (CBT) involves working with a therapist to look at patterns of cognition and behavior that predispose them to experience problems with anxiety or depression or are keeping them from improving once they become anxious or depressed. Once these patterns are recognized, the person can make changes to replace these patterns with ones that reduce their symptoms, promote positive mood, and improve coping. CBT can be conducted with individuals or in group settings. CBT has been tested in well-designed studies and found to be effective for older adults with anxiety and depression. It can be used effectively in both residential care and community settings and with family caregivers.

A range of therapies have grown out of CBT. For example, behavior therapy focuses on specific learnt behaviors and how the environment has an impact on those behaviors. Acceptance and commitment therapy (ACT) is another variation on CBT. Rather than teaching people how to change their thinking and behavior, ACT teaches them to notice and accept their thoughts and feelings. In this respect, ACT is similar to mindfulness-based approaches. There is limited evidence to support the use of ACT with older adults.

Mindfulness-based stress reduction and mindfulness-based cognitive therapy both rely on mindfulness – a type of meditation that teaches people to focus on the present moment and to notice pleasant and unpleasant experiences without trying to change them. Both approaches have been used successfully with older people, including those with mild cognitive decline.

Summary

Later life is a period characterized by a range of relatively severe life events, including widowhood and other bereavements, loss of social roles, and the development of frailty and risk of

hospitalization (Seematter-Bagnoud et al. 2010). Some older people take on inherently stressful roles, such as being a family caregiver for a person with dementia. However, many older people appear to cope well with the life events and transitions they encounter. Important factors include the degree of control that can be exerted over the life event, personality traits such as having an optimistic and positive focus, and a range of coping strategies, including reappraisal and seeking social support. Older people who are at risk of poor emotional wellbeing may be assisted by a range of simple pleasurable activities (such as enjoying music and exercise) and interventions provided by mental health professionals.

Synonyms

Life management, self-regulation; Successful aging, positive aging

Definitions

- Life management: An action-theoretical construct encompassing the active shaping of one's environment as well as reactive adaptation to a changing environment across the life span
- Elective selection: Development, delineation, and commitment to a subset of alternative goals
- Loss-based selection: Selection that occurs in response to a loss in goal-relevant means
- Optimization: Acquisition and investment of means in the service of achieving higher levels of performance

- Compensation: Substitution or intensification in the use of means after experiencing a loss in goal-relevant means

How do people manage their lives? How do they actively shape their development well into old age while, at the same time, reacting to the changing environment? The model of selection, optimization, and compensation (SOC) proposes that three distinct yet interrelated processes are central for life management: selection, optimization, and compensation (Baltes and Baltes 1990).

This entry takes a life span perspective on aging and as such is based on the idea that because development spans the entire life span from conception to death, aging does not start when entering old age. Instead, aging can be conceived of as a lifelong process. Experiences and life choices accumulate across the life span and shape people into the older person they will be. Thus, a full understanding of aging requires investigating how people manage their lives throughout the life span. What choices do they make? How do they acquire and maintain resources that help them to achieve their goals and maintain a level of functioning that allows them to lead their lives according to their wishes and standards? Thus, after giving a general introduction into the SOC model, this entry is concerned with the development of SOC through adolescence, the use and usefulness of SOC throughout adulthood, and finally the importance of SOC in old age.

The Life Management Strategies of Selection, Optimization, and Compensation

Life span psychology conceptualizes development throughout the entire life span as encompassing gains and losses as well as stability and change. The ratio of gains to losses in resources, however, changes with age. Whereas gains are predominant at younger phases of the life span, aging adults are more and more

confronted with losses (e.g., Baltes et al. 2006). Thus, a developmental theory of life management needs to address how people achieve gains, manage losses, and maintain stability in their functioning in a changing environment and an increasingly negative ratio of gains and losses. The SOC model was first introduced by Paul and Margret Baltes (Baltes and Baltes 1990; Baltes 1997) as a meta-model of general developmental processes operating on different levels of analysis (e.g., individual, society) and applicable to different domains of functioning (e.g., cognition, motivation). The SOC model takes an action-theoretical perspective and posits that the role of a person in his or her development is not only to react to a changing environment of social, cultural, and biological constraints and opportunity structures but also to create the environment that best fits the personal preferences and goals. More specifically, the SOC model holds that the *selection* of goals (or developmental pathways), the *optimization* of functioning through acquiring and refining resources and skills, and the maintenance of functioning in the face of loss or decline through *compensation* are central processes of developmental regulation. These processes are described in more detail below.

Selection involves specifying a pathway of development by narrowing down of a range of alternatives within the scope of biologically and culturally defined constraints. Selection concentrates resources on a subset of goals and thereby contributes to specification and differentiation, constituting a basis for the acquisition of new resources and skills. In the SOC model, selection can occur either electively (choosing to jog for fitness; termed “elective selection”) or after losses (e.g., disengaging from jogging after injury and instead pursuing swimming; termed “loss-based selection”).

Optimization entails acquiring and investing resources into achieving higher levels of functioning in the selected developmental pathways. Resources can be defined as means that help to achieve one’s goals. Thus, what constitutes a resource depends on the goal and context.

Life Management Through Selection, Optimization, and Compensation, Table 1 Typical instances of elective selection, optimization, compensation, and loss-based selection for an older adult

Instance	Example
<i>Elective selection</i>	
Specification of goals	Setting the goal of regular weight training to address declines in bone density
Goal system (hierarchy)	Prioritizing weight training exercises over cardiovascular exercises
Goal commitment	Pledging to engage in weight training exercises at least three times a week
<i>Optimization</i>	
Acquiring new skills/resources	Learning the correct form for weight training exercises
Persistence	Engaging in weight training three times a week, as planned
Modeling successful others	Watching weight training videos or hiring a weight training instructor for guidance
<i>Compensation</i>	
Substitution of means	Focusing on leg-based weight training after injury to shoulder
Use of therapeutic intervention	Visiting a physical therapist to address the shoulder injury
Use of external aids/help of others	Wearing a shoulder brace when returning to weight training
<i>Loss-based selection</i>	
Focusing on most important goals	Focusing on overall fitness and well-being after repeated shoulder setbacks
Reconstruction of goal hierarchy	Prioritizing cardiovascular exercises and calcium supplements over weight training
Adaptation of standards	Contenting oneself with light weekly weight training instead of lifting weights three times a week after repeated overuse injuries

Compensation refers to managing impending or actual losses in functioning by intensifying the investment of available resources or by substituting resources that are no longer available. Consistent with optimization, compensation entails acquiring and investing resources, but in contrast, compensation is instead focused on maintaining functioning in the face of losses.

Life Management Through Selection, Optimization, and Compensation, Table 2 Sample items of the SOC questionnaire: each item consists of the description of behavior indicative of selection, optimization, or compensation paired with a description of an alternative, non-SOC behavior. Participants are asked to choose between these two options. Research has shown that this particular format decreases the effects of social desirability and contributes to more balanced item difficulty (see Freund and Baltes (2002) for more information on the questionnaire)

SOC-related (“target”) behavior	Alternative behavior
<i>Elective selection</i>	
I always pursue goals one after the other	I always pursue many goals at once, so I easily get bogged down
I know exactly what I want and what I don’t want	I often only know what I want as the result of a situation
When I decide on a goal, I stick to it	I can change a goal again at any time
<i>Loss-based selection</i>	
When things don’t go as well as before, I drop some goals to concentrate on the more important ones	When things don’t go as well as before, I wait for better times
When something gets increasingly difficult for me, I define my goals more precisely	When something gets increasingly difficult for me, I try to distract myself
When something gets increasingly difficult for me, I consider which goals I could achieve under the circumstances	When something gets increasingly difficult for me, I accept it
<i>Optimization</i>	
I think about exactly how I can best realize my plans	I don’t think long about how to realize my plans, I just try to
When something is important to me, I don’t let setbacks discourage me	Setbacks show me that I should turn to something else
I make every effort to achieve a given goal	I prefer to wait for a while and see if things will work out by themselves
<i>Compensation</i>	
When things don’t go as well as they used to, I keep trying other ways until I can achieve the same result I used to	When things don’t go as well as they used to, I accept it
When something in my life isn’t working as well	When something in my life isn’t working as well as it used to, I decide what

(continued)

Life Management Through Selection, Optimization, and Compensation, Table 2 (continued)

SOC-related (“target”) behavior	Alternative behavior
as it used to, I ask others for help or advice	to do about it myself, without involving other people
When it gets harder for me to get the same results I used to, I keep trying harder until I can do it as well as before	When it gets harder for me to get the same results I used to, it is time to let go of that expectation

For examples of selection, optimization, and compensation processes in the health domain (an important goal domain for older adults), see Table 1; for examples of questionnaire items that are typically used to measure selection, optimization, and compensation processes, see Table 2.

Although the selection, optimization, and compensation can be considered individual processes of developmental regulation, they need to be coordinated over time in order to successfully manage gains and losses over the life span. In fact, most developmental processes entail all three components. For instance, older adult osteoarthritis patients have to been shown to restrict their activities (loss-based selection), practice certain movements (optimization), and use aids (e.g., a walking aid; compensation) in order to manage their condition (Gignac et al. 2002).

From this perspective, goals can be considered building blocks of development. Goals are states a person (personal goals) or group (social expectations or cultural values) deems desirable or undesirable, as well as the means to achieve (or avoid) them. They organize and structure behavior over time and across situations into hierarchical action sequences of setting and pursuing goals (Freund and Riediger 2006). In line with this approach, the SOC model posits that developing and committing to a set of personal goals (elective selection) and engaging in goal-directed actions and means (optimization) contributes to achieving higher levels of functioning. Intensifying or substituting means in order to maintain a goal in the face of loss in goal-relevant means (compensation) or reconsidering and reconstructing one’s goals or adapting goal standards (loss-based selection)

contributes to managing losses and maintaining functioning.

For instance, social expectations are not restricted to the content of goals (e.g., founding a family in young adulthood) but also include the process of selecting these goals (e.g., the “right” way of finding a partner). Social expectations can directly influence behavior and also which goals a person selects and pursues at a certain age (Freund 2007). Social expectations channel goal selection and pursuit into certain paths, but they also often indicate the availability of resources to pursue and achieve them. For instance, the expectation to retire from work at a certain age is in most industrialized western societies accompanied by laws and regulations that provide a pension securing a certain standard of living when stopping to work at a specified age. In this way, setting and pursuing goals in line with social expectations can foster development. However, the SOC model holds that goals are not only determined by social expectations but also by individual values, preferences, motives, as well as skills and internal and external resources available to the individual. These individual characteristics lead to variability in the content and timing of personal goals and in the way people pursue them. However, despite the variations in the expressions of goal setting and pursuit, the SOC model maintains that the processes of selection, optimization, and compensation are general across different societal and cultural contexts and individuals. The following section describes how SOC develops and contributes to successful development across the life span, with a focus on old age.

SOC in Adolescence

Understanding intra- and interindividual changes in the orientation toward growth, maintenance, or loss minimization across the life span is necessary for the study of self-regulation at any one period. In other words, a person’s behavior or development during any one period cannot be properly understood outside of the context of their preceding or proceeding periods. Therefore, to contextualize the development of the use of SOC

processes in old age, we must first understand the development of SOC processes at earlier periods in the life span. For these reasons, theoretical and empirical work on the SOC model has recently extended into adolescence young adulthood.

The majority of this work has been conducted through the 4-H Study of Positive Youth Development, a multiyear longitudinal study conducted in the United States (e.g., Bowers et al. 2010). Comprised of data from over 7,000 youth from over 40 states collected roughly annually for 9 years, the 4-H Study assessed predictors of thriving in adolescence, including self-reported levels of SOC behaviors. In general, this research has produced three key findings. First, evidence suggests that selection, optimization, and compensation processes are not well differentiated in early adolescence (Gestsdóttir and Lerner 2007). In other words, youth aged 10–11 years report, on average, that they either consistently use or do not use selection, optimization, and compensation in their goal pursuits. Selection, optimization, and compensation processes only seem to typically differentiate (that is, adolescents can be strong in one, but weak in the other) from age 12.

A second key finding indicates that across adolescence, greater use of SOC behaviors is associated with adaptive functioning across a variety of domains (e.g., academic, general life satisfaction). After differentiation, self-reported levels of optimization and compensation, in particular, seem to be strongly associated with positive outcomes. These results have informed a variety of interventions that aim to promote the development of SOC processes in adolescence through mentoring services or youth groups.

Third, some work suggests that there are age-specific variations in adaptive use of SOC processes among adolescents. Compared to older adulthood, adolescence is a period of marked developmental plasticity, where myriad trajectories or outcomes are possible. In this light, it may be less adaptive for some to make highly selective, focused investments in a small number of goals. In this way, low levels of elective selection may result in some adolescents' greater benefit, allowing them exploring a diverse range of potential developmental potentialities (Napolitano

et al. 2011). Conversely, high levels of elective selection in some youth could result in their foreclosing on potential opportunities. Future work on the development of SOC in adolescence will need to focus on identifying the particular constellations of SOC processes that are most adaptive for youth in a diverse range of contexts.

SOC in Young and Middle Adulthood

During adulthood, the two life domains of work and family are pivotal (e.g., Wiese et al. 2000, 2002). Most young adults invest a great deal of time and effort into building their professional careers and, at the same time, into establishing a stable partnership and raising children. These life domains can be highly demanding well into middle age and neither of them can be postponed into older adulthood. Not surprisingly given the many demands middle-aged adults face, the self-reported frequency of implementing SOC strategies is highest in middle adulthood compared to younger or older adulthood (Freund and Baltes 2002). Given these increasing demands, it is not surprising that the use of SOC strategies helps to manage the simultaneous demands of work and family and contribute to successful development in middle adulthood (Wiese et al. 2000, 2002). More specifically, over the period of 2 years, use of SOC strategies did not only predict increases in general subjective well-being but also an increase in subjective success in the work domain and job satisfaction. Put differently, adults who develop a clear set of goals and build a goal hierarchy (selection), who acquire and invest goal-relevant means into the pursuit of the selected goals (optimization), and who substitute goal-relevant means that are no longer available or increase their efforts after a loss (compensation) also show higher levels of subjective developmental success over time.

There is evidence that the SOC is especially beneficial when demands are high and resources in the work environment are low (e.g., low supervisor support; Young et al. 2007). The use of SOC strategies in the work domain is associated with a focus on opportunities, for example, how many

new goals, options, and possibilities one has in one's personal future at work, which can be seen as a criterion of successful aging at work (Zacher and Frese 2011).

Young and middle adulthood is also the time when most people start a family. Raising children and care for a family is demanding in terms of time and energy, the very same resources needed to successfully establish and consolidate a professional career. Thus, pursuing goals in the work and the family domain simultaneously (as is typical for many adults) can lead to goal conflict due to competing demands drawing on the same limited resources. Goal conflicts are associated with lower subjective and affective well-being as well as psychosomatic complaints (Freund et al. 2013). Successful development in middle adulthood, then, critically involves selecting goals in the different life domains in a way that they minimize conflict and maximize facilitation. One obvious strategy – namely to be selective regarding the number of goals one pursues – is difficult in middle adulthood, given that both life domains are of central importance to most people. In other words, many adults cannot simply postpone work goals in favor of family goals, or vice versa. Not surprisingly in this light, younger and middle-aged adults report more goal conflict and less facilitation than older adults (Riediger et al. 2005). However, this age-related difference does not seem to be due to restricting oneself to fewer goals but instead to another facet of selection, namely to focusing on similar and central goals (Riediger and Freund 2006). Focusing, in turn, is related to lower goal conflict and also seems to contribute to the maintenance of goal involvement in older adults.

Evidence suggests that combined use of all SOC strategies helps to reduce goal conflicts between work and family. SOC behaviors in the work and in the family domain are associated with fewer stressors in these domains (Baltes and Heydens-Gahir 2003). To experience fewer stressors is, in turn, associated with lower conflicts between work and family.

Taken together, the existing literature suggests that the use of SOC strategies in adulthood helps to successfully pursue goals in core life domains such as work and family and helps to reduce

conflict. Given the importance of managing multiple goals during this phase of the life span, the use of SOC strategies in general – and of focusing as one facet of selection in particular – can be considered essential for successful development across adulthood. Note that SOC is not a model that was developed to address the question of how to solve work-family conflicts. Instead, it is a general theoretical framework of development across the life span and across different levels and domains of functioning. The topic of work-family conflict was chosen as one area of inquiry as this conflict emerges because multiple highly demanding developmental tasks have to be pursued during a time of limited resources, a situation in which the use of SOC strategies should help to manage.

SOC in Old Age

There is considerable research on the use of SOC strategies in old age. Studies by Freund and Baltes (2002, 1998) demonstrate that SOC is associated with higher levels of subjective indicators of successful aging such as subjective well-being, positive emotional experience, loneliness, and satisfaction with aging. The pattern of correlations is stable and robust from mid adolescence across adulthood into old and very old age (the oldest participants in these studies were centenarians). Similar to the findings that the SOC strategies are particularly useful in demanding situations in young and middle adulthood (Young et al. 2007; Zacher and Frese 2011), in old and particularly in very old age, SOC strategies buffer against negative effects of restricted resources (Jopp and Smith 2006). Comparing resource-rich and resource-poor older adults longitudinally replicated the results that SOC can protect against the negative effect of declining resources in old age.

Does the Importance of the Three SOC Strategies Change with Age?

Given the dramatic shift in the ratio of gains to losses over the life span from a predominance of

gains in younger ages toward more and more losses in older adulthood, it is not surprising that older adults appear to be more oriented toward the maintenance of functioning in the face of losses (compensation) compared to younger adults who are more oriented toward achieving gains (optimization) (Heckhausen 1999). Ebner et al. (2006) demonstrated this motivational shift in the orientation of personal goals and provided evidence for its adaptiveness: For middle-aged and older adults, an orientation toward maintenance is positively related to subjective well-being, but an orientation toward loss avoidance was negatively related to subjective well-being in younger adults. Moreover, a set of experimental studies showed that older adults are more persistent when pursuing a goal that is oriented toward compensating for a loss, whereas younger adults are more persistent when pursuing gains (optimization) (Freund 2006). The shift in orientation from a predominant focus on optimization goals in young adulthood toward a stronger focus on compensation goals in older adulthood might help younger adults to achieve gains and increase resources and prevent declines in functioning and contribute to the maintenance of functioning in old age.

A different approach to investigating the role of SOC for successful aging uses the dual-task paradigm where people have to perform more than one task at the same time. A comparison of the performance on one task with the performance on both tasks simultaneously (i.e., dual-task costs) can provide insights into how people allocate limited resources. Given the overall decline in resources in the late periods of the life span, older adults should become more selective in their resource allocation and prioritize the task that has higher immediate importance. For instance, when performing a memory task and a balance task at the same time, older adults should focus more on keeping their balance than on memorizing a word list. Falling might cause serious health-related problems threatening their mobility, whereas forgetting a word typically does not have such severe consequences (Lindenberger et al. 2000). In fact, a set of studies combining a cognitive and a motor balance task

supported this hypothesis (Li et al. 2001; Rapp et al. 2006): Older adults allocated more resources into keeping their balance than into the cognitive task. Moreover, in keeping with the increased importance of compensation in old age, older adults invested more compensatory means into the maintenance of keeping their balance, and they profited more from them than younger adults. Taken together, studies using the dual-task approach support the usefulness of selectively investing resources into more vital goals, and this is particularly the case when resources are limited as is the case in old age.

Summary and Conclusions

Successful aging can be defined as the process of simultaneously promoting gains and preventing losses across the life span. The processes of selection, optimization, and compensation (SOC) seem to be central for this process across the life span and into old and very old age. Delineating and committing to important goals (selection) focuses limited resources on a subset of possible alternative goals and thus allows effective optimization. Equally important are processes geared toward counteracting losses in resources that occur particularly in old age. Processes aimed at maintaining functioning in the face of losses are loss-based selection (i.e., restructuring and adjusting one's goals to the available resources) and compensation (i.e., acquiring and investing the remaining resources into the maintenance of functioning).

SOC seems to develop from a fairly undifferentiated global process in childhood into a more differentiated and elaborated structure of three interrelated yet distinct processes in adolescence and across adulthood. The emphasis of achieving new gains and increasing one's resources at younger ages shifts to a stronger focus on maintenance and avoiding losses in older adulthood. This shift seems adaptive both for subjective well-being as well as for persistence in goal pursuit.

Self-report studies have shown that the use of SOC contributes to subjective and affective well-being across the life span and into old and very old

age. In addition, studies using the dual-task paradigm provide evidence that older adults allocate their resources primarily to functional domains of high importance when resources are limited. More generally, several studies have shown that engaging in SOC is particularly useful when the demands of a task are high and/or resources are strongly limited also in younger age groups. In sum, then, there is strong empirical evidence that selection, optimization, and compensation processes are associated with successful development and aging.

Outlook

Is self-report the best way to measure SOC? Do we need external observation and are there biological indicators of SOC? Is optimization the same for a 15- and a 105-year-old, are selection and compensation? There are only very few studies that address these important questions. The self-report measure of SOC (Gestsdóttir and Lerner 2007; Napolitano et al. 2011; Wiese et al. 2000, 2002; Freund and Baltes 2002, 1998) allows use of the same items across adolescence and adulthood into old age. However, the specific goals and goal-related behaviors associated with SOC depend on the functional domain and, most likely, also on the life phase under consideration. Whereas a 15-year-old adolescent typically still has to develop career goals, commit to them, and then pursue them over the period of years and decades, the 85-year-old retiree typically does not. Conversely, a 15-year-old adolescent is unlikely to be confronted with losses in sensory functioning and does not have to engage in behaviors helping to compensate for these losses. This makes it difficult to directly compare the frequency and intensity of SOC-related behaviors across the life span.

Designs such as observing the use of compensatory and optimizing means in a dual-task paradigm in different age groups (Lindenberger et al. 2000; Li et al. 2001; Rapp et al. 2006) or the use of experimental designs to study the processes underlying age-related differences (Ebner et al. 2006; Freund 2006) are certainly needed to

complement the still dominant self-report approach. Moreover, the use of intensive assessments of SOC in everyday life using experience sampling methods will help to further understand how much people of different ages and in different contexts use and profit from SOC-related behaviors.

Finally, investigating the limits of the usefulness of SOC (such as over-selection, neglecting important goals by focusing too much on a subset of goals; over-optimization, exhausting one's resources in order to achieve a certain goal or standard at the expense of other goals or sustainability; or overcompensation, maintaining a goal in the face of losses instead of flexibly adjusting one's goals when the compensatory strategies are too costly to be maintained over time) will help to better understand the constraints of these processes.

Definition

Life span developmental psychology examines patterns of change and stability in psychological characteristics across the life course. The field focuses on both intraindividual ontogenesis (i.e., development within an individual) and interindividual differences in developmental trajectories.

Life span developmental psychology is concerned with understanding continuity and change in psychological characteristics across the life course. The central questions addressed by the field focus on intraindividual ontogenesis (i.e., development within an individual) as well as interindividual differences in developmental trajectories. Life span developmental psychology focuses on development in cognition, emotion, personality, and social interactions while acknowledging neurobiological, environmental, societal, and cultural contexts. It covers the entire life course from infancy to old age, but, given the context of this volume, this entry focuses predominantly on adulthood and aging.

This entry begins with a description of several key controversies relevant to the study of life span development as well as a brief historical overview of the field, including a summary of early theories of human development. This overview is followed by a description of prominent contemporary theories and common methodological approaches used to study intra- and interindividual continuity and change across the life span. The entry concludes with remarks on future directions for theory and research.

Key Controversies

Several key controversies regarding developmental change have been important to the study of adulthood and aging. One of the most prominent issues centers on the relative influence of *nature* (i.e., hereditary, genetic, and biological factors) versus *nurture* (i.e., environmental factors and experience) on psychological development.

A second theoretical question concerns whether psychological development is *continuous*

or *discontinuous*. On the one hand, theories that accept the continuous perspective contend that developmental processes occur gradually over time. Stage theories, on the other hand, propose that development occurs as a series of phases characterized by distinct patterns of behavior, cognition, or emotion with abrupt transformations or discontinuities between stages. Some stage theories further contend that such phases follow a specific sequence and that the transition from one stage to the next is irreversible.

A related controversy revolves around whether developmental change is best conceptualized as *quantitative* or *qualitative*. Whereas quantitative change refers to specific amounts or degrees of change in a given characteristic (e.g., decline in information processing speed in later life), qualitative change refers to categorical changes in behavior, thinking, or attitudes. For example, a toddler who lacks the ability to take the perspective of others is qualitatively different from a child who understands that other people have beliefs and desires that differ from his or her own.

While early theoretical perspectives tended to show strong polarization along these fault lines, most present-day scholars adopt a more balanced perspective emphasizing the reciprocal influence between nurture and nature over the course of development and acknowledge that psychological development encompasses both quantitative and qualitative changes and may progress stepwise or continuously, depending on the domain of development and point in the life span under consideration. To appreciate the historical roots of contemporary perspectives, it is nonetheless useful to consider early theoretical accounts of developmental psychology.

Historical Perspective and Early Theories of Development

Among the first to publish on life span development was the German scholar Johann Nikolaus Tetens with his contribution, *Menschliche Natur and ihre Entwicklung* (Human Nature and Its Development, 1777). It described human development as a lifelong process of gains and losses that is

both embedded in and refined by societal and historical contexts. In many respects, this perspective foreshadows modern conceptualizations of life span development, although, until recently, Tetens' early contributions were not fully recognized (Muller-Brettel and Dixon 1990).

It was more than a century later that the study of human development began to take shape in the United States. At the turn of the twentieth century, theory and research predominantly focused on child development. One of the most influential and formative early approaches to studying development was the psychoanalytic perspective. According to this view, as people move through developmental stages, they confront conflicts between social expectations and biological impulses. Only through the successful resolution of each conflict can individuals move on to the next stage.

Two of the most widely recognized psychoanalytic theories are Sigmund Freud's psychosexual theory (Freud 1957) and Erik and Joan Erikson's psychosocial theory (Erikson 1968). Whereas Freud focused on the formative role of sexual and aggressive impulses in the early years of life, the Eriksons' focused on people's identity and relationship issues over the life course. Perhaps most importantly, they rejected Freud's view that psychological development ends at age 5. Instead, they delineated the phases of development across the life span from birth to late adulthood (although the majority of the proposed stages still focused on early life) and argued that normal development must be understood in within a cultural context.

While psychoanalytic approaches tended to focus on the development of personality, emotion, and interpersonal processes, the influential work by Jean Piaget in Switzerland emphasized successive stages of cognitive development emerging from an interplay between biological maturation and experience (Piaget 1936). However, his model ended with attainment of the formal operational stage in adolescence and did not speak to development in young adulthood and beyond.

A radically different perspective on psychological development was conveyed by behaviorism (Watson 1914a) which also emerged in the early 1900s and exerted a dominant influence on psychological research by the middle of the twentieth

century, especially in the United States. It contended that behaviors and actions are determined by experiences, not inborn traits or heredity. In North America, behaviorism began with the work of John Watson, who was inspired by Russian physiologist Ivan Pavlov's studies of animal learning (Pavlov 1927). Watson is best known for his research on children's behavior and classical conditioning, a type of learning that involves involuntary responses outside of one's conscious control (Watson 1914b). Extending the behavioral principles set forth by Watson, B.F. Skinner's operant behavior theory (Skinner 1938) proposed that behavior can be increased through reinforcement (e.g., food, praise) or extinguished through punishment (e.g., removal of privileges). Rather than viewing human development as an age-graded phenomenon like the psychoanalytic approach and Piaget's concept of cognitive stages, behaviorists contended that the same principles of reinforcement learning shape human behavior from infancy to old age. Nonetheless, a disproportionate emphasis was placed on the formative effect of early learning experiences (Watson 1914b).

Toward the middle of the twentieth century, the field began to extend beyond the earlier focus on child development toward the later part of the life span. Notable advancements were made by German researcher Charlotte Bühler whose book *Der menschliche Lebenslauf als psychologisches Problem* (The Course of Human life as a Psychological Problem, 1933) presented a model of adult psychological development supported by biographical data collected from middle-aged adults.

Soon thereafter, theoretical perspectives and empirical research on later life development began to take shape. This process was fostered by the establishment of key professional associations including the Gerontological Society of America (est. 1945) and the "Division of Adulthood and Aging" of the American Psychological Association (est. 1946). As the founder and first president of the Division, Sidney Pressey encouraged empirical investigation of later life development while emphasizing the clinical relevance of behavioral research. Along with two of his students, Pressey coauthored the text *Life: A Psychological Survey*

(Pressey et al. 1939), a pioneering effort to educate young psychologists about the full life span, including midlife and beyond. Such efforts were bolstered by the launch of large-scale longitudinal studies such as the Baltimore Longitudinal Study of Aging (BLSA, est. 1958) under the leadership of Nathan Shock in the United States and the Bonn Longitudinal Study on Aging (BOLSA, est. 1965) spearheaded by Hans Thoma, which sought to investigate interindividual differences in physiological, psychological, and social variables and their implications for longevity.

Although some attempts were made to advance a life span developmental approach, much of the resulting theoretical advances focused selectively on aging. The first formal theory of aging, *disengagement theory* [1961], was proposed by University of Chicago researchers Elaine Cumming and William Henry. In their book, *Growing Old: The Process of Disengagement*, they argued that normal aging involves gradual withdrawal and disengagement from society (Havighurst 1961). They further reasoned that older individuals and society mutually and gradually sever ties so that the social system remains intact once the individual reaches death. In opposition to this perspective, Robert Havighurst argued that there is no psychological or social need for older people to become isolated or withdrawn. Instead, he proposed an alternative theory of optimal aging, *activity theory* (Baltes and Baltes 1989), which contends that when older adults stay active and maintain their social relationships into their later years, they age successfully.

As an elaboration of activity theory, *continuity theory* (1971) was proposed by Robert Atchley to distinguish normal aging from pathological aging. He believed that continuity is an adaptive strategy which allows individuals to prevent or minimize the effects of aging through internal (ideas, personality, emotions) and external continuity (environment, roles, activities). For example, continuity of interpersonal relationships preserves social support, continuity of physical activities allows individuals to minimize degenerative health effects of growing old, and continuity of personality upholds unique characteristics of the individual.

These formative theories of aging laid the groundwork for a broader expansion of the field

in the 1980s and 1990s. In those decades, scholars reevaluated the traditional concept of maturational development as a linear construct and instead proposed that adaptive change across the life course is both multidimensional and multidirectional (Baltes 1987). Extending from this notion, theoretical models began to acknowledge ontogenetic development as the dynamic interplay of gains and losses, which set the stage for subsequent theories to consider age-related changes in motivation, emotion, cognition, and personality as well as the broader social and environmental contexts of human development.

Contemporary Perspectives

Contemporary perspectives on life span development vary in the degree to which they address the life span as a whole as opposed to the aging process in particular. They also differ in the proposed mechanisms of development and in their general scope, with some perspectives covering a broad range of domains while others focus on select aspects of functioning. The following overview moves from domain-general frameworks to models targeting specific domains of development.

Meta-theoretical Frameworks

The Life Span Perspective. The Life Span Perspective is an overarching meta-theoretical framework that guides much of contemporary research in life span developmental psychology. Developed by researchers Paul and Margret Baltes and their colleagues (Baltes et al. 1977, 1980; Baltes 1997), it postulates the following key principles of human development.

The first principle contends that development is a *lifelong process* ranging from birth to death with no specific life stage taking precedence over others. At all life stages, both continuous (cumulative) and discontinuous (qualitatively distinct) processes are at play.

A second core assumption is that development is *multidimensional*, with an interplay of external and internal factors influencing development across multiple domains of functioning, and it is *multidirectional* in that developmental trajectories

may involve increments, decrements, or stability in functioning.

Extending the premise of multidirectionality, the third principle asserts that developmental *gains and losses* are present throughout the life span. According to this assumption, no process of development consists exclusively of growth or decline. Instead, both gains and losses vary according to systematic age-related changes.

Fourth, development shows *plasticity* in that there are multiple possible trajectories within a given individual. This assumption challenges traditional beliefs that development follows a fixed course. Although the Life Span Perspective concedes that certain genetic prerequisites may limit the scope of biological plasticity, unfavorable developments may be overcome by appropriate interventions.

The final principle proposed by the Life Span Perspective is that development is embedded in a *sociocultural and historical context* which may steer individuals toward or away from certain types of pathways. Therefore, developmental trajectories may vary by historical and cultural conditions.

With regard to contextual influences (Baltes et al. 1980), life span theory distinguishes among *normative age-graded factors* that exert a similar effect on all persons within a given age range (e.g., mandatory retirement age), *normative history-graded factors* that selectively affect the individuals living within a given generation or historical period (e.g., World War II), and *nonnormative factors* that are distinctive for each person and not tied to an age or birth cohort (e.g., accidents).

In combination, the tenets of life span theory imply that human development results from a *biocultural coconstruction*, an interplay of biological, psychological, and sociocultural factors. Following from this notion, research on life span development should ideally take a *multidisciplinary approach*, suggesting that life span psychologists may benefit from collaborating with neuroscientists, anthropologists, sociologists, or historians.

Selection, Optimization, and Compensation. Although the Life Span Perspective asserts a

co-occurrence of gains and losses throughout the life span, it acknowledges a shift toward a relative preponderance of developmental losses in later life. Specifically, genetic advantages associated with evolutionary selection are thought to become less salient in later life, and therefore, individuals must draw upon culture-based processes (cognitive skills, socialization strategies) to maintain a high level of function (Baltes 1987).

The conceptual framework of Selective Optimization with Compensation (Baltes and Baltes 1989; Baltes 1997) proposes that individuals adapt to developmental losses by selecting specific domains for which they optimize functioning while simultaneously compensating for deficits in other areas of life. Although Selective Optimization with Compensation was originally developed as a domain-general model, it has since been adapted for a range of domains and contexts, some of which are highlighted in subsequent parts of this entry.

The Ecological Systems Perspective. Dovetailing with the emphasis on sociocultural context inherent in the Life Span Perspective, contemporary sociological models of human development emphasize the external environments and conditions in which an individual grows and matures. In his Ecological Systems Perspective (Bronfenbrenner 2000), Urie Bronfenbrenner proposed that development occurs through a set of interactions between the individual and his surrounding environment. Specifically, his theory focused on nested environmental systems: microsystems (immediate interactions within a specific setting), mesosystems (interactions across multiple microsystems), exosystems (interactions of a person's microsystems with external settings), and macrosystems (cultural and societal factors). More recently, the chronosystem was added to capture relevant changes in subsystems over time.

The Successful Aging Perspective. Whereas the Life Span and Ecological Systems Perspectives emphasize the mechanisms and processes underlying life span development, contemporary research has also been informed by Rowe and Kahn's model of successful aging (Rowe and Kahn 1997), which emphasizes a specific set of

outcomes. Refuting the long-standing belief that aging successfully is simply the absence of disease, this model postulates three characteristics that define successful aging: (1) absence of disease and disability, (2) high physical and psychological functioning, and (3) active social engagement.

Domain-Specific Theories

Guided by the broad meta-theoretical frameworks described above and informed by a growing body of rich longitudinal datasets, the last two decades have seen the emergence of a new generation of life span developmental theories. These models move beyond a selective focus on old age and an emphasis on age-related losses to explain the mechanisms that allow individuals to maintain adaptive functioning across the adult life span.

In particular, these domain-specific models have focused on four key areas of psychological development: cognition, motivation, emotion, and personality. The following sections present the chief contemporary perspectives in each of these areas.

Cognition

Fluid Versus Crystallized Cognition. The study of cognitive aging has traditionally categorized cognitive functioning into two types of abilities: *fluid* and *crystallized* (Salthouse 2010). *Fluid* cognition represents one's capacity for abstract reasoning, problem solving, and information processing and is characterized by the ability to think logically and analyze complex patterns and associations. In general, fluid cognition is reflected in one's short-term memory, spatial orientation, and information processing speed. In contrast, *crystallized* cognition is associated with general knowledge garnered through lived experiences and education and is demonstrated by one's verbal comprehension and social judgment. Important to the study of cognitive aging, crystallized abilities tend to remain stable or increase across the life span, whereas fluid abilities tend to decline from early adulthood onward.

Although the fluid-crystallized terminology is most commonly used, the two types of abilities

have also been described as *processes* and *products* (Salthouse 1998). The term *process* refers to the efficiency or effectiveness of processing at the time of the cognitive assessment and reflects one's ability to solve novel problems. *Products* are the cumulative result of processing carried out in the past and are demonstrated by one's acquired knowledge. Cognitive *processing* has been further delineated into *effortful* versus *automatic*. Whereas automatic processing requires little or no mental capacity, effortful processing requires substantial mental resources, which are employed consciously and deliberately. Importantly, research has shown pronounced age differences in effortful processing, which is thought to reflect declines in cognitive resources (Salthouse 1998) and reductions in processing speed (Salthouse 1996).

Processing Speed. Processing-speed theory, proposed by Timothy Salthouse (1996), contends that two distinct mechanisms underlie the relationship between speed and fluid cognition. The *limited time mechanism* proposes that the ability to perform later mental operations may be restricted by spending excess time on earlier operations. This mechanism is most relevant when processing time is limited by external constraints or when accuracy is affected by the number of operations that can be carried out in the allotted time period. The *simultaneous mechanism* comes into play when a mental operation requires the simultaneous integration of one concept with another. In such a case, processing deficits may occur if earlier mental operations take too long (or information is lost) by the time later processing is complete.

Sensory Deficits. Empirical evidence also suggests that cognitive deficits in later life are strongly correlated with deficits in hearing and vision (Li and Lindenberger 2002). According to the common cause hypothesis, such associations are due to broad neurodegenerative processes affecting both cognitive and sensory functioning. Alternatively, there may be cross-domain resource competition with cognition and sensation drawing on the same limited pool of attentional resources. Further research is needed to tease apart these possibilities, integrate them with other theoretical

perspectives, and identify strategies for intervention (Li and Lindenberger 2002).

Motivation

Contemporary perspectives have also begun to acknowledge the role of motivation in life span development, with growing agreement in the field that broad motivational priorities and specific goals vary systematically with age. However, specific theoretical perspectives disagree on the underlying mechanisms that drive such effects.

Life-Span Theory of Control. Drawing on the principles of selection, optimization, and compensation from Baltes' SOC framework, Heckhausen and Schulz (1995) proposed the life-span theory of control which asserts that selection and compensation are essential to optimizing life span development and that the individual is an active agent in controlling his or her developmental outcomes. Specifically, individuals are thought to master developmental challenges through *primary control strategies* (changing the environment and outside factors) and *secondary control strategies* (changing internal, mostly motivational, states). Although both strategies are proposed to steadily increase until midlife, primary control begins a slow and gradual decline in older adulthood. As primary control wanes in the later years, individuals are thought to call upon secondary control strategies to buffer the negative effects of losses in primary control.

Motivational Theory of Lifespan Development. Expanding on the life-span theory of control, the motivational theory of lifespan development (MTLD) (Heckhausen et al. 2010) proposes that adaptive development is defined by the extent to which an individual maintains primary control across multiple domains (e.g., work, family, health) and across the life span. MTLD further argues that the attempt to regulate one's developmental trajectory is organized around the pursuit of goals (through engagement and disengagement), a quest which enables individuals to take an active role in shaping their life course. In particular, MTLD emphasizes that opportunities for certain developmental goals wax and wane at various stages, which may be due to biological maturation (e.g., child bearing) or socially

constructed norms and expectations (e.g., school, career, retirement). MTLD also acknowledges that historical trends may influence the age-related sequencing of normative life course trajectories. Overall, MTLD proposes that as human societies continue to evolve, so will the timing of opportunities for developmental goal pursuit and in turn life course trajectories.

Growth Versus Maintenance Goals. A related perspective (Ebner et al. 2006) which also draws on the SOC model highlights the role of age-related shifts in the ratio of developmental gains versus losses. Young adults who experience a preponderance of gains are thought to prioritize growth-oriented goals, whereas older adults who are faced with accumulating losses of internal and external resources are thought to prioritize maintenance goals and prevention of losses. Consistent with this assertion, empirical evidence suggests that compared to younger adults, older adults are more likely to report maintenance and loss prevention goals than growth goals (Carstensen 1995).

Socioemotional Selectivity Theory. Socioemotional selectivity theory (Carstensen 2006) offers a complementary perspective. Whereas the theories discussed so far emphasize age-related losses in internal and external resources, SST suggests that age-related motivational changes reflect a proactive response to shifting time horizons. Specifically, SST proposes that whereas younger adults perceive their time horizons as expansive, future time is seen as more and more limited with advancing age. This shift in time horizons is thought to shape motivational priorities such that younger adults prioritize future-oriented goals such as information acquisition, career development, or social network expansion, whereas older adults prioritize present-oriented goals aimed at optimizing current well-being and maintaining close and rewarding relationships (Charles and Carstensen 2010).

Emotion

A growing body of research suggests that emotional well-being and functioning remain remarkably stable across the life span (Labouvie-Vief 2003). Given the preponderance of age-related

losses in other areas of functioning, this phenomenon has been termed the “paradox of aging” and a range of developmental explanations have been advanced. These accounts, including SST described above, agree that cognitive resources play a key role for emotional processing and regulation but vary in the proposed mechanisms by which this is thought to occur.

Dynamic Integration Theory. According to dynamic integration theory (Reed and Carstensen 2012), emotion regulation depends on two core elements, *optimization*, an automatic process of enhancing affect, and *differentiation*, a complex, conscious process of incorporating one’s own feelings and knowledge with the thoughts and feelings of others. Specifically, DIT proposes that as cognitive-affective complexity increases from adolescence to middle adulthood, the conscious mode of *differentiation* becomes prominent. However, as executive functioning declines with advanced age, the simpler, automatic mode of *optimization* takes priority. Overall, this age-graded shift is thought to be a compensatory process resulting from older adults’ limited cognitive capacity. As such, older adults are thought to experience increased positive affect, but also impaired regulation in situations that require deeper emotional exploration and analysis.

Motivated Cognition and the “Positivity Effect.” An alternative explanation for preserved emotional well-being in later life draws on the framework of SST and proposes that, because of the age-related shift toward present-oriented goals, older adults actively direct cognitive resources (i.e., attention, memory) toward positive and away from negative stimuli. This phenomenon, also known as the “positivity effect” (Reed and Carstensen 2012), has been interpreted as an example of *motivated cognition* (Mather and Carstensen 2005) in that cognitive control mechanisms are engaged to support a certain goal state (viz., emotional well-being) as opposed to equally processing all available information. In contrast to DIT, this perspective proposes that maintaining emotional well-being in later life is not the result of cognitive decline but rather requires the active allocation of cognitive resources.

Strength and Vulnerability Integration Model.

The strength and vulnerability integration (SAVI) model (Charles 2010) builds on prior theories to offer a more comprehensive understanding of variations in emotion regulation across the life span. It argues that aging is associated with both strengths (e.g., experience-based knowledge, focus on positive information) and vulnerabilities (e.g., limited cognitive resources, reduced ability to recover from physiological arousal). Depending on whether a given context allows individuals to capitalize on age-related strengths or brings out age-related vulnerabilities, older adults may experience better or worse emotion regulation than older counterparts. For instance, older adults do well when a potentially problematic interpersonal situation can be avoided but fare worse if a difficult interaction is inevitable (Goldberg 1990).

Personality Development

With regard to personality traits, most contemporary life span researchers have adopted some form of the big five model according to which personality traits can be described along the broad dimensions of neuroticism, extraversion, openness, agreeableness, and conscientiousness (Roberts et al. 2005a). Across a variety of cultures and birth cohorts, mean-level changes in personality generally show age-associated increases in agreeableness, conscientiousness, and emotional stability and decreases in openness to experience (Terracciano et al. 2005; McCrae and Costa 1999). Theorists also agree that personality becomes progressively more stable with age, although perspectives vary regarding the degree to which personality remains malleable in the later years and the factors that initiate personality change.

Five-Factor Theory. The five-factor theory (FFT) (Roberts et al. 2005b) proposes that endogenous personality characteristics are independent of environmental influences (e.g., life events, historical context, and culture). When change in basic traits does occur, it is thought to arise from a species-wide genetic predisposition, innate maturation, or changes in neurobiology (e.g., brain injury, dementia). According to FFT, dispositional

traits express themselves in interaction with contextual factors and form *characteristic adaptations* including goals, competencies, self-perceptions, and attitudes that may flexibly respond to age-graded changes in opportunity structures while the underlying system of basic traits remains comparatively stable.

Social Investment Theory. Social investment theory offers an alternative explanation of personality development across the life span (Lachman et al. 2015). Although this position acknowledges that genetic factors are important to personality development, it further contends that normative changes in personality may also result from transactional (social contact and interaction with others) and stochastic (randomly determined) factors, including life experiences and life lessons. This theory proposes that normative personality change is influenced by quasi-universal role investments (e.g., marriage, family, developing a career), and in turn, role expectations and contingencies set by the individual's social network promote a reward structure for appropriate behavior and personality change (i.e., becoming more agreeable, conscientious, and emotionally stable with age).

The Role of Life Stories and Personal Narratives. In recent years, McAdams and colleagues (McAdams and Pals 2006) have advocated a more comprehensive understanding of personality development, encompassing not only basic traits and characteristic adaptations but also personal narratives and life stories that situate the developing individual within its rich historical and cultural context. Their model outlines three levels of personality: (1) *dispositional traits* that constitute broad individual differences in behavior and feeling, but show general consistency across situations and over time, (2) *characteristic adaptations* (e.g., feelings, goals, and coping mechanisms) that change in response to certain situations and environments, and (3) *self-defining life narratives* that help to provide a sense of purpose, meaning, and identify. According to this perspective, all three levels are embedded within a social and environmental context, which in turn shapes personality development.

Limitations and Future Directions for Theory Development

Over the past century, the field of life span developmental psychology has evolved from examining ontogenetic change from a maturational perspective to conceptualizing human development as a multifaceted and dynamic process. Although theoretical models have shed light on the cognitive, motivational, and socioemotional features of development, there is still room for a stronger connection to individuals' environmental and cultural contexts.

By and large, contemporary theories have focused almost exclusively on intraindividual change and individual development, with a relatively weak connection to the individual's social or historical environments. Whereas the Life Span Perspective (Baltes et al. 1980) acknowledged the reciprocal influence of endogenous (internal) and exogenous (external) forces on an individual's development, specific theories tend to examine one feature (e.g., emotion regulation) with lesser connection to the individual's external environment, including cultural or historical contexts. Despite the early coevolution of life span psychology and life course sociology, a vast disconnect exists between these traditions (Cheng et al. 2015). As such, life span psychology remains individual focused, whereas sociology of the life course considers the individual within a social context.

Moreover, the preponderance of theoretical development and research has been conducted in the United States and Western Europe, both of which are individualistic cultures. Although some cross-cultural initiatives are being developed, as is the case in personality research, robust efforts are needed to systematically examine the extent to which contemporary theories extend to other cultural contexts, particularly collectivist cultures (Mayer 2003). As research begins to fill in these gaps, a broader understanding of the limitations of current theories will likely become evident.

One theoretical perspective which is well suited to address these gaps was originally developed for studying child development:

Bronfenbrenner's Ecological Systems Perspective (Cumming and Henry 1961). As described earlier in this chapter, Bronfenbrenner's model focuses on four environmental systems: microsystems, mesosystems, exosystems, and chronosystems. This framework could be used to examine a variety of research contexts, including end-of-life or treatment decision-making in medical settings (proximal processes within a microsystem), intergenerational relationships and caregiving in later life (mesosystem), community health services and senior centers (exosystem), cultural or ethnic differences in the perception of death and dying (macrosystem), or bereavement after a spouse's death (chronosystem).

Moreover, this theory could inform testable hypotheses concerning individuals nested within environmental systems. For example, the ecological model could be used to examine the impact of social isolation (lack of mesosystem and exosystem support) on older adults' psychological health and well-being (microsystem) or to develop elder law and policy (macrosystem) to benefit proximal systems, including assisted living home environment (mesosystem) and health services (exosystems).

In addition to theoretical developments, the recent advent of novel technologies, including functional imaging (fMRI) and neuroendocrine sampling (e.g., salivary cortisol), has offered new opportunities to combine neurological, physiological, and psychological data and ultimately gain insight into the relationships among these processes and how they may change across the life span. For example, as part of the Midlife in the United States (MIDUS), a national longitudinal study of health and well-being, researchers have begun to integrate self-report data (e.g., questionnaires) with biomarker (e.g., cardiovascular, neuroendocrine, inflammatory, musculoskeletal) and cognitive and affective neurological data (e.g., brain images and functioning). In combination, these assessments offer a comprehensive understanding of links between biological and psychosocial aspects of development. In addition, the longitudinal nature of this dataset offers a

unique opportunity to examine the relative influence of earlier (developmentally *distal*) and later (developmentally *proximal*) experiences on subsequent functioning and adjustment (Cheng et al. 2015). This line of inquiry is especially valuable given that lack of differentiation between proximal and distal influences has been a key limitation in prior research.

Conclusion

Over the past century, great advances have been made in the field of life span developmental psychology. Several key controversies have been particularly influential in advancing theory development and challenging scholars to consider whether life span development is (a) the result of *nature* or *nurture*, (b) a *continuous* or *discontinuous* process, and (c) conceptualized as *quantitative* or *qualitative*. Whereas formative theories focused primarily on child development from a maturational perspective, expansion of the field in the twentieth century led to a broader conceptualization of life span development as a multidirectional and multidimensional process, one that involves both gains and losses. In recent decades, researchers have considered age-related interindividual differences and intraindividual changes in cognition, motivation, emotion regulation, and personality. With robust expansion of theory and research over the past century, the field is now poised to chart new territory in cross-cultural and diverse socioenvironmental contexts.

Definition

Lifespan developmental psychopathology refers to pathological aging processes over the lifespan, including pathways to cognitive and affective disorders in old age as well as resources and resilience to maintain well-being in old age.

Introduction

Within the broader field of the psychology of aging, lifespan developmental psychopathology has a major focus on pathological aging, as indicated by mental health problems, dysfunctions, and disorders in adulthood and old age (Kessler et al. 2014). At the same time, lifespan developmental psychopathology considers individuals'

potential for normal and successful aging. It is important to integrate these two perspectives in order to understand and to deal with the enormous *heterogeneity* of mental health/mental illness in old age, as reflected in the coexistence of both highly vulnerable/mentally ill and highly resilient/healthy older individuals. For example, people over the age of 60 have the highest rates of suicide in almost two-thirds of the countries worldwide. Men over the age of 75 are the group most at risk. Moreover, among 90–100-year-olds, dementia has a prevalence of about 50%. At the same time, epidemiological research has consistently shown that older people have lower prevalence rates of depression and anxiety that fulfill the criteria of a mental health diagnosis than do young and middle-aged adults (Jorm 2000). Furthermore, there is a consistent cross-sectional and longitudinal evidence that levels of negative affect do not increase in the normal population of older and very old people, while life satisfaction and high-arousal positive affect (e.g., excitement) are stable and show only a small decline in very old age (Röcke and Brose 2013).

Mental Health in Old Age: A Lifespan Perspective

Aging from a Lifespan Perspective

According to lifespan developmental psychology (Baltes et al. 2006), individual aging is a lifelong and dynamic process driven by biological (e.g., basic cognitive capacity, physical health), socio-cultural (e.g., healthcare provisions, social relations, financial resources, social status), and psychological factors (e.g., coping strategies, knowledge, self-efficacy). Furthermore, it is assumed that aging individuals are, to a large extent, agents of their own development. In other words, human aging is shaped by the actions and reactions of the developing individual – herself or himself – while negotiating developmental challenges over the lifespan. In such a view, aging is an integral part of development that comes with growth and decline, as does every other life period. At the same time, some defining characteristics of the later phase of life deserve reflection

(Kessler et al. 2014). First, biological resources and capacities show a strong normative decline over the adult lifespan. With age, plasticity – as indexed by an individual’s change potential – decreases; furthermore, the genetic materials, associated genetic mechanisms, and genetic expressions become less effective. Increasing levels of multimorbidity, sensory impairment, and functional limitations lead to a growing gap between biological potential and individual-cultural goals. Theories of normal and successful aging assume that people continuously adapt to such changing biological requirements by allocating their resources primarily to maintenance and recovery, rather than to growth (as in childhood and early adulthood) (Baltes and Baltes 1990). Second, old age and particularly advanced old age are the culturally least-defined life periods, as compared to all other periods. There is a significant lag between the current potential of old age and the existing societal opportunity structures serving to unfold such potential. Third, the life period of old age has, by definition, the most cumulative “learning history,” which in the domain of personality development may come with normative advantages (e.g., a large repertoire of coping styles and compensatory strategies) and disadvantages (e.g., stable or even declining levels of openness to experience and self-insight) (Kessler and Staudinger 2010).

Defining Mental Illness/Mental Health in Old Age

According to prominent definitions of mental health, such as the World Health Organization (WHO) definition, mental health is usually defined as a state, without explicitly including development and aging. From a lifespan perspective, an older individual’s mental health can be defined as a unique configuration of biological, psychological, and sociocultural risk factors and protective factors having accumulated over the whole life course that is potentially reflected in various degrees of adaptive behavior (Kessler et al. 2014). Consequently, a lifespan perspective situates risk and protective factors of mental health *developmentally* (Fiske et al. 2009). A lifespan approach proposes that people across

the whole lifespan actively and purposefully select and create developmental contexts. Specifically, individuals define, prioritize, adjust, and possibly give up developmental aims and respective goal criteria, thereby contributing to their own mental health.

However, mental health is increasingly challenged by the “age unfriendliness” of the biological system. In addition, many decisions of individuals operate in kind of a “cultural vacuum.” Therefore, contexts such as social networks, the healthcare system, new media technology, and living environments are crucial elements of mental health in old age. As a consequence of such biological and sociocultural changes, aging individuals can only realize the potentials of mental healthcare measures if the health services for older people as well as specific training opportunities for healthcare professionals take those limitations into account (Kessler and Bowen 2015a).

Given the lack of sociocultural resources, biological losses, and potential accumulation of disadvantages, avoiding mental health distress and achieving well-being are the challenges for aging individuals. Mental illness occurs if the individual’s biological, psychological, and sociocultural deficits outweigh that individual’s resources, resulting in clinically significant problems that interfere with daily functioning and quality of life in old age. Mental health problems normally go along with subjective complaints, as well as behavior that deviates from social norms. Mental health disorders refer to a pattern of symptoms meeting established criteria for psychiatric diagnoses, as provided by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the *International Classification of Diseases* (ICD-10).

Despite these challenges aging individuals are faced with, subjective well-being remains relatively stable in representative samples (Ryff 1989). A balanced view of lifespan developmental psychopathology, thus, includes not only the abovementioned losses but also a range of personal, social, and biological resources that remain or increase during the aging process (Kessler et al. 2014). Concepts and processes of “positive” mental health are described in the next sections.

Major Concepts Underlying Lifespan Developmental Psychopathology

Resources and Resilience

The phenomenon that positive mental health remains relatively stable from adulthood into old age despite various challenges, ranging from daily hassles, gradual and normative age-related changes, and sudden, major life events (“well-being paradox of old age”), (Diener and Suh 1998) points to high levels of *resilience* for the majority of older individuals. Resilience refers to an individual’s positive adaptation to such adverse conditions using personal (e.g., coping strategies, knowledge), social (e.g., social relations, social status, institutional structures, financial resources), and biological resources (e.g., basic cognitive capacity, physical health) (Kessler and Staudinger 2010). More specifically, resilience is defined as the maintenance and/or reestablishment of a certain normative or pre-disruption level of psychosocial functioning in the face of stress, threat, and loss – both without *and* with the help of external interventions. It is determined by an individual constellation of resources on one hand and the specific demands of the stressor on the other hand. Within the lifespan developmental psychology literature, resilience has been researched as one form of positive plasticity, that is, an individual’s potential for positive change. Research on resilience in adulthood and old age can be roughly categorized as following one of two approaches (Kessler and Bowen 2015b). First, resilience in adulthood and old age has been studied concerning specific, age-related experiences (e.g., maintaining/regaining well-being after widowhood or retirement, regaining health after a major health event). Second, resilience in adulthood and old age has been studied concerning the aging process in general as an agglomeration of social, psychological, and biological challenges and declines. Indeed, it has been a fundamental goal of aging research to identify the antecedents of and processes underlying successful aging (e.g., maintained cognitive functioning, low levels of disease, high well-being, unusually long life) (Baltes and Baltes 1990).

Developmental Regulation

Models of psychosocial development have elaborated on the underlying dynamics behind positive mental health in old age. These dynamics address the overarching processes of developmental regulation across the lifespan. In classic stage models, development is conceptualized as a life-long task, reaching its end point only in advanced age; positive mental health is achieved as the end of an ideal trajectory. For example, Erikson (1994) described lifelong personality development as a series of eight characteristic, age-related, psychosocial crises. Successful solution of psychosocial crises in late adulthood is regarded as a prerequisite of positive mental health and requires an integration of two conflicting forces: ego integrity vs despair. Achievement of ego integrity is perceived as the final aim of lifelong development, including the ability to perceive continuity and meaning in life and to accept one’s own life as lived, including finitude, definitiveness, failure, and omissions.

Three models focus on self-regulation strategies that foster successful aging. According to the model of *selective optimization with compensation* (SOC) (Baltes and Baltes 1990), three strategies help people, as they age, become increasingly better at adjusting to losses and negative events. These strategies include selecting or adjusting one’s goals in order to decrease the discrepancy between the present situation and aspired goals, optimizing preserved skills, and compensating for losses by practical means. The *dual-process model of assimilative and accommodative coping* (Brandstädter and Rothermund 2002) focuses on selection and adaptation processes and differentiates between an “assimilative” strategy of changing the situation so that it conforms more closely with personal goals and an “accommodative” strategy of adjusting the goal to given situational constraints. The accommodative mode is particularly important in old age when aspired goals drift out of the person’s span of control and includes strategies such as disengaging from blocked goals, rescaling personal expectations to the given, or letting go of self-images that do not fit the actual self anymore. Going further,

socioemotional selectivity theory (Charles and Carstensen 2010) focuses on gains in emotion regulation strategies. As people age and perceive their restricted lifetime, they become more motivated to maximize positive affect and minimize negative affect, e.g., by attending to and remembering positive stimuli better than negative ones (compared to younger individuals) and by investing more time and energy in emotionally relevant relationships with significant others.

According to recent *models of autobiographical remembering* (Pasupathi et al. 2006), another form of developmental regulation is reminiscence because it allows autobiographical memories to be integrated into a coherent life narrative that supports stability of identity and emotion regulation in old age. Three broad forms or functions of reminiscence can be distinguished that all serve developmental regulation in old age, i.e., social, instrumental, and integrative functions (Westerhof and Bohlmeijer 2014). First, sharing personal memories can enhance emotionally relevant relationships and foster generativity by teaching about past experiences (social function). Second, recollecting previously applied coping strategies can help in present coping processes, and thinking about past positive memories is an important emotion regulation strategy (instrumental function). Third, reflecting on past experiences can stabilize one's sense of self, and integrating negative experiences into biography may help to increase well-being and make meaningful commitments in life, especially in times of change (integrative function). There is a rich literature, including cross-sectional and longitudinal studies, showing that these reminiscence functions are positively related to well-being in old age (Westerhof and Bohlmeijer 2014). Overall, a likely explanation for this positive effect of reminiscence is that it activates personal and social resources such as self-efficacy, coping, self-esteem, meaning in life, and supportive relationships. However, also impairing reminiscence styles can be found, such as ruminating upon negative experiences ("bitterness revival") or escaping from present problems into the glorious past ("boredom reduction"). These reminiscence styles, in their chronic and inflexible form, are

linked to maladaptation and mental disorders such as depression and anxiety (Westerhof and Bohlmeijer 2014).

Pathways of Lifespan Developmental Psychopathology

Given the multiplicative relationship among biological, psychological, and sociocultural factors, lifespan developmental psychopathology conceptualizes mental health and mental health problems as probable rather than determined and, as such, never fully predictable. Moreover, different etiological pathways can result in similar clinical syndromes and presentations (Kessler et al. 2014). As a simplified example, patients may develop depressive symptoms, following an accumulation of various stressful life events that started in childhood, or within the context of a physical or neurological illness in old age, together with a lack of social support. This observation corresponds to the paradigm of equifinality in lifespan theory (Baltes et al. 2006). For heuristic reasons and in line with central assumptions of developmental psychopathology, three pathways to psychopathology can be distinguished in old age, namely, chronic pathological processes persisting from earlier life periods, dysfunctional psychological reactions to normal aging, and mental health problems in the course of pathological aging of the brain (Kessler et al. 2014).

Chronic Pathological Processes Persisting from Earlier Life Periods

Mental health problems might start in the first half of life; are manifest in clinically relevant disorders during childhood, adolescence, or adulthood; and then persist into old age (typically labeled as mental health disorder "with early onset"). Within the ICD-10 and DSM-5, these mental health disorders are characterized as chronic or recurrent mental health disorders. Distinguishing between individuals who first experienced mental illness earlier in life and those whose first encounter with mental illness occurs in old age is an important heuristic in clinical practice and is supported by empirical research. This is well illustrated in the example of

depression in old age. There is consensus that the distinction between “late-onset” depression (arising in adults 60–70 years and older) and “early-onset” depression portends differences in etiology and prognosis. Those with early-onset depression are more likely than those with late-onset depression to have a family history of depression and are also more likely to have a higher prevalence of personality disorder or elevated scores on neuroticism (Brodaty et al. 2001). Those with late-onset manifestation of depression often show a history of cerebrovascular disease and symptoms of psychomotor retardation, anhedonia, and concomitant executive-functioning deficits (Fiske et al. 2009). Neurological findings, including white-matter hyperintensities or leukoencephalopathy, are reported as common among late-onset but not among patients with early-onset depression (Brodaty et al. 2001).

Dysfunctional Psychological Reactions to Normal Aging

The relatively high level of mental health and well-being in old age is well documented in a large body of empirical research. However, acute and chronic exposure to normative age-related losses or common events in old age can massively interfere with daily functioning and well-being. The loss of a romantic partner, retirement, or chronic illness are three examples of events that are considered to be common stressors that increase distress for older adults and set limits to resilience in a significant proportion of older people. Older adults who are widowed are at high risk of developing depression and/or anxiety disorders, according to a systematic review (Onrust and Cuijpers 2006). The percentage of people who reported symptoms meeting the criteria for major depressive disorder (MDD) a year following the death of the spouse was estimated at 16%, compared to the 4–8% observed in same-aged, non-bereaved sample. In the case of retirement, men who retire early may experience an elevated risk of depression, even though retirement is not associated with depression in the older population in general. Furthermore, chronic illness predicts changes in depressive symptoms in late life, with functional impairment probably accounting for

most of the association between chronic illness and depression. Notably, dysfunctional reactions to aging-related losses often do not fulfill the criteria of any particular nonorganic mental disorder (such as depression, anxiety, or post-traumatic stress disorder), but are rather subsyndromal. However, this might be due to the fact that health professionals have poor diagnostic practice with older adults, and the phenomenology of depression and other mental disorders differs somewhat compared to younger adults, but the criteria are based on young adult presentations (Hegeman et al. 2012).

Mental Health Problems in the Course of Pathological Aging of the Brain

Pathological processes in the aging brain can be – directly or indirectly – associated with mental health problems. The most prominent example of a late-life disease is AD, which is characterized by loss of neurons and synapses in the cerebral cortex and certain subcortical regions. Typical psychological symptoms of AD are short-term and long-term memory loss, confusion, irritability and aggression, mood swings, and problems with language. This disease typically does not become manifest until age 70, with the exception of the 5–10% of people suffering from “early-onset” AD (i.e., diagnosed before the age of 65) (Wernicke et al. 2000). After age 70, however, incidence increases markedly. Furthermore, lifespan developmental psychopathology addresses the psychological correlates and consequences of other age-related neurodegenerative conditions, such as Parkinson’s disease, as well as those of cerebrovascular events, such as stroke (going along with a broad range of cognitive, affective, motivational, and behavioral dysfunctions).

Uncovering Different Pathways in Clinical Practice

In clinical practice, it is a challenging task to uncover the different etiological pathways behind similar clinical presentations (Kessler et al. 2014). In the case of depression, for example, research has identified indicators that help to discern different developmental trajectories and causes. Depression following stroke is less likely to

include dysphoria and is more strongly characterized by vegetative symptoms than other forms of late-life depression (Fiske et al. 2009). Depression associated with Parkinson's disease (PD) is a milder form of depression and is associated with dysphoria and anhedonia less frequently than depression in older adults without neurological illness. Depression linked with vascular dementia, compared to depression linked with Alzheimer's disease (AD), is characterized by more vegetative symptoms, such as fatigue, muscular weakness, and weight loss. Moreover, pathological and normal aging processes cannot always be classified as distinct processes. For example, recent research has suggested that cognitive impairment is a continuum, starting with subjective cognitive impairment (SCI; no supporting objective evidence from neuropsychological testing or evidence of functional decline), moving to MCI, and culminating in full-blown dementia (Walters 2010). It is still unclear whether cognitive deficits observed in people with AD and other forms of dementia are exaggerated or accelerated versions of normal aging on this continuum. As another example, it is sometimes difficult in clinical practice to distinguish between normal grief, prolonged grief, and depression after the death of a spouse. Going further, late-onset mental health problems often cannot clearly be separated from vulnerabilities and dysfunctional dispositions in the first half of life. In line with the assumption of lifespan diathesis-stress models of depression (Fiske et al. 2009), certain types of childhood trauma continue to constitute risk factors for depression in old age, possibly moderated by alterations in the serotonin gene-linked promoter region. Notably, childhood trauma outweighed more proximal causes, such as widowhood, recent life events, or vascular and neurologic disorder. Finally, psychological dysfunction as a direct effect of pathological aging of the brain cannot be clearly distinguished from its indirect psychological effects, such as changes in social networks, financial resources, living environment, etc. For example, depression symptoms in the course of PD are regarded as an interaction between several vulnerabilities, including genetic factors, cognitive diathesis (e.g., ruminative and avoidant coping

styles), age-associated neurobiological changes, and stressful events in late life (Fiske et al. 2009).

A Lifespan Account on Mental Disorders: The Sample Case of Alzheimer's Disease

A research on AD illustrates the need of a lifespan account on mental health disorders in old age in terms of etiology and preventive measures. A comprehensive model of the development of AD and a causal treatment is not available yet, despite continuing progress in the understanding of the neuropathology of AD. However, the research has revealed several biological and psychological risk and protective factors across the lifespan that influence risk of developing AD (Forstmeier and Maercker 2009). The most well-established risk factors for AD and other dementias are old age, genetic susceptibility, familial aggregation (which is related to genetic susceptibility but also to common environmental exposure), and female sex. However, modifiable risk factors of AD are more important than those unmodifiable risk factors because they enable researchers to develop prevention strategies that may help people to maintain or enhance their cognitive health in older age and to prevent or postpone the development of dementia.

Vascular risk factors (e.g., hypertension, hypercholesterol, and smoking) and related diseases (e.g., diabetes mellitus, obesity) belong to the most important modifiable risk factors of AD. There is also accumulating evidence that they are risk factors for AD, if they are already present in mid-life (Luchsinger et al. 2005). These factors may play a causal role in AD by influencing neurodegenerative processes in the brain. Negative effects of vascular risk factors that begin in late life seem less evident. Findings also show that the risk of AD and dementia increases with the number of vascular risk factors (Luchsinger et al. 2005). Treatment of these conditions is thus an important target for the prevention of dementia.

Stimulating activities reflect lifespan aspects of the development of AD and, thus, are a psychologically very relevant category of risk/protective

factors. Activities that stimulate the brain lower the risk of AD, as a multitude of studies has shown (Forstmeier and Maercker 2009). Several types of activities have been in focus of research. Participation in cognitive activities (e.g., reading books and newspapers, writing, studying, doing crossword puzzles) in mid- to late life has the potential to lower the risk of AD (Wilson et al. 2002), although effect sizes of this relationship are only small in most studies.

Special variables reflecting cognitive activities are educational and occupational attainment (Caamano-Isorna et al. 2006). Although there is strong evidence that low education is a risk factor for AD, the mechanisms underlying this association are not yet clear. Most authors explain the protective effect of education in terms of cognitive reserve (Stern 2006): education is thought to stimulate underlying brain networks and make them more efficient and flexible. In individuals with higher cognitive reserve, the underlying brain pathology may not become clinically manifest until later because their brain networks are more capable or because different, intact networks are used to replace or bypass the disrupted networks. The idea of cognitive reserve implies that once the reserve is depleted past some critical threshold, the clinical symptoms of dementia emerge. As a consequence, individuals with higher cognitive reserve decline more rapidly after onset of symptoms because brain pathology has progressed to a larger degree until the point when the brain cannot tolerate the pathology any more. The most prominent cognitive reserve model (Stern 2006) assumes that there might be two processes by that cognitive reserve is implemented on a neural level: neural reserve and neural compensation. The former refers to cognitive processing in the normal aging brain that differs between individuals; the latter refers to different coping mechanisms with brain pathology once it emerges. However, the specific neural substrates of cognitive reserve are not fully understood so far. Other explanations of the association between education and dementia suggest that education is strongly linked with early life circumstances (e.g., socioeconomic status), motivational ability, or health behavior (e.g., nutrition and physical activity).

The association of participation in regular physical activities (e.g., walking, dancing, swimming) in mid- to late life and risk of AD is also strongly supported by research (Rovio et al. 2005). Several possible mechanisms may underlie this association, including reduction of vascular risk factors, promotion of brain plasticity and brain reserve, and general cognitive ability resulting in better health behavior.

Motivational processes, i.e., processes involved in goal setting and goal striving, are important for an active lifestyle. Important motivational processes are, for example, self-efficacy, i.e., the belief in being able to master difficult demands, and motivational self-regulation, i.e., the ability to motivate oneself to persevere in the face of difficulties during the implementation of goals. It has been proposed that motivational processes, beside cognitive and physical activities, contribute to a brain reserve that provides the individual with resilience to neuropathological damage (Forstmeier and Maercker 2008). This is supported by the results of a longitudinal study that has shown that occupation-related motivational abilities at mid-life reduce the risk of MCI by 35% (Forstmeier et al. 2012). The effect on the risk of Alzheimer's disease depends on the existence of an ApoE ϵ 4 allele, which was found to intensify the biochemical disturbances that are characteristic of AD including beta amyloid deposition, tangle formation, neuronal cell death, and synaptic plasticity. Mid-life motivational abilities were associated with reduced risk of AD in ApoE ϵ 4 carriers but not in noncarriers (Forstmeier et al. 2012). Two other studies support this finding using other measures of motivation-related concepts. Conscientiousness, i.e., the individual's tendency to act self-disciplined, thorough, and goal directed, was associated with a reduced risk of AD (Wilson et al. 2007). The purpose in life, which is associated with intentionality and goal-directed action that guides behavior, was related to a reduced risk of MCI and AD (Boyle et al. 2010). Finally, participation in regular social activities (e.g., going to the theatre, participating in social groups, visiting friends) in late life has also been shown to be related to risk of dementia (Wang et al. 2002). Several possible mechanisms

may underlie this association, including promotion of brain plasticity and brain reserve and emotional health resulting from fulfilling relationships. Thus, several psychological processes throughout life contribute to the development of AD. The case of AD illustrates the need of a lifespan account on mental health disorders in old age.

Practical Implications

As argued, a lifespan approach to psychopathology in old age is vital to both diagnostic and treatment considerations and should be included in treatment manuals of late-life mental disorders (Kessler et al. 2014). A defining feature of mental dysfunction and disorder in old age is deviance from normative behavior including its developmental history. This emphasizes the importance of understanding normal aging as well as cultural contexts when working with older adults with mental disorders. Furthermore, adequate assessment in geropsychological practice encompasses the use of multiple data sources from a variety of disciplines, including the whole bandwidth of biological, psychological, and social-environmental factors. In order to gain a full appreciation of the driving forces of aging, clinicians should assess both deficits and resources. Most importantly, a thorough assessment of the wide range of risk and protective factors clearly goes beyond a person's present deficits. Furthermore, the understanding of psychopathology that first emerges in later adulthood must consider a different set of influential factors as compared to psychopathology that has either intermittently or chronically been present for much of an individual's adult life. A lifespan-informed approach to psychopathology in old age also considers the possibility that mental health dysfunction is not the end point of an individual's development, but can rather be a precursor for a variety of pathological pathways, as well releasing a cascade of developmental growth. In the face of heterogeneity and etiological complexity, neither consensus on intervention aims nor means-end relationships can be taken for granted.

Treatment considerations in geropsychological practice should be strictly grounded in individual assessment – not only of symptoms and problems, but also of individual goals and aspirations. Development and implementation of intervention measures must proceed from a comprehensive understanding of individual lifelong goals, goal pursuit, and goal adjustment. In addition to individual diagnostic results, clinicians should have state-of-the-art knowledge of the range of lifelong plasticity in various mental health disorders, including organic as well as nonorganic mental health disorders. This is a key prerequisite to focus the treatment schema on either maintenance of psychological function (or even further growth), or at least on the attenuation and delay of symptom presentation. Lifespan-oriented prevention and intervention programs should be based on models of developmental regulation in order to promote aging individuals' resources across the whole life span.

In line with this reasoning, SOC-based psychotherapeutic interventions have, for example, recently been proposed as an effective tool to treat depression in older adults (Laidlaw and Kishita 2015); moreover, structured reminiscence interventions that helps to balance positive and negative experiences and fosters integrative and instrumental remembering are effective in reducing depression and anxiety and increasing well-being (Pinquart and Forstmeier 2012). One central challenge in clinical practice is to combine existing measures from the already large “tool box” of clinical geropsychology (e.g., combining training programs from the health and exercise sciences with psychotherapeutic interventions) and to implement them in a wide array of intervention settings (laboratory environments, nursing homes and day care centers, rehabilitation units, the family setting, and the community at large).

personal and professional development (U.S. House 1965). This definition acknowledges the role of lifelong learning in the context of the workplace as well as outside of it (Sterns 1986; Sterns and Spokus 2013). Specifically, informal learning opportunities can occur across multiple contexts: (a) community development, (b) adult literacy, (c) workplace training, or (d) personal interest pursuits (Zepke and Leach 2006).

Lifelong learning is best understood within the framework of lifespan development theory. Lifespan development theory recognizes that lifelong learning is characterized by individual level mechanisms such as: (a) continuous and discontinuous processes, (b) multidirectionality, (c) gains and losses, and (d) plasticity (Baltes 1987). Furthermore, it necessitates understanding lifelong learning as it is situated within environmental influences such as: (e) historical embeddedness, (f) contextualism, and (g) multidisciplinary research.

History and Purpose of Lifelong Learning

The conceptualization of adults as learners was more formally enhanced in the early 1970s by Knowles (Knowles et al. 2005). This led to an increase in research, theory development, and debate in the field. Culturally and empirically, learning has been conceptualized as taking place in formal education during childhood and early adulthood as well as a method of informal updating in the workplace during adulthood to remain competitive. As illustrated in Fig. 1, this is an *age-differentiated* view that places education, work, and leisure as occurring at different parts of the lifecourse based on the age of the individual (Riley 1994). Thus, the concept of lifelong learning has been subject to age and institutionally bound understandings. A call to move away from an age-differentiated understanding to an *age-integrated* understanding was advocated by Riley (1994) as the former encourages a fragmented understanding of age, education, work, and leisure. An age-integrated understanding recognizes the role of education, work, and leisure across the lifecourse, an understanding that

Definition

Lifelong learning is a multidimensional construct that is defined and measured differentially throughout the literature. The Higher Education Act of 1965 defined lifelong learning as both formal and informal education, training, and activities with the goal of gaining knowledge and skills for both

Lifelong Learning and Work, Fig. 1 Age-integrated versus age-segregated structuring of the roles of education, work, and leisure (After Riley 1994)

can break down social and institutional barriers between generations. Further, as the definition of lifelong learning within a lifespan development context would suggest, learning can take place within the roles of education, work, and leisure (Manheimer 2008).

The link between lifelong learning and work cannot be ignored. According to a recent report by the National Center for Education Statistics education early in life can impact employability in adulthood (Snyder and Dillow 2015). High school dropouts are less likely to be an active member of the workforce than those who completed high school, 23.8% and 45.7%, respectively. Additionally, level of education is associated with median annual earnings in adulthood, with income steadily increasing for individuals with higher levels of educational attainment (i.e., bachelor's degree holders have higher median incomes than associate degree holders). It is important to note females have lower median incomes than males, across all educational attainment levels. Worldwide, there has been a trend over the past decade toward increased enrollment in elementary, secondary (i.e., high school), and postsecondary (i.e., attending college or technical school) education which will serve upcoming cohorts in terms of their competitiveness in the workplace. However, in order to remain competitive in the workplace,

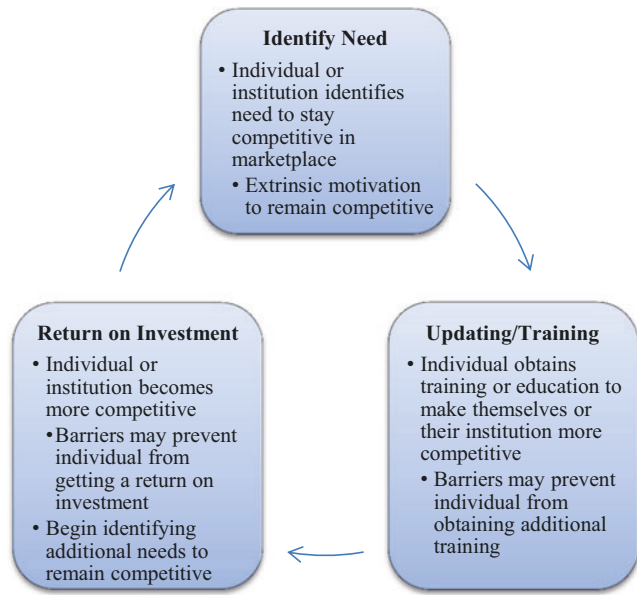

learning cannot stop after formal education has ended. The best predictor of education and training later in life is previous education (Sterns and Doverspike 1989).

While lifelong learning is beneficial and has a role in multiple facets of an individual's life (e.g., personal growth and leisure activities), it is critical to maintaining the human capital needed to be successful in the workforce. Thus, individuals need to continue to engage in training and updating to maintain work performance and reduce the potential for *obsolescence*; obsolescence occurs when an individual's knowledge, skills, and abilities become out-of-date due to technological or structural changes (Lovász and Rigó 2013). Work performance decrements due to obsolescence can be corrected with appropriate training. For example, a recent study by Lovász and Rigó (2013) analyzed data from the Hungarian Wage and Employment Survey collected at multiple time points between 1986 and 2008. Due to a major economic transition between 1989 and 1994 in Hungary from a communist to a democratic government, this provides a unique opportunity to look at the effects of obsolescence between older and younger workers over time due to the sudden influx of new technology and management practices that rendered previous work experience and knowledge obsolete. The authors found a significant productivity gap between skilled older and younger workers in the years immediately following this transition; however, no such decrease in productivity occurred for unskilled older workers compared to younger workers after the transition. Thus, the authors point to the need for continued opportunities for training for skilled workers in order for them to maintain productivity, particularly in the face of industry change.

Understanding Lifelong Learning: Theories, Strategies, and Outcomes

There is no shortage of theoretical models for conceptualizing lifelong learning throughout the existing literature; however, the challenge lies in

Lifelong Learning and Work, Fig. 2 A conceptual illustration of the human capital model of lifelong learning

the ability to synthesize the commonalties among the current theories. A recent review by Regmi (2015) simplifies the literature by concluding that current models of lifelong learning are based on two foundational models: the human capital model and the humanistic model. The *human capital model* views lifelong learning as a tool with which an individual or institution (e.g., employer, government) can invest in education and training to maximize economic growth and remain competitive. This model, depicted in Fig. 2, posits that individual skills and knowledge are a commodity, and increases in this commodity will result in a greater economic return on investment; thus, in the context of work, employers view their employees as economic resources, whereby offering opportunities for training results in a return on their investment by increasing their institution’s competitiveness in the marketplace. Thus, both individuals and institutions are extrinsically motivated to engage in updating to keep their competitive edge.

The first step in the human capital model is for the individual or the institution to identify a need for updating in order to remain competitive. Kanfer (2009) emphasizes the importance of the person-job fit and notes that a gap in an

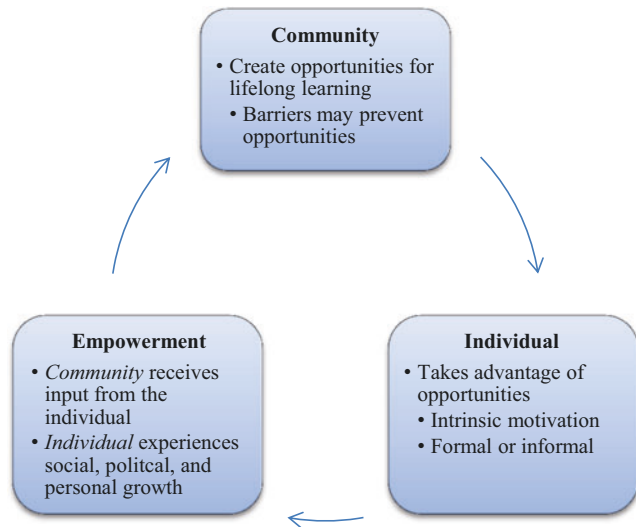

individual’s knowledge, skills, and abilities and the requirements of their particular job lead to the necessity for continued training to prevent decrements in job performance. This places a burden on the institution to continually appraise and evaluate the performance of the individual to identify concerns regarding person-job fit in order to maximize job performance to remain competitive in the marketplace. Additionally, the human capital model has been criticized for placing a burden on the individual to continuously seek opportunities for training to stay competitive as well as for not recognizing the constraints preventing some individuals from seeking training (e.g., financial concerns, family commitments) Regmi (2015). Thus, it is important that both the institution and the individual share this responsibility, as the institution can make the individual aware of performance gaps and provide opportunities for training and updating before decrements in performance result in the need for a different job role or in negative self-perceptions by the individual.

The *humanistic model*, depicted in Fig. 3, views lifelong learning as not only an opportunity for economic development but also as a method of enhancing the welfare of individuals and communities by empowering them to: (a) own their right

Lifelong Learning and Work, Fig. 3

A conceptual illustration of the humanistic model of lifelong learning

to a free and equitable education, (b) utilize education for personal and not just economic growth, and (c) be an active participant in social, political, and economic movements on a local and global scale. This model places the burden on society to create a culture of learning that facilitates the internalization of the importance of lifelong learning and the development of *social capital*, resources actualized via collaborations with others. This model also moves lifelong learning beyond the constraints of the workplace and recognizes its importance from a more holistic perspective in terms of individual growth within the context of societal level influences and processes.

Self-management and personal responsibility – “the protean career” – place responsibility on the individual (Sterns and Spokus 2013). It also recognizes the ability for the individual to engage in *self-directed learning*, learning initiated and managed by the learner, an informal learning strategy associated with higher levels of motivation, self-efficacy, locus of control, peer support, and better performance outcomes in a meta-analysis of 34 studies (Boyer et al. 2014). Furthermore, in contrast to the human capital model, the humanistic model promotes collaboration rather than competition between individuals and institutions (Regmi 2015).

Barriers to Lifelong Learning

Barriers to lifelong learning can be categorized into two broad conceptual categories: individual level barriers and environmental level barriers. Individual level barriers include, but are not limited to: negative self-concepts, readiness to learn, stereotype threats, locus of control, self-efficacy, motivation, health concerns, life events, age-related declines (e.g., changes in cognition, audition, and vision), role changes (e.g., caregiving, family planning), and lack of financial resources (Boyer, et al. 2014; Knowles et al. 2005).

Age-based stereotype threats occur when an older adult, due to their membership in a group associated with negative stereotypes, is put in a situation whereby their behavior can result in a confirmation of an age-related negative stereotype (Lamont et al. 2015). For example, an older adult given a memory task may be concerned that their performance on the task may confirm a common stereotype that older adults have poor memories. This concern, or stereotype threat, can result in poorer performance on the task. Lamont and colleagues conducted a meta-analysis on 22 published and 10 unpublished studies and found that age-based stereotype threats negatively

impacted the performance of older adults overall, impacting performance on memory and cognitive tasks in particular. Further, there was no interaction with either the age or gender of the participants. Membership in two stereotyped categories, female and old, did not result in poorer performance.
